Preface
Acknowledgments

Introduction: Cardiovascular Medicine: A Historical Perspective
W. Bruce Fye

SECTION I: PREVENTIVE CARDIOLOGY
PAUL D. THOMPSON

1. Atherosclerotic Biology and Epidemiology of Disease
Peter L. Weissberg and James H. F. Rudd

2. Diet, Nutritional Issues, and Obesity
Neil J. Stone

3. Lipid Disorders
Daniel J. Rader

4. Exercise and Physical Activity
Debra L. Sherman, Giulia L. Cebulla, and Gary J. Balady

5. Hypertension: Context, Pathophysiology, and Management
Peter Rudd and Lars G. Osterberg

6. Smoking
Raymond Niaura and Michael G. Goldstein

7. Diabetes
Doron Aronson and Elliot J. Rayfield

8. Estrogen, Female Gender, and Heart Disease
Robert H. Knopp and Keiko Aikawa

9. Ethanol and the Heart
Luis H. Arroyo and Timothy J. Regan

10. Other Risk Factors for Coronary Artery Disease: Homocysteine, Lipoprotein(a), Fibrinogen, and Plasminogen Activator Inhibitor
Killian Robinson and Joseph Loscalzo

11. Behavioral Medicine and Heart Disease
Charles F. Emery and John N. O'Neil

12. Cardiac Rehabilitation and Secondary Prevention
Philip A. Ades

13. An Integrated Approach to Risk-Factor Modification
Ravi Rasalingam and Thomas A. Pearson

SECTION II: CLINICAL CARDIOLOGY
ROBERT M. CALIFF

14. The History
Eric J. Topol

15. Physical Examination
Kanu Chatterjee

16. Stable Ischemic Syndromes
Paul W. Armstrong

17. Non–ST-Elevation Acute Coronary Syndromes: Unstable Angina and Non–ST-Elevation Myocardial Infarction
Harvey D. White

18. Acute Myocardial Infarction: Early Diagnosis and Management
Eric J. Topol and Frans J. Van de Werf

19. Acute Myocardial Infarction: Complications
Judith S. Hochman and Bernard J. Gersh

20. Post–Myocardial Infarction Management
Deepak L. Bhatt and Eric J. Topol

21. Mitral Valve Disease
Joseph S. Alpert, Joseph F. Sabik III, and Delos M. Cosgrove

22. Aortic Valve Disease
William J. Stewart and Blase A. Carabello

23. Acquired Tricuspid and Pulmonary Valve Disease
Melvin D. Cheitlin and John S. MacGregor

24. Prosthetic Valve Disease
Mario J. Garcia

25. Infective Endocarditis
Daniel J. Sexton and Thomas M. Bashore

26. Diseases of the Pericardium, Restrictive Cardiomyopathy, and Diastolic Dysfunction
Allan L. Klein and Craig R. Asher

27. Pulmonary Hypertension and Cor Pulmonale
Clara I. Restrepo and Victor F. Tapson

28. Venous Thromboembolism
Victor F. Tapson

29. Hypertrophic Cardiomyopathy
William J. McKenna and Perry M. Elliott

30. Congenital Heart Disease
Robert M. Freedom and David G. Nykanen

31. Adult Congenital Heart Disease
Ariane J. Marelli and Douglas S. Moodie

32. The Heart and Pregnancy
Kenneth L. Baughman

33. Aging and the Heart
Christopher M. O'Connor and Gottlieb C. Friesinger

34. End-of-Life Care
Gary S. Francis

35. The Heart and Other Organ Systems
Robert M. Califf

A. Endocrine Systems and the Heart
Marco Roffi

B. Hematologic and Oncologic Disorders and the Heart
Peter B. Amsterdam and David M. Yamada

C. The Heart and the Renal System
Lynda Anne Szczech, Derek P. Chew, Joseph A. Coladonato, and Donal N. Reddan

D. Cardiac Manifestations of Selected Neurologic Disorders
Kenneth W. Mahaffey and Daniel T. Laskowitz

E. Cardiovascular Manifestations of Rheumatic Diseases
David H. Lewis

F. The Heart and Infectious Diseases
Andrew James Boyle

36. Substance Abuse and the Heart
Robert A. Kloner and Shereif H. Rezkalla

37. Athlete's Heart
Paul D. Thompson and N. A. Mark Estes III

38. Cardiac Trauma
Samir R. Kapadia and Eric J. Topol

39. Cardiac Neoplasms
William C. Roberts

40. Basic Principles of Cardiovascular Clinical Pharmacology
Raymond L. Woosley

41. Role of the Cardiology Consultant
Saeed R. Shaikh, Mylan C. Cohen, and Kim A. Eagle

42. Medical Economics in Cardiovascular Medicine
Daniel B. Mark

43. Considerations in the Design and Conduct of Clinical Studies and the Interpretation of Quantitative Evidence
Robert M. Califf and Eric J. Topol

44. Databases in Cardiology
Michael S. Lauer and Eugene H. Blackstone

45. Medical Errors and Quality of Care in Cardiovascular Medicine
Eric J. Topol and Robert M. Califf

SECTION III: CARDIOVASCULAR IMAGING

JAMES D. THOMAS

46. Principles of Imaging
James D. Thomas

47. Plain Film Examination of the Chest
Lawrence M. Boxt

48. Exercise Electrocardiography
Peter M. Okin

49. Transthoracic Echocardiography
Rebecca L. Smith and James D. Thomas

50. Stress Echocardiography
Thomas H. Marwick

51. Doppler Assessment
Frank A. Flachskampf

52. Transesophageal Echocardiography
Brian P. Griffin

53. Nuclear Imaging Techniques
Ami E. Iskandrian and Mario S. Verani

54. Magnetic Resonance Imaging
Paulo R. Schvartzman and Richard D. White

55. Positron Emission Tomography
Markus Schwaiger and Sibylle I. Ziegler

56. Computed Tomography of the Heart
Robert Detrano and J. Jeffrey Carr

57. Intraoperative Echocardiography
William J. Stewart

SECTION IV: ELECTROPHYSIOLOGY AND PACING

ERIC N. PRYSTOWSKY

58. Mechanisms of Cardiac Arrhythmias
Augustus O. Grant and David W. Whalley

59. Electrocardiography
Elena B. Sgarbossa and Galen S. Wagner

60. Electrocardiographic Diagnosis of Arrhythmias
Hein J. Wellens

61. Ambulatory and Signal-Averaged Electrocardiography and T-Wave Alternans
Stephen C. Hammill

62. Electrophysiologic Testing
John D. Fisher

63. Bradycardias: Sinus Nodal Dysfunction and Atrioventricular Conduction Disturbances
Deborah L. Wolbrette and Gerald V. Naccarelli

64. Atrial Fibrillation
Eric N. Prystowsky and Amos Katz

65. Atrioventricular Nodal–Independent Supraventricular Tachycardias
Albert L.Waldo and Lee A. Biblo

66. Atrioventricular Nodal–Dependent Tachycardias
Thomas J. Dresing, Robert A. Schweikert, and Douglas L. Packer

67. Ventricular Tachycardia
Patrick J. Tchou

68. Sudden Cardiac Death
Sanjay S. Deshpande and Masood Akhtar

69. Cardiopulmonary Resuscitation
Joseph P. Ornato and Mary Ann Peberdy

70. Arrhythmias in Congenital Heart Disease
Ronald J. Kanter and Arthur Garson, Jr.

71. Syncope
David G. Benditt

72. Antiarrhythmic Drugs
Dan M. Roden

73. Catheter Ablation Therapy for Arrhythmias
David E. Haines

74. Pacemakers
David L. Hayes

75. Implantable Cardioverter-Defibrillators
Sergio L. Pinski and Peng-Sheng Chen

76. Transthoracic Electrical Defibrillation and Cardioversion
Gordon A. Ewy

77. Clinical Assessment of the Autonomic Nervous System
Christopher R. Cole, Michael S. Lauer, and J. Thomas Bigger

SECTION V: INVASIVE CARDIOLOGY AND SURGICAL TECHNIQUES

ERIC J. TOPOL

78. Coronary Angiography
Deepak L. Bhatt and Frederick A. Heupler, Jr.

79. Cardiac Catheterization and Hemodynamic Assessment
Richard A. Lange and L. David Hillis

80. Percutaneous Coronary Intervention
Bernhard Meier

81. New Techniques in Interventional Cardiology: Radiation, Emboli Protection, and Therapeutic Angiogenesis
Judah Weinberger, A. Michael Lincoff, and Jeffrey J. Popma

82. Coronary Artery Bypass Surgery
A. Marc Gillinov and Floyd D. Loop

83. Restenosis: Epidemiology and Treatment
David J. Moliterno and Eric J. Topol

84. Approaches to the Patient with Prior Bypass Surgery
John S. Douglas, Jr.

85. Intravascular Ultrasonography, Angioscopy, Doppler Flow, and Pressure Measurements
E. Murat Tuzcu, Carlo Di Mario, and Steven E. Nissen

86. Valvuloplasty
Alec Sylvain Vahanian

87. Catheter Interventions in Congenital Heart Disease
Alan M. Mendelsohn, David Shim, and Robert H. Beekman III

SECTION VI: HEART FAILURE AND TRANSPLANTATION

JAMES B. YOUNG

88. Pathophysiology of the Heart Failure Clinical Syndrome
Gary S. Francis

89. Health Care Impact of Heart Failure
Randall C. Starling

90. Cardiomyopathy and Myocardial Failure
Suzanne R. Lutton, Norman B. Ratliff, and James B. Young

91. Acute Heart Failure Management
Garrie J. Haas and James B. Young

92. Chronic Heart Failure Management
James B. Young

93. Diagnosis and Medical Treatment of Inflammatory Cardiomyopathy
Dennis M. McNamara

94. Cardiac Transplantation
Dale G. Renlund and David O. Taylor

95. Surgical Considerations in the Treatment of Heart Failure
Nicholas G. Smedira

SECTION VII: MOLECULAR CARDIOLOGY

JUDITH L. SWAIN

96. General Techniques in Molecular Cardiology
Mark E. Lieb and Mark B. Taubman

97. Molecular Genetics
Qing Wang, Meredith Bond, Robert C. Elston, and Xiao-Li Tian

98. Genetics of Atherosclerosis
Aldons J. Lusis, Ari Weinreb, Thomas A. Drake, and Hooman Allayee

99. Genetics of Hypertension
Xavier Laurent Jeunemaitre, Sandra A. Disse-Nicodème, Anne-Paule Gimenez-Roqueplo, and Pierre Corvol

100. Genetic Studies of Myocardial and Vascular Disease
Qing Wang, Reed E. Pyeritz, Christine E. Seidman, and Craig T. Basson

101. Gene Therapy
Elizabeth G. Nabel

102. Myocyte Structure and Function
Arnold M. Katz

103. Molecular Basis of Heart Development
Madhu Gupta, Rene A. Arcilla, and Mahesh P. Gupta

SECTION VIII: VASCULAR BIOLOGY AND MEDICINE

JEFFREY M. ISNER

104. Pathobiology of Hypertension
Gary H. Gibbons

105. The Biology of Restenosis
Eric Van Belle, Christophe Bauters, and Jeffrey M. Isner

106. Angiogenesis
Jeffrey M. Isner

107. Diseases of the Pulmonary Vasculature
Marlene Rabinovitch

108. Diseases of the Aorta
Peter C. Spittell

109. Noninvasive Assessment of Vascular Disease
D. Eugene Strandness, Jr.

110. Cerebrovascular Disease
Cathy A. Sila and Anthony J. Furlan

111. Disease of Peripheral Vessels
Kenneth Rosenfield, Peter R. Vale, and Jeffrey M. Isner

112. Renal Artery Disease
Jeffrey W. Olin and Susan M. Begelman

Editor

ERIC J. TOPOL, M.D.
Provost and Chief Academic Officer
Chairman, Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

Associate Editors

ROBERT M. CALIFF, M.D.
Professor of Medicine
Director, Duke Clinical Research Institute
Durham, North Carolina

JEFFREY M. ISNER, M.D.*
Professor of Medicine and Pathology
Department of Medicine/Vascular Medicine
Tufts University School of Medicine
Chief of Vascular Medicine and Cardiovascular Research
St. Elizabeth's Medical Center
Boston, Massachusetts

ERIC N. PRYSTOWSKY, M.D.
Director, Electrophysiology Laboratory
The CARE Group
Indianapolis, Indiana

JUDITH L. SWAIN, M.D.
Arthur L. Bloomfield Professor of Medicine
Chairman, Department of Medicine
Stanford University School of Medicine
Stanford, California

JAMES D. THOMAS, M.D.
Professor of Medicine and Biomedical Engineering
Director of Cardiovascular Imaging
The Cleveland Clinic Foundation
Cleveland, Ohio

PAUL D. THOMPSON, M.D.
Professor of Medicine
Department of Cardiology
University of Connecticut School of Medicine
Farmington, Connecticut
Director, Preventive Cardiology
Hartford Hospital
Hartford, Connecticut

JAMES B. YOUNG, M.D.
Professor of Medicine
Medical Director, Kaufman Center for Heart Failure
The Cleveland Clinic Foundation
Cleveland, Ohio

**Deceased*.

Dedicated to the memory of
Jeffrey M. Isner, M.D., associate editor for the first and second editions, and one
of the most extraordinary researchers and individuals in the history of cardiovascular medicine

CONTRIBUTING AUTHORS

PHILIP A. ADES, M.D.
Professor of Medicine
Division of Cardiology
University of Vermont College of Medicine
Burlington, Vermont

KEIKO AIKAWA, M.D.
Fellow in Cardiology
Department of Medicine
Division of Cardiology
University of Washington Medical Center
Seattle, Washington

MASOOD AKHTAR, M.D.
Clinical Professor of Medicine
University of Wisconsin Medical School
Milwaukee Clinical Campus
Milwaukee, Wisconsin

HOOMAN ALLAYEE, PH.D.
Postdoctoral Fellow
Department of Human Genetics
University of California, Los Angeles, UCLA School of Medicine
Los Angeles, California

JOSEPH S. ALPERT, M.D.
Robert S. and Irene P. Flinn Professor of Medicine
Head, Department of Medicine
University of Arizona Health Sciences Center
Tucson, Arizona

PETER B. AMSTERDAM, M.D.
Department of Cardiology
Grant Medical Center
Heart Care, Inc.
Columbus, Ohio

RENE A. ARCILLA, M.D.
Professor of Pediatrics
University of Illinois at Chicago College of Medicine
Chicago, Illinois
Director of the Heart Institute for Children
Hope Children's Hospital
Oak Lawn, Illinois

PAUL W. ARMSTRONG, M.D.
Professor of Medicine
University of Alberta Faculty of Medicine and Dentistry
Edmonton, Alberta, Canada

DORON ARONSON, M.D.
Department of Cardiology
Rambam Medical Center
Haifa, Israel

LUIS H. ARROYO, M.D.
Department of Cardiology
Newark Beth Israel
Medical Center
Newark, New Jersey

CRAIG R. ASHER, M.D.
Assistant Staff
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

GARY J. BALADY, M.D.
Professor of Medicine
Section of Cardiology
Boston Medical Center
Boston, Massachusetts

THOMAS M. BASHORE, M.D.
Professor of Medicine
Division of Cardiology
Duke University Medical Center
Durham, North Carolina

CRAIG T. BASSON, M.D., PH.D.
Assistant Professor of Medicine
Cardiology Division
Weill Medical College of Cornell University
New York Presbyterian Hospital–Cornell Medical Center
New York, New York

KENNETH L. BAUGHMAN, M.D.
Professor of Medicine
The Johns Hopkins University School of Medicine
Baltimore, Maryland

CHRISTOPHE BAUTERS, M.D.
Professor of Cardiology
CHRU de Lille
Lille, France

ROBERT H. BEEKMAN III, M.D.
Professor of Pediatric Cardiology
Department of Pediatrics
Children's Hospital Medical Center
Cincinnati, Ohio

SUSAN M. BEGELMAN, M.D.
Associate Staff
Department of Cardiovascular Medicine
Section of Vascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

DAVID G. BENDITT, M.D.
Professor of Medicine
Department of Medicine/Cardiology
University of Minnesota Medical School—Minneapolis
Minneapolis, Minnesota

DEEPAK L. BHATT, M.D.
Staff Cardiologist
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

LEE A. BIBLO, M.D.
Associate Professor of Medicine
Case Western Reserve University School of Medicine
MetroHealth Medical Center
Cleveland, Ohio

J. THOMAS BIGGER, M.D.
Professor of Medicine and Pharmacology
Department of Medicine
Columbia University College of Physicians and Surgeons
New York, New York

EUGENE H. BLACKSTONE, M.D.
Professor of Surgery
Department of Thoracic and Cardiovascular Surgery
The Cleveland Clinic Foundation
Cleveland, Ohio

MEREDITH BOND, PH.D.
Staff, Department of Molecular Cardiology
The Cleveland Clinic Foundation
Cleveland, Ohio

LAWRENCE M. BOXT, M.D.
Professor of Clinical Radiology
Albert Einstein College of Medicine of Yeshiva University
Bronx, New York
Department of Radiology
Beth Israel Medical Center
New York, New York

ANDREW JAMES BOYLE, M.D.
Clinical Fellow
Department of Heart Failure and Cardiac Transplantation
The Cleveland Clinic Foundation
Cleveland, Ohio

ROBERT M. CALIFF, M.D.
Professor of Medicine
Director, Duke Clinical Research Institute
Durham, North Carolina

BLASE A. CARABELLO, M.D.
Professor of Medicine
Baylor College of Medicine
Houston Veterans Affairs Medical Center
Houston, Texas

J. JEFFREY CARR, M.D.
Associate Professor
Department of Public Health Sciences
Division of Radiological Sciences
Wake Forest University Baptist Medical Center
Winston-Salem, North Carolina

GIULIA L. CEBULLA, M.D.
Fellow in Cardiology
Boston Medical Center
Boston, Massachusetts

KANU CHATTERJEE, M.B.
Professor of Medicine
Lucie Stern Professor of Cardiology
University of California, San Francisco, School of Medicine
San Francisco, California

MELVIN D. CHEITLIN, M.D.
Emeritus Professor of Medicine
Department of Cardiology
University of California, San Francisco, School of Medicine
Former Chief of Cardiology
San Francisco General Hospital

San Francisco, California

PENG-SHENG CHEN, M.D.
Professor of Medicine
Department of Medicine/Cardiology
Cedars-Sinai Medical Center
Los Angeles, California

DEREK P. CHEW, M.B.B.S.
Interventional Fellow
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

MYLAN C. COHEN, M.D., M.P.H.
Clinical Associate Professor of Medicine
Division of Cardiology
University of Vermont College of Medicine
Burlington, Vermont
Maine Medical Center
Portland, Maine

JOSEPH A. COLADONATO, M.D.
Fellow, Department of Nephrology
Duke University Medical Center
Durham, North Carolina

CHRISTOPHER R. COLE, M.D.
Electrophysiology Fellow
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

PIERRE CORVOL, M.D.
Professor of Medicine
Department of Experimental Medicine
College de France
Paris, France

DELOS M. COSGROVE, M.D.
Chairman, Department of Thoracic and Cardiovascular Surgery
The Cleveland Clinic Foundation
Cleveland, Ohio

SANJAY S. DESHPANDE, M.D.
Clinical Associate Professor of Medicine
Department of Cardiology
University of Wisconsin-Milwaukee Clinical Campus
Sinai Samaritan and St. Luke's Medical Centers
Milwaukee, Wisconsin

ROBERT DETRANO, M.D., PH.D.
Professor of Medicine
Department of Cardiology
South Bay Heart Watch
Harbor-UCLA Research and Education Institute
Torrance, California

CARLO DI MARIO, M.D., PH.D.
Department of Interventional Cardiology
San Raffaelo Hospital
Milan, Italy

SANDRA A. DISSE-NICODÈME, PH.D.
Department of Gene Identification
Centre National de Genotypage
Cedex, France

JOHN S. DOUGLAS, JR., M.D.
Professor of Medicine
Director, Interventional Cardiology
Emory University Hospital
Atlanta, Georgia

THOMAS A. DRAKE, M.D.
Professor of Pathology and Laboratory Medicine
University of California, Los Angeles, UCLA School of Medicine
Los Angeles, California

THOMAS J. DRESING, M.D.
Clinical Fellow
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

KIM A. EAGLE, M.D.
Albion Walter Hewlett Professor of Internal Medicine
Department of Internal
Medicine/Cardiology
University of Michigan Medical School
Ann Arbor, Michigan

PERRY M. ELLIOTT, M.B.B.S., M.D.
Senior Lecturer in Cardiology
Department of Cardiological Sciences
St. George's Hospital Medical School
London, United Kingdom

ROBERT C. ELSTON, PH.D.

Professor of Epidemiology and Genetics
Department of Epidemiology and Biostatistics
Case Western Reserve University School of Medicine
MetroHealth Medical Center
Cleveland, Ohio

CHARLES F. EMERY, PH.D.
Associate Professor of Psychology
The Ohio State University
Columbus, Ohio

N. A. MARK ESTES III, M.D.
Professor of Medicine
Tufts University School of Medicine
Boston, Massachusetts

GORDON A. EWY, M.D.
Professor and Chief of Cardiology
Department of Medicine
University of Arizona College of Medicine
Arizona Health Sciences Center
Sarver Heart Center
Tucson, Arizona

JOHN D. FISHER, M.D.
Professor of Medicine
Director, Arrhythmia Services
Department of Cardiology
Montefiore Medical Center
Bronx, New York

FRANK A. FLACHSKAMPF, M.D.
Associate Professor of Medicine
Medizinische Klinik II
University Erlangen–Nürnberg
Erlangen, Germany

GARY S. FRANCIS, M.D.
Professor of Medicine
Director, Coronary Intensive Care Unit
The Cleveland Clinic Foundation
Cleveland, Ohio

ROBERT M. FREEDOM, M.D.
Chief, Division of Cardiology
The Hospital for Sick Children
Toronto, Ontario, Canada

GOTTLIEB C. FRIESINGER, M.D.
Betty and Jack Bailey Professor of Cardiology
Department of Medicine
Vanderbilt University Medical Center
Nashville, Tennessee

ANTHONY J. FURLAN, M.D.
Head, Section of Stroke and Neurological Intensive Care
Medical Director, Cerebrovascular Center
Department of Neurology
The Cleveland Clinic Foundation
Cleveland, Ohio

W. BRUCE FYE, M.D.
Professor of Medicine
Cardiovascular Division
Mayo Medical School
Mayo Clinic
Rochester, Minnesota

MARIO J. GARCIA, M.D.
Staff Cardiologist and Director of Echocardiography
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

ARTHUR GARSON, JR., M.D., M.P.H.
Professor of Pediatrics (Cardiology)
Department of Pediatric Cardiology
Baylor College of Medicine
Houston, Texas

BERNARD J. GERSH, M.D., CH.B., D.PHIL.
Professor of Medicine
Division of Cardiovascular Diseases
Mayo Clinic
Rochester, Minnesota

GARY H. GIBBONS, M.D.
Associate Professor of Medicine
Director, Cardiovascular Research Institute
Morehouse School of Medicine
Atlanta, Georgia

A. MARC GILLINOV, M.D.
Heart Surgeon
Department of Thoracic and Cardiovascular Surgery
The Cleveland Clinic Foundation
Cleveland, Ohio

ANNE-PAULE GIMENEZ-ROQUEPLO, M.D., PH.D.

Department of Molecular Genetics
Hôpital Européen Georges Pompidou
Paris, France

MICHAEL G. GOLDSTEIN, M.D.
Adjunct Professor
Department of Psychiatry and Human Behavior
Brown University School of Medicine
The Miriam Hospital
Providence, Rhode Island
The Bayer Institute for Health Care Communication
West Haven, Connecticut

AUGUSTUS O. GRANT, M.B., CH.B., PH.D.
Professor of Medicine
Duke University Medical Center
Durham, North Carolina

BRIAN P. GRIFFIN, M.D.
Director, Cardiovascular Training Program
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

MADHU GUPTA, PH.D.
Assistant Professor
Department of Physiology and Biophysics
University of Illinois
Hope Children's Hospital
Palos Heights, Illinois

MAHESH P. GUPTA, PH.D.
Associate Professor
Department of Surgery (Cardiac
and Thoracic)
The University of Chicago Pritzker
School of Medicine
Chicago, Illinois

GARRIE J. HAAS, M.D.
Director, Heart Failure Disease Management Program
Mid Ohio Cardiology Consultants
Riverside Methodist Hospital
Columbus, Ohio

DAVID E. HAINES, M.D.
Professor of Medicine
Cardiovascular Division
University of Virginia
Health System
Charlottesville, Virginia

STEPHEN C. HAMMILL, M.D.
Professor of Medicine
Director, Electrocardiography
and Electrophysiology
Mayo Clinic
Rochester, Minnesota

DAVID L. HAYES, M.D.
Professor of Medicine
Mayo Medical School
Consultant, Division of
Cardiovascular Diseases and
Internal Medicine
Mayo Clinic
Rochester, Minnesota

FREDERICK A. HEUPLER, JR., M.D.
Staff Cardiologist
Department of Cardiovascular
Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

L. DAVID HILLIS, M.D.
Professor and Vice Chair
Department of Internal Medicine
University of Texas Southwestern Medical Center at Dallas
Dallas, Texas

JUDITH S. HOCHMAN, M.D.
Professor of Medicine
Department of Cardiology
Columbia University College of Physicians and Surgeons
St. Luke's-Roosevelt Hospital Center
New York, New York

AMI E. ISKANDRIAN, M.D.
Distinguished Professor of Medicine and Radiology
Section Chief, Nuclear Cardiology
Division of Cardiovascular Disease
University of Alabama School
of Medicine
Birmingham, Alabama

JEFFREY M. ISNER, M.D.*
Professor of Medicine and Pathology
Department of Medicine/Vascular Medicine
Tufts University School of Medicine

Chief of Vascular Medicine and Cardiovascular Research
St. Elizabeth's Medical Center
Boston, Massachusetts

XAVIER LAURENT JEUNEMAITRE, M.D., PH.D.
Professor of Genetics
Hôpital Européen Georges Pompidou
Paris, France

RONALD J. KANTER, M.D.
Associate Professor of Pediatrics
Department of Pediatric Cardiology
Duke University Medical Center
Durham, North Carolina

SAMIR R. KAPADIA, M.D.
Assistant Professor
Department of Cardiology
University of Washington School
of Medicine
Seattle, Washington

AMOS KATZ, M.D.
Professor of Medicine
Department of Cardiology
Soroka University Medical Center
Beersheva, Israel

ARNOLD M. KATZ, M.D.
Professor of Medicine Emeritus
University of Connecticut School
of Medicine
Farmington, Connecticut
Visiting Professor of Medicine
Dartmouth Medical School
Hanover, New Hampshire

ALLAN L. KLEIN, M.D.
Professor of Medicine
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

ROBERT A. KLONER, M.D., PH.D.
Professor of Medicine
Division of Cardiology
University of Southern California School of Medicine
Director of Research
Heart Institute
Good Samaritan Hospital
Los Angeles, California

ROBERT H. KNOPP, M.D.
Professor of Medicine
University of Washington School
of Medicine
Director, Northwest Lipid
Research Clinic
Seattle, Washington

RICHARD A. LANGE, M.D.
Professor of Medicine
Department of Internal Medicine
University of Texas Southwestern
Medical Center at Dallas
Dallas, Texas

DANIEL T. LASKOWITZ, M.D.
Assistant Professor of Medicine (Neurology) and Anesthesiology
Department of Medicine
Duke University School
of Medicine
Duke University Medical Center
Durham, North Carolina

MICHAEL S. LAUER, M.D.
Director of Clinical Research
Department of Cardiovascular
Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

DAVID H. LEWIS, M.D.
Cardiologist
Mid America Heart Institute
Kansas City, Missouri

MARK E. LIEB, M.D.
Assistant Professor of Medicine
Mount Sinai School of Medicine of the City University of New York
New York, New York

A. MICHAEL LINCOFF, M.D.
Associate Professor of Medicine
Director, Experimental Interventional Laboratory
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

FLOYD D. LOOP, M.D.
Chief Executive Officer
The Cleveland Clinic Foundation
Cleveland, Ohio

JOSEPH LOSCALZO, M.D., PH.D.
Wade Professor and Chairman
Department of Medicine
Boston University School of Medicine
Boston Medical Center
Boston, Massachusetts

ALDONS J. LUSIS, PH.D.
Professor
Departments of Medicine and
Human Genetics
Division of Cardiology
University of California, Los Angeles, UCLA School of Medicine
Los Angeles, California

SUZANNE R. LUTTON, M.D.
Diagnostic Cardiology Associates
Youngstown, Ohio

JOHN S. MACGREGOR, M.D., PH.D.
Associate Professor of Medicine
University of California, San Francisco, School of Medicine
San Francisco, California

KENNETH W. MAHAFFEY, M.D.
Assistant Professor of Medicine
Department of Cardiology
Duke Clinical Research Institute
Duke University Medical Center
Durham, North Carolina

ARIANE J. MARELLI, M.D.
Assistant Professor of Medicine
McGill University Faculty
of Medicine
Director, Adult Congenital Heart
Disease Unit
McGill University Health Center
Montreal, Quebec, Canada

DANIEL B. MARK, M.D., M.P.H.
Professor of Medicine
Department of Cardiology
Duke University Medical Center
Durham, North Carolina

THOMAS H. MARWICK, M.B.B.S., PH.D.
Professor of Medicine
University of Queensland
Princess Alexandra Hospital
Brisbane, Queensland, Australia

WILLIAM J. MCKENNA, M.D., D.SC.
Professor of Molecular
Cardiovascular Sciences
Department of Cardiological Sciences
St. George's Hospital
Medical School
London, United Kingdom

DENNIS M. MCNAMARA, M.D.
Associate Professor of Medicine
Cardiovascular Institute
University of Pittsburgh
Medical Center
Pittsburgh, Pennsylvania

BERNHARD MEIER, M.D.
Professor of Cardiology
and Chairman
Cardiovascular Department
University Hospital
Bern, Switzerland

ALAN M. MENDELSOHN, M.D.
Associate Director of Cardiovascular Medical Affairs
Centocor, Inc.
Malvern, Pennsylvania

DAVID J. MOLITERNO, M.D.
Associate Professor of Medicine
Department of Cardiovascular
Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

DOUGLAS S. MOODIE, M.D.
Chairman, Department of
Pediatrics
Ochsner Clinic Foundation
New Orleans, Louisiana

ELIZABETH G. NABEL, M.D.

Scientific Director
National Heart, Lung, and
Blood Institute
National Institutes of Health
Bethesda, Maryland

GERALD V. NACCARELLI, M.D.
Professor of Medicine and Chief
Division of Cardiology
Director, Cardiovascular Center
Pennsylvania State University College
of Medicine
Hershey, Pennsylvania

RAYMOND NIAURA, PH.D.
Professor of Psychiatry
Centers for Behavioral and
Preventive Medicine
Brown University School of Medicine
The Miriam Hospital
Providence, Rhode Island

STEVEN E. NISSEN, M.D.
Professor of Medicine and
Vice Chairman
Department of Cardiovascular
Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

DAVID G. NYKANEN, M.D.
Division of Cardiology
Miami Children's Hospital
Miami, Florida

CHRISTOPHER M. O'CONNOR, M.D.
Associate Professor of Medicine
Duke University Medical Center
Durham, North Carolina

PETER M. OKIN, M.D.
Professor of Medicine
Division of Cardiology
Weill Medical College of
Cornell University
New York, New York

JEFFREY W. OLIN, D.O.
Director, The Heart and
Vascular Institute
Morristown, New Jersey

JOHN N. O'NEIL, PH.D.
Postdoctoral Fellow
Department of Psychology
The Ohio State University
Columbus, Ohio

JOSEPH P. ORNATO, M.D.
Professor and Chairman
Department of Emergency
Medicine
Virginia Commonwealth University School of Medicine
Richmond, Virginia

LARS G. OSTERBERG, M.D.
Clinical Assistant Professor of Medicine
Department of Internal Medicine
Stanford University School of Medicine
Stanford University Medical Center
Stanford, California

DOUGLAS L. PACKER, M.D.
Professor of Medicine
Divisions of Cardiovascular Diseases
and Electrophysiology
Mayo Clinic
Rochester, Minnesota

THOMAS A. PEARSON, M.D.,
PH.D., M.P.H.
Albert D. Kaiser Professor
and Chair
Department of Community and Preventive Medicine
University of Rochester School of Medicine and Dentistry
Rochester, New York

MARY ANN PEBERDY, M.D.
Assistant Professor of Medicine and Emergency Medicine
Department of Internal Medicine
Virginia Commonwealth University School of Medicine
Richmond, Virginia

SERGIO L. PINSKI, M.D.
Associate Professor of Medicine
Section of Cardiology
Rush Medical College of
Rush University
Rush-Presbyterian-St. Luke's
Medical Center

Chicago, Illinois

JEFFREY J. POPMA, M.D.
Associate Professor of Medicine
Cardiovascular Division
Brigham and Women's Hospital
Boston, Massachusetts

ERIC N. PRYSTOWSKY, M.D.
Director, Electrophysiology Laboratory
The CARE Group
Indianapolis, Indiana

REED E. PYERITZ, M.D., PH.D.
Professor of Medicine and Genetics
Chief, Division of Medical Genetics
Department of Medicine
University of Pennsylvania School
of Medicine
Philadelphia, Pennsylvania

MARLENE RABINOVITCH, M.D.
HSFO Research Endowed Chair
Professor of Pediatrics and
Pathology Medicine
University of Toronto
Director, Cardiovascular Research Program
Hospital for Sick Children
Toronto, Ontario, Canada

DANIEL J. RADER, M.D.
Associate Professor of Medicine
University of Pennsylvania Medical Center
Philadelphia, Pennsylvania

RAVI RASALINGAM, M.B., CH.B.
Department of Medicine
Strong Memorial Hospital
Rochester, New York

NORMAN B. RATLIFF, M.D.
Professor of Pathology
Faculty Director of Cardiovascular Pathology and Autopsy Service
Department of Anatomic Pathology
The Cleveland Clinic Foundation
Cleveland, Ohio

ELLIOT J. RAYFIELD, M.D.
Clinical Professor of Medicine
Mount Sinai School of Medicine of the City University of New York
New York, New York

DONAL N. REDDAN, M.B., M.H.S.
Associate in Medicine
Department of Medicine/Nephrology
Duke University Medical Center
Durham, North Carolina

TIMOTHY J. REGAN, M.D.*
Professor of Medicine
New Jersey Medical School
Newark, New Jersey

DALE G. RENLUND, M.D.
Professor of Internal Medicine
University of Utah School of Medicine
LDS Hospital
Salt Lake City, Utah

CLARA I. RESTREPO, M.D.
Instructor
Department of Medicine
Division of Pulmonary and Critical
Care Medicine
National Jewish Medical and Research Center
University of Colorado Health
Sciences Center
Denver, Colorado

SHEREIF H. REZKALLA, M.D.
Clinical Professor of Medicine
University of Wisconsin Medical School
Madison, Wisconsin
Director, Cardiovascular Research
Department of Cardiology
Marshfield Clinic
Marshfield, Wisconsin

WILLIAM C. ROBERTS, M.D.
Medical Director
Baylor Heart and Vascular Center
Baylor University Medical Center
Dallas, Texas

KILLIAN ROBINSON, M.D.
Associate Professor of Cardiology and Internal Medicine
Department of Internal Medicine
Section of Cardiology
Wake Forest University School
of Medicine

Wake Forest University Baptist
Medical Center
Winston-Salem, North Carolina

DAN M. RODEN, M.D.
Professor of Medicine and Pharmacology
Vanderbilt University School
of Medicine
Nashville, Tennessee

MARCO ROFFI, M.D.
Fellow in Interventional Cardiology
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

KENNETH ROSENFIELD, M.D.
Assistant Professor of Medicine
Department of Cardiovascular Medicine and Research
Tufts University School of Medicine
St. Elizabeth's Medical Center
Boston, Massachusetts

JAMES H. F. RUDD, M.B.
BHF Clinical Research Fellow and Honorary Registrar in Cardiology
Division of Cardiovascular Medicine
University of Cambridge
Addenbrooke's Hospital
Cambridge, United Kingdom

PETER RUDD, M.D.
Professor of Medicine
Department of General
Internal Medicine
Stanford University School of Medicine
Stanford, California

JOSEPH F. SABIK III, M.D.
Heart Surgeon
Department of Thoracic and Cardiovascular Surgery
The Cleveland Clinic Foundation
Cleveland, Ohio

PAULO R. SCHVARTZMAN, M.D.
Fellow in Cardiovascular Imaging
Department of Radiology
The Cleveland Clinic Foundation
Cleveland Ohio

MARKUS SCHWAIGER, M.D.
Professor of Nuclear Medicine
Klinikum Rechts der Isar
Technische Universität München
München, Germany

ROBERT A. SCHWEIKERT, M.D.
Staff Cardiologist
Department of Cardiovascular Medicine
The Cleveland Clinic Foundation
Cleveland, Ohio

CHRISTINE E. SEIDMAN, M.D.
Professor of Medicine and Genetics
Department of Genetics
Harvard Medical School
Boston, Massachusetts

DANIEL J. SEXTON, M.D.
Professor of Medicine
Division of Infectious Diseases
Duke University Medical Center
Durham, North Carolina

München, Germany

**Deceased*.

PREFACE

Textbook of Cardiovascular Medicine, *2nd Edition*
A Pioneering Concept in the Era of Electronic Textbook Publishing

The success of the first edition of the *Textbook* was largely predicated on fulfilling its mission: “building a new, authoritative reference textbook in the field of cardiovascular medicine . . . based on the radical changes that have taken place in the past decade.” These changes not only include coverage of the largest specialty within medicine, but also the fully transformed electronic capabilities that have become both pervasive and prosaic. The CD-ROM version of the first edition of the *Textbook* received significant recognition and acclaim as a single disc that contained the entire expanded, two-volume *Comprehensive Cardiovascular Medicine* and hundreds of digital images and multimedia video clips to bring the text alive. Subsequent to the launch of this project, we were the first to make its entire contents fully available on the Internet at http://www.theheart.org/.

In this edition of the *Textbook* , we have developed an entirely new concept of electronic textbook publishing. This takes into account a broad embracing of digital technology, with a CD-ROM fully integrated with the textbook. The book and CD-ROM are a unit, with each component providing invaluable support for the other. The hard copy of the book is intended to capture the core material in our specialty; those sections of each chapter and whole chapters that are critical to providing a comprehensive reference source of the field are incorporated in the CD-ROM. This model of full integration of hard copy and an electronic medium has not been done before in medical textbook publishing. It is intended to cater to the realities of and need for rapidly looking up something in a book, which is simplified and limited in bulk, while at the same time providing in-depth probing of virtually all aspects of cardiovascular medicine, from its molecular areas to health care policy. Only via the electronic medium using the CD-ROM can all the detail be provided along with the extensive graphic support without being too voluminous.

The graphics are extensively hyperlinked to the text in an effort to broaden the presentation to not only words, but also multimedia imagery. The extent of this graphic support in magnitude has not been approached to date by any medical textbook, let alone the full integration concept. Clearly, this has been an ambitious and futuristic project for medical textbooks.

Beyond the book and electronic hybridization, there have been radical updates of nearly every chapter from the first edition (with the exception of such topics as history and physical examination!). New chapters include End-of-Life Care, Athlete’s Heart, Clinical Assessment of the Autonomic Nervous System, Percutaneous Coronary Intervention, Surgical Considerations in the Treatment of Heart Failure, Gene Therapy, and Molecular Basis of Heart Development. The updates and new chapters were built on the original framework of the eight sections of the book, which we believe continue to represent the optimal partitioning of the field’s major components. The digital anchoring of this project fully supports updates in the field, such as the significant advance in a clinical trial of rapamycin-coated stents that proved highly effective in reducing the incidence of restenosis after percutaneous coronary revascularization.

To execute this prodigious effort, we relied on nearly 200 expert contributing authors from all over the world. One of the most significant contributors to and editors of this project from its inception was Dr. Jeffrey M. Isner, who was a veritable pioneer in this field. His untimely death in late 2001 has sent shock waves throughout the biomedical community. Besides all the leadership he provided in gene therapy, angiogenesis, and translational research, he was deeply committed to this book and the value it would have for our field. Although it is only one dimension of Dr. Isner’s rich legacy, the editors and authors hope that this initiative will prove helpful in day-to-day care of patients with cardiovascular disease, serve as a stimulus for future research in basic and clinical science, and provide a utilitarian reference for all health care professionals, trainees, and biomedical researchers active in the field of cardiovascular medicine in the twenty-first century.

Eric J. Topol, M.D.
The Cleveland Clinic Foundation

ACKNOWLEDGMENTS

As in the first edition, this project has been utterly consumptive and, without question, the most challenging and enormous undertaking that I have ever encountered. For it to be accomplished, a huge number of dedicated individuals came together in a highly synergistic fashion. The people behind the project include the superb section editors, nearly 200 contributing authors from all over the world, and two project teams. One, based at The Cleveland Clinic Foundation, included Donna Wasiewicz-Bressan, Managing Editor; Steve Nissen, CD-ROM Producer and Director; Suzanne Turner, Charlene Surace, Mary Ann Citraro, and Marion Tomasko, graphic artists; with extensive CD-ROM contributions from Timothy Crowe, Paula Shalling, Arman Askari, Ron Aviles, Keith Ellis, Murray Estess, Hitinder Gurm, Barbara Hesse, Matt Hook, Chris Jones, David Lee, Tom McRae, Chris Merritt, Adrian Messerli, David Rodriguez, Ravish Sachar, Niranjan Seshadri, Barb Srichai, Mike Yen, and Frank Zidar. Heart sounds were collected by Deb Mukherjee, Steve Lin, Khaldoun Tarakji, and Raymond Migrino. The other group, based at Lippincott Williams & Wilkins and Silverchair Science + Communications, included Ruth Weinberg, Executive Editor, and the editorial and production teams of Sonya Seigafuse, Brian Brown, Mary Ann McLaughlin, Alyson Langlois, Holly Hoe, and Lisa Cunningham. Only with the tight collaboration and dedication of all the editors, authors, and the project teams could such a vast endeavor come together so successfully. My personal appreciation to all of these people runs very deep and cannot be adequately expressed in words.

INTRODUCTION

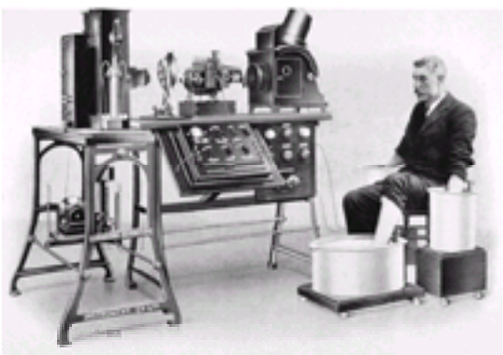
This chapter provides a brief overview of some of the milestones in the history of cardiovascular disease. In it I describe several factors that stimulated cardiology's growth, especially in the United States, and set the stage for the discoveries and inventions that gave heart specialists so many powerful tools to help them diagnose and treat various cardiovascular diseases (1,2). Cardiology's remarkable growth in recent decades was fueled by new knowledge gained from research and controlled observation, the high prevalence of cardiovascular disease, and an impressive series of procedural and technological innovations. Social and economic factors (operative at local, regional, national, and international levels) also modulated the specialty's development. In the United States, a few doctors began to invent the specialty of cardiology in New York, Boston, and other large cities just before World War I. The process was dynamic and to some extent drew on European models of research and practice. The first physicians who identified heart disease as their main professional interest were a diverse group. Some focused on science, some on practice, and others on the socioeconomic consequences of cardiac disease. Their combined vision and contributions resulted in the differentiation of cardiology as a special field of endeavor.

ELECTROCARDIOGRAPH

Beginning with the electrocardiograph (ECG), invented in 1902 by Dutch physiologist Willem Einthoven, technology has played a major role in defining cardiology as a specialty (3,4 and 5). It became apparent within a few years that the ECG was a powerful research and clinical tool for studying cardiac arrhythmias (6). Within a decade, Einthoven's large and complicated instrument had migrated from the physiologist's laboratory to the hospital, where electrical cables connected it to patients. British physician and researcher Thomas Lewis was the first person in the English-speaking world to acquire an ECG machine for clinical investigation (in 1909). During the second decade of the twentieth century, his laboratory at University College Hospital, London, became a factory of new knowledge as a result of his passion for research and his possession of an ECG machine (eFig. 1). Lewis, a role model for aspiring cardiologists, did much to popularize the new diagnostic technique (7,8 and 9).



***e*FIGURE 1** A table-model Einthoven electrocardiograph made by the Cambridge Scientific Instrument Company (London) in 1911. [From an advertising leaflet in *Heart* 1912;4(2). Author's collection.]

World War I stimulated some Americans to become heart specialists. In 1917, several American internists with an interest in heart disease were assigned to the 700-bed Military Heart Hospital in Colchester, England. This huge facility offered unprecedented opportunities for the care and study of heart patients (10). It also meant that several dozen American physicians were exposed to Thomas Lewis and to James Mackenzie, who supervised two of the hospital's four services. Mackenzie, a Scottish general practitioner whose research focused on cardiac arrhythmias, was a role model for several of America's first-generation cardiologists (11).

During the 1920s, heart specialists began to appear in several of America's largest cities. Most were general practitioners or internists who focused their practice on cardiac disease; they were "partial" specialists. Very few physicians limited their practice to cardiology at this time; there simply was not enough specialty work. The career path to cardiology was informal. These first-generation heart doctors had little, if any, formal cardiology training. Most had completed an internship and a year of medical residency, and some had taken brief postgraduate courses on heart disease or ECG interpretation (12).

By the mid-1920s, a few teaching hospitals had appointed heart specialists to their staffs. These were part-time appointments; there were virtually no full-time academic posts for cardiologists until after World War II (13). Until then, academic cardiologists earned most or all of their income by seeing private patients and interpreting ECGs. The academic cardiologists' influence on the development of cardiology was substantial. They helped shape the specialty as lecturers and authors, as organizers of cardiac clinics and local heart associations, as consultants, and as role models. Through informal networks and through the American Heart Association (AHA), created in 1924, academic cardiologists had greater influence on the character of the emerging specialty than the much larger group of practitioner cardiologists.

The 1920s also resulted in additional opportunities for cardiologists in the United States, as more than 200 cardiac clinics opened in larger cities, and many hospitals sought electrocardiographers. Meanwhile, as public awareness of the frequency and implications of cardiac disease increased, more patients wanted to see a heart specialist (14). The AHA and other organizations encouraged apparently healthy persons to get periodic health examinations to identify unrecognized heart disease. Warning readers about the risk of heart attack and sudden death, a writer in the popular magazine *Hygeia* declared: "No business man who expects to succeed would think of neglecting to take inventory of his stock once a year." He urged them to get an annual examination supplemented by "instruments of precision" because "you can't get another heart" (15).

While heart specialists used the stethoscope, chest x-ray, and fluoroscope to help detect and classify heart disease, the ECG was the tool that set them apart from other practitioners. Because of its high cost, the ECG would not become the twentieth-century equivalent of the stethoscope—a diagnostic tool carried by all physicians (16). For many patients during the middle decades of the century, a doctor who possessed an ECG machine was, *de facto*, a heart specialist.

CHALLENGE OF TREATING HEART DISEASE

Between the world wars, the number of practitioner cardiologists in the United States increased significantly as a result of the public demand for cardiac evaluations, which usually included an ECG. Although doctors found the ECG helpful in detecting and characterizing heart disease, they still had few effective treatments to offer cardiac patients. James Herrick, a Chicago internist best known for his classic description of the clinical syndrome of acute myocardial infarction (AMI), told a group of doctors in 1928: “The cynic said to me, when he heard that I was to discuss the treatment of heart disease: ‘Why not condense and say there is no treatment for heart disease save rest and digitalis?’” Herrick admitted, “Really, the cynic is not far wrong” (17).

Three years later, Paul White (eFig. 2), America’s prototypical academic cardiologist, published a 931-page book on heart disease that revealed much about contemporary cardiology theory and practice. He divided cardiac disease into three main groups in order of frequency: coronary, hypertensive, and rheumatic heart disease were common; syphilitic and thyroid heart disease were fairly common; and bacterial endocarditis and congenital heart disease were uncommon. White’s sections on treatment show that practitioners used a wide variety of medicines and nonpharmacologic approaches to treat cardiac patients. But a close reading of the text reveals the serious limitations of contemporary therapeutics—something that White, like Herrick, acknowledged (18,19).

***e*FIGURE 2** Paul Dudley White. (From the Rare Books and Manuscript Division, Francis A. Countway Library of Medicine, Boston, Massachusetts, with permission.)

Although the sphygmomanometer (invented in the late nineteenth century) made it possible to detect hypertension, White conceded that treating hypertension was a “difficult and almost hopeless task.” Advances in electrocardiography, such as the introduction of precordial leads in the 1930s, helped doctors diagnose AMI and heightened their awareness of the spectrum of symptoms caused by coronary artery disease. But despite these new insights, White conceded that there was “no specific treatment for coronary disease” (18). In this preantibiotic era, infective endocarditis was invariably fatal, and there were no specific cures for syphilis or streptococcal infections. Valvular heart disease defied treatment, despite a few heroic attempts to operate for mitral stenosis.

Digitalis, quinidine, morphine, and nitroglycerin were the main cardiac drugs available to practitioners in the 1930s, and they are still used today. There were no antibiotics, potent diuretics, or antihypertensive agents. Congestive heart failure was treated with digitalis and diuretics (mercury compounds or purine derivatives like theophylline), but these drugs had significant side effects or had to be administered by injection. Rest was a mainstay of therapy for heart failure and angina.

UNITED STATES DECLARES WAR ON HEART DISEASE

The 1940s was a decade of transition in medical and surgical treatment of heart disease. It was also a time of great ferment in America’s small but expanding research community. There was a growing conviction that medical scientists could discover ways to cure or prevent many diseases, if only they had enough money and time for their research (20). Ambitious but largely unfunded, the medical scientists and clinical investigators who belonged to the AHA were becoming impatient.

During World War II, the leaders of the AHA decided that their association should follow the example of other disease-specific organizations, such as the National Foundation for Infantile Paralysis, which were raising huge sums of money from the public for research. During 1946 to 1948 they transformed the AHA from a professional society into a voluntary health organization whose public fund-raising drive would focus on research (21). The AHA leaders also joined forces with a group of legislators, government officials, and concerned citizens to form the “heart lobby.” Using a military metaphor to describe their goal, they told the American people and their political leaders that heart disease could be conquered if only enough money were given to support cardiovascular research (22).

The federal government’s role in financing cardiovascular research (and medical research in general) expanded dramatically after World War II. In 1948, Wisconsin Republican Frank Keefe claimed that “every member of Congress is thoroughly aware of the tremendous inroads that diseases of the heart are making upon the American people.” He urged the creation of a “heart control program” patterned after the government-sponsored cancer program (23). Later that year, Congress passed and Harry Truman signed the National Heart Act, designed “to support research and training in diseases of the heart and circulation.” The act established the National Heart Institute (NHI) as a division of the National Institutes of Health (NIH) and created the National Advisory Heart Council to review grant requests for research projects and training programs.

Paul White, Executive Director of the National Advisory Heart Council and Chief Medical Advisor to the NHI, first appeared before Congress in 1949. White, business woman and philanthropist Mary Lasker, and other members of the heart lobby stated and restated their simple message: If the nation invested in academic medical centers—facilities, researchers, and equipment were needed—practical discoveries were inevitable. Wartime programs had proved that systematic support of categorical research produced results. In the case of heart disease, the goals were prevention, earlier diagnosis, better treatments, and cures. Individuals would be helped, but the nation would be the real beneficiary. Lower mortality and morbidity from heart disease would result in a healthier and more productive work force.

The heart lobby worked tirelessly to ensure generous and consistent government support of the nation’s few organized cardiovascular research and training programs. Several medical advances helped White, Lasker, and their allies make their case to America’s citizens and their political leaders (24). In the decade after World War II, new drugs dramatically changed the way doctors cared for patients with cardiovascular disease. Antibiotics, oral diuretics, and effective antihypertensive medications were all introduced at this time (25). The significance of these and other advances is underscored by the case of Franklin Roosevelt. Crippled by polio, the president died from complications of malignant hypertension just before effective antihypertensive drugs and the Salk polio vaccine were developed (26).

At midcentury, heart specialists and their patients sensed they were entering a new era in the diagnosis and treatment of cardiovascular disease (27,28). The first truly dramatic therapeutic advances—ones that offered cardiac patients the possibility of cure—were in the emerging field of cardiovascular surgery (29,30). Although a few surgeons had tried to repair diseased heart valves in the 1920s, they abandoned the approach, because nearly all of the patients died. There was renewed interest in cardiovascular surgery after Boston surgeon Robert Gross successfully ligated a patent ductus arteriosus in 1938, and Swedish surgeon Clarence Crafoord successfully repaired a coarctation of the aorta 6 years later.

CARDIAC CATHETERIZATION

Meanwhile, a powerful new diagnostic technique—cardiac catheterization—was being developed (31). Just as the ECG made it possible to study cardiac electrophysiology in humans, the cardiac catheter allowed doctors to evaluate the heart’s structure and function. German surgeon Werner Forssmann had performed the first human cardiac catheterization in 1929—on himself. But his goal was not to advance cardiac diagnosis, it was to improve on a risky therapeutic procedure used in some cases of cardiac arrest. Forssmann had hoped to find a safer way than direct cardiac puncture to deliver medicines like adrenalin into the central circulation after cardiac arrest (32).

Twelve years later, André Cournand, Dickinson Richards, and their colleagues at Bellevue Hospital in New York City reported the results of the first series of heart catheterizations in humans. Although they were interested in cardiopulmonary physiology rather than cardiac diagnosis, these researchers showed that cardiac output and intracardiac pressures could be measured safely in patients (33). By 1945, the cardiac catheter was being used to study cardiopulmonary physiology in humans in Boston (Lewis Dexter), Atlanta (James Warren and Eugene Stead), London (John McMichael and Edward Sharpey-Schaefer), and Paris (Pierre Maurice and Jean Lenègre).

One surgeon’s desire for more accurate preoperative diagnosis helped to transform cardiac catheterization from an esoteric research tool into a standard clinical diagnostic technique. Johns Hopkins surgeon Alfred Blalock performed an operation in 1944 that inaugurated a new era in the treatment of cardiac disease. With

pediatric heart specialist Helen Taussig, he developed the “blue baby operation” for tetralogy of Fallot, the most common form of cyanotic congenital heart disease (eFig. 3) (34). News of the operation electrified the medical community and the public.

***e*FIGURE 3** An early Blalock-Taussig heart operation performed at the Johns Hopkins Hospital, 1945. (From the Alan Mason Chesney Medical Archives of the Johns Hopkins Medical Institutions, Baltimore, Maryland, with permission.)

Once surgeons began performing heart operations that were both life-saving and life-threatening, the limitations of standard diagnostic techniques (history, physical examination, auscultation, electrocardiography, x-ray, and fluoroscopy) became more apparent. Blalock knew that accurate preoperative diagnosis was crucial, and he thought the new technique of cardiac catheterization could provide useful physiologic information as part of the routine evaluation of his heart patients. He hired Richard Bing (eFig. 4) in 1945 to organize the world’s first *diagnostic* cardiac catheterization laboratory at Johns Hopkins (35).

***e*FIGURE 4** Richard J. Bing. (From the author’s collection.)

Later that year, Lewis Dexter developed a diagnostic cardiac catheterization program in Boston at the Peter Bent Brigham Hospital. He published a paper in 1946 that demonstrated the value of catheterization in the evaluation of children with congenital heart disease. Once catheterization was shown to be useful clinically, several innovations were introduced that enhanced the value of the cardiac catheter as a diagnostic tool. These included technical advances, such as improved pressure gauges and instruments to measure oxygen saturation, and new procedures, such as injecting dyes into the circulation to document intracardiac shunts (36).

ADVANCES IN THE TREATMENT OF CARDIOVASCULAR DISEASE

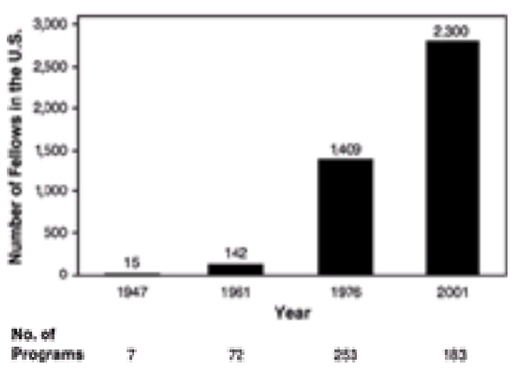
World War II contributed directly to the development of cardiovascular surgery, which in turn created demand for cardiologists trained to perform catheterization. Working in the European theater, Boston surgeon Dwight Harken adopted an aggressive approach for removing shell fragments from in and around the heart and great vessels. His experience proved that the heart was not the fragile organ that generations of doctors had assumed it to be. After the war, Harken resumed studies on the surgical treatment of mitral stenosis that Eliot Cutler had abandoned two decades earlier when almost every operated patient died (37). In 1948, Charles Bailey of Philadelphia and Harken independently performed successful operations on patients with mitral stenosis. Bailey used a special scalpel blade attached to his finger, whereas Harken relieved the obstruction by splitting the fused valve leaflets with his finger. Although several of their first patients died, they persisted and proved that such an operation could help some patients with mitral stenosis (38).

Meanwhile, the introduction of penicillin promised to change cardiology practice, because it was effective in treating (and preventing recurrent) streptococcal infections, by now recognized as the underlying cause of acute rheumatic fever. As the incidence of rheumatic fever declined, so did its cardiac complications (39). Penicillin also transformed bacterial endocarditis from a disease with a “hopeless prognosis” (Paul White, 1931) into “the most frequent curable cardiac disease” (Charles Friedberg, 1949) (18,40). Other medical advances also had important implications for patients with heart disease. For example, it was clear by 1950 that anticoagulants—intravenous heparin and oral dicumarol—were useful in the prevention and treatment of some forms of cardiovascular disease (41).

CONGRESS CATALYZES CARDIOLOGY

The federal government’s ambitious program of research funding after World War II energized academic medicine in the United States (42). Between 1945 and 1949, the NIH budget for extramural research increased 100-fold to $10 million. This resulted in discoveries and inventions that transformed medicine in general and cardiology in particular. The nation’s small but growing community of academic cardiologists and their institutions benefited from the creation of the NHI in 1948 and its program of extramural grants for researchers, facilities, equipment, and staff (43).

Specialty training also changed dramatically when the government began to subsidize research programs in university medical centers. The politicians who passed the National Heart Act wanted to be sure that their constituents benefited from the discoveries that academicians promised would result from the endowment of research. They thought this goal could best be achieved by producing more and better-trained heart specialists. Today, when 2,300 doctors are enrolled in the nation’s 183 cardiology fellowship programs, it is hard to comprehend that in 1947 there were just seven cardiology training programs that offered just 15 positions (eFig. 5) (44). The creation of the NHI (and the government funds it disbursed) had an immediate impact. In just 5 years, the number of cardiology training programs and fellowship positions quadrupled; by 1952, there were 27 training programs that offered 61 positions (45).



***e*FIGURE 5** Cardiology trainees and training programs.

Liberal government funding of academic medical centers led to an extraordinary expansion of the nation's capacity for biomedical research (eFig. 6). And the funds kept coming. In 1957, less than a decade after the creation of the NHI, the institute's budget exceeded $33 million (46). That year, the AHA budget was $20 million—half of it targeted to support research (21). The money was having the desired effect: more investigators, more research, and more well-trained heart specialists.

***e*FIGURE 6** United States Capitol. (From the author's collection.)

Basic and clinical research was paying off, and some of the most dramatic advances during the 1950s were in cardiovascular surgery. There were many challenges, however. Surgeons who hoped to develop operations for a variety of congenital and acquired cardiac defects knew they needed to *see* what they were doing inside the heart and *have time* to do it—no small feat in a beating, blood-filled organ. Open-heart surgery was possible once a heart-lung machine, which allowed surgeons to operate in a bloodless intracardiac field, was invented (47).

The earliest cardiac operations were performed on children with relatively simple congenital heart defects and middle-aged adults with rheumatic mitral stenosis. Before long, however, surgeons were developing procedures and inventing devices to treat other heart problems. The heart lobby could point with pride to these achievements, many of which represented the application of knowledge gained through basic research that was sponsored, at least in part, by the NHI (48).

Innovations in cardiac surgery catalyzed the further development and diffusion of cardiac catheterization and angiocardiography. These tests helped cardiologists and surgeons classify heart defects, quantitate their severity, and plan treatment. Referrals to heart specialists increased as cardiac patients and their family doctors learned about catheterization and heart surgery, as cardiologists and surgeons introduced these procedures into more hospitals, and as more Americans were covered by hospital insurance.

A 1964 survey of America's hospitals documented the rapid diffusion of cardiac catheterization and heart surgery from academic medical centers to community hospitals. There were 513 cardiac catheterization laboratories, 649 angiocardiography suites, 327 open-heart surgery programs, 777 closed-heart surgery programs, and 303 "fully equipped centers" offering all four procedures. That year, 30,654 catheterizations, 18,095 angiocardiograms, 8,792 open-heart operations, and 8,448 closed-heart operations were performed. More than half of these procedures were for congenital heart disease (49). This fact underscores how much cardiology and cardiac surgery would change when two new techniques—selective coronary angiography and saphenous vein coronary artery bypass graft (CABG) surgery—were introduced shortly after the survey was completed.

ASCENT OF CORONARY HEART DISEASE

During the 1960s, the focus of cardiology research and practice shifted from congenital and rheumatic heart disease to coronary artery disease. This trend was accelerated greatly by three innovations: selective coronary angiography, the coronary care unit (CCU), and CABG. Coronary angiography had the greatest impact on cardiology practice. Beginning in 1945, a few radiologists and cardiologists had developed techniques to visualize the coronary circulation by injecting contrast material in the proximal aorta. But these nonselective methods did not provide adequate images of the coronary arteries consistently, because most of the contrast material flowed down the aorta rather than into the coronary vessels (50).

Mason Sones, Jr. (eFig. 7), a cardiologist at The Cleveland Clinic, inadvertently performed a selective coronary angiogram in 1958, while doing an aortogram in a 26-year-old man with rheumatic heart disease. The catheter tip had migrated and contrast was injected directly into the right coronary artery. Sones was relieved when the patient experienced no ill effects—he expected his heart to arrest as a result of so much contrast entering the artery (51). Realizing he had discovered a technique for acquiring clear and detailed pictures of the entire coronary circulation, Sones published a description of his invention in 1962 (52). This procedure changed the practice—and the profession—of cardiology, just as the ECG had half a century earlier. Coronary angiography and other innovations in patient care placed coronary artery disease at the center of cardiology research and practice. The trend accelerated when the CCU concept was introduced almost simultaneously.

***e*FIGURE 7** Mason Sones, Jr. (*left*). (From the archives of The Cleveland Clinic Foundation, Cleveland, Ohio, with permission.)

AMI, with its risk of sudden death, is the most serious complication of coronary artery disease. Two innovations developed during the 1950s, the pacemaker and the external defibrillator, gave doctors the power to control some life-threatening arrhythmias that could complicate AMI and set the stage for the invention of the CCU (53,54). Boston cardiologist Paul Zoll published his method of using an external pacemaker to stimulate the heart of a patient who had developed asystole in 1952 (55). Two years later, he reported that ventricular fibrillation could be terminated by a shock delivered through the chest wall (56). The modern era of cardiopulmonary resuscitation began in 1960 when electrical engineer William Kouwenhoven and his colleagues at Johns Hopkins combined Zoll's defibrillation technique with closed-chest cardiac massage and mouth-to-mouth respiration (57,58).

These advances led to new strategies for delivering care to patients with AMI. In 1961, Desmond Julian of Edinburgh and Hughes Day of Kansas City, Kansas, independently developed a team approach for resuscitating hospitalized patients who had a cardiac arrest after an infarction (59,60). Their other innovation was to group vulnerable patients in a specific hospital setting—a CCU—equipped with cardiology's new electronic tools and staffed with nurses trained to use them and perform cardiopulmonary resuscitation. Continuous ECG monitoring of AMI patients in CCUs alerted nurses to sudden rhythm changes, and it also helped to clarify how they died. Whereas cardiac arrhythmias were shown to cause almost one-half of in-hospital AMI deaths, an equal number of patients died from shock and congestive heart failure. This finding led to new treatment strategies and stimulated research into ways to limit infarct size (61).

Although the advent of the CCU transformed the care of AMI patients and stimulated the job market for cardiologists, the nearly simultaneous expansion of indications for cardiac catheterization and coronary angiography had an even greater impact on the specialty. The major stimulus for the diffusion of coronary angiography in the late 1960s and early 1970s was the widespread adoption of a new surgical technique to treat angina.

Cleveland Clinic surgeon René Favaloro first described CABG as a treatment for angina in 1968, 6 years after his colleague Mason Sones, Jr., reported his technique of coronary angiography (62). As it became apparent that bypass surgery often improved anginal symptoms, the operation spread rapidly. Coronary angiography was a mandatory step if CABG was being considered, because it provided crucial information for deciding whether angina patients should be treated with medicines or surgery. If an operation was feasible, coronary angiography gave the surgeon a road map for the procedure. This stimulated the demand for cardiologists.

Meanwhile, echocardiography, another powerful diagnostic imaging technique, gave heart specialists a way to evaluate the heart's structure and function noninvasively. Diagnostic ultrasound evolved from military research that led to the invention of sonar and radar. The technique was first used to image the heart in 1954 by physicist Helmuth Hertz and cardiologist Inge Edler of the University of Lund, Sweden (63). Echocardiography migrated to the United States through the University of Pennsylvania, where biomedical engineers John Reid and Herman Schwann collaborated with cardiologist Claude Joyner to repeat and extend Hertz and Edler's work (64).

Harvey Feigenbaum, a cardiologist at Indiana University who became America's most vocal champion of echocardiography during the late 1960s and 1970s, was impressed with ultrasound's ability to detect pericardial effusion (65). The portable echocardiograph machine made it possible to detect a pericardial effusion promptly, noninvasively, and without risk. It also became apparent that the technique was useful in the evaluation of patients with congestive heart failure and heart murmurs. Meanwhile, other medical scientists and clinical investigators were inventing the important field of nuclear cardiology (66).

Technological innovations were not limited to diagnosis. Permanent, implantable electronic cardiac pacemakers were invented in Sweden and the United States in the late 1950s. Later in the decade, other researchers—most notably groups headed by Walton Lillehei in Minneapolis, Seymour Furman in New York City, and Ake Senning in Sweden—developed transvenous cardiac pacemakers for clinical use (67,68). University of Buffalo surgeon William Chardack reported the successful "implantation" of a battery-powered pacemaker built by engineer Wilson Greatbatch in 1960 (69). This report of a "permanent" pacemaker heralded a new era in the treatment of patients with symptomatic heart block and bradycardia.

During the second half of the twentieth century, market forces encouraged the rapid migration of these new cardiac diagnostic technologies and therapeutic procedures from academic medical centers to community hospitals across the country (70). Cardiovascular disease was common in middle-aged and older people—more than one million Americans had heart attacks each year. Citizens were becoming better informed about health care as the news media continued to emphasize medical "breakthroughs." The accelerating suburbanization of America also encouraged the spread of sophisticated heart care.

MEDICARE REVOLUTIONIZES AMERICAN MEDICINE

The increasing availability of health insurance as a benefit of employment also stimulated demand for specialized heart care. Between 1948 and 1965, the NHI had spent more than three-fourths of a billion dollars supporting its mission, and it could point with pride to many practical discoveries made by researchers it had funded. But as government-sponsored research led directly and indirectly to discoveries and innovations, concern grew that medical advances were diffusing too slowly into patient care (71). Congress passed laws in the mid-1960s designed to accelerate the practical application of new knowledge and to make health care more available to older and indigent Americans.

The Social Security Amendments of 1965 Act established Medicare, a program that entitled all U.S. citizens 65 years of age and older to government-funded hospital insurance benefits, and Medicaid, a program that paid for care delivered to the indigent. Medicare Part A paid for hospital-based diagnostic and treatment services provided to older Americans who were guaranteed "free choice" to "obtain health services from any institution, agency, or person qualified to participate." Medicare Part B covered many physicians' services through a voluntary "supplementary medical insurance" program eventually administered by nongovernment third-party payers (72).

Just as NIH research grants had helped many academic medical centers build and equip catheterization laboratories during the 1950s, Medicare made it possible for many larger nonteaching hospitals to install them after 1965. This fueled the demand for invasive cardiologists across the country. Cardiology technology and trainees went hand-in-hand. Liberal government funding had created an academic infrastructure capable of rapid expansion, and cardiology training programs were poised to meet the growing demand for practitioner cardiologists to diffuse new diagnostic tools like coronary angiography and echocardiography. Between 1961 and 1976, the number of cardiology training programs grew from 72 to 253, and the number of fellows increased *tenfold* from 142 to 1,409 (2).

Medicare had important implications for heart specialists, because it provided payment for office-based services and outpatient diagnostic tests, an area of cardiology that would expand rapidly during the 1970s. Medicare and private health insurance reimbursement policies helped transform cardiology from a technology-*oriented* into a technology-*dominated* specialty. The field was poised for growth as new equipment and techniques were invented, indications for their use were liberalized, and access to them was enhanced by expanding health insurance coverage. Cost was no longer a barrier to specialty care for many patients with an acute illness who required hospitalization. If they had (or got) heart disease, insured patients wanted access to "modern" cardiac care close to home, and this meant technology and heart specialists. By the mid-1970s, the nation's cardiology and cardiothoracic surgery training programs were producing a record number of practitioners to meet the demand. These doctors transferred innovations like coronary angiography, echocardiography, and open-heart surgery from academic centers to community hospitals across town and around the country.

Along with this explosion of technology and hospital-based care, the number of physicians increased dramatically in the United States, beginning in the late 1960s as a result of new government policies (73). The federal government first committed significant resources to augment the physician work force in 1963 with enactment of the Health Professions Educational Assistance Act. Congress gave medical schools more than $5 billion in direct funding between 1965 and 1971. This led to a dramatic increase in the number of medical schools and students (74). It also helped to swell the ranks of cardiologists and other specialists. By this time, the academics who taught America's medical students and residents were not part-time practitioners or primary care physicians—they were full-time clinical scientists and specialists.

CARDIAC CATHETER BECOMES A THERAPEUTIC TOOL

Cardiology entered a new era in the late 1970s when medical heart specialists began to perform *therapeutic* catheterization procedures. German cardiologist Andreas Grüntzig (*e*Fig. 8) performed the first percutaneous transluminal coronary angioplasty (PTCA) for the treatment of angina in September 1977 in Zurich, Switzerland (75). PTCA migrated to the United States within a few months of Grüntzig's first procedure. Powerful social and economic forces encouraged the spread of angioplasty before the procedure's efficacy had been proved scientifically. Understandably, many angina patients chose PTCA over CABG, because it seemed to work and meant they could avoid the discomfort, risks, and recovery time of open-heart surgery.

***e*FIGURE 8** Andreas Grüntzig. (From Willis Hurst, Emory University School of Medicine, with permission.)

Angioplasty revolutionized cardiology, much like open-heart surgery and the ECG had one and two generations earlier. But there were important differences. Before PTCA, cardiologists had used the catheter as a *diagnostic* tool to help channel patients to surgeons. Now, a new type of medical heart specialist, the interventional cardiologist, used a special catheter to perform *therapeutic* procedures on patients with angina. This changed the traditional relationship between medical and surgical heart specialists—collaborators suddenly became competitors who offered angina patients radically different treatment approaches (76).

During the 1980s, PTCA spread rapidly as many cardiologists learned the technique by attending "demonstration" courses or from their colleagues, and hundreds of fellows trained to perform the procedure entered practice. Meanwhile, clinical investigators and equipment manufacturers collaborated to develop new balloon

catheters to simplify the procedure, and innovators showed that multiple coronary lesions and multiple vessels could be safely dilated in a sequential fashion. Other important innovations in interventional cardiology, such as stents, are beyond the scope of this historical review. By the 1990s, the number of angioplasties equaled the number of bypass operations performed in the United States.

Concurrent with the development of PTCA, other medical scientists and heart specialists were inventing new techniques and refining old ones to study and treat arrhythmias (77). Beginning with the efforts of Benjamin Scherlag and his colleagues at the Staten Island Public Health Service Hospital, the field of invasive clinical electrophysiology had evolved into a formal subspecialty of cardiology by the mid-1970s. This field grew dramatically during the 1980s and 1990s with the invention of the automatic implantable defibrillator and the development of radiofrequency ablation (78).

Meanwhile, the treatment of AMI was being revolutionized by the introduction of thrombolytic therapy (79). This advance resulted from the efforts of many scientists and clinical investigators, beginning with bacteriologist William Tillett who discovered in 1933 that beta-hemolytic streptococci produced a fibrinolytic substance that he named *fibrinolysin*, later called *streptokinase* (80). Anthony Fletcher, Sol Sherry (who had worked with Tillett), and their associates first reported giving streptokinase to patients with AMI in 1958 (81). However, the clinical use of streptokinase was delayed because of concerns regarding the pyrogenicity and antigenicity of the substance.

Although E. I. Chazov and colleagues from Russia reported successful reperfusion of the infarct-related artery after intracoronary administration of streptokinase and heparin in 1976, their report was published in Russian with a brief English summary and went largely unnoticed. The modern era of thrombolytic therapy for acute myocardial infarction began 3 years later when Peter Rentrop and his associates from Göttingen, Germany, published a report on the intracoronary administration of streptokinase in five patients (82). The following year, Spokane cardiologist Marcus DeWood and his colleagues reported the high prevalence of total coronary occlusion during the early hours of AMI, documented by coronary angiography (83). The papers by Rentrop and DeWood led to widespread introduction of intracoronary streptokinase therapy.

Several European and American groups soon published studies that demonstrated the efficacy of intravenous streptokinase, an important observation for those AMI patients hospitalized in institutions without a cardiac catheterization laboratory (84,85). Meanwhile, other European groups were studying another thrombolytic agent, tissue plasminogen activator (t-PA), discovered in 1947 by Danish biologists Tage Astrup and Per Permin (86). A quarter of a century later, W. Weimar, Desire Collen, and their associates in Belgium and the Netherlands reported the successful intravenous administration of t-PA in an attempt to lyse a renal and iliofemoral thrombus in a renal transplant recipient (87).

Collen and his collaborators in the United States reported in 1983 that t-PA could lyse intracoronary thrombus that had been induced experimentally in dogs (88). The successful cloning and expression of the human t-PA gene that year meant that sufficient quantities of the substance could be produced for commercial marketing (89). The many clinical trials of thrombolytic therapy during the past two decades are beyond the scope of this review, but they proved that this approach saved lives (90).

EPILOGUE

Cardiology is one of modern medicine's greatest triumphs. During the second half of the twentieth century, cardiovascular mortality declined dramatically. Today, millions of heart patients are living longer and living better as a result of decades of research and specialty care. But medicine has entered a new era in the United States. The managed-care paradigm frames specialists and their tools and techniques as expensive resources. The issue is no longer what has been accomplished and what is still possible, but rather what is affordable. Practitioners and academicians share many concerns about how new health care delivery models, reimbursement strategies, and societal attitudes will affect cardiovascular research, education, and practice (91,92).

Resources are limited, and medical research and health care delivery must become more efficient. Now, more than ever, doctors must learn how to use technology wisely and prescribe cost-effective treatments. Outcomes research and practice guidelines, still in their infancy, will help them achieve this goal. But in this era of cost-containment, we must not lose sight of how the gains made against heart disease since World War II were achieved. By understanding the past, we will be better able to shape the future of health care and ensure that patients have access to the breakthroughs still to come.

ACKNOWLEDGMENTS

EPIDEMIOLOGY OF CARDIOVASCULAR DISEASE

Atherosclerosis, with its complications, is the leading cause of mortality and morbidity in the developed world. In the United States, a snapshot of the population would reveal that 60 million adults currently suffer from atherosclerotic cardiovascular disease, which accounts for 42% of all deaths annually, at a cost to the nation of $128 billion. Fortunately, despite this catastrophic burden of disease, much evidence has emerged over the last decade suggesting that the progression of atherosclerosis can be slowed or even reversed in many people with appropriate lifestyle and drug interventions.

The origin of the current epidemic of cardiovascular disease can be traced back to the time of industrialization in the 1700s. The three factors largely responsible for this were an increase in the use of tobacco products; reduced physical activity; and the adoption of a diet high in fat, calories, and cholesterol. This rising tide of cardiovascular disease continued into the twentieth century but began to recede when data from the Framingham study identified a number of modifiable risk factors for cardiovascular disease, including cigarette smoking, hypertension, and hypercholesterolemia (1).

The number of deaths per 100,000 attributable to cardiovascular disease peaked in the Western world in 1964 to 1965, since which time there has been a gradual decline in death rates (Fig. 1.1) (2). The age-adjusted coronary heart disease mortality in the United States dropped by more than 40% and cerebrovascular disease mortality by more than 50%, with the greatest reductions being seen among whites and males. This reduction has occurred despite a quadrupling of the proportion of the population older than 65 years of age and has been due to a number of factors, particularly major health promotion campaigns aimed at reducing the prevalence of Framingham risk factors. Indeed, there has been a substantial change in the prevalence of population cardiovascular risk factors over the last 30 years (Table 1.1). The war is not won, however, and the decline in the death rate from cardiovascular disease slowed in the 1990s (Fig. 1.2). This is likely due to a large increase in the prevalence of both obesity and type 2 diabetes mellitus, as well as a resurgence of cigarette smoking in some sectors of society (3). Female death rates from cardiovascular disease overtook male death rates in 1984 and have shown a smaller decline over the last 30 years (4). The consequences of atherosclerosis are also beginning to be felt in less well-developed regions of the globe (5), with death from atherosclerotic cardiovascular disease set to replace infection as the leading cause of death in the Third World in the near future.

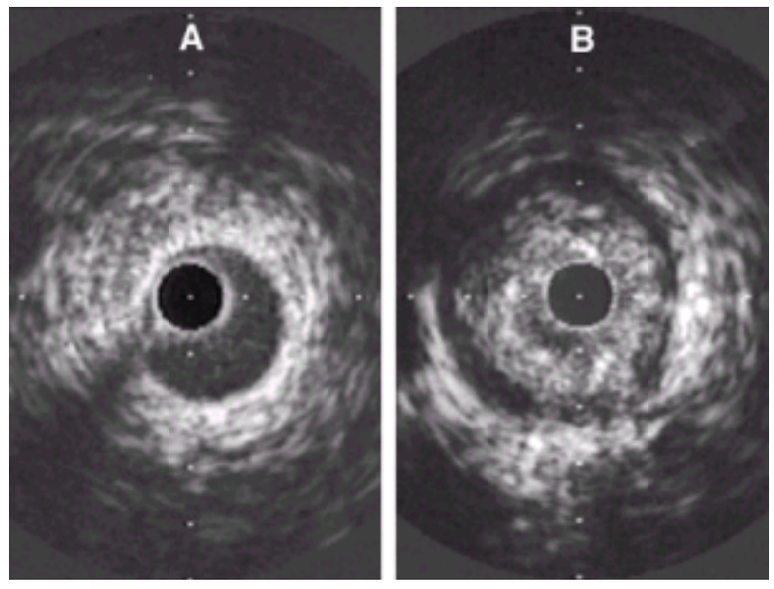
BIOLOGY OF ATHEROSCLEROSIS

Traditionally, atherosclerosis has been viewed as a degenerative disease, affecting predominantly older people, slowly progressing over many years, and eventually leading to symptoms through mechanical effects on blood flow. The perceived insidious and relentless nature of its development has meant that a somewhat pessimistic view of the potential to modify its progression by medical therapy has held sway. There has been little emphasis on the diagnosis and treatment of high-risk asymptomatic patients. Disease management has instead been dominated by interventional revascularization approaches, targeting the largest and most visible or symptomatic lesions with coronary angioplasty or bypass surgery.

Recently, for three reasons, this defeatist view of the pathogenesis and progression of atherosclerosis has begun to change. First, careful descriptive studies of the underlying pathology of atherosclerosis have revealed that atherosclerotic plaques differ in their cellular composition and that the cell types predominating in the plaque can determine the risk of fatal clinical events. Second, recent cellular and molecular biologic work has emphasized the importance of inflammatory cells and inflammatory mediators in the pathogenesis of atherosclerosis. The third and most important reason is because several large-scale clinical trials have reported that drugs—in particular, the HMG-CoA reductase inhibitors—are able to reduce the number of clinical events in patients with established atherosclerosis and do so without necessarily affecting the size of atherosclerotic plaques. These three strands of evidence have shown that, rather than being an irreversibly progressive disease, atherosclerosis is a dynamic, inflammatory process that may be amenable to medical therapy. Understanding the cellular and molecular interactions that determine the development and progression of atherosclerosis brings with it opportunities to develop novel therapeutic agents targeting key molecular and cellular interactions in its etiology. In addition, the recognition that the clinical consequences of atherosclerosis depend almost entirely on plaque composition argues for a new approach to diagnosis, with less emphasis placed on the degree of lumen narrowing and more interest in the cellular composition of the plaque.

NORMAL ARTERY

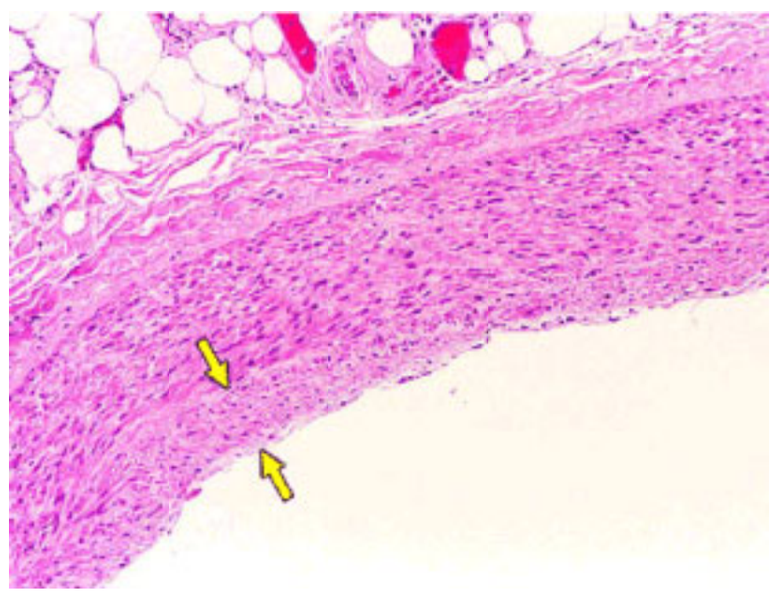
The healthy artery consists of three histologically distinct layers. Innermost and surrounding the lumen is the tunica intima, which comprises a single layer of endothelial cells in close proximity to the internal elastic lamina. The tunica media surrounds the internal elastic lamina, and its composition varies depending on the type of artery. The tunica media of the smallest arterial vessels, arterioles, comprises a single layer of vascular smooth muscle cells (VSMCs). Small arteries have a similar structure but with a thicker layer of medial VSMCs. Arterioles and small arteries are termed *resistance vessels* because they contribute vascular resistance and, hence, directly affect blood pressure. At the opposite end of the spectrum are large elastic or conduit arteries, named for the high proportion of elastin in the tunica media. The tunica media of all arteries is contained within a connective tissue layer that contains blood vessels and nerves and that is known as the *tunica adventitia*. In normal arteries, the vessel lumen diameter can be altered by contraction and relaxation of the medial VSMCs in response to a variety systemic and locally released signals.



Comparison of normal (A) vs. atherosclerotic coronary morphology (B).

ATHEROSCLEROTIC VESSEL

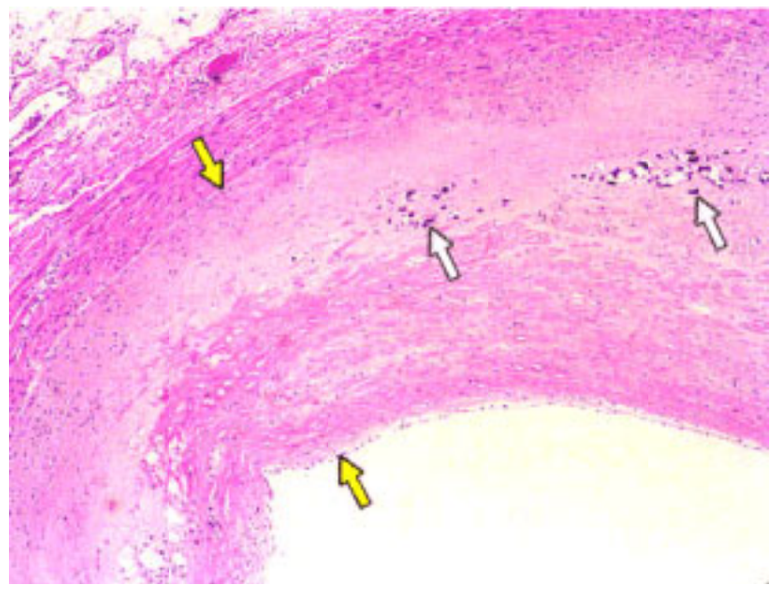
Atherosclerosis is primarily a disease affecting the intimal layer of elastic arteries. For reasons that remain largely unknown, some arterial beds appear more prone than others. Coronary, carotid, cerebral, and renal arteries and the aorta are most often involved. The arteries supplying the lower limb are also vulnerable to disease. Interestingly, the internal mammary artery is almost always spared, making it an invaluable vessel for coronary bypass surgery.



Early changes of coronary atherosclerosis. There is intimal proliferation (between the yellow arrows). The media and adventitia remain normal.

Atherosclerotic lesions develop over many years and pass through several stages. Histologically, the earliest lesion is a subendothelial accumulation of lipid-laden macrophage foam cells and associated T lymphocytes known as a *fatty streak*. Fatty streaks are asymptomatic and nonstenotic. Postmortem examinations have

shown that they are present in the aorta at the end of the first decade of life, are present in the coronary arteries by the second, and begin to appear in the cerebral circulation by the third decade. With time, the lesion progresses and the core of the early plaque becomes necrotic, containing cellular debris, crystalline cholesterol, and inflammatory cells, particularly macrophage foam cells. This necrotic core becomes bounded on its luminal aspect by an endothelialized fibrous cap, consisting of VSMCs embedded in an extensive collagenous extracellular matrix. Inflammatory cells are also present in the fibrous cap, concentrated particularly in the “shoulder” regions, where T cells, mast cells, and especially macrophages have a tendency to accumulate. Advanced lesions may become increasingly complex, showing evidence of calcification, ulceration, new vessel formation, and rupture or erosion. Thus, the composition of atherosclerotic plaques is variable and complex, and it is the interaction between the various cell types within a plaque that determines the progression, complications, and outcome of the disease.



Advanced coronary atherosclerosis. There is fibrotic intimal thickening marked by the yellow arrows with small areas of intimal calcification (*white arrows*).

THEORIES OF ATHEROGENESIS

Over the years, several theories have been advanced to explain the process of atherosclerosis. None of these is able to account for all aspects of the disease. The most recent, which views atherosclerosis as a consequence of inflammation in the vessel wall, is supported by the results of large-scale clinical trials, as discussed below. Several of these hypotheses are discussed briefly below.

Lipid Hypothesis

The lipid hypothesis, proposed initially in 1913 by Anitschkow, holds that the development of atherosclerosis is the result of the gradual accumulation of lipid in the arterial wall, with its presence at that site being responsible for the generation of the characteristic tissue changes of atheroma. In animal models, hyperlipidemia, as a result of either a high-fat diet or genetic modification, reliably leads to the development of atherosclerotic lesions in many species. This idea is supported by the wealth of evidence that links elevated serum lipid levels with the risk of development of atherosclerotic lesions in humans (6).

Thrombogenic Hypothesis

The thrombogenic hypothesis holds that atherosclerotic lesions grow by the gradual incorporation of luminal thrombus into the arterial wall. It is supported by the finding of fibrin (7) and platelet-derived proteins in both developing and mature atherosclerotic plaques (8). In addition, thrombus contains large amounts of platelet-derived growth factor, a potent VSMC mitogen. However, this theory is difficult to prove because plaque infiltration by immature blood vessels is common in advanced lesions, and consequent hemorrhage and thrombosis also occur frequently. Therefore, thrombus may appear directly as a result of atherosclerosis rather than as a causative factor.

The initiating factor for atherosclerosis formation in both of the above theories can be considered to be endothelial dysfunction. In the lipidic theory, a defective endothelial cell barrier may permit the gradual seepage of lipid into the arterial intima layer, allowing the plaque formation process to begin. In the thrombogenic theory, a dysfunctional endothelium may allow local platelet aggregation and clot formation that might subsequently become incorporated into the arterial wall. The idea that endothelial dysfunction is central to atherosclerosis has dominated recent theories about the origin of atherosclerosis.

Response to Injury Hypothesis

The response to injury hypothesis was initially proposed by Virchow in 1856, who believed that the degenerative changes associated with atherosclerosis were due to a healing response of the arterial intima to a prior mechanical injury.

Modified Response to Injury Hypothesis

In 1973, Russell Ross and John Glomset published a modified version of the response to injury hypothesis (9). They noted histologic similarities between advanced native atherosclerotic plaques and those created in monkeys' aortas by balloon injury of the endothelium. They suggested that atheroma was the result of excessive VSMC proliferation in response to an endothelial injury. This idea was later revised, and subsequent versions of the theory have claimed that endothelial dysfunction from any cause—not necessarily a mechanical injury—is crucial for the development of atherosclerosis (10,11). These injurious agents are what we today regard as risk factors for atherosclerosis and include hypertension, hyperlipidemia, and cigarette smoking.

Inflammation Theory

In his most recent review of the pathogenesis of atherosclerosis (12), Ross continues to state the importance of endothelial dysfunction in the origin of atherosclerosis but also highlights the role played by inflammation at every step of the pathogenesis of atherosclerosis. The key roles played in this process by endothelial, inflammatory, and smooth muscle cells are reviewed in the next section.

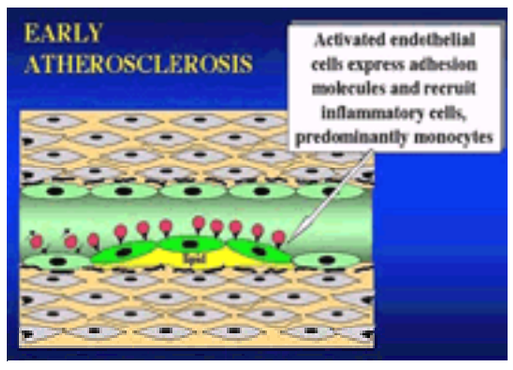
CELLULAR ROLES IN ATHEROGENESIS

Endothelial Cells

The endothelium plays a central role in maintaining vascular health by virtue of its vital antiinflammatory and anticoagulant properties. Many of these characteristics are mediated by the nitric oxide molecule (NO). This molecule was discovered in the 1980s, having been isolated from lipopolysaccharide-primed macrophages (13). NO is synthesized by endothelial cells under the control of the enzyme endothelial nitric oxide synthase and has a number of antiatherogenic properties. First, it acts as a powerful inhibitor of platelet aggregation on endothelial cells. Second, it can reduce inflammatory cell recruitment into the intima by abrogating the expression of genes involved in this process, such as those encoding intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), P-selectin, and monocyte chemoattractant protein-1 MCP-1) (14,15 and 16). There is some evidence that NO may also reduce lipid entry into the arterial intima (17). NO is also a potent antiinflammatory molecule and, depending on concentration, may be a scavenger or a producer of potentially destructive oxygen free radicals, such as peroxynitrite (18,19 and 20).

The earliest detectable manifestation of atherosclerosis is a decrease in the bioavailability of NO in response to pharmacologic or hemodynamic stimuli (12). This may occur for two reasons. Either there may be decreased manufacture of NO because of endothelial cell dysfunction, or increased NO breakdown may take place. There is evidence that both mechanisms may be important in different situations (21). Many atherosclerosis risk factors can lead to impaired endothelial function and reduced NO bioavailability. For example, hyperlipidemic patients have reduced NO-dependent vasodilatation. This reduction is reversed when patients are treated with lipid-lowering medication (22). Patients with diabetes mellitus also have impaired endothelial function, occurring primarily as a result of impaired NO production. There is, however, some evidence to suggest that increased oxidative stress leading to enhanced NO breakdown may also be a factor (23). Similarly, other risk factors for atherosclerosis, such as hypertension and cigarette smoking, are associated with reduced NO bioavailability (24,25). In cigarette smokers, endothelial impairment is thought to be due to enhanced NO degradation by oxygen-derived free radical agents such as the superoxide ion. There are also other consequences of an increased reactivity between NO and superoxide species. The product of their interaction, ONOO– (peroxynitrite), is a powerful oxidizing agent and can reach high concentrations in atherosclerotic lesions. This may result in cellular oxidative injury.

Another consequence of endothelial cell dysfunction that occurs in early atherosclerosis is the expression of surface-bound selectins and adhesion molecules, including P-selectin, ICAM-1, and VCAM-1. These molecules attract and capture circulating inflammatory cells and facilitate their migration into the subendothelial space (eFig. 1.2.1) (12). Normal endothelial cells do not express these molecules, but their appearance may be induced by abnormal arterial shear stress, subendothelial oxidized lipid, and, in diabetic patients, advanced glycosylation products in the arterial wall. The importance of selectins and adhesion molecules in the development of atherosclerosis is demonstrated by experiments using mice, which lack their expression. These animals develop smaller lesions with a lower lipid content and fewer inflammatory cells than control mice when fed a lipid-rich diet (26). Animal models have reinforced the importance of inflammatory cell recruitment to the pathogenesis of atherosclerosis, but because inflammatory cells are never seen in the intima in the absence of lipid, the results suggest that subendothelial lipid accumulation is also necessary for the development of atherosclerosis.



***e*FIGURE 1.2.1** Early atherosclerosis. (From Weissberg PL. Atherogenesis: current understanding of the causes of atheroma. *Heart* 2000;83:247–252, with permission.)

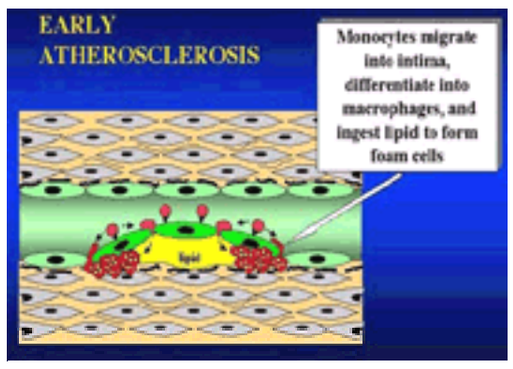
The tendency for atherosclerosis to occur preferentially in particular sites may be explained by subtle variations in endothelial function. This is probably caused by variations in local blood flow patterns, especially conditions of low flow, which can influence expression of a number of endothelial cell genes, including those encoding ICAM-1 and endothelial nitric oxide synthase (27,28). In addition to flow speed, flow type can have a direct effect on cell morphology. In areas of laminar flow, endothelial cells tend to have an ellipsoid shape, contrasting with the situation found at vessel branch points and curves, where turbulent flow induces a conformational change toward polygonal-shaped cells. Such cells have an increased permeability to low-density lipoprotein (LDL) cholesterol and may promote lesion formation (29).

These data are consistent with the idea that the primary event in atherogenesis is endothelial dysfunction. The endothelium can be damaged by a variety of means, leading to dysfunction and, by unknown mechanisms, subsequent subendothelial lipid accumulation. In this situation, the normal homeostatic features of the endothelium break down; it becomes more adhesive to inflammatory cells and platelets, it loses its anticoagulant properties, and there is reduced bioavailability of NO. Importantly, endothelial function is improved by drugs that have been shown to substantially reduce death from vascular disease, including statins and angiotensin-converting enzyme inhibitors (30,31).

Inflammatory Cells

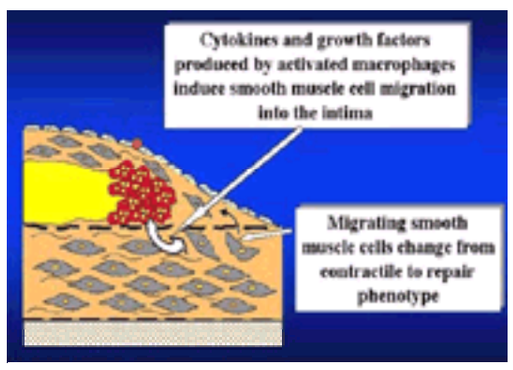
LDL from the circulation is able to diffuse passively through the tight junctions that bind neighboring endothelial cells. The rate of passive diffusion is increased when the circulating levels of LDL are elevated. In addition, other lipid fractions may be important in atherosclerosis. Lipoprotein(a) has the same basic molecular structure as LDL, with an additional apolipoprotein(a) element attached by a disulfide bridge. It has been shown to be highly atherogenic (32), to accumulate in the arterial wall in a manner similar to LDL (33), to impair vessel fibrinolysis (34), and to stimulate smooth muscle cell proliferation (35). The accumulation of subendothelial lipids, particularly when at least partly oxidized, is thought to stimulate the local inflammatory reaction that initiates and maintains activation of overlying endothelial cells. The activated cells express a variety of selectins and adhesion molecules and also produce a number of chemokines—in particular, MCP-1, whose expression is upregulated by the presence of oxidized LDL in the subendothelial space (36). Interestingly, the protective effect of HDL against atherosclerotic vascular disease may be partly explained by its ability to block endothelial cell expression of adhesion molecules (37,38). Chemokines are proinflammatory cytokines that are responsible for chemoattraction, migration, and subsequent activation of leukocytes. Mice lacking the MCP-1 gene develop smaller atherosclerotic lesions than normal animals (39). The first stage of inflammatory cell recruitment to the intima is the initiation of "rolling" of monocytes and T cells along the endothelial cell layer. This phenomenon is mediated by the selectin molecules, which selectively bind ligands found on these inflammatory cells. The subsequent firm adhesion to and migration of leukocytes through the endothelial cell layer is dependent on the endothelial expression of adhesion molecules such as ICAM-1 and VCAM-1 and their binding to appropriate receptors on inflammatory cells. Once present in the intima, monocytes differentiate into macrophages under the influence of chemokines such as macrophage colony-stimulating factor. Such molecules also stimulate the expression of the scavenger receptors that allow macrophages to ingest oxidized lipids and to develop into macrophage foam cells, the predominant cell in an early atherosclerotic lesion (eFig. 1.2.2). The formation of scavenger receptors is also regulated by peroxisome

proliferator-activated receptor-g, a nuclear transcription factor expressed at high levels in foam cells (40).



***e*FIGURE 1.2.2** Early atherosclerosis. (From Weissberg PL. Atherogenesis: current understanding of the causes of atheroma. *Heart* 2000;83:247–252, with permission.)

In early atherosclerosis at least, the macrophage can be thought of as performing a predominantly beneficial role as a “neutralizer” of potentially harmful oxidized lipid components in the vessel wall. However, macrophage foam cells also synthesize a variety of proinflammatory cytokines and growth factors that contribute both beneficially and detrimentally to the evolution of the plaque. Some of these factors are chemoattractant (osteopontin) (41,42) and growth-enhancing (platelet-derived growth factor) for VSMCs. Under the influence of these cytokines, VSMC migrate from the media to the intima, where they adopt a synthetic phenotype, well-suited to matrix production and protective fibrous cap formation (*e*Fig. 1.2.3).



***e*FIGURE 1.2.3** Smooth muscle cell migration and phenotype change.

However, activated macrophages have a high rate of apoptosis. Once dead, they release their lipid content, which becomes part of the core of the plaque, thereby contributing to its enlargement. The apoptotic cells also contain high concentrations of tissue factor, which may invoke thrombosis if exposed to circulating platelets (43).

Immunohistochemical studies have demonstrated that T lymphocytes are present in atheromatous plaques, located predominantly in the subendothelial space. The cells are in an activated state, as evidenced by expression of human leukocyte antigen-DR, CD-25 (interleukin-2 receptor), and CD-30 (44). The cells are mainly of the T-helper type 1 class, characterized by the production of interleukin-2 and interferon-g (IFN-g). These factors can alter plaque morphology and can also upregulate adhesion molecule expression by endothelial cells, thereby recruiting more cells to join the inflammatory process.

It is now generally recognized that the pathologic progression and consequences of atherosclerotic lesions are determined by dynamic interactions between inflammatory cells recruited in response to subendothelial lipid accumulation, and the local reparative “wound healing” response of surrounding VSMCs (Fig. 1.3).

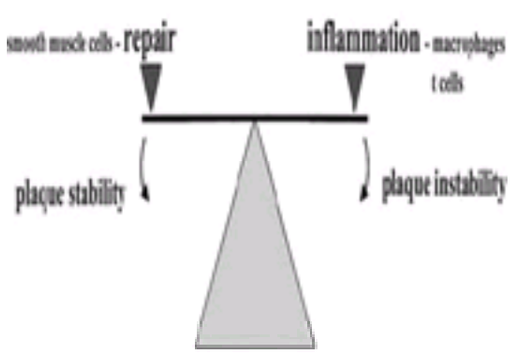


FIGURE 1.3 Factors influencing plaque stability.

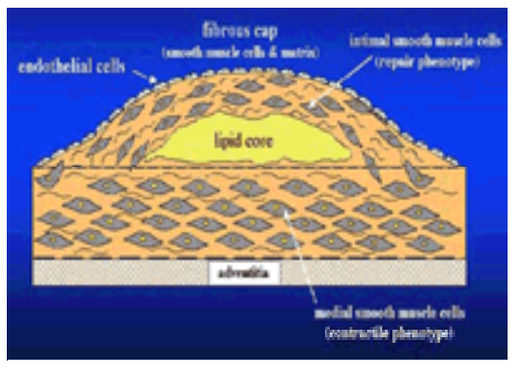
Vascular Smooth Muscle Cells

VSMCs reside mostly in the media of healthy adult arteries, where their role is to regulate vascular tone. Thus, medial VSMCs contain large amounts of contractile proteins, including myosin, alpha-actin, and tropomyosin. Continued expression of this “contractile” phenotype is maintained by the influence of extracellular proteins in the media, which act via integrins in the VSMC membrane. In atherosclerosis, however, the cells become influenced by cytokines produced by activated macrophages and endothelial cells. Under these influences, VSMCs migrate to the intima and undergo a phenotypic change characterized by a reduction in content of contractile proteins and a large increase in the number of synthetic organelles (*e*Fig. 1.2.3). This migration of VSMCs from the media to the intima, and the consequent change from a contractile to a “synthetic” phenotype, was previously thought be a crucial step in the development of atherosclerosis in the modified response to injury hypothesis discussed previously. More recently, it has been recognized that intimal VSMCs in atherosclerotic plaques bear a remarkable similarity to VSMCs found in the early developing blood vessels (45), suggesting that intimal VSMCs may be performing a beneficial, reparative role rather than a destructive one in atherosclerosis. VSMCs are well-equipped for this action. First, they can express the proteinases that they require to break free from the medial basement membrane and allow them to migrate to the site of inflammation or injury in response to chemokines. Second, they can produce various growth factors, including vascular endothelial growth factor and platelet-derived growth factor, that act in an autocrine loop to facilitate their proliferation at the site of injury. Finally, and most important, they produce large quantities of matrix proteins, in particular glycosaminoglycans, elastin, and collagen isoforms 1 and 3, necessary to repair the vessel and form a fibrous cap over the lipid-rich core of the lesion. This fibrous cap separates the highly thrombogenic lipid-rich plaque core from circulating platelets and the proteins of the coagulation cascade and also confers structural stability to the atherosclerotic lesion. And because the VSMC is the only cell capable of synthesizing this cap, it follows that VSMCs play a pivotal role in maintaining plaque stability and protecting against the potentially fatal thrombotic consequences of atherosclerosis (*e*Fig. 1.3.1 and *e*Fig. 1.3.2) (46).



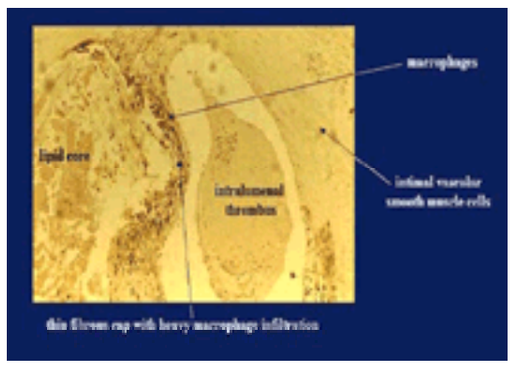
***e*FIGURE 1.3.1** Stable atherosclerotic plaque. (From Weissberg PL. Atherogenesis: current understanding of the causes of atheroma. *Heart* 2000;83:247–252, with permission.)

***e*FIGURE 1.3.2** Pathogenesis of atherosclerosis. VSMC, vascular smooth muscle cell.

CELLULAR INTERACTIONS AND LESION STABILITY

Generally, early atherosclerosis progresses without symptoms until a lesion declares itself in one of two ways. As discussed previously, macrophage foam cells may undergo apoptosis, especially in the presence of high concentrations of oxidized LDL. Their cellular remnants then become part of an enlarging lipid-rich core. Plaque size thus increases, and there may be a consequent reduction in vessel lumen area. At times of increased demand, such as exercise, this may be sufficient to cause ischemic symptoms such as angina. More hazardous is if the plaque presents with disruption of the fibrous cap, leading to exposure of the thrombogenic lipid core. This is likely to result in subsequent platelet accumulation and activation, fibrin deposition, and intravascular thrombosis. Depending on factors such as collateral blood supply, extent of arterial thrombus and local fibrinolytic activity, the end result may be arterial occlusion and downstream necrosis.

By studying the pathology of ruptured plaques, several characteristics have been identified that seem to be predictive of the risk of rupture in individual lesions (47). Plaques that are vulnerable to rupture tend to have thin fibrous caps with a high ratio of inflammatory cells to VSMCs and contain a lipid core that occupies more than 50% of the volume of the plaque. Of these, the most important is the cellular composition of the fibrous cap. Plaques containing a heavy inflammatory cell infiltrate and relatively few VSMCs have the highest risk of rupture (*e*Fig. 1.3.3) (48).



***e*FIGURE 1.3.3** Macrophages accumulate in the thin fibrous cap of unstable plaques.

Inflammatory cells in plaques act to promote plaque rupture by a number of synergistic mechanisms. First, activated T cells produce proinflammatory cytokines, typified by IFN-g, that directly inhibit VSMC proliferation (49) and almost completely shut down collagen synthesis (50,51). Thus, VSMCs in the vicinity of activated T cells in plaques are poorly able to lay down or repair extracellular matrix. Second, macrophage-derived inflammatory cytokines, in particular interleukin-1b and tumor necrosis factor-a, along with IFN-g from T cells, are synergistically cytotoxic for VSMCs, causing depletion in cell number by apoptosis (52). These cytokines are found at high levels in vulnerable plaques (53). Third, activated macrophages can induce VSMC apoptosis by direct cell-cell contact (54). Finally, and probably most important, macrophages secrete a variety of matrix metalloproteinases that degrade the matrix components of the fibrous cap by proteolytic cleavage of its protein components (46). The production of matrix metalloproteinases is upregulated by inflammatory mediators such as tumor necrosis factor-a. As well as being under threat from such an array of insults, VSMCs themselves within the fibrous cap of a mature plaque have a reduced ability to proliferate (55,56) and an enhanced susceptibility to apoptosis (57). Thus, inflammatory cells can destroy the fabric of the fibrous cap, and resident VSMCs are poorly equipped to compensate, particularly in the presence of inhibitory inflammatory cytokines (*e*Fig. 1.3.4 and *e*Fig. 1.3.5). It is important to note that all of these features can be present in small, hemodynamically insignificant plaques that are clinically silent and angiographically invisible. Thus, plaque composition is far more important than plaque size in determining outcome.

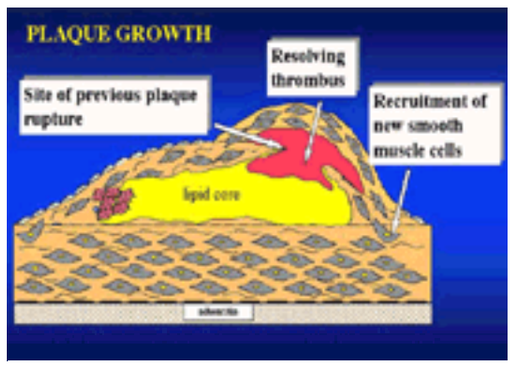
INFLAMMATORY MARKERS IN ATHEROSCLEROSIS

The cell biology of plaque development and subsequent rupture illustrates that atherosclerosis is fundamentally an inflammatory condition. Confirmation of the inflammatory basis of atherosclerosis has come from several studies that have all demonstrated a correlation between levels of markers of systemic inflammation, principally C-reactive protein (CRP), and risk of a clinical event due to plaque rupture (58,59,60 and 61). However, unlike in other systemic inflammatory conditions, such as rheumatoid arthritis, levels of CRP in atherosclerosis are characteristically not elevated above the conventional normal range, and a correlation between CRP level and coronary events was demonstrated only after development of a highly sensitive assay for CRP that was capable of measuring levels below the lower limit of detection of conventional assays. Similar, although less compelling, correlations with clinical events have also been published for other markers of inflammation, including soluble ICAM-1 (62), VCAM-1 (63,64), P-selectin (65), and interleukin-6 (the primary driver of CRP production) (66). Results of these studies have been interpreted by some as indicating that atherosclerosis arises as a consequence of a systemic inflammatory process, for example chronic infection, and by others that it reflects the inflammatory processes of atherosclerosis itself. However, there is accumulating evidence in favor of the latter interpretation.

TWO FORMS OF PLAQUE DISRUPTION: FIBROUS CAP RUPTURE AND ENDOTHELIAL EROSION

Atherosclerotic plaques become life-threatening when they initiate clot formation in the vessel lumen and disturb blood flow. This can occur in two different ways. Either there can be fibrous cap rupture, with consequent exposure of the thrombogenic extracellular matrix of the cap and the tissue factor–rich lipid core to circulating blood, or less commonly, there is erosion of the endothelial cells covering the fibrous cap, also potentially leading to the buildup of platelet-rich thrombus. Endothelial erosion probably accounts for approximately 30% of acute coronary syndromes overall and seems particularly common in females (67). Both forms of plaque disruption invariably lead to local platelet accumulation and activation. This may result in triggering of the clotting cascade, thrombus formation and, if extensive, complete vessel occlusion. Platelet-rich thrombus contains chemokines and mitogens, in particular platelet-derived growth factor and thrombin that induce migration and proliferation of VSMCs from the arterial media to the plaque and transforming growth factor-b that contributes to healing of the disrupted lesion (68). Platelets also express CD40 on their cell membranes, which causes local endothelial cell activation, resulting in the recruitment of more inflammatory cells to the lesion and perpetuating the cycle of inflammation, rupture, and thrombosis. However, fibrous cap rupture or erosion does not invariably lead to vessel occlusion. Up to 70% of plaques causing high-grade stenosis contain histologic evidence of previous subclinical plaque rupture with subsequent repair (69). This is particularly likely to occur if high blood flow through the vessel prevents the accumulation of a large occlusive thrombus. Thus, nonocclusive plaque rupture induces formation of a new fibrous cap over the organizing thrombus, which restabilizes the lesion but at the expense of increasing its size (*e*Fig. 1.3.6 and *e*Fig. 1.3.7). Because this occurs suddenly, there is little opportunity for adaptive remodeling of the artery, and the healed lesion may now impede flow sufficiently to produce ischemic symptoms. This explains why patients who have previously had normal exercise tolerance may suddenly develop symptoms of stable angina pectoris. It also follows that if lesions can grow as a consequence of repeated episodes of silent rupture and repair, a reduction of plaque rupture rate will reduce progression of atherosclerosis. Therefore, atheromatous plaques may become larger by two methods. The first is a gradual increase in size as a consequence of macrophage foam cell apoptosis and the plaques' incorporation into an enlarging necrotic lipid-laden plaque core. The second is a stepwise increase in size because of repeated, often silent episodes of plaque rupture or erosion with subsequent VSMC-driven repair.



***e*FIGURE 1.3.6** Plaques may enlarge by repeated episodes of rupture and repair. (From Weissberg PL. Atherosclerosis involves more than just lipids: plaque dynamics. *Eur Heart J* 1991;1:T13–T18, with permission.)

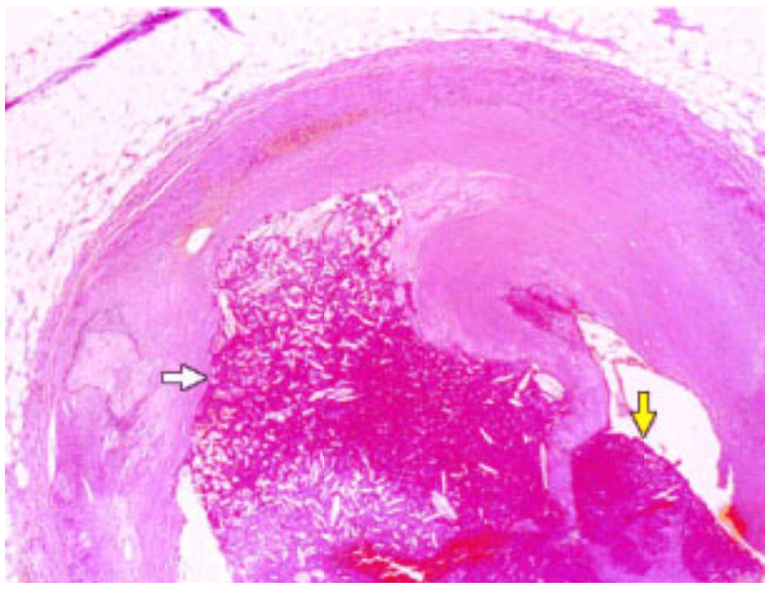
Severe ulcerated plaque of the left main trunk discovered on diagnostic angiography.



Organized intraplaque thrombus (*white arrow*) with overlying, near-occlusive fresh thrombus (*yellow arrow*). Ruptured atherosclerotic lesion of the right coronary artery 5 days after a balloon angioplasty procedure.

BALANCE OF ATHEROSCLEROSIS: THERAPEUTIC IMPLICATIONS

Atherosclerosis is a dynamic process in which the balance between the destructive influence of inflammatory cells and the reactive, stabilizing effects of VSMCs determines outcome (Fig. 1.4 and (*e*Fig. 1.4.1). This balance can be tipped toward plaque rupture by factors such as an atherogenic lipoprotein profile, high levels of lipid oxidation, local free radical generation, and genetic variability in expression and activity of certain central inflammatory molecules. For example, an association between plaque progression and a polymorphism in the stromelysin-1 gene promoter has been described (70). It is also possible that infectious organisms might be involved in atherosclerosis, either as plaque initiators or as having some role in initiating plaque rupture. This fiercely debated question has still to be resolved. *Chlamydia pneumoniae* remains the most plausible candidate pathogen. It is found in plaques, localizing at high concentrations within macrophages, but is rarely found in normal arteries (71). Although these data imply a pathologic association between the presence of chlamydia infection and atherosclerosis, neither a causative role nor an association between serum markers of infection and ischemic heart disease has been established. Animal work has shown that healthy rabbits that are nasally inoculated with chlamydia develop extensive atherosclerosis (72). The situation appears to be somewhat different in humans. Two large prospective studies and an extensive metaanalysis of previous data failed to show any association between serum markers of infection with chlamydia and incidence of or mortality from ischemic heart disease (73,74). The results of these two studies effectively exclude a strong association but allow the possibility of a weaker link, and several trials of antichlamydial antibiotics for the prevention of ischemic heart disease are in progress (ACES, WIZARD, PROVEIT, MARBLE, STAMINA).

***e*FIGURE 1.4.1** The balance of atherosclerosis.

The balance can be tipped toward plaque stability by a reduction in plaque inflammation or an increase in VSMC-driven repair. Lipid reduction, by whatever means, reduces clinical events. Evidence that this may be due to a plaque-stabilizing effect comes from animal studies that showed that statins reduced inflammatory cell and increased VSMC content of plaques (75,76), changes that would be expected to enhance stability. More important, however, evidence from human clinical studies also

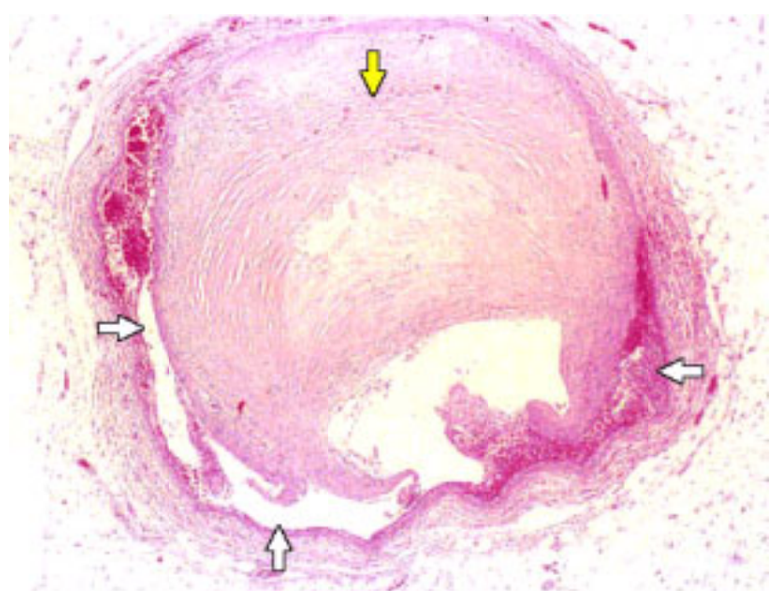
points to a plaque-stabilizing effect of statins. Angiographic studies have shown that statins produce only a small, hemodynamically insignificant reduction in progression of established stenoses (77,78 and 79). They also reduce new lesion formation, and, importantly, the number of new vessel occlusions. These arise after a plaque ruptures, leading to an occlusive thrombus in the context of a well-collateralized myocardial circulation. This seems to imply that statins are stabilizing plaques by reducing rupture rate. This conclusion is supported by the results of all the large primary and secondary prevention studies, which have demonstrated that statins (pravastatin, simvastatin and lovastatin) produce major reductions in events due to plaque rupture, such as myocardial infarction and stroke (30,80,81,82 and 83). Because statins have only a modest effect on plaque size but cause profound reductions in the number of clinical events, these studies highlight the inadequacy of angiography for the prediction of clinical events and suggest that statins have beneficial effects on plaque inflammation in addition to, or as a result of, their lipid-lowering effects. Importantly, this notion is supported by the observation that the reduction in clinical events due to statin therapy is accompanied by a parallel reduction in highly sensitive assay for CRP levels that is unlikely to be due to effects of statins on nonatherosclerotic inflammation (84,85). Also, in the first study of its kind, it has been shown that statins reduce inflammation and increase plaque collagen content in human carotid artery atherosclerosis (86).

Statin drugs may help stabilize plaques in a number of different ways (*e*Fig. 1.4.2). It is known that they can exert direct effects on endothelial cell function, inflammatory cell number and activity, VSMC proliferation, platelet aggregation, and thrombus formation (87,88,89,90 and 91). Evidence that non–lipid-lowering effects may be important *in vivo* comes from animal studies in which pravastatin caused beneficial changes in plaque composition (but not size), even when lipid levels were maintained at pretreatment levels (76). Additionally, in mice, simvastatin has direct antiinflammatory effects comparable to those of indomethacin (92). Recently, a newly recognized effect of statins as immune modulators has been described, whereby major histocompatibility complex class II mediated T-cell activation is reduced by a variety of statins (93). These observations point to potentially important effects of statins that are poorly understood and have yet to be fully defined.

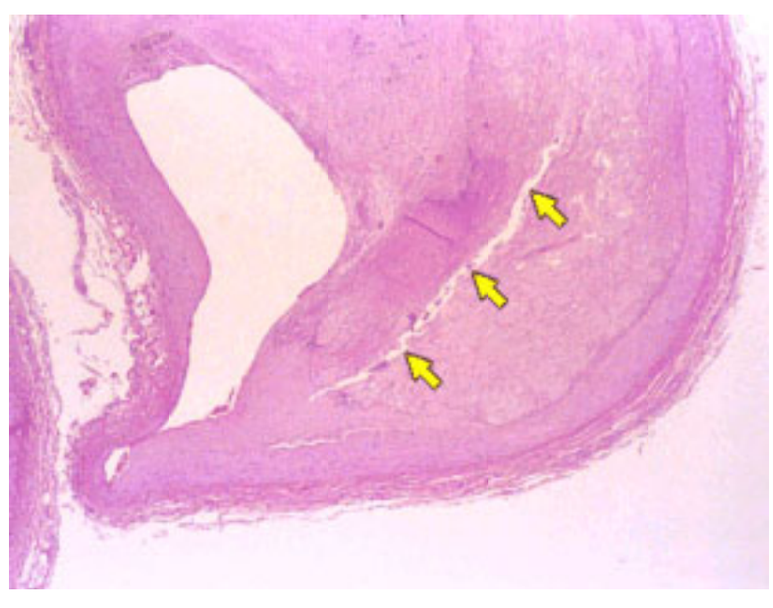
***e*FIGURE 1.4.2** The pleiotropic effects of statins on plaque biology. VSMC, vascular smooth muscle cell.

RESTENOSIS

Restenosis is the term used for the late loss of gain in lumen diameter achieved immediately after balloon dilatation of an atherosclerotic plaque. For many years, it has been thought of as an undesirable response to vascular injury. However, in effect, it represents an extreme form of plaque stabilization. Whether performed on a stable or unstable plaque, angioplasty causes endothelial disruption and often substantial damage to the full thickness of the vessel wall. The initial thrombotic response that would otherwise lead to early vessel occlusion is prevented by antiplatelet and antithrombotic therapy. There then follows a reparative response driven by medial VSMCs and adventitial myofibroblasts. The former form a matrix-rich neointima over the exposed plaque, whereas the latter produce a collagenous matrix in the adventitia. The net result is that the adventitial reaction “splints” the vessel and prevents the remodeling that would normally allow expansion of the vessel to accommodate the neointima. However, although this phenomenon may lead to angiographic or clinical restenosis, much more important, it renders the lesion stable, making the likelihood of a further plaque rupture at that site extremely remote. In effect, by stimulating a vigorous VSMC repair response, balloon angioplasty tips “the balance of atherosclerosis” in favor of plaque stability (Fig. 1.4 and (*e*Fig. 1.4.1). This phenomenon undoubtedly underlies the success of angioplasty in the treatment of acute myocardial infarction. Most of the adverse effects of the response to balloon angioplasty on remodeling can be countered by deployment of a stent. Nevertheless, the neointimal response remains problematic but is probably a worthwhile price for the stability achieved because restenosis is rarely life-threatening.



Linear, circumferential dissection 2 days after balloon angioplasty of a restenotic lesion. Note the extensive neointimal proliferation (*yellow arrow*) and dissection (*white arrows*).



Restenotic lesion. Residual tear in atherosclerotic plaque (*yellow arrows*) and large amount of neointimal proliferation 76 days after balloon angioplasty.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Many issues concerning the initiation and progression of atherosclerosis remain to be resolved. In particular, controversy persists over the extent to which endothelial dysfunction precedes or is the consequence of intimal lipid accumulation; the relative contributions of endothelial erosion and plaque rupture to clinical events; the specific role, if any, of infective agents such as *C. pneumoniae* in the pathogenesis and progression of atherosclerosis; and the extent to which statins achieve their plaque stabilizing effects directly via lipid lowering or by their so-called pleiotropic effects on the intercellular interactions that lead to plaque rupture. Integral to this latter issue is the outstanding question of what is the optimal level of lipid reduction. In other words, is greater always better?

Despite these controversies, it is certain that drug treatment will become increasingly prominent in the management of patients with, and at high risk of developing, atherosclerosis. Improvements in drug design will come from a number of complementary approaches. First, improvement will come by modifications of existing molecules, based on understanding how currently available drugs such as statins and angiotensin-converting enzyme inhibitors influence plaque progression. This will include evaluation of how other lipid-modifying strategies, such as inhibiting cholesterol absorption in the gut and modifying the balance between pro- and antiatherogenic lipoproteins and triglycerides, might influence the atherosclerotic process. Second, improvements will come by targeting molecular interactions known to be involved in atherogenesis. Likely candidates include endothelial adhesion molecules, matrix metalloproteinases, inflammatory cytokines and their signaling molecules, in particular, nuclear factor-kB and its downstream transcriptional activators. Here the challenge lies in identifying pathways or molecular species that are specific for atherosclerosis whose modification will not compromise the normal inflammatory response to pathogens. This approach will include developing regulators of VSMC behavior, such as modulators of transforming growth factor-b–driven matrix production, that may lead to enhanced maintenance of the fibrous cap. Another important example includes establishing the role of drugs targeting peroxisome proliferator–activated receptors in modifying inflammation and the vascular consequences of the metabolic syndrome that links insulin resistance, diabetes, hypertension, and dyslipidemia with premature atherosclerosis. The potentially beneficial effects of thiazolidinediones (the glitazones) on atherosclerotic events have yet to be determined. The third approach is to use new technologies such as proteomics to design new therapeutic molecules and gene array technologies to identify new molecular targets in vascular disease. In addition, as a consequence of sequencing the human genome, a number of “orphan” receptors have already been identified that might provide vascular specific targets for novel therapies.

THE FUTURE

It is almost inconceivable that the combination of these approaches will not lead to the development of new drugs that will act synergistically with statins and angiotensin-converting enzyme inhibitors. Furthermore, we predict that advances in genetics and diagnostics will combine with therapeutic advances to produce substantial reductions in premature cardiovascular deaths. Thus, new gene polymorphisms and mutations will be identified that confer increased likelihood either of developing atheroma or of experiencing its consequences. This will lead, in turn, to better prescription of lifestyle modifications and better targeting of current and new therapies for primary prevention of cardiovascular events. This approach will be aided by new diagnostic tests—based on specific circulating markers of vascular inflammation or imaging of the inflammatory process underlying plaque rupture—that will lead to better preclinical diagnosis of patients at greatest risk of cardiovascular events and better monitoring of plaque-modifying therapies.

OVERVIEW

Diet plays an important role in the primary and secondary prevention of coronary artery disease (CAD). It has beneficial effects on the lipid profile and is a crucial part of the treatment of individuals who have multiple metabolic risk factors ("the metabolic syndrome"). Moreover, data on the value of diet in reducing oxidant stress, thrombotic tendencies, ischemic ventricular arrhythmia, and sudden death are encouraging.

The American Heart Association's (AHA) recommended population or "healthy" diet focuses on healthy eating patterns and foods. It replaces the older AHA Step I diet. It recommends an overall healthy eating pattern with general advice that should help prevent obesity, hypertension, and hypercholesterolemia (Table 2.1). For individuals who have medical problems that necessitate consumption of a therapeutic cardiovascular diet, consultation with a dietitian for medical nutrition therapy is recommended for guidance in making the necessary lifestyle changes. To reduce levels of low-density lipoprotein cholesterol (LDL-C), the earlier AHA Step II diet restricted saturated fatty acids to less than 7% of energy and dietary cholesterol to less than 200 mg per day. The current AHA dietary module to reduce LDL-C preserves this recommendation and also suggests a reduction in *trans* fatty acids (TFAs). For individuals with multiple metabolic risk factors and obesity, treatment begins with caloric restriction and increased energy expenditure. For those with elevated blood pressure, a low-salt regimen with increased emphasis on fruits and vegetables, nonfat dairy products, and weight reduction, if needed, is suggested.

Have a healthy eating pattern	Achieve and maintain a healthy body weight	Achieve a desirable blood cholesterol profile	Achieve and maintain a desirable blood pressure
Variety of fruits, vegetables, grains, low-fat or nonfat dairy products, fish, legumes, poultry, lean meats	Match energy intake to energy expenditures with appropriate changes to achieve weight loss when indicated	Limit foods high in saturated fat and cholesterol; substitute unsaturated fat from vegetables, fish, legumes, and nuts	Limit salt and alcohol; maintain a healthy body weight and a diet with emphasis on vegetables, fruits, and low-fat or nonfat dairy products

TABLE 2.1 REVISION 2000: AMERICAN HEART ASSOCIATION DIETARY GUIDELINES SUMMARIZED

The response to diet is variable and probably is genetically based. Therapeutic diets that reduce risk factors must be targeted to the specific characteristics of the individual [high LDL-C level, combined elevation of cholesterol and triglyceride (TG) levels, obesity, hypertension]. These individual characteristics may also underlie individual responsiveness to diet.

Understanding the response of the individual to various dietary components is useful, because some people may use the therapeutic diet to reach their LDL-C goal or reduce their need for medication to reach LDL-C goals. The response of LDL-C to dietary cholesterol is highly variable. People with combined forms of hyperlipidemia may be the most sensitive to diet. Dietary options such as plant sterol and stanol esters taken as margarines reduce cholesterol absorption significantly and can reduce LDL-C by 10% or more. Some saturated fats raise blood cholesterol more than others. Stearic acid is converted to oleic acid and may even lower blood cholesterol. Nonetheless, restriction of saturated fats is the hallmark of the cholesterol-lowering diet. TFAs, when consumed in high amounts, can raise LDL-C and lower high-density lipoprotein cholesterol (HDL-C). Sources high in TFAs, such as stick margarine, cookies, biscuits, and cakes, should be avoided. Butter contains cholesterol and saturated fat and is cholesterol-raising compared with soft margarine. Therapeutic diets should be low in both saturated fatty acids and TFAs.

Diets high in sources of monounsaturated fats such as canola and olive oil do not lower HDL-C as much as do high-carbohydrate diets. Such diets may be preferred for individuals with the metabolic syndrome or for diabetic patients, when weight control is not an issue. Patients need to be reminded, however, that an excess intake of fats—monounsaturated or not—can lead to weight gain. Reducing excess body weight can be a crucial factor in improving the lipid profile. The addition of regular exercise to changes in diet can be particularly beneficial in helping a patient maintain weight loss. Recent data suggest that omega-3 fatty acids, particularly docosahexaenoic acid (DHA) may reduce cardiovascular events by a mechanism other than improvement of lipid profiles. Several trials have shown a reduction in cardiac death among patients consuming DHA-supplemented diets, and animal models of coronary heart disease (CHD) suggest that an increase in the ventricular fibrillation threshold accompanies consumption of DHA.

Mild alcohol consumption, especially among middle-aged and older adults, is associated with decreased rates of CAD compared with rates among teetotalers. Approximately one-half of the benefit of alcohol can be attributed to increased levels of HDL-C. Benefit is not dependent on the kind of beverage consumed. Excess amounts of alcohol can lead to significant cardiovascular problems, including arrhythmias, cardiomyopathy, and left ventricular hypertrophy (LVH). Women are more

sensitive to alcohol than men and develop cardiomyopathy and a decrease in left ventricular function at a lower dose.

Large clinical trials have not shown beneficial effects of vitamin E or beta-carotene supplementation either on total mortality or on cardiovascular end points in both primary and secondary prevention trials. These supplements cannot be recommended for reduction of cardiovascular risk. Diets that emphasize sources of antioxidants in fruits, vegetables, nuts, and whole-grain products are recommended.

The prevalence of overweight and obesity is increasing. This is a serious concern; obesity is now considered to be the second leading cause of preventable death in the United States (after cigarette smoking). The use of the body mass index (BMI) to define overweight as a BMI of 25.0 to 29.9 and obesity as a BMI of 30 or higher is useful in clinical practice. Weight gain into the overweight range increases insulin resistance. The clinical presentation of insulin resistance includes multiple metabolic abnormalities such as high TG levels, low HDL-C levels, glucose intolerance, hypertension, and hypercoagulability. Treatment begins with regular physical activity and reduction of excess weight. The importance of prompt recognition and treatment of individuals with the metabolic syndrome is underscored by data showing that weight gain after the age of 18 years is an important precursor of diabetes and CAD. Most therapies for obesity result in benefits in the short term, with disappointingly low rates of success at 5 years. Popular diets can achieve short-term weight loss, but there is no convincing evidence of long-term efficacy. Medications such as fenfluramine and phentermine or dexfenfluramine are no longer used to treat obesity because of the associated occurrence of valvular lesions that resemble those seen with serotonin excess. Newer medical approaches to weight loss include use of sibutramine and orlistat, which may help the obese patient achieve a 5% to 10% weight loss in 1 year. Gastric bypass surgery is particularly useful for those with marked obesity. Lifestyle change is important even for individuals who are being treated with medication and/or surgery. Thus, a comprehensive approach to weight loss is recommended. Prevention of obesity should be a high priority for public policy, and physicians should consider intervention when patients initiate measures strongly associated with weight gain. Examples include smoking cessation, use of steroids, and initiation of certain antidiabetic or antidepressant medications known to promote weight gain.

GLOSSARY

Alpha-linolenic acid: Plant-based omega-3 polyunsaturated fatty acid.

Android or male pattern obesity: Increased waist-to-hip ratio associated with increased CAD risk and with hypertension, visceral obesity, glucose intolerance, and insulin resistance.

BMI: Body mass index. Calculated as weight/height^2. This index minimizes the effect of height on body weight and has become the preferred index for categorizing levels of obesity. It does not provide information, however, on the pattern of obesity.

Cis: Naturally occurring double bonds that produce a bend in the molecule that impairs crystallization.

DART Trial: Diet and Reinfarction Trial.

DASH Trial: Dietary Approaches to Stop Hypertension Trial.

Dietary cholesterol: A crucial waxy substance that is found in animal cells. Response of blood cholesterol to its consumption is highly variable.

Familial dyslipidemic hypertension: Hypertension and dyslipidemia aggregating in family members.

Gynoid or female pattern obesity: Waist to hip ratio is not increased as fat increases in femoral-gluteal regions. Not associated with increased heart risk.

Insulin-resistance syndrome: Increased insulin levels relative to glucose levels. In some studies, this is an independent predictor of CAD risk. Associated with atherogenic dyslipidemia, hypertension, and visceral obesity.

Linoleic acid: Major human polyunsaturated fatty acid; an essential fatty acid.

Mediterranean diet pyramid: Graphic summary of eating style that excludes all fats but olive oil; recommends fish, poultry, and red meat less frequently, and includes physical activity and consumption of wine in moderation.

Metabolic syndrome: Describes constellation of multiple metabolic risk factors likely due to insulin resistance. These include high TG levels, low HDL-C level, hypertension, glucose intolerance or diabetes, hypercoagulability, and increased inflammatory markers.

Monounsaturated fatty acids: Fatty acids, such as oleic acid, whose carbon chains have one double bond. Foods high in monounsaturated fats include canola and olive oil.

NHANES II, III: National Health and Nutrition Exam Surveys II (1976–1980) and III (1988–1994).

Oleic acid: A monounsaturated fatty acid.

Omega-3 or *n*-3 polyunsaturated fatty acid: Fatty acids whose first double bond is 3 carbon atoms from the methyl end of the fatty-acid chain. Fish oils and alpha-linolenic acid are *n*-3 fatty acids.

Omega-6 or *n*-6 polyunsaturated fatty acid: Polyunsaturated fatty acids whose first double bond is six carbon atoms from the methyl end of the fatty-acid chain. Linoleic acid is an example.

Partial hydrogenation: A process whereby hydrogen atoms are added to fatty acids. Produces TFAs.

Phytoestrogens: Plant compounds that have estrogen-like activity.

Polyunsaturated fatty acids: Fatty acids whose carbon chains have one or more double bonds.

Saturated fatty acids: Fatty acids whose carbon chains have no double bonds.

SCRIP: Stanford Coronary Risk Intervention Project.

STARS: St. Thomas Atherosclerosis Regression Study.

Syndrome X: Also known as the *metabolic syndrome*, with insulin resistance, glucose intolerance, dyslipidemia, and hypertension as its hallmarks. Patients have visceral obesity. The cardiologic syndrome X is microvascular angina. The link between the two syndromes may be insulin resistance.

***Trans* fatty acids:** Fatty-acid configuration in which the molecule is straightened out, leading to a more densely packed form. Solid at room temperatures.

USDA: United States Department of Agriculture.

USDA Diet Pyramid: Graphic summary of eating style based on the dietary guidelines of the USDA.

Waist to hip ratio: Measurement of waist or waist to hip ratio used to determine the pattern of obesity. Men with waist greater than 100 cm (approximately 40 in.) or waist to hip ratio greater than 0.9 and women with waist greater than 90 cm (35 in.) or waist to hip ratio greater than 0.8 are believed to have increased adiposity.

DIETARY PRESCRIPTION AND LIFESTYLE CHANGES TO REDUCE CORONARY ARTERY DISEASE

The contemporary practice of preventive cardiology requires an understanding of the use of dietary prescriptions to reduce the risk of CAD. Diets designed to lower cholesterol and improve multiple metabolic risk factors can lower the risk of CAD. A conference on dietary fatty acids and cardiovascular health reviewed in detail the epidemiologic, clinical trial, and nonhuman primate evidence supporting an important relationship between dietary fat and CAD (1). There are real benefits to an emphasis on solid nutritional principles. Cholesterol-lowering diets may allow therapeutic goals for LDL-C to be reached without additional medication (2). For example, a multicenter trial noted that the effects of intensive dietary therapy added to treatment with lovastatin resulted in a very modest gain of approximately 5% additional lowering of LDL-C levels (3). This trial had several design features that may have caused the value of diet to be underestimated. Nonetheless, even this modest lowering may allow LDL-C targets to be attained without the need to resort to an increased statin dose. For many patients, diet can reduce the expense of medication. In addition, for those with high TG, LDL-C, or HDL-C levels and associated features of the metabolic syndrome, diet, exercise, and weight loss may be particularly effective in normalizing lipid profiles or reducing the need for complex medication regimens (3). Finally, the use of dietary therapy alone, often in conjunction with either reduced tobacco intake or regular exercise, has been associated with significant cardiovascular benefit, including reductions in total mortality (4), angiographic progression (5,6), CHD end points [particularly CHD death (7,8 and 9)], and symptoms in patients with CAD (10). [See Table 2.2 and Table 2.3 for a comprehensive look at clinical and angiographic trials (11).]

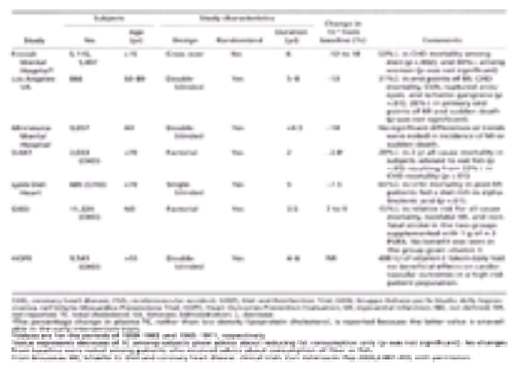

TABLE 2.2 SELECTED BLINDED, CONTROLLED DIETARY INTERVENTION TRIALS USING CHD MORBIDITY OR MORTALITY AS END POINTS

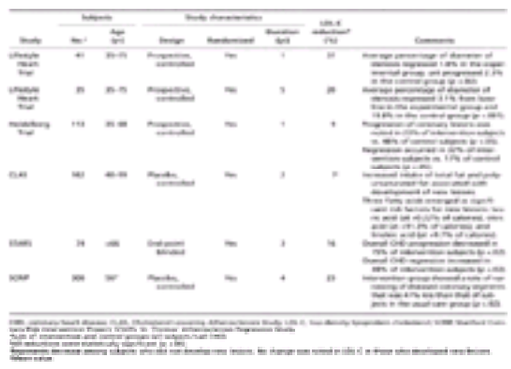

TABLE 2.3 SELECTED CONTROLLED DIETARY INTERVENTION TRIALS USING RESULTS OF ANGIOGRAPHY AS AN END POINT

For the population as a whole, the implications of a “healthy” diet that shifts the population mean for serum cholesterol are exciting to contemplate. It has been speculated that a shift in the population mean cholesterol level by 10% would prevent 30% of all CAD events, whereas lifelong treatment with cholesterol-lowering drugs of individuals with cholesterol values in the highest 10% would achieve only a 15% to 20% reduction in CAD events (12).

NATIONAL CHOLESTEROL EDUCATION PROGRAM GUIDELINES FOR DIET

Overall Goals

One major goal of the National Cholesterol Education Program (NCEP) guidelines for diet is to use diet and lifestyle to reduce both risk factors and morbidity and mortality from CHD. The NCEP, through its population and adult treatment panels (13,14), believes that adherence to its dietary recommendations could result in a 10% decrease in blood cholesterol levels (Fig. 2.1). Since those reports were published, emerging information on fiber, plant sterol/stanol esters, alcohol, fish oil, and antioxidants indicate continued relevance of dietary considerations in a total program to reduce CHD risk. Moreover, reducing or preventing obesity is a major goal because it not only indirectly affects CHD risk, through its link with risk factors, but also independently predicts CAD (15).

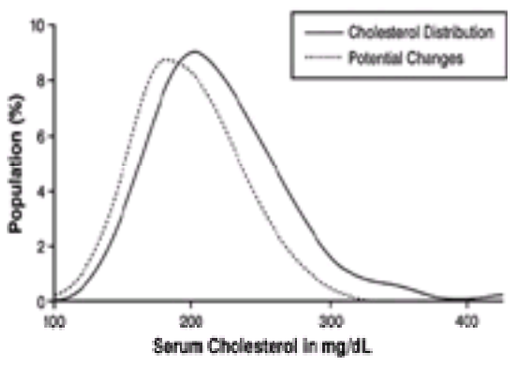

FIGURE 2.1 Cholesterol distribution in the U.S. population from the National Health and Nutrition Exam Survey, showing data from 1976 to 1980 and changes possible (*dotted lines*) if population goals for diet are attained. (Adapted from National Cholesterol Education Program. Report of the expert panel on population strategies for blood cholesterol reduction. Publication NIH 90–3046. Bethesda, MD: National Institutes of Health, US Department of Health and Human Services, 1990, with permission.)

Therapeutic Diets: Step I and II Diets Give Way to Revised Diets for Year 2000

The NCEP Adult Treatment Panel and the AHA previously recommended the Step I and Step II diets to lower cholesterol and to achieve LDL-C goals (13). The Step I diet restricted total fat to less than 30% of energy, saturated fat to less than 10% of energy, and dietary cholesterol to less than 300 mg per day. The Step II diet also restricted total fat to less than 30% of energy but limited saturated fat to less than 7% of energy, and dietary cholesterol to less than 200 mg per day. To put these diets in proper perspective, the Step I diet was really the “population diet,” designed to shift the mean cholesterol level of the population to a lower value, and the Step II diet was the therapeutic or “clinical” diet, designed to provide more optimal lowering of total cholesterol and LDL-C levels. For patients with TG levels that exceed 1,000 mg per dL, the Step II diet’s focus on LDL-C lowering was inadequate. Dietary control of severe hypertriglyceridemia requires weight loss, marked fat restriction, and possibly omega-3 fatty acids.

In the new AHA Dietary Guidelines known as “Revision 2000,” the Step I diet is supplanted by major guidelines for the general population (16) (Table 2.1). These

include the following population goals:

1. Achieve an overall healthy eating pattern
2. Achieve and maintain appropriate body weight
3. Achieve a desirable cholesterol profile
4. Achieve a desirable blood pressure

The revised guidelines stress three underlying principles. First, there are dietary patterns that all individuals can follow throughout their life span that promote and encourage cardiovascular health. This includes particular emphasis on patterns that help individuals avoid obesity. Second, the focus should shift to healthy dietary practices over an extended period of time, rather than insisting on "perfection" with each meal. This allows for the inclusion of a wide variety of healthy foods and avoids restricting the diet to repetitious and unsatisfying dietary experiences. Finally, the new guidelines form a framework on which specific recommendations can be made to individuals, based on their health and risk-factor status, and appropriately modified by their dietary preferences and cultural background.

The new NCEP Adult Treatment Panel III guidelines (17) essentially advocate the Step II diet for individuals with raised LDL-C but provide specific nutritional and lifestyle options for those who need more intensive nutritional efforts to lower LDL-C or who require an approach that more specifically targets the metabolic syndrome. Along with the DASH (Dietary Approaches to Stop Hypertension) diet (18) for individuals with high blood pressure and guidelines for obesity to guide those with weight excess, clinicians can individualize the dietary prescription to address not only an abnormal lipid profile, but also associated hypertension, obesity, and risk of sudden death.

Efficacy of Diets in Affecting Lipid Levels

Denke divided the efficacy studies of diet into those addressing healthy populations, those addressing high-risk populations, and finally, those addressing populations with known coronary disease (19). In all three categories, diet was effective if dietary counseling continued during the trial. Again, the crucial importance of weight loss in achieving the results with diet was emphasized.

Clinical and Biologic Factors Affecting Dietary Responsiveness

Any critical analysis of diet must include a consideration of the various factors that influence the results. Although a small study of men with elevated LDL-C and normal TG levels showed that restriction of saturated fat and dietary cholesterol in outpatients could achieve the results predicted by inpatient metabolic diet studies, the responsiveness for individuals was highly variable (20). Denke and Grundy suggested that this variability was influenced by both clinical and biologic factors (eTable 2.3.1). Clinical factors include compliance to diet and changes in body weight (20). Studies of compliance have documented the difficulty of maintaining adherence to a diet low in saturated fats (21,22).

***e*TABLE 2.3.1** GENETIC FACTORS DETERMINING RESPONSIVENESS TO DIET

Genetic mechanisms	Effect on cardiac health
Familial hypercholesterolemia[22]	Usually can't normalize LDL-C by diet.
Specific isoforms of apoprotein E[23]	Those with apolipoprotein E4 may absorb more dietary cholesterol than those with apolipoprotein E2.
Inherited changes in apoprotein A-IV[20]	Decreased cholesterol response to diet in patients heterozygous for this allele.
Changes in the gene encoding apoprotein B[20]	Reductions in TC and LDL-C; apolipoprotein B and HDL-C were greater in subjects homo- or heterozygous for the presence of the Xbal cutting site (X1X2 or X2X2 genotype, designated X2+) compared with those lacking the cutting site (X1X1 genotype, designated X2–).
Changes in gene encoding the apoprotein A-I promoter region[28]	Differences seen in LDL-C with diet in those with anadenine to guanine (A¬G) mutation in the promoter region of the apolipoprotein A-I gene.
LDL subclasses[39]	With low-fat diets, some men change from pattern A (large, buoyant LDL) to pattern B (small, dense LDL). Men with pattern B may respond unfavorably to a low-fat diet.

HDL-C, high-density lipoprotein cholesterol; LDL, low-density lipoprotein; LDL-C, low-density lipoprotein cholesterol; TC, total cholesterol.

Biologic factors include specific changes in dietary composition, the initial serum cholesterol concentration, metabolic responsiveness, and genetic factors. When Denke and Frantz (23) reexamined the Minnesota Coronary Survey Dietary Trial, taking into account the regression toward the mean phenomenon, they found that patients with high initial serum cholesterol levels had an 18% reduction in serum cholesterol levels, whereas those with lower levels had an 11% reduction. They found that subjects with high serum cholesterol levels were significantly more diet-responsive than those with normal values. Other studies have shown the importance of the presence of excess body weight (24,25) and the fractional catabolic rate of LDL with a diet high in saturated fatty acid in causing variability in diet-responsiveness (20).

A common cause of dietary resistance is familial hypercholesterolemia, in which affected children are unlikely to normalize their cholesterol values by diet alone (26). This highlights the importance of genetic factors in determining genetic response. Better knowledge of genetic determinants of dietary response may also permit targeting of specific dietary interventions toward different genotypes. An important genetic contribution appears to be associated with the presence of specific apoprotein E isoforms. Subjects with apoprotein E4 absorb more dietary cholesterol than do those with apoprotein E2 (27). Lopez-Miranda and coworkers (28) compared the responsiveness of men and women to a Step I diet and found that the apparent differences in mean LDL-C level reduction of 15% in men and 8% in postmenopausal women were related to the presence of the apoprotein E phenotype. Men with the apoprotein E3/4 genotype had a significantly greater reduction in LDL-C levels and the ratio of LDL to HDL than did men with the apoprotein E3/3 genotype or similarly affected women. A retrospective analysis reviewing diet and apoprotein E phenotype suggested that women with the apoprotein E3/2 phenotype derived little benefit from a diet with a high ratio of polyunsaturated fat to saturated fat because of reduction in the more protective HDL-C, whereas men with the apoprotein E4/3 phenotype showed the greatest improvement in the ratio of LDL to HDL. (29). Other factors shown to play a role in dietary responsiveness are apoprotein A-IV (30,31), changes in the gene-encoding apoprotein B (32) or the apoprotein A-I promoter region (33), and the LDL subclasses (34).

Using Diet to Alter Risk for Coronary Artery Disease

There are several principles that must be remembered in treating patients. First, the response of patients to diets is variable, as discussed earlier. Currently, we cannot predict how a given patient will respond to a particular therapeutic diet. Second, adherence to diets that produce an excellent reduction in serum lipids often also results in clinically important weight loss. Third, dietary factors that lower LDL-C levels include restriction of cholesterol-raising fatty acids and dietary cholesterol and inclusion of plant sterol/stanol esters to reduce cholesterol absorption. Other important factors include substituting mono- or polyunsaturated fats or complex carbohydrates for saturated fats, reducing intake of animal protein, and increasing intake of viscous fiber or cereal. Fourth, factors that affect HDL-C or TG levels include changes in body weight and consumption of sugars, alcohol, and omega-3 fatty acids or fish oils. Supplementation of the diet with fish may reduce cardiovascular end points independent of its effects on the lipid profile. Weight loss or restriction of simple sugars, for example, raises HDL-C levels and lowers TG levels. On the other hand, alcohol intake raises both HDL-C and TG levels. Fifth, changes seen in the first few months of a diet often are not sustained over time. This is particularly true for weight loss. The real hurdle for those with excess weight is not beginning a therapeutic program, it's maintaining the dietary habits and resulting weight loss. For weight maintenance, regular physical activity can be invaluable. The goal, of course, is sustained, not temporary, benefit.

EFFECT OF DIETARY FACTORS ON LIPIDS AND CORONARY ARTERY DISEASE

In published landmark studies, Keys (35) and Hegsted (36) quantified the response of serum cholesterol levels in humans to consumption of varying proportions of dietary fat and cholesterol. They demonstrated that saturated fatty acids (C12:0 to C16:0) are approximately twice as potent in raising cholesterol as polyunsaturated fats are in lowering them. Both investigators showed an independent effect of dietary cholesterol on serum cholesterol, although monounsaturated fats (*cis* C18:1) were believed to have no specific independent effect. These equations do not take into account the effects of behenic acid (22:0), caprylic acid (8:0), and capric acid (10:0) that are cholesterol raising as well (37). Moreover, as will be shown later, these equations do not account for the increase in LDL-C levels seen with intake of TFAs and *n*-3 fatty acids that should be considered in any contemporary review of current dietary habits.

Cholesterol-Raising Factors: Dietary Cholesterol

Mechanism

The most significant quantitative response to increased dietary cholesterol is the suppression of hepatic cholesterol synthesis (38). In addition, the effect of dietary cholesterol on receptor-mediated LDL clearance is strikingly affected by the proportion of saturated fat consumed. Studies of cholesterol feeding in humans, however,

are characterized by the great variability of their results (39). Hyper- and hyporesponders to dietary cholesterol are seen. Incredibly, significant within-person fluctuations may be found, even at the same level of serum cholesterol (40). Despite several attractive genetic mechanisms that might explain this variability, no simple test is available to discriminate responders in a quantitative fashion.

Feeding Studies

Age and gender may be important variables in determining the response to dietary cholesterol. Dietary studies involving healthy young men and women showed that consumption of one or two eggs daily, when added to a Step I AHA diet, may have only a small effect on blood cholesterol values (41,42). Unlike their male counterparts, in whom the rise in total cholesterol levels with consumption of eggs was almost completely accounted for by a rise in LDL-C, in young women, approximately 75% of the rise in total cholesterol levels was due to an increase in LDL-C, with a significant increase in HDL-C as well. On the other hand, when Lichtenstein and associates (43) added moderate amounts of dietary cholesterol to reduced-fat diets followed by hyperlipidemic middle-aged and elderly men and women, significant increases in LDL-C were seen, despite different dietary fat composition.

Other variables that help explain dietary responses to cholesterol include race and lipid profile. White individuals respond with higher cholesterol responses than individuals from other racial backgrounds (44). Careful egg-consumption studies suggest that people with combined hyperlipidemia are more sensitive to dietary cholesterol than those with elevations of cholesterol levels only (45).

Dietary Cholesterol and Coronary Artery Disease

Currently, the average daily consumption of cholesterol is 331 mg for men and 213 mg for women (46). Studies performed when average dietary cholesterol intakes were higher than they are now have shown that dietary cholesterol intake is clearly related to atherosclerosis. The Western Electric Study showed that dietary cholesterol was significantly associated with risk for CAD, independent of the serum cholesterol level (47). In three additional prospective studies, a 200 mg higher intake of cholesterol per 1,000 kcal at baseline was associated with a 30% higher rate of CAD (48). On the other hand, food frequency data gleaned from prospective cohort studies involving men and women suggested that one egg per day did not increase CHD risk (49), although subgroup analysis from this large cohort suggested that egg consumption was associated with increased CHD risk in diabetic men and women.

Plant Stanol/Sterol Esters

Cholesterol is the sterol component of mammalian cell membranes. Plant sterols are structurally similar to cholesterol and, when ingested by humans, inhibit cholesterol absorption. Of the many plant sterols found in nature, beta-sitosterol is particularly abundant and has been used since the 1950s to lower serum cholesterol (50). Stanols are saturated sterols without double bonds in the sterol ring structure. Recently, soybean and tall oils have been esterified to create fat-soluble plant sterols and stanols that facilitate cholesterol lowering in normo- and hypercholesterolemic men and women, individuals with diabetes, people with CHD, and children (51,52).

Mechanism

Plant sterol/stanol esters compete with dietary cholesterol for absorption via mixed micelles. They can reduce cholesterol absorption efficiency by as much as 65%. Only a small amount of plant sterols and an even smaller amount of plant stanols are absorbed. Ingestion of products enriched with plant sterol/stanol esters does not cause fat malabsorption.

Feeding Studies

The efficacy of the plant sterol/stanol esters appears to be similar. Using doses of 2 to 3 g per day, feeding studies show that reductions in LDL-C levels range from 6% to 20% in most studies.

Metaanalysis shows that the dose-response relation is continuous up to a dose of approximately 2 g of plant sterol or stanol per day, although there is considerable variability in response (50). The reduction in the concentration of LDL-C at each dose is significantly greater in older people than in younger people. Levels of TGs and HDL-C are not affected. A randomized clinical trial in the United States suggested a dose-dependent response after ingestion of 3 g per day lowered LDL-C by 10.1%, with no significant reduction in serum vitamin A or 25-hydroxyvitamin D levels (53). Consumption of plant sterol/stanol ester–enriched products appears to be generally safe, but a reduction in beta-carotene absorption occurs. This has prompted concern from the AHA about the use of these products by children and pregnant women. The AHA nutritional advisory committee has recommended that further studies and long-term monitoring be undertaken to determine the long-term safety of consumption of foods enriched with plant sterol/stanol esters (54,55).

Relationship to Coronary Heart Disease

Based on their proven ability to lower LDL-C, Law (50) suggested that a reduction of CHD of approximately 25% could be expected to accompany regular dietary supplementation with plant stanol esters. A subgroup analysis of the Scandinavian Simvastatin Survival Study indicated that patients with CHD who had evidence of low cholesterol absorption and high synthesis experienced reduced CHD events during simvastatin treatment. This suggested a combined role for plant sterols and statins in individuals with high cholesterol absorption and low synthesis (56).

Cholesterol-Raising Fatty Acids

Saturated Fats

The major saturated fats in the diet are lauric (C12:0), myristic (C14:0), palmitic (C16:0), and stearic fatty acids (C18:0) (eTable 2.3.2). They have no double bonds and are solid at room temperature. Foods that are rich in saturated fats primarily include those of animal origin, such as meat and dairy products, and selected vegetable fats, such as coconut oil, palm kernel oil, palm oil, and vegetable shortening. Palmitic acid is the predominant saturated fat in animal and dairy fats, whereas lauric acid is the predominant fat in coconut oil and palm kernel oil.

***e*TABLE 2.3.2** CHOLESTEROL-RAISING FATTY ACIDS

Fatty acid	Chain length	Examples
Lauric	12	Coconut oil, palm kernel oil
Myristic	14	Coconut oil, palm kernel oil
Palmitic	16	Palm oil, beef tallow, butter, chicken fat
Elaidic[a]	18:1	Shortening, partially hydrogenated oils and margarines
Behenic	22:0	
Caprylic	8:0	
Capric	10:0	

[a] This is a *trans* fatty acid that, like the other saturated fats, raises serum and low-density lipoprotein cholesterol levels.

Mechanism

Detailed studies have determined that saturated fats raise LDL-C by suppressing LDL-receptor activity (38).

Feeding Studies

When the lipid profiles of adult lactovegetarians, whose major sources of dietary saturated fat and cholesterol are dairy products, were compared with those of strict vegetarians, the lactovegetarians have 24% higher LDL-C levels and 7% higher HDL-C levels (57). The author of that study concluded that in vegetarian populations, the ingestion of dairy products rich in saturated butterfat raises the LDL-C level on a percentage basis approximately three times higher than it raises the HDL-C level. Indeed, changes in the dietary intake of saturated fat appear to have been instrumental in lowering CAD in eastern Finland, an area that historically had the world's highest rates of mortality associated with CHD (58). Recently, a multicenter, randomized, crossover trial of the effects of reducing dietary saturated fatty acids on

plasma lipid and lipoprotein levels in 103 healthy adults aged 22 to 67 years was carried out in older men and postmenopausal women, with both white and black subjects. Compared to an average American diet in which 15% of energy comes from saturated fatty acids, lowering saturated fatty acids to 6.1% reduced LDL-C levels by 11% (59). Interestingly, lipoprotein(a) [Lp(a)] increased in a stepwise fashion as LDL-C decreased.

Although most studies have examined saturated fat as a single entity, there are important differences among saturated fatty acids. Lauric acid (12:0) raises LDL-C levels more than oleic acid does, although it is not as potent in this regard as palmitic acid (16:0) (60). Lauric acid also raises HDL-C levels more than palmitic acid does (61). Stearic acid (18:0), the second most abundant saturated fatty acid in animal fats, is not a cholesterol-raising fatty acid and does not raise LDL-C levels relative to the effect of oleic acid (62). Myristic acid (14:0) is more potent in raising cholesterol than is palmitic acid (63). In middle-aged and elderly hyperlipidemic individuals, consumption of beef tallow–enriched diets produces higher concentrations of total cholesterol and LDL-C and a higher ratio of total cholesterol to HDL-C than consumption of corn oil–enriched diets does (64). Thus, curtailment of beef tallow consumption as part of a cholesterol-lowering diet seems appropriate. On the other hand, the amount of saturated fat and dietary cholesterol in lean beef is such that it need not be totally eliminated from cholesterol-lowering diets.

Saturated Fats and Coronary Artery Disease

Epidemiologic Data The Seven Countries Study showed a direct relationship between saturated fat intake and rates of CAD (65). In that trial, Finland had the highest rate of CAD mortality, Mediterranean groups were far lower, and the Japanese, who had low intakes of saturated fat, had the lowest rates of CAD. The Ni-Hon-San Trial compared the diets and clinical status of native Japanese men with Japanese men who had migrated to Hawaii or to California. After migration toward the mainland of the United States, the diet increased in calories and saturated fat and the resulting increases in weight and serum cholesterol levels paralleled increases in rates of CAD (66,67). A notable exception to the observation that national diet often predicts risk of CAD is France. Despite similar intakes of saturated fat and dietary cholesterol to those in other Western countries, the rate of CHD in France is lower. The inverse association between wine ethanol and CHD has been one possible explanation for what has become known as the “French paradox” (68). Artaud-Wild and colleagues (69) reviewed the cholesterol–saturated fat index scores for foods eaten in these countries. They speculated that consumption of milk and butterfat was markedly higher in Finland than in France. They suggested that the lower rates of fatal CAD in France were related to a less thrombogenic diet containing more plant foods and vegetables and small amounts of liquid vegetable oils. Law (70) noted that serum HDL-C levels explained little of the difference and offered a time-lag observation, suggesting that consumption of animal fat increased more recently in France than in Britain and that this accounted for the difference.

Clinical Trial Data As noted earlier, clinical trials using lipid-lowering drugs with the ability to markedly reduce LDL-C levels have shown more convincing results than have trials involving dietary adjustments alone (71). Nonetheless, the insights gained from the entire range of dietary trials are worth reviewing, even if any single trial is, by itself, not conclusive in proving that dietary reduction of saturated fats prevents CAD.

Interpretation of many of the dietary trials that used clinical end points is hindered by faulty design (Table 2.2 and Table 2.3). This is particularly true of early trials that were underpowered, so that achieving a positive result was more difficult. The Minnesota Coronary Survey, for example, did not have sufficient patients on the therapeutic diet for a sufficient length of time to achieve a significant effect—if, in fact, one was possible (72). Other examples of flawed study design that have made interpretation difficult include the Oslo Dietary and Smoking Intervention Trial, which changed smoking habits as well as diet (73), the Los Angeles Veterans Administration Trial, which combined both primary and secondary prevention (74), and the Finnish trial, which suffered from flawed randomization (75). Despite the fact that it was not a “pure” dietary trial, the results of the Oslo trial suggested that dietary reductions in cholesterol may be important in reducing rates of CAD. In this study, participants were randomly assigned to consume a diet low in saturated fat and counseled to reduce smoking. A 47% reduction in the incidence of sudden death and myocardial infarction (MI) was achieved in the intervention group, compared with the control group. The dietary change resulted in a net difference of 10% in serum cholesterol levels between intervention and control groups. The authors used statistical analysis to show that dietary change influenced the reduction in CAD events more than smoking did. At 5 years, the difference between both groups in total mortality became marginally significant, with a 33% lower mortality rate in the intervention group than in the control group.

Three large, multiple–risk factor intervention trials in which dietary change was a component also resulted in a smaller decrease of serum cholesterol values than was anticipated (76,77 and 78). When intervention trials (multifactorial or not) that use dietary changes are viewed as a whole, it appears that modest lowering of serum cholesterol by approximately 10% by dietary intervention over a short trial period is unlikely to show significant differences in CHD risk as compared to that seen in a control group.

Clinical trials with angiographic end points have the advantage of providing additional information about the potential beneficial effects of a diet low in total and saturated fat but involve sample sizes that are easier to recruit (Table 2.3). An individual’s initial response to a diet can decrease with time, as seen in the Heidelberg trial, in which total fat restriction to less than 20% of calories resulted in initial LDL-C level decrease of 25% in subjects after 3 weeks on a metabolic ward (7). At the end of 1 year, the decrease in LDL-C levels had fallen to 4% as adherence to diet fell sharply. This produced an average lowering of LDL-C levels of 8% over the course of the year. The intervention group also participated in intensive physical exercise. When follow-up angiograms were reviewed, a significant decrease in progression and an increase in regression were seen in the intervention group. In this study, apolipoproteins, lipids, and lipoproteins were measured. Although the exercise component was an important part of this study, the best metabolic predictors of angiographic disease progression were the ratio of total cholesterol to HDL-C and the level of LDL-C (79).

In the St. Thomas Atherosclerosis Trial (STARS), CAD patients were randomly assigned to received treatment with usual care, diet, or diet and cholestyramine resin (6). The diet restricted total fat intake to 27% of total energy and saturated fat intake to 8% to 10% of energy and was high in fiber, chiefly pectin. The primary end point of this angiographic trial was the per-patient change in the mean absolute width of coronary segments. Progression of angiographic CAD correlated significantly with in-trial plasma total cholesterol, LDL-C, apolipoprotein B, and Lp(a) levels. By multiple regression analysis, LDL-C level was the best predictor of change in the diameter of the coronary vessel, appearing to account for 24% of the variance.

Further detailed dietary analysis showed that total fat intake was higher in the usual-care group than in the diet group (97 g vs. 61 g) (80). Patients in whom disease progression occurred consumed 42 g per day of saturated fat, whereas patients who experienced regression consumed only 21 g per day. These distinctions were important, because there were linear correlations between decreased intake of saturated or total fat and increased size of the artery lumen. When multiple regression analysis was used, the associations between change in coronary vessel diameter and total or saturated fat intake persisted, despite adjustment for LDL-C and other clinical descriptors. Thus, in this study of middle-aged British men, progression of CAD was strongly influenced by the intake of saturated fatty acids, possibly mediated in part by mechanisms other than the effect of saturated fat on LDL-C levels.

These studies suggest a role for reducing saturated fatty acids and cholesterol in the diet. The effects seen with these dietary changes are not as great as those seen with 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors. Moreover, they do not produce results as dramatic as those seen in individuals who consume diets supplemented with *n*-3 fatty acids, in which benefit appears to be mediated through a nonlipid effect (see Fish Oils).

Trans Fatty Acids

Saturated fatty acids are not the only cholesterol-raising fatty acids. TFAs are found in meat and dairy products (they are a byproduct of fermentation in ruminant animals) and in products containing partially hydrogenated oils. The most common TFA in the American diet is elaidic acid, the *trans* isomer of oleic acid, which is found in stick margarines, shortenings, milk, butter, cheese, commercially processed baked goods, and vegetable oils used for frying.

Feeding Studies

When TFAs are ingested as 7.7% or more of energy, they raise total cholesterol and LDL-C levels and lower HDL-C levels (81,82). At 3.8% of energy, TFAs raise LDL-C levels significantly less than do saturated fat and oleic acid and do not lower HDL-C levels (83). To put these findings into perspective, the average intake of TFAs in the United States is approximately 2% to 4% of energy. TFA may increase Lp(a) (84), although this has not been a consistent finding (85).

Mechanism

Partial hydrogenation has been used by the food industry to improve the texture acceptability and increase the oxidative and thermal stability of vegetable oils (86). Hydrogenation is accomplished by converting the naturally occurring *cis* double bonds, which produce a bend in the molecule, impair crystallization and keep the oil liquid, to their straighter *trans* isomers, which can be more tightly packed and hence are solid at room temperature. The change in HDL-C levels seen with TFA consumption appears to be mediated through an increase in cholesterol ester transfer protein (87).

Trans Fatty Acids and Coronary Artery Disease

Willet and colleagues (88) used dietary questionnaires in the Nurses Health Study to demonstrate that intake of *trans* isomers, after adjustment for age and total energy

intake, was directly related to risk of CAD. They noted that consumption of foods that are major sources of TFA [e.g., margarine, cookies (biscuits), cake, and white bread] were each significantly associated with higher risks of CAD.

How can this information on TFA be used to reduce CHD risk? Butter is clearly an undesirable choice in a cholesterol-lowering diet, because it contains both cholesterol and saturated fats. Stick forms of margarine, with their higher content of saturated fatty acids and TFA, also should be avoided. The preferred choices for spreads are either soft or tub forms of reduced-fat or *trans*-free margarines (89). The major focus of the public health message remains on restriction of sources of saturated fatty acids, but consumers should also be encouraged to keep calories from TFA low.

Cholesterol-Lowering Interventions

Unsaturated Fatty Acids

Unsaturated fatty acids lower LDL-C levels when they are exchanged for saturated fatty acids in the diet. The more unsaturated a fatty acid, the more liquid it tends to be at room temperature. There are important differences, however, in various groups of unsaturated fatty acids that should be considered in the design of therapeutic diets. The two major groups are the polyunsaturated fatty acids (PUFAs) and the monounsaturated fatty acids (MUFAs). A recent metaanalysis found no significant differences in total cholesterol, LDL-C, and HDL-C levels when MUFAs and PUFAs are directly compared (90). Real differences may relate to effects on oxidation and coagulation parameters.

Polyunsaturated Fatty Acids

PUFAs, however, are not a homogenous class but are divided into two groups by the position of the first double bond from the terminal end of the carbon chain. Examples of *n*-6 fatty PUFAs include corn, sunflower, safflower, sesame, and cottonseed oils. The major *n*-6 PUFA, linoleic acid (18:2) is an 18-carbon “essential” fatty acid that cannot be synthesized by the body. Linoleic acid is needed for normal immune response, and essential fatty acid deficiency impairs B and T cell–mediated responses (91). The *n*-3 PUFAs are often referred to as “marine lipids” or “fish oils.” Marine *n*-3 PUFAs have a major effect on TG levels, as is discussed later. Alpha-linolenic acid is a plant-based *n*-3 PUFA. Common sources of alpha-linolenic acid are tofu, soybean and canola oil, nuts, and flax seed. These are healthy additions to the diets of vegetarians and those who do not eat seafood; however, alpha-linolenic acid does not appear to lower TG levels as strikingly as do fish oils (92).

Feeding Studies

In the past, diets high in *n*-6 PUFAs were recommended to counterbalance the effect on serum cholesterol of a high intake of saturated fat. Today, diets high in *n*-6 PUFA are no longer recommended, for several reasons. First, there are no large populations that habitually ingest significantly more than 10% of energy as PUFAs. Second, excess PUFA intake can have unwelcome side effects, such as weight gain and cholelithiasis (93). Third, excess consumption of linoleic acid has been associated with tumor growth in animals, although this effect has not been verified in human trials (91). There was no association between PUFA intake and the mortality rate at 10.5 years in the large Multiple Risk Factor Intervention Trial (MRFIT) (94), but the AHA guidelines recommend restriction of total PUFA intake to <10% of calories, because there is also no conclusive evidence that high PUFA intake is safe.

Polyunsaturated Fatty Acids and Coronary Artery Disease

The *n*-6 PUFAs appear to reduce risk of CAD more than MUFAs in older epidemiologic trials (1). This was also seen in human primate studies. The benefits of consumption of *n*-3 PUFAs on CHD, particularly fatal CHD, are noteworthy. The dietary effects appear to be independent of improved lipid profiles. This is discussed in the section Fish Oils.

Monounsaturated Fatty Acids

The role of MUFAs in reducing risk of CHD has prompted an AHA Science Advisory (95). This class of fatty acids has only one double bond. Oleic acid is representative of the *cis* (hydrogen atoms are on the same side) forms of MUFAs. Common sources include canola (rapeseed) oil, olive oil, peanut oil, almonds, and avocados.

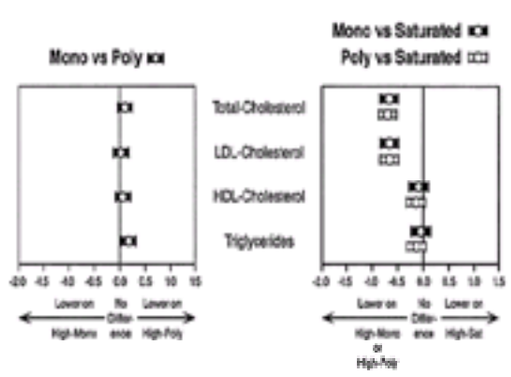
Mechanism

In contrast to PUFAs, MUFAs do not appear to lower HDL-C when they are added to the diet (96). Most important, LDL isolated from subjects on diets rich in MUFA is less susceptible to oxidation than LDL isolated from subjects on diets rich in polyunsaturated fats (97,98). This suggests that there are theoretical, but unsubstantiated, advantages to a diet high in MUFAs for individuals with small, dense LDL-C particles (99).

Feeding Studies

Grundy (100) noted that a high-carbohydrate diet raises TG levels and lowers HDL-C levels, whereas a diet high in monounsaturated fat does not. Mensink and Katan (101), in studying 57 outpatient volunteers, used foods enriched with olive oil. The olive oil–rich diet caused a specific decrease in non-HDL cholesterol and did not significantly change TG levels. Moreover, when a Step I diet in which total fat accounted for 30% of calories was compared with a Step I diet in which fat accounted for 38% of calories but that was enriched with monounsaturated fat, no significant difference was seen in the extent to which LDL-C was reduced, suggesting that monounsaturated fats have a neutral effect on LDL-C (102).

Gardner and Kraemer (90) performed a metaanalysis of 14 studies to demonstrate that there were no significant differences in lipid levels when a diet high in monounsaturated fats was compared with a diet high in polyunsaturated fats (*e*Fig. 2.1.1). A recent randomized, double-blind, five-period crossover design study in normocholesterolemic subjects with normal HDL-C levels compared the effects of three diets high in monounsaturated fat with an average American diet and the Step II diet (103). The high-MUFA diets lowered LDL-C by 14%, similar to the reduction seen with the Step II diet. TG concentrations, however, were higher with the Step II diet than with the high-MUFA diets. HDL-C levels were maintained by the high-MUFA diets, whereas they were lowered by 4% by the average American diet. Thus, with respect to HDL-C and TG levels, the high-MUFA diets had a more favorable response on these important cardiac risk factors.

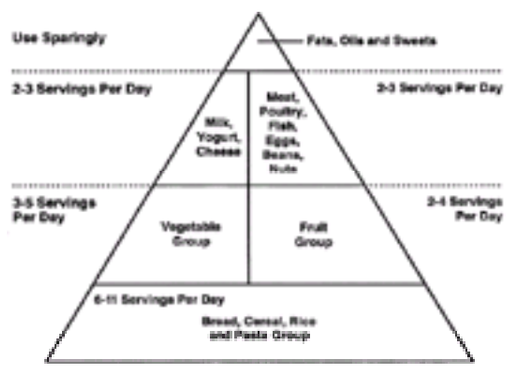


***e*FIGURE 2.1.1** Metaanalysis of the effects of high-monounsaturated (mono) versus high-polyfat (poly) diets on lipid levels. HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Some investigators have suggested following a Mediterranean diet pyramid that differs from the one endorsed by the U.S. Department of Agriculture (104) (*e*Fig. 2.1.2 and *e*Fig. 2.1.3). A wholesale shift to the Mediterranean diet pyramid that excludes all fats but olive oil; recommends less frequent consumption of fish, poultry, and red meat; and includes physical activity and wine in moderation would require major changes in agricultural policy for the United States (105). Diabetic patients may benefit from an emphasis on more monounsaturated fats, such as canola or olive oil, in the diet (106). A high-carbohydrate, low-fat diet can worsen blood sugar control and increase levels of TG levels compared with a diet enriched with monounsaturated fat. With a high–monounsaturated fat diet, levels of HDL-C are likely to be maintained

better as well.

***e*FIGURE 2.1.2** The Mediterranean diet pyramid. This pyramid is based on the dietary traditions of Crete, circa 1960, structured in light of current nutrition research. *Olive oil is the region's principal fat. In the optimal Mediterranean diet, total fat can be as high as 35% to 40% of calories.



***e*FIGURE 2.1.3** The U.S. Department of Agriculture (USDA) diet pyramid. This pyramid is based on the dietary guidelines established in 1992 by the USDA.

Monounsaturated Fatty Acids and Coronary Artery Disease

Epidemiologists have long pointed to the favorable experiences among Mediterranean populations that subside on an olive oil–based, so-called Mediterranean-type diet, in which the incidence of CAD is lower than would be expected based on the cholesterol levels of the population (10). The AHA Scientific Advisory contrasted the favorable effects of MUFAs on lipid levels, factors related to thrombogenesis, *in vitro* LDL oxidative susceptibility (compared with high-PUFA diets), and insulin sensitivity, reporting that MUFAs have accelerated atherosclerosis in monkeys and have increased the presence of chylomicron remnants. They called for additional data to resolve this issue.

The Lyon Trial compared a Mediterranean-type diet rich in alpha-linolenic acid with the AHA Step I diet in 605 subjects with a history of MI (107). It supplied a canola oil–based margarine to the intervention group that was high in oleic acid and even higher in alpha-linolenic acid. The intervention group diet was also lower in saturated fat and cholesterol and higher in fiber than the diet of the control group. There was no significant difference in alcohol ingestion between the groups. The control group had a total and saturated fat intake higher than that recommended by a Step I AHA diet. A Step II diet would have been a more appropriate control diet for this CHD population; nonetheless, despite a lack of improvement in BMI and lipid profiles, there was a striking difference in mortality, with eight sudden deaths occurring in the control group and none occurring in the treatment group. A follow-up of the original results showed that the significant difference in CHD end points was maintained at 47 months (108). Although these results are impressive, it is hard to know what individual factor in intervention mediated the reduction in CHD. There were several interventions used, including more *n*-3 fatty acids, such as alpha-linolenic acid; more fiber; more MUFAs; and less saturated fatty acids and dietary cholesterol in the diet.

Low-Fat, High-Carbohydrate Diets

A diet low in fat and high in complex carbohydrates is typical of an "Asian-style" diet. Often the percentage of energy that comes from carbohydrates is 60% to 65%, allowing total fat calories to be as low as 15% to 20% of total energy. Thus, intakes of saturated fat and dietary cholesterol are very low.

Mechanism

The usual response of a subject to a high carbohydrate diet is an increase in TG levels, which lowers HDL-C levels. Yet when patients are *gradually* introduced to a high-carbohydrate, low-fat diet, significant reductions of plasma total cholesterol and LDL-C levels are seen without the invariable carbohydrate-induced hypertriglyceridemia that is characteristic of an abrupt transition to such a diet (109).

Feeding Studies

Pritikin espoused diets that were severely limited in fat to prevent CHD (110). With this regimen, initial improvements in total cholesterol and LDL-C can be dramatic. On the other hand, the strictness of the regimen makes it difficult to obtain high rates of adherence. Possible explanations for the short-term gains seen when patients embark on such diets include regression to the mean, the effect of institutionalization (if the diet was introduced in such a facility), reduction in saturated fatty acids and dietary cholesterol, regular exercise, acute caloric restriction, and weight loss (111). Weight loss may be crucial in obtaining desired lipoprotein profiles. When Lichtenstein and colleagues (112) compared a reduced-fat diet, a low-fat diet without change in energy, and a low-fat diet in which decreased caloric intake was allowed to occur, only in the third diet was the overall change in the ratio of LDL-C to HDL-C favorable. A metaanalysis of 37 dietary intervention studies in free-living subjects published from 1981 to 1997 showed that exercise resulted in greater decreases in LDL-C and TG levels and prevented the decrease seen in HDL-C levels that is associated with low-fat diets (113).

Low-Fat Diets and Coronary Artery Disease

Some studies have emphasized a total fat content less than 30% of calories and a lowered intake of saturated fat in the diet. The Leiden study was an uncontrolled study of the effects of a vegetarian diet in 39 men who had angina pectoris. The study demonstrated that subjects who improved the ratio of total cholesterol to HDL-C had the least progression of CAD on follow-up angiography (114). Blackenhorn and colleagues (115) noted a striking difference between the 18 men in the placebo group of the Cholesterol Lowering Atherosclerosis Study (CLAS), who developed new atherosclerotic coronary lesions, and the 64 men in the diet group, who did not. Their analysis of the nutritional data suggested that this was related to dietary choices. Subjects who did not show progression had substituted low-fat meats and dairy products for high-fat products. The effect of an increased intake of total, saturated, and polyunsaturated fat was to foster a greater likelihood of new lesion development. These observational results are consistent with, but did not prove, the premise that for individuals at risk, the diet should be low in both total fat and saturated fat to reduce the likelihood of coronary progression.

The value of a low-fat vegetarian-style diet as part of a comprehensive lifestyle intervention that includes exercise was examined in the Lifestyle Heart Trial (10). In this provocative study, a highly motivated group of patients with symptomatic coronary disease consumed a diet in which fewer than 10% of calories came from fat and no cholesterol was allowed. The treatment group lost 22 lb, whereas the control group, who were on what was essentially a Step II diet, did not lose any weight. The intervention subjects showed a decline in LDL-C levels of 37.8%, to 100 mg per dL.

At the end of 1 year, the intensively treated group had decreased progression and/or regression of angiographic CAD compared with the control group. The

improvement in angiographic appearance went beyond simple improvements in percentage of stenosis; the treatment group had complex shape-change and stenosis-molding characteristics suggestive of augmented flow reserve (116). At the end of 5 years, improvement was documented by both angiography and decreased size and severity of perfusion abnormalities as seen while the patient was at rest, using dipyridamole positron emission tomography (PET) (117). The small sample size, the difficulties caused when 49% of the subjects refused to participate after randomization, and the fact that multiple interventions were in place, including exercise, stress reduction, and the significant weight reduction seen in the treatment group, preclude any generalizations about the value of the very-low-fat diet to the coronary patient that might be based on the results of this study.

Singh and coworkers (118) performed a randomized, single-blind, controlled clinical trial in patients with acute MI to determine the effect of adding more fruits, vegetables, nuts, and grains to the usual post-MI fat-reduced diet. Both groups consumed a principally vegetarian diet, eating eggs four to five times per week and meat one to two times per week. The treatment group's goal was to eat at least 400 g per day of fruits and vegetables. The results were striking: blood cholesterol and the incidence of cardiac events were significantly lower in the treatment group. Even total mortality was significantly improved. It is important to note that weight fell by 6.3 kg in the treatment group versus 2.4 kg in the usual-care group. As seen in other trials, reduction in LDL-C, particularly when it is accompanied by loss of excess weight, appears to be associated with improvement in rates of CAD events.

The Stanford Coronary Risk Intervention Project was a 4-year multifactor intervention trial. The study used serial, quantitative coronary angiography in 300 men and women to show a significant reduction in new lesion formation in the coronary arteries of those randomly assigned to the risk-reduction group, compared with that in the usual-care group (119). All risk-reduction group subjects were instructed to consume a low-fat, low-cholesterol, and high-carbohydrate diet, with a goal of intake of less than 20% of energy from fat, less than 6% of energy from saturated fat, and less than 75 mg of cholesterol per day. Increased physical activity and a specific endurance exercise-training program were recommended. A staff psychologist supervised a stop-smoking program for smokers. Major goals were to decrease LDL-C levels to fewer than 110 mg per dL and TG levels to fewer than 100 mg per dL, and to increase HDL-C levels to greater than 55 mg per dL, using dietary and pharmacologic interventions. Multiple regression analysis identified in-study dietary fat intake as the best correlate with new lesion formation. Participants randomly assigned to the risk-reduction group preferentially increased complex carbohydrate intake to offset reduction in dietary fat restriction. The authors suggested that the reduction in dietary fat accomplished by subjects in their study, as in the CLAS placebo group, decreased the rate of new lesion formation by mechanisms not limited to LDL reduction.

In addition, a low-fat diet may help relieve symptoms through mechanisms apart from the lipid-lowering effects on atherosclerosis. Several studies that used low-fat diets as part of a multiple intervention approach showed early symptomatic improvements in cardiac status. Ornish (10) reported that patients in the experimental group of his Lifestyle Trial experienced a 91% reduction in frequency of angina, a 42% reduction in duration of angina, and a 28% reduction in severity of angina, whereas angina worsened in the control group. A decrease in angina was also seen in the Heidelberg Trial (7). Both of these studies used intensive exercise regimens. Interestingly, a beneficial effect on angina was seen in the intervention groups in STARS, but not in the control group, even though there was no difference in the exercise advice given to control and to intervention subjects. Gould and colleagues (120) showed that relatively short-term, intensive cholesterol lowering over the course of 90 days resulted in improved myocardial perfusion capacity, as measured noninvasively by dipyridamole PET.

A likely explanation for short-term improvement that occurs with changes in diet is improved endothelial regulation of vasomotion. In both animal and human studies of hypercholesterolemia, abnormal blood-vessel reactivity occurs early and involves both large vessels with overt atherosclerotic change and the microcirculation, where atherosclerosis does not develop (121). Harrison and coworkers demonstrated that dietary treatment of atherosclerosis in monkeys not only produced morphologic improvement of the atherosclerotic lesion, but also restored endothelium-dependent vascular relaxation to normal (122). Later work in rabbits also showed that cholesterol-lowering diets improved endothelium-dependent vascular relaxation (123).

The mechanism by which diet restores endothelium-dependent vascular relaxation to normal most likely involves diet-related reduction of LDL-C levels. Further studies have demonstrated the more potent effects of adding LDL-lowering therapy to diet. Leung and coauthors (124) demonstrated that impairment of endothelium-dependent relaxation in hypercholesterolemic patients with healthy coronary arteries can be reversed by cholesterol-lowering therapy with diet and a lipid-lowering resin that lowered LDL-C levels by 35.7%. In patients with CAD, adherence to a cholesterol-lowering diet and HMG-CoA-reductase therapy for 5.5 months significantly improved endothelium-dependent coronary reactivity in hypercholesterolemic patients, compared with patients whose condition was managed solely by adherence to a Step I diet (125). Anderson and colleagues (126) documented even greater improvement when probucol (which is no longer clinically available, but was used as an antioxidant in this study) was added to treatment with lovastatin. Because the effects of diet may be additive to the effects of drug therapy, these data support the notion that drug therapy should be added to dietary therapy and not given alone.

Dietary Fiber

Fiber, or nondigestible plant-based carbohydrate, is an important part of a balanced diet. Some believe that the ideal diet for both cancer and heart disease prevention is the 25/25 diet (i.e., intake of 25% of calories from fat and 25 g of total fiber per day) (127). However, for the optimal cholesterol-lowering diet, it is useful to think of fiber in terms of its viscous (formerly called "soluble") and nonviscous ("insoluble") forms. Nonviscous fiber aids in the treatment of constipation but is not lipid-lowering.

Mechanism

Viscous fiber in oat bran appears to act in the gastrointestinal tract by altering bile-acid metabolism and decreasing cholesterol synthesis (128). Fiber-rich foods have an increased ratio of protein to carbohydrate, and this has been suggested to have beneficial effects on insulin sensitivity (129). Good sources of viscous fiber include dried beans, oat products (they have more viscous fiber than any other grain), and certain fruits, vegetables, and grains. The latter items contain pectin, guar gums, and mucilages. Psyllium is a common source of viscous fiber used in dry cereals or obtainable as a dietary supplement.

Feeding Studies

Fiber lowers serum cholesterol levels modestly beyond the reduction expected from a cholesterol-lowering diet among patients who have elevated cholesterol levels. A metaanalysis that identified ten randomized, controlled trials in which oat products were included in the diet showed that the greatest lipid-lowering effects were seen when trials enrolled patients who had higher total cholesterol values (greater than 229 mg per dL) and when a dose of 3 g or more of viscous fiber was used (130). On average, an increase of viscous fiber of 5 to 10 g per day should lead to an approximately 5% reduction in LDL-C levels (131). Three grams of viscous fiber is equivalent to one large bowl of ready-to-eat oat bran or three packets of instant oatmeal. Psyllium is particularly useful in lowering LDL-C levels in both adults and children (132). When 5.1 g twice daily is added to a low-fat diet, it can lower LDL-C levels by 6.4%, a degree of LDL-C lowering equivalent to that achieved by doubling a statin dosage (133).

In addition, even when saturated fat and dietary cholesterol are greatly reduced, very high intakes of foods rich in viscous fiber lower LDL-C levels and also HDL-C levels, although to a lesser degree (134). Improvements that occur with increased consumption of fiber are not temporary. Hunninghake and associates (135) used 20 g of fiber daily, predominantly viscous guar gum and pectin, to treat 59 subjects who had mild to moderate increases in LDL-C levels (131 to 191 mg per dL) and were already on a Step I diet. After approximately 1 year, the mean percentage reductions from baseline were approximately 9% for LDL-C and 11% for the ratio of LDL to HDL.

Fiber and Coronary Artery Disease

The benefits of increased intake of dietary fiber for cardiovascular disease may extend beyond lowering of LDL-C levels. Khaw and Barrett-Connor (136) used 24-h dietary fiber intake by recall in a cohort of men and women in southern California aged 50 to 79 to show a significant inverse relationship between fiber intake and CAD. A 6-g increment in daily fiber intake was associated with a significant 25% reduction in mortality from CAD. A recent report of 43,757 U.S. male health professionals 40 to 75 years of age showed that there was a reduced risk of MI in men in the highest quintile for total dietary fiber intake (137). A 10-g increase in dietary fiber corresponded to a significant 19% reduction in risk. Within the three main dietary contributors to total fiber intake (vegetables, fruits, and cereals), *cereal fiber* was most strongly associated with reduced risk for MI. Finally, fruit and vegetable intake was found to reduce the all-stroke risk, including risk of transient ischemic attack, in men followed in the Framingham Trial, even after adjustment for multiple risk factors, including total fat, ethanol, and total energy intake (138).

Vegetable Protein

Soy protein has been consumed worldwide for centuries, and some Asian populations are known to consume 20 g of soy protein daily in products such as soy milk, tempeh, and tofu (139). This would seem to attest to the long-term safety of a diet enriched with soy protein. The mechanism by which soy lowers cholesterol levels is still unclear (140). The presence of the soybean isoflavone fraction appears to be important to cholesterol-lowering effects (141,142). In addition, high isoflavone intakes in soy breakfast cereals may reduce oxidized LDL levels, even though LDL-C is not significantly lowered (143). The benefit of this on atherosclerosis is not established.

Feeding Studies

A metaanalysis of clinical studies that examined the effects of consumption of a diet high in soy protein showed that cholesterol lowering may be one result in individuals who are hypercholesterolemic (144). In individuals who have cholesterol levels lower than 255 mg per dL, the changes were not striking. HDL-C levels remained unchanged. It is, of course, quite reasonable to choose soy-based food products within an overall balanced diet. In fact, textured vegetable-protein may have high acceptability.

Soy Protein and Coronary Artery Disease

There are no good data from clinical trials that examined the effects of soy protein on CAD end points. Although there are practical concerns regarding intake of sufficient soy protein to improve LDL-C values, products made with soy may prove useful as substitutes for products high in animal fat.

Additional Dietary Factors

Coffee

There has been considerable interest in whether coffee has deleterious effects on the coronary risk profile. A critical analysis must distinguish between filtered coffee and boiled coffee, such as is consumed in Scandinavia, France, or Turkey, which is associated with elevated cholesterol values.

Mechanism

Cafestol is a lipid-soluble diterpene present in coffee beans that is responsible for the cholesterol-raising effects associated with coffee consumption (145). In a special mouse model (apoE*3 Leiden), cafestol increases serum cholesterol levels by suppressing bile acid synthesis and decreases the LDL receptor by means of elevated secretion of cholesteryl esters in very-low-density lipoproteins (VLDLs) (146). Human studies using kinetic analysis of VLDL levels documented that cafestol increased plasma TG levels by increasing the mean rate of VLDL apolipoprotein B production (145).

Feeding Studies

Studies of filtered coffee have yielded conflicting results. Superko and coworkers (147) studied 186 coffee drinkers and found that a change from filtered, caffeinated coffee to decaffeinated coffee increased LDL-C and apoprotein B levels, whereas cessation of consumption of caffeinated coffee had no effect on these lipid parameters. A randomized, controlled study involving 119 students that examined intake of two types of filtered, decaffeinated coffee found no significant change when subjects were switched from filtered, caffeinated coffee (148). However, large amounts of filtered, caffeinated coffee may be associated with lipid changes. A randomized clinical trial involving 100 healthy male volunteers demonstrated that daily consumption of 720 mL of caffeinated coffee led to a small increase in plasma and total cholesterol levels, which was due to an increase in both LDL-C and HDL-C levels, even though this increase was not seen with an intake of 360 mL (149).

Coffee and Coronary Artery Disease

A prospective cohort analysis from the Health Professionals Study has provided the largest sample to date used to collect data about coffee's effects on cardiovascular disease (150). Although follow-up was only 2 years, they found that increased consumption of caffeinated coffee did not lead to higher risks for cardiovascular disease. They did note that greater consumption of decaffeinated coffee was associated with a marginally significant increase in the risk for CAD. A longer follow-up was used in the Nurses' Health Study, which documented 712 cases of CAD after 10 years of follow-up (151). There was no increase in CAD among women who drank six or more cups of caffeinated coffee, compared with that among women who drank none. The results of a study by La Croix and colleagues (152) that followed 1,130 male medical students for 19 to 35 years supported an independent, dose-responsive association between coffee and overt CAD among coffee drinkers who had more than 5 cups per day. In the absence of a placebo-controlled, clinical trial that would eliminate unknown confounding variables, it would appear that individuals who drink, on average, one to two cups of filtered coffee per day probably incur little change in lipid levels or CAD rates, as long as the coffee consumption is neither associated with the use of dairy creamers nor accompanied by cigarette smoking.

Garlic

The effects of garlic on cholesterol levels are inconsistent. One metaanalysis suggested that among individuals who have cholesterol levels greater than 200 mg per dL, one-half to one clove of garlic per day decreases total cholesterol levels by approximately 9% (153). Yet among 50 moderately hypercholesterolemic subjects, a double-blind, randomized, placebo-controlled trial of consumption of 300 mg of a standardized garlic tablet three times daily for three months showed that garlic therapy had no effect on major plasma lipoprotein levels (154). Moreover, clinical studies show that garlic has no impact on HDL subclasses, Lp(a), apolipoprotein B, postprandial TG, or LDL subclass distribution (155).

Dietary Factors That Affect High-Density Lipoprotein Cholesterol and Triglyceride Levels

The dietary factors that alter HDL-C and TG levels are not the same as those that alter LDL-C levels. The emphasis shifts to excess dietary energy, high carbohydrate intake, alcohol, and fish oil.

Excess Dietary Energy

Knuiman and colleagues (156) reviewed epidemiologic data on the relationship between diet and HDL-C levels and concluded that three partly opposing dietary factors determine the ratio of total cholesterol to HDL-C in an adult population. They convincingly argued that the proportion of energy from saturated fat raised total cholesterol and LDL-C levels, the proportion of energy from total fat raised HDL-C levels, and an excess in dietary energy, which produces obesity, lowered HDL-C levels. In addition, weight loss markedly affects TG levels and can improve HDL-C levels. A clinical study involving obese men and women quantified the effects of weight loss on the lipid profile as additive to those reducing fat and saturated fat (157). In this 13-week trial, weight loss in and of itself appeared to explain approximately 50% of the decrease in total cholesterol, 60% of the decrease in LDL-C, and 70% of the decrease in TGs. Moreover, although a low-fat, low–saturated fat diet alone reduced HDL-C by 11.1% and the ratio of HDL-C to LDL-C by 7.7%, weight loss reversed this trend, resulting in an increase in HDL-C of 12.5% and in the ratio of HDL-C to LDL-C of 24%. A metaanalysis of studies on the effects of weight loss on lipid and lipoprotein levels showed a significant negative correlation between weight loss and total cholesterol, LDL-C, and TG levels (158). HDL-C levels decreased during the active weight loss phase but increased by 0.009 mmol per L with every kilogram of weight loss when weight was maintained.

Mechanism

The means by which a low-fat diet reduces HDL-C is not clear. Brinton and colleagues (159) demonstrated that the mechanism by which diet lowers HDL-C differs substantially from the mechanisms that create differences in HDL-C among individuals who are on a fixed diet. Thus, the reduction in HDL-C that occurs quite commonly when a low-fat diet is begun may not be equivalent to the significance of an initial low HDL-C level on a usual diet when risk for CAD is being assessed.

High-Carbohydrate Diets

TG levels have a marked influence on HDL-C levels and are very sensitive to dietary change. Dietary influences on TG levels include high carbohydrate consumption, which, as noted earlier, can both elevate TG levels and lower HDL-C levels. Avoidance of simple sugars is particularly important, because they not only promote dental caries, but also can lead to caloric excess and obesity. The current trend toward fat-free foods has produced many food choices that are high in calories as a result of the addition of corn syrup solids or sucrose. Patients should be cautioned that such fat-free foods cannot be eaten in unlimited quantities. Although limited amounts of these foods can be part of a healthy dietary regimen, a diet that is fat-free is not necessarily nutritious.

Alcohol Intake

Alcohol consumption raises TG levels but, unlike a high-carbohydrate diet, also raises HDL-C levels. The Framingham Offspring Study's analysis of 1,584 middle-aged

men and 1,639 middle-aged women showed that TG levels, BMI, and alcohol intake all contributed significantly to fasting HDL-C and apoprotein A-I variability (160).

Mechanism

Alcohol consumption increases VLDL and TG levels by increasing VLDL synthesis (161). A metaanalysis of studies that assessed biomarkers consistently modified by alcohol showed that an experimental daily dose of 30 g of ethanol increased HDL-C by almost 4 mg per dL, apolipoprotein A-I by 8.8 mg per dL, and TGs by 5.7 mg per dL (162). Several hemostatic factors were modestly affected by alcohol intake.

Feeding Studies

Excess alcohol consumption is a common cause of secondary hyperlipidemia (163). Alcohol not only exacerbates fasting hypertriglyceridemia, but also augments postprandial lipemia. Delayed TG clearance, however, appears to occur in inactive, but not in exercise-trained, subjects, and the effect of alcohol on plasma HDL subfractions may differ between these groups (164). For individuals prone to severe hypertriglyceridemia, alcohol use must be prohibited to prevent the occurrence of the chylomicronemia syndrome, which can lead to acute pancreatitis.

Alcohol and Coronary Artery Disease

Dietary and alcohol consumption data from 21 countries indicate that alcohol consumption has a strong negative correlation with CAD mortality (68) (Fig. 2.2). Among middle-aged or older British men whose average intake of alcoholic beverages was 1 to 2 U per day, consumption of alcohol was associated with significantly lower all-cause mortality than was consumption of no alcohol or of greater amounts of alcohol (165). A genetic “proof of principle” was seen in a study of individuals with a polymorphism for the gene for alcohol dehydrogenase-3 that alters the rate of alcohol metabolism. Men homozygous for the allele, which is associated with a slow rate of oxidation, who consumed at least one drink per day had the greatest reduction in risk and the highest plasma HDL-C levels (166). This interaction was confirmed in an independent study of postmenopausal women.

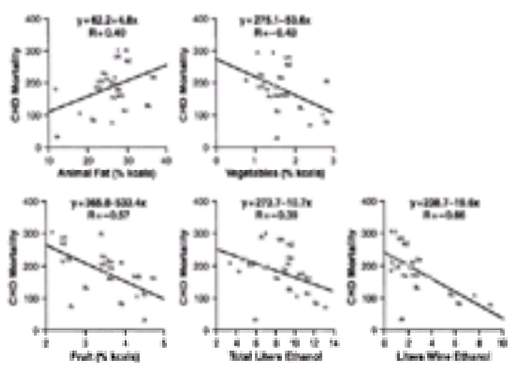


FIGURE 2.2 Graphs showing epidemiologic correlations between intake of fat, vegetables, fruit, alcohol, and wine ethanol. Au, Australia; Ca, Canada; CHD, coronary heart disease; De, Denmark; Fi, Finland; Fr, France; Ic, Iceland; Ir, Ireland; Is, Israel; It, Italy; Ja, Japan; Ne, The Netherlands; No, Norway; NZ, New Zealand; Sp, Spain; Sw, Sweden; Sz, Switzerland; UK, United Kingdom; US, United States; WG, West Germany. (From Criqui MH, Ringel BL. Does diet or alcohol explain the French paradox? *Lancet* 1994;344:1719–1723, with permission.)

In the MRFIT prospective experience among middle-aged men who were light-to-moderate drinkers, HDL-C levels largely demonstrated the inverse association between alcohol consumption and death from CAD (167). Metaanalysis of 42 experimental studies suggested that 30 g of alcohol per day would cause an estimated reduction of 24.7% in risk of CHD (162). There has been speculation that an effect of alcohol on platelet function could explain the low mortality from CAD that is seen among the population in France despite consumption of a diet that is comparable in intake of saturated fat to those of other nations in which CAD rates are higher (168). Other effects of alcohol on coagulation include a positive association between moderate alcohol intake and plasma levels of endogenous tissue-type plasminogen activator (169).

Various reports indicate that one kind of alcoholic beverage is not preferred over others. A systematic review of 12 ecologic, 3 case-control, and 10 separate prospective cohort studies indicates that *all* alcoholic drinks are linked with lower risk (170). Indeed, a study comparing red and white wine did not show that red wine selectively decreased the susceptibility of LDL to oxidation (171).

Although older men and women may benefit from the effects of mild-to-moderate alcohol intake in reducing rates of CAD, public health considerations argue against an uncritical encouragement of alcohol consumption (172). In men and women younger than 40 years, alcohol consumption has a particularly negative benefit/risk profile; the cardiovascular risk is already low, and the increase in all-cause mortality that accompanies drinking more than offsets any possible health advantage (173). Moreover, individuals who consume five or more drinks per occasion are nearly twice as likely to die from injuries than persons who drink less (174). Cardiac patients, in particular, may suffer from aggravation of hypertension, as well as increased arrhythmia, stroke risk, cardiomyopathy, and LVH, with excess drinking (175).

An important caveat pertains to alcohol intake among women. Women reporting any amount of alcohol consumption in the First National Health and Nutrition Exam Survey had an approximately 20% decrease in risk for CAD compared with women who abstain (176). A recent study that examined asymptomatic alcoholic women and men noted a similar prevalence of cardiomyopathy and myopathy in both groups (177). The threshold dose for the development of cardiomyopathy was significantly lower among women, and the decline in ejection fraction with increasing amounts of alcohol was significantly steeper than among men. These data suggest an increased sensitivity in women to the toxic effects of alcohol on cardiac muscle (Fig. 2.3).

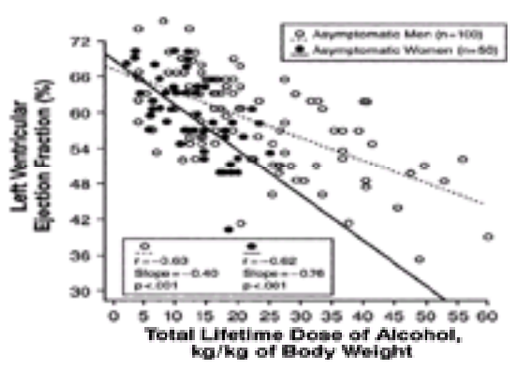

FIGURE 2.3 Lifetime dose of alcohol and left ventricular ejection fraction in men and women.

Fish Oils

The omega-3 PUFAs known as *n*-3 fatty acids can be obtained from either plant or marine sources. Alpha-linolenic acid is a plant-based omega-3 PUFA found in tofu, soybean, canola oil, and nuts. Plant-based omega-3 PUFAs do not lower TG levels in a striking fashion in contrast to the marine-based omega-3 fatty acids known as “eicosapentenoic acid” and DHA (92). The sum of these long-chain *n*-3 PUFAs in a capsule or fish product determines the amount of omega-3 PUFAs present. Fatty fish such as salmon and mackerel are good sources of *n*-3 fatty acids.

Feeding Studies

Marine lipids lower elevated TG values. This can be of particular clinical importance for individuals with TG values greater than 1,000 mg per dL for whom secondary-cause correction, diet, exercise, and gemfibrozil have proven inadequate (178). Marine lipids also have important effects on coagulation parameters. Populations who consume a diet rich in marine lipids show reduced platelet aggregation and prolonged bleeding times (179).

There are detrimental aspects to the wider use of fish oils for milder forms of hypertriglyceridemia. In one study, the beneficial decrease in TG levels was accompanied by a rise in LDL-C levels (180). In other studies, increased blood sugars were seen in diabetic patients, although this was not invariably the case (181,182). Nevertheless, in these studies, a rise in LDL-C levels that was associated with fish oil ingestion was seen. Finally, a careful analysis of the immunologic effects of fish supplementation of a Step II AHA diet demonstrated changes in delayed hypersensitivity (183). Additional studies are needed to understand the long-term consequences of these effects. Finally, there is concern about mercury contamination.

Fish Oil and Coronary Artery Disease

Studies using fish or fish oil capsules challenge the traditional diet-lipid-heart paradigm, although fish oil capsules are useful in the control of moderate to severe hypertriglyceridemia. The relationship between fish intake and lowered rates of CHD stemmed from early observational studies comparing Greenland Inuit with their Danish counterparts. The Inuit diet included a strikingly higher intake of *n*-3 PUFAs, in which marine sources, such as seal and whale, are rich. The biochemical and hematologic profiles of the Inuit showed lower values for total cholesterol, TG, LDL-C, and VLDL-C, increased values for HDL-C, increased bleeding times, and lower rates of CAD (184). In addition, prospective epidemiologic studies confirmed that men who ate at least some fish every week had a lower mortality from CAD than did men who ate none (185,186,187 and 188). In two studies, however, in which fish intake was high, a beneficial effect was not documented (189,190).

Despite these intriguing results, the results of most primary prevention studies of fish, fish oil, and CAD have been negative. The Health Professionals Follow-up Study, a large-scale prospective cohort study, reported no association between increases in consumption of fish and CAD (191). The authors concluded that increasing fish intake beyond one or two servings per week is not beneficial in the primary prevention of CAD. A nested case-control study among the 14,916 participants of the Physician's Health Study also showed no beneficial effect from consumption of fish oil on CAD (192). No association was found between fish oil levels and the incidence of MI, even when results were adjusted for major cardiovascular risk factors. Fish oil has not always produced beneficial results in trials of secondary CAD prevention. A clinical trial large enough to find a significant effect if one existed showed that 8 g per day of *n*-3 PUFA was well-tolerated, but not helpful in preventing clinical restenosis after angioplasty (193). Among normocholesterolemic men with angiographically documented CAD, fish oil treatment (6 g of *n*-3 PUFAs for 2 years) did not produce significant changes in the diameter of the coronary arteries (194).

Yet the ability of fish and fish oil capsules to reduce all-cause mortality in two intervention trials and a putative relationship between increased omega-3 fatty acid ingestion and CHD mortality in a third trial are compelling data that must be examined carefully (8,9,195). The Diet and Reinfarction Trial (DART) noted that those men who were instructed to eat fish after they had experienced MI showed a 29% decline in all-cause mortality compared with those in the placebo group (8). The mechanism for this beneficial effect was independent of lipid levels. In this trial, a group of the men (25%) who could not tolerate fish were given 875 mg of fish oil in capsule form. This study raised speculation that the beneficial effect of fish oil in survivors of MI may relate to its effects on thrombosis and/or risk for arrhythmia. The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardio (GISSI)–Prevenzione Trial, a large-scale open-label, randomized, controlled trial involving 11,324 MI survivors, demonstrated that 875-mg fish oil capsules, but not vitamin E, reduced the primary cumulative end point of all-cause mortality, nonfatal MI, and nonfatal stroke (9). Neither intervention significantly reduced the other primary end point, the cumulative rate of cardiovascular death, nonfatal MI, and nonfatal stroke. Analysis of secondary end points suggested that the benefit lay in reduction of mortality and not in reduction of nonfatal MI. It was a safe intervention, although LDL-C levels were slightly increased as TG levels were decreased.

The Lyon Trial, which was mentioned previously in the section on Mediterranean diet, used a diet rich in a vegetable-based omega-3 fatty acid known as *alpha-linolenic acid* (107). The striking reduction in sudden death, similar to that seen in DART, suggested a beneficial effect on cardiac health from intake of omega-3 fatty acids, independent of any lipid-lowering effect. Viewed critically, the Lyon results seem almost too good to be true: When the major primary and secondary end points are combined, 59 events occurred in control subjects and 14 events occurred in study patients—a risk reduction of 76% (195). Although these data seem to overestimate the true effect of such dietary change, they do suggest that certain components of the Mediterranean-type diet, such as omega-3 fatty acids, oleic acid, and dietary antioxidants, may play important roles in reducing the risk for CAD. Moreover, a cohort questionnaire study involving 43,757 male health professionals aged 40 to 75 years and free of cardiovascular disease or diabetes reported that subjects who consumed diets high in alpha-linolenic acid had a reduced risk of CAD (196).

These provocative findings were followed by a carefully done population-based case-control study from Seattle and King County, Washington (197). Among 334 patients who had experienced primary cardiac arrest, the monthly intake of *n*-3 PUFAs was significantly less than that seen in age- and sex-matched community controls. The equivalent of one fatty-fish meal per week was associated with a 50% reduction in the risk for primary cardiac arrest after adjustment for potential confounding factors. These findings were consistent with experimental evidence suggesting that the *n*-3 PUFAs have an important effect on the vulnerability to ventricular fibrillation in the setting of myocardial ischemia (198).

Recommending consumption of one or two fish-based meals weekly is reasonable, particularly if it substitutes for sources of protein in the diet such as fatty meats, which increase total saturated fat intake. Patients should be cautioned to avoid fish contaminated with mercury and other toxins. Mercury contamination not only could prove an important hazard to susceptible persons (children, pregnant women), but has been shown to attenuate the cardiac benefits of fish (199). The use of fish oil capsules can be considered for MI survivors, based on the GISSI trial, but additional studies and standardized, widely available preparations are needed before this is a routine recommendation (200). The potential benefit of decreasing sudden cardiac death using fish oil therapy is exciting to contemplate. Additional research studies are awaited.

Antioxidants, Vitamins, and Coronary Artery Disease

The available data support the hypothesis that oxidation of LDL by cells in the arterial wall is a pivotal step in the initiation of the early lesions seen in coronary atherosclerosis (201). Thus, there has been a heightened interest in antioxidants, which may work to prevent or retard this process. Several lines of evidence support an important role for vitamin E (or alpha-tocopherol), which is carried on LDL and is a potent lipid-soluble antioxidant. There is also considerable interest in beta-carotene, which is lipid soluble, and in vitamin C, which is a water-soluble vitamin. Food sources of vitamin E include seed oils, nuts, avocados, whole-grain and fortified cereals, eggs, and green vegetables. Food sources of beta-carotene include carrots and boiled broccoli. Vitamin C is widely available in fruits and vegetables, but losses of vitamin C can occur with cooking.

Mechanism

Two putative mechanisms are involved in the effect of antioxidants on reduction of oxidative stress and improvement of endothelial dysfunction. When added to plasma, vitamin E, but not vitamin C or beta-carotene, seems to make LDL more resistant to oxidation (202). Moreover, in one study, 2.0 g of ascorbic acid improved brachial artery endothelial-dependent response to ischemia in 46 patients 2 h after ingestion (203).

Vitamin E and Coronary Artery Disease

The effects of vitamin E on atherosclerosis and clinical CAD are controversial and do not support enthusiastic recommendation of the vitamin. To be sure, early observational studies suggested a beneficial effect of vitamin E (204,205 and 206). Furthermore, a prospective study of postmenopausal women from Iowa showed that the intake of vitamin E from foods is inversely associated with the risk by death from CAD. Importantly, the data suggested that such women might lower their risk without using vitamin supplements (207). These were not randomized clinical trials, and unforeseen bias may have influenced the results.

The Cambridge Heart Antioxidant Study used a randomized, double-blind design in 2,002 patients with angiographic CAD who were assigned to receive 400 IU of alpha-tocopherol daily or placebo. Nonfatal MI decreased significantly at 1 year among subjects who took vitamin E (208). One feature of the study that is worthy of concern was the lack of a significant reduction in either total mortality or cardiovascular deaths in the alpha-tocopherol group. In fact, a slight, nonsignificant increase was seen in these categories in the treatment group. Since publication of the results of this trial, two large randomized trials have shown no benefit from vitamin E on primary end points. In the previously mentioned GISSI trial, vitamin E did not affect either of the two primary combined end points. Although benefit was suggested in a secondary analysis that examined cardiovascular death, the authors speculated that a longer trial would be required to show beneficial effects from vitamin E on cardiovascular end points. The Heart Outcomes Prevention Evaluation Study found no significant effect associated with daily ingestion of 400 U of vitamin E on cardiovascular end points in 9,541 high-risk subjects older than 55 years who were randomly assigned to receive vitamin E or placebo and followed for 4.5 years (209). Moreover, a substudy of this trial showed no differences in atherosclerosis progression rates, as determined by carotid ultrasound, associated with ingestion of vitamin E, whereas a beneficial effect was seen with the angiotensin-converting enzyme inhibitor ramipril (210). Because strong evidence for effects associated with vitamin E on subclinical atherosclerosis as well as clinical rates of CHD is lacking, a routine recommendation for its use is not reasonable at this time.

Vitamin C and Coronary Artery Disease

A large prospective observation of 19,496 men and women in a nine-country study showed that plasma ascorbic acid levels were inversely related to mortality from all causes, from cardiovascular disease, and from ischemic heart disease (211). The authors speculated on the potential benefits of a small increase in intake of fruits and vegetables. The Atherosclerosis Risk in Communities Study examined the relationship between the intake of dietary and supplemental vitamin C, alpha-tocopherol, and provitamin A carotenoids and average carotid artery–wall thickness among 6,318 women and 4,989 men aged 45 to 64 years (212). Among men and women older than 55 years, but not among individuals younger than 55 years, who had not recently begun a special diet, there was a significant inverse relationship between vitamin C intake and average carotid artery wall thickness, adjusted for pertinent variables. In Kuopio, in Eastern Finland, men and postmenopausal women in a double-masked, two-by-two factorial trial were randomly assigned to four strata and received either 136 IU daily of D-alpha-tocopherol, 250 mg of slow-release vitamin C, a combination of these, or placebo for 3 years. Progression of common carotid atherosclerosis was decreased significantly among men who received a combination of D-alpha-tocopherol and slow-release vitamin C (213).

Beta-Carotene and Coronary Artery Disease

The European Community Multicenter Study on Antioxidants, Myocardial Infarction, and Breast Cancer was a controlled study that looked at adipose tissue levels of beta-carotene and alpha-tocopherol in individuals with a history of MI (214). The data suggested that consumption of foods rich in beta-carotene, such as carrots and green leafy vegetables, might reduce the risk for MI.

In contrast, three carefully done trials using beta-carotene supplementation did not show beneficial effects on cancer or cardiovascular disease (215,216 and 217). Moreover, the Beta Carotene and Retinol Efficacy Trial showed that the combination of beta-carotene and vitamin A may have led to an adverse effect on lung cancer and the risk of death from lung cancer, from cardiovascular disease, and from all causes in both cigarette smokers and workers exposed to asbestos. Thus, the time and expense necessary to obtain clinical trial data to document or refute contentions derived from observational data was clearly worth it. There is no good evidence to support the endorsement of beta-carotene supplementation to reduce cardiovascular disease end points.

Flavonoids

Flavonoids are strong antioxidants that occur naturally in foods such as vegetables (onions) and fruits (apples) and in beverages such as tea and wine. On a milligram per day basis, the intake of antioxidant flavonoids still exceeds that of the antioxidants beta-carotene and vitamin E (218). Thus, flavonoids represent a potentially important source of dietary antioxidants.

Flavonoids and Coronary Artery Disease

In the Zutphen Elderly Study, flavonoid intake was measured in 805 men aged 65 to 84 years who were then followed for 5 years (219). Flavonoid intake was significantly inversely associated with mortality from CAD, and an inverse association was seen with MI that was of borderline significance (219). In a larger sample from the Seven Countries Study, flavonoid intake contributed only slightly to reduction in CAD risk (approximately 8%), whereas saturated fat contributed the major dietary risk (approximately 73%) (220).

Minerals and Coronary Artery Disease

Minerals such as iron and selenium have been implicated in heart disease.

Iron

Menstrual loss of iron has been proposed as an explanation for the reduced risk for CAD among women (221). Menstrual loss of iron may reduce oxidative stress on LDL and hence lower rates of atherosclerosis. A review of the literature noted that 18 of 25 epidemiologic studies showed either a negative association or no association between CAD and indicators of body iron (222). In a 4-year prospective study that collected data from diet questionnaires completed by 44,933 men aged 40 to 75 years who had no history of cardiovascular disease, iron intake in the form of non-*heme* iron was not related to the incidence of CAD (223). However, incidence of fatal CAD or nonfatal MI was higher among men in the top quintile of *heme* iron intake compared with men in the lowest quintile, despite adjustment for dietary cholesterol and fats. That iron intake is associated with CAD appears to be a testable hypothesis, but more data from various population groups will be required before firm conclusions can be reached (224).

Selenium

Selenium is an essential trace element. It is a cofactor of the enzyme glutathione peroxidase. Deficiency of selenium has been associated with a cardiomyopathy described in China called “Keshan disease” (225). Data relating it to risk for CAD are scanty, and more detailed studies are required before recommendations can be made.

OBESITY, LIPIDS, CORONARY ARTERY DISEASE, AND CARDIOVASCULAR DISEASE

The terminology of the obesity literature can be confusing. Terms useful to the following discussion are summarized in *e*Table 2.3.3. Bray has proposed a classification of obesity that avoids misleading descriptors such as “progressive” or “morbid” (226). Using the BMI, obesity can be classified from Class 1 to Class 4, at the extreme. This system is summarized in *e*Table 2.3.4.

***e*TABLE 2.3.3** TERMS ASSOCIATED WITH OBESITY AND EXAMPLES

Term	Definition
Obesity	BMI ³30
Overweight	BMI 25–30
BMI	Weight (kg) divided by height^2 (m)
Increased waist circumference	>102 cm (>40 in.) for men; >88 cm (>35 in. for women)
Abdominal obesity	Male pattern or android obesity; metabolically active abdominal fat; increases risk of coronary artery disease
Gluteal-femoral obesity	Female pattern or gynecoid obesity; fat concentrated in hips and thighs; cosmetic problem
Morbid obesity or class IV obesity	BMI ³40

Body mass index (BMI) is calculated in kg/m^2 or 703 ¥ lb/in.^{2}

***e*TABLE 2.3.4** CLINICAL CLASSIFICATION OF OBESITY

Class of obesity	Body mass index (kg/m^2)	Mortality and coronary heart disease risk class
0	20–25	Not obese
1	25–30	Mild risk
2	30–35	Moderate risk
3	35–40	High risk
4	³40	Very high risk

From Bray G. Pathophysiology of obesity. *Am J Clin Nutr* 1992;55[Suppl]:488S–494S, with permission.

According to recent data, 50% of all adult Americans are overweight or obese (227). This reflects an increasing prevalence over the course of the past decade. This finding is worrisome, because obesity, over the long term, increases the risk for death (228,229,230 and 231). In addition, obesity contributes to at least one-half of the diseases that are chronic in Western societies (232). Although abdominal obesity is cause for particular concern, noncentral obesity is not metabolically benign. A cross-sectional study in Manitoba showed that, in its survey of adults aged 18 to 74 years, the BMI as an overall measure of obesity compared favorably with waist-to-hip ratio in predicting effects of obesity on blood pressure, glucose, and plasma lipids (233).

A review published in 1993 of 13 reports from 11 diverse populations looked at weight changes in subjects aged 17 years or older (234). It concluded that the highest mortality rates occur in adults who either have lost weight or have gained excessive weight. Andres (235) believed that data suggesting that the lowest mortality rates in these studies accompanied modest weight gains in adulthood supported his previously held views. This was disputed by a detailed analysis of U.S. women enrolled in the Nurses' Health Study (236) (eTable 2.3.5). The data showed that body weight and all-cause mortality were directly related. Lean women did not show excess mortality, and a weight increase ³10 kg after the age of 18 was associated with increased mortality in middle adulthood. When the BMI exceeded 27, mortality was substantially elevated. In terms of attributable risk, 53% of deaths among women with a BMI greater than 29 could be attributed to their obesity. Mortality from CAD in this study was more strongly related to waist-hip ratio, which is a measure of abdominal obesity.

***e*TABLE 2.3.5** EFFECT OF WEIGHT CHANGE ON RISK OF DEATH AND CORONARY HEART DISEASE (CHD): NURSES' HEALTH STUDY DATA

Weight change	No. of deaths	Relative risk for all causes	Relative risk for CHD
Lost >10 kg	16	0.7	0.3
Lost 4–9 kg	54	1.2	0.6
Stable	224	1.0	1.0
Gained 4–9 kg	269	1.0	0.7
Gained 10–19 kg	292	1.2 (1.0–1.4)	2.6 (0.7–12.8)
Gained >20 kg	204	1.6 (1.3–1.9)	7.4 (2.4–21.7)

From Pouliot MC, Despres J-P, Lemieux S, et al. Waist circumference and abdominal sagittal diameter: best simple anthropometric indexes of abdominal visceral adipose tissue accumulation and related cardiovascular risk in men and women. *Am J Cardiol* 1994;73:460–468, with permission.

The Nurses' Health Study data should be compared with observations from the Honolulu Heart Program, in which men who had a weight loss of 4.5 kg or more, large fluctuations in weight, or both over the course of a 6-year period were in poorer health than those whose weight was more stable (237). Like the Nurses' Health Study, an increase in mortality occurred primarily among subjects with a BMI greater than 27. Subjects whose weight fluctuated the most had a significantly higher risk for death from cardiovascular causes. This relationship was not seen in healthy men who had not smoked. In fact, one of the problems with analyzing "weight cycling" is the inability to distinguish between intentional and unintentional weight loss. Stunkard (238) noted that evidence that weight cycling is a cause of either upper-body obesity with metabolic changes or increased mortality is lacking.

In a prospective cohort study of Dutch men and women aged 30 to 54 years, with an average follow-up of 12 years, all-cause mortality was increased among obese men (BMI greater than 30) and among underweight men, but not among women (239). The Framingham Heart Study looked at the relationship of weight at age 65 among 1,723 nonsmokers who were followed for a mean of 9.5 years (240). The study found that the risk of death was increased twofold over the course of the entire follow-up period for persons with a BMI higher than the 70th percentile at both 55 and 65 years of age. This works out to a BMI greater than or equal to 28.5 that is attained by a 5-ft 9-in. man who weighs at least 193 lb.

Mechanism

To be sure, obesity and the response to overfeeding have a definite genetic component (241). A detailed discussion of the genetic component is beyond the scope of this section. Instead, we focus on environmental influences in susceptible subjects. The impact of the environment on the prevalences of obesity and non–insulin-dependent diabetes (NIDDM) was dramatically illustrated by a comparative study of Pimas in Arizona with their distant relatives living in a remote mountainous location in northwestern Mexico (242,243). Arizona Pimas eat a higher-fat diet and have a higher prevalence of diabetes than do their Mexican relatives, who are lighter, shorter, more active, and expend more energy. The increases in obesity, cholesterol, and glucose intolerance seem directly related to environmental factors. This suggests that the high rate of obesity among Arizona Pimas may be due to genetic susceptibility promoted by an unhealthy lifestyle.

Physiologic changes related to gender and aging must be considered as well. A study of 427 healthy men aged 17 to 90 years and women aged 18 to 88 years showed that fat mass increased with age, and that the rate of increase was higher among women (244). The increase in waist circumference with age was also greater among women. Increasing waist circumference with age among men and women was most strongly associated with declines in leisure-time physical activity and in peak volume of oxygen utilization.

Obesity is also associated with a multiplicity of risk factors for CAD. Although it is often incorrectly assumed that obese patients uniformly have hypercholesterolemia, Grundy and Barnett (245) observed that significant hyperlipidemia in obesity was usually associated with an underlying defect in lipid metabolism. Because obesity and excess calories lead to an overproduction of VLDL, dyslipidemia is seen among individuals who have defects in the clearance of TG (impaired lipolysis) or cholesterol (deficient LDL receptors). Thus, it is possible for a Class 4 obese patient who is 40% overweight to have a normal LDL-C level (246).

Nonetheless, a major health hazard of obesity is a result of the metabolic changes that accompany the deposition of abdominal or visceral fat. Despres and coworkers have stressed the need to focus on high-risk abdominally obese patients (247). Their group has proposed that the waist circumference or the abdominal sagittal diameter, rather than the waist-to-hip ratio, be used as an index of abdominal visceral adipose-tissue deposition in the assessment of risk for CAD (248). Bouchard and colleagues (249) noted that waist circumference values greater than approximately 100 cm, or abdominal sagittal diameters greater than 25 cm, are most likely to be associated with potentially atherogenic metabolic disturbances. The crucial distinction, however, is that for a given level of body mass, subjects with anthropomorphic measures of visceral obesity such as waist-to-hip ratio or the more precise waist circumference represent the subgroup of individuals at highest risk for CAD (250). This is likely conferred through multiple risk factors, including dyslipidemia, hypertension, and glucose intolerance. Walton and associates (251) measured lipid and lipoprotein levels in 103 healthy men aged 21 to 77 years who underwent dual energy x-ray absorptiometry to determine the ratio between total body fat tissue and total body lean tissue. Both adiposity and fat distribution correlated with total serum cholesterol and TG concentrations. Fat distribution negatively correlated with HDL2 cholesterol. On multivariate analysis, waist-to-hip ratio was independently associated with elevated total TG and decreased HDL2 levels.

The association of dyslipidemia, hypertension, and glucose intolerance with visceral adiposity and insulin resistance is a recognizable multiple metabolic risk factor syndrome, or simply, "the metabolic syndrome" (4). This was initially designated "syndrome X" by Reaven (252). Data from the Bogalusa Heart Study show that clustering of risk factors for CAD begins in children and young adults and persists throughout life (253). The lipid abnormalities seem to fit best with a constellation of findings called "atherogenic dyslipidemia." Grundy (254) has characterized the typical picture as borderline total cholesterol, high TG, low HDL-C, and increased small, dense LDL-C particles. The second component is insulin resistance, both with and without impaired glucose tolerance (255). The insulin-resistance syndromes were recently reviewed, and several points are worth emphasizing (256). Genetic predisposition, sedentary lifestyle, and central obesity are viewed as determinants, with insulin resistance being the measurable abnormality that leads to metabolic dysregulation with a compensatory hyperinsulinemia, dyslipidemia, hypertension, glucose intolerance, and hyperuricemia. Also seen are abnormalities of coagulation with increased plasminogen activator inhibitor type 1 and decreased tissue plasminogen activator accompanying hypertriglyceridemia.

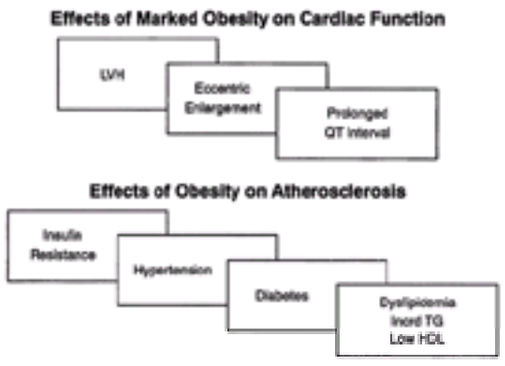
Williams and colleagues (257) have described a subset of hypertension associated with metabolic abnormalities involving lipids, insulin, and often obesity, all of which aggregate strongly in families. They called this "familial dyslipidemic hypertension" and noted an association with a particularly high risk for early coronary disease. They observed that the clinical and biochemical features of familial dyslipidemic hypertension shared similarities with Reaven's Syndrome X: (a) familial combined hyperlipidemia, (b) dense LDL subfractions, (c) diabetes, (d) impaired glucose tolerance, (e) central and general obesity, (f) prediabetes, (g) prehypertension, and (h) genetic deficiency of lipoprotein lipase (heterozygous). Interestingly, women who had microvascular angina (the cardiology syndrome X, with chest pain and an abnormal exercise electrocardiogram despite normal appearance of vessels on coronary angiography) tend to be insulin resistant and have lower HDL-C levels, although not all of the other features of the metabolic syndrome X previously described are seen (258).

The presence of multiple metabolic risk factors, such as raised fasting insulin levels, apolipoprotein B concentration, and an increased proportion of small, dense LDL particles are associated with a 20-fold increase in the risk of developing CHD in initially asymptomatic middle-aged men who were followed for 5 years (259). This underscores the need for more-effective prevention of adult-onset weight gain. Although drug therapy for these risk factors is usually required, the additive beneficial effects of weight loss, regular exercise, and diet should be recognized.

Obesity and the Heart

Cardiac output and blood volume increase in obesity to supply the increased adipose stores (eFig. 2.3.1). Systolic function is generally preserved, even in patients with marked obesity. Nonetheless, in a small subgroup who had low left ventricular fractional shortening before surgical therapy for morbid obesity, the mean fractional shortening increased significantly when body weight decreased from 13 to 79 kg of the amount over ideal body weight. Blood pressure and left ventricular internal dimension in diastole also decreased (260). Obesity affects diastolic function and is a strong stimulus for LVH. Messerli (261) noted, among subjects matched for blood pressure values, that LVH was found in more than 50% of all obese subjects and only in less than 20% of nonobese subjects. When heart size is examined, eccentric enlargement is seen in obese patients with hypertension, compared with symmetric LVH in hypertensive patients who were not obese. In addition to magnitude of obesity, the duration of obesity must also be taken into account (262). In the Framingham Heart Study, BMI was strongly associated with echocardiographic LVH,

particularly when the BMI was greater than 30 kg per m^2 (263). Finally, obesity leads to a prolonged QT interval, which may increase the potential for arrhythmias (264).



***e*FIGURE 2.3.1** Obesity and the heart. HDL, high-density lipoprotein; LVH, left ventricular hypertrophy; TG, triglycerides.

For the Class 4 obese patient, the situation is especially grim. Cardiovascular disease is the most frequent cause of death (265). Life-table techniques that compare the mortality among Class 4 obese individuals with that among men in the general population demonstrated a 12-fold excess mortality among obese patients aged 25 to 34 years, and a sixfold excess among those aged 35 to 44 years. This ratio diminished with advancing age. Postmortem examination of 12 Class 4 obese patients aged 12 to 59 years disclosed dilated left ventricular and right ventricular cavities, but only two patients had one or more epicardial coronary arteries that had narrowed at least 75% in cross-sectional diameter (266). Kasper and colleagues (267) looked at patients greater than 35% overweight who presented with congestive heart failure and compared them with patients whose weight was normal. A significantly higher percentage of the obese patients had a dilated cardiomyopathy. Among patients with similar degrees of cardiomyopathy, obese patients had elevated right-heart pressures, cardiac outputs, and pulmonary vascular resistance index. On biopsy, the most common finding in the obese group was mild myocyte hypertrophy.

Importantly, the cardiac dysfunction associated with obesity may occur with weight loss (268). Cardiac studies were repeated in 12 Class 4 obese patients after a 54.8 ± 1.9-kg weight loss. Echocardiography documented a decrease in dilatation (27.3% to 9.1%) and a significant decrease in hypertrophy. After the weight loss, radionuclide and right-heart catheterization studies demonstrated improved cardiac function with reduced filling pressures and increased left ventricular work during fluid and exercise challenges. In addition, the prolonged QT interval seen in obese patients may shorten after weight reduction (269).

The Class 4 obese patient may present with significant noncardiovascular problems as well. The Pickwickian syndrome, involving sleep apnea, pituitary/gonadal dysfunction, acanthosis nigricans, and pronounced osteoarthritis, is well described (226). Weight loss achieved by consumption of a very-low-calorie diet improves lung volumes in morbidly obese patients but may not be enough to improve arterial oxygenation (270). In one study, hypoxemia was not relieved in patients who assumed a supine position but was significantly relieved when patients stood up, both before and after weight loss. Comorbidity seen with significant obesity includes respiratory disease, gout, osteoarthritis, and gallbladder disease (271). The presence of obesity more than doubles the risk for gallstones, because it increases the flux of cholesterol through the biliary tree. In fact, after 8 weeks of dieting, sludge was detected in three subjects and gallstones in 25.5% of subjects, compared with nonfasting control subjects (272). Depression commonly accompanies significant obesity. Individuals more likely to show symptoms of emotional illness include patients with a history of obesity from childhood, those undergoing severe caloric restriction, and those undergoing outpatient treatment (273).

Treatment of Obesity

The Obesity Education Initiative from the National Heart, Lung, and Blood Institute noted that obesity-related conditions are significantly improved with a weight loss of only 5% to 10% (274). Yet successful weight loss is not easy to achieve. A survey of 192 participants in the Sandoz Nutrition Diet Program showed that, on average, the group lost 22 kg during the diet program (275). After 3 years of follow-up, the mean weight was within 3.3 kg of initial weight at the start of the diet. Only 12% of the subjects maintained 75% of the weight loss after leaving the diet program; 57% maintained at least 5% of the loss; and 40% gained back more weight than they lost while on the diet. The best predictor of recidivism was television viewing, whereas frequency of exercise was the strongest predictor of weight loss maintenance. The long-term results of behavioral treatment are also discouraging. Resumption of the obese state occurs, and only less than 5% of subjects remain lean for more than 4 years (276).

What about popular diets? A scientific review prepared for the U.S. Department of Agriculture divided these diets into three categories:

1. High-fat (55% to 65%), low-carbohydrate, high-protein diets
2. Moderate-fat (20% to 30%) diets, high in carbohydrates and moderate in protein
3. Low-fat (11% to 19%) and very-low-fat (<10%) diets; very-high-carbohydrate, moderate-protein diets

This report concluded that caloric balance is the major determinant of weight loss, and that any of the diets that result in reduced caloric intake will result in weight loss. In the absence of physical activity, it was estimated that an optimal diet would contain approximately 1,400 to 1,500 kcal per day. It was further noted that all low-calorie diets result in loss of body weight and body fat. Macronutrient composition did not appear to play a major role. On the other hand, low-carbohydrate, ketogenic diets cause a greater loss of body water than body fat. Moreover, although the moderate-fat diet is nutritionally adequate, high-fat, low-carbohydrate diets are nutritionally inadequate and require supplementation, and very-low-fat diets are deficient in vitamins E and B_{12}, and zinc. Despite various claims, there does not appear to be an optimal diet for reducing hunger. Long-term compliance is likely a function of psychological issues rather than macronutrient composition.

Emphasizing the basic strategies mentioned in this chapter was shown to be particularly effective in a study of 522 overweight subjects with impaired glucose tolerance who were randomly assigned to receive either frequent individualized dietary and exercise counseling or occasional general recommendations over the course of an approximately 3-year period (277). Individualized counseling was aimed at reducing weight by 5% or more, reducing total fat intake to less than 30% of energy intake, reducing saturated fat intake to less than 10% of energy intake, increasing fiber intake to greater than 15 g per 1,000 kcal, and increasing regular exercise to more than 4 h per week. This resulted in a reduction in new diabetic cases of 58% in comparison with the rate among control subjects.

The very-low-calorie diet promised a more intensive approach to weight loss, but the early experience with very-low-calorie diets was problematic; at least 58 deaths were reported among very obese patients who underwent rapid weight loss by consuming diets low in protein of good biologic value (278). Current very-low-calorie diets provide 400 to 800 kcal per day of energy and 45 to 100 g per day of high-quality protein and are associated with only minor complications when administered in selective fashion by physicians trained in their use (279). These diets should be limited to use in patients who are at least 30% overweight. The appropriate duration for most patients is approximately 12 to 16 weeks. Careful monitoring with attention to electrolytes during the treatment, refeeding, and weight maintenance periods is important. These diets may prove to be valuable for patients who have serious respiratory abnormalities or NIDDM. Nonetheless, the recidivism rate is still high, as it is for all dietary strategies that are used in obese patients, prompting concern that the long-term benefits may not outweigh the risks.

Why does diet therapy for obesity fail over the long term? Hirsch and colleagues (280), in elegant experiments, showed that maintenance of either a reduced or increased body weight is associated with compensatory changes in energy expenditure that oppose the maintenance of a body weight that is different from the usual weight. This seems to explain the results of a study in which obese and nonobese subjects were followed for 5 years; in 19% of the subjects, weight varied no more than 5 lb higher or lower during that 5-year period (281). This group included three times as many normal-weight subjects as obese subjects. Eckel (282) suggested that metabolic reasons for patients' return to original weight include maintenance of raised concentrations of fasting adipose tissue lipoprotein lipase, the enhanced responsiveness of adipose tissue lipase to insulin, and failure of corn-oil ingestion to inhibit the insulin-stimulated adipose tissue lipoprotein lipase–response, all of which support accelerated uptake and storage of lipid fuels.

Interventions that focus on health behaviors have the advantage of emphasizing the positive aspect of voluntary actions. Wing (283) noted that behavioral approaches to obesity are usually used in the context of short-term (10 to 20 week) treatment interventions. These programs produce weight losses averaging 10 kg at the end of the program and 6.6 kg at 1-year follow-up. These have proven useful in NIDDM; at 1 year, patients who lost more than 6.9 kg or had a greater than 5% reduction in body weight had significant improvements in glycosylated hemoglobin values (284). Kayman and colleagues (285) studied obese women who regained weight after successful weight reduction. Most subjects who maintained the weight loss exercised regularly, used available social support, and confronted problems directly, whereas most subjects who relapsed did not. The authors noted that subjects who maintained weight loss were more likely to use personally developed strategies to help themselves. When obese children aged 8 to 12 years were randomly assigned to treatment groups that targeted increased exercise, decreased sedentary behavior, or both, the greater decrease in percentage of overweight was seen in the group that targeted sedentary behavior (286). However, reported estimates of diet

and activity may overestimate exercise and underestimate caloric intake (287), which is a real problem in interpretation.

There are many benefits to regular exercise for the obese patient. Lifestyle changes that increase the level of physical activity may be advantageous in blunting age-related increases in total-and central-body fatness. Bouchard and associates (288) carefully studied young men who developed negative energy balance through exercise and a maintained energy intake. They showed clearly that it is quite possible to lose fat while preserving fat-free mass through regular, prolonged exercise of moderate intensity, when energy intake is kept constant at a baseline level. They underscored the importance of individual differences in response to negative energy balance. Foreyt and colleagues (289) undertook a prospective 4-year natural history study that examined psychological correlates of physical activity. They noted that individuals who reported participating in physical activity had a better psychological profile at 1 and 5 years, with improvements in eating self-efficacy and well-being. When diet and exercise are combined, the results are encouraging. Tremblay and colleagues (290) noted in four obese women who had been previously trained in exercise that addition of a low-fat diet could normalize the glucose/insulin profile of obese women, even if their adiposity remains higher than that of lean women. It seems prudent that every physician should encourage patients to engage in 30 minutes or more of moderate-intensity physical activity on most, and preferably all, days of the week (291).

For much of the 1990s, appetite suppressant drugs that acted via a serotonergic mechanism were prescribed for weight control (292). The association by Mayo investigators of unusual valvular morphology and regurgitation after approximately 12 months of fenfluramine and phentermine therapy led physicians to reconsider the pharmacologic approach to obesity (293). In that investigation, five patients who went to surgery had valvular abnormalities reminiscent of those associated with the carcinoid syndrome. Devereaux (294) summarized well the lessons learned from the careful studies that were done to determine the severity and extent of the problem. First, he noted that the investigations validated the decision of the U.S. Food and Drug Administration to pull these appetite suppressants from the market. Second, he noted that clinically overt valvular disease after the use of appetite suppressants for 3 or fewer months was low after 4 years of follow-up. He concluded that clinically important valvular disease would probably not develop after short-term exposure to these drugs. Third, the converse appears to be true. Exposure to a high dose or a long duration of use makes valvular abnormalities more likely. He suggested that patients who have taken these drugs be followed carefully, that those with clinical or echocardiographic evidence for valvular heart disease be given endocarditis prophylaxis instructions, and that caution should be urged before other appetite suppressant drugs that act via serotonergic mechanisms are used. Further investigation has established that activation of 5-HT_{2B} receptors is necessary to produce these valvular lesions, and that serotonergic medications that do not activate 5-HT_{2B} receptors are unlikely to create the difficulties seen with the offending drugs. It has been suggested that all clinically available medications with serotonergic activity and their active metabolites be screened for agonist activity at 5-HT_{2B} receptors, so that clinicians can consider suspending their usage if necessary (295). Of historical note, before the discovery of valvular abnormalities associated with use of these drugs, there was a historical concern relating to primary pulmonary hypertension and certain appetite-suppressant drugs (296).

Currently, the two major drugs available to clinicians for patients who require assistance with weight loss are sibutramine and orlistat. It is instructive to compare the results of 1-year clinical trials with each drug. Sibutramine is a norepinephrine-serotonin reuptake inhibitor and is approved for long-term use. To determine efficacy and safety in obese patients with drug-controlled hypertension, both white and black subjects between 27 and 40 years old were randomly assigned to receive sibutramine (n = 150) or placebo (n = 74) with minimal behavioral intervention for 52 weeks (297). Among subjects receiving sibutramine, 13.4% lost 10% or more of their body weight, compared with 4.3% of subjects in the placebo group (p <.05). The benefits of sibutramine-induced weight loss included reduced waist circumference and improvement in quality-of-life measures, as well as significant improvements in TG, HDL-C, glucose, and uric acid levels. Subjects treated with sibutramine had small but statistically significant mean increases (similar among blacks and whites) in diastolic blood pressure (2.0 mm Hg) and pulse rate (4.9 beats/min) compared with placebo-treated patients (–1.3 mm Hg and 0.0 beats/min). The most common adverse event resulting in discontinuation among subjects receiving sibutramine was hypertension (which occurred in 5.3% of patients receiving sibutramine, vs. 1.4% of patients receiving placebo).

Orlistat inhibits pancreatic lipase and can block 30% of the triacylglycerol hydrolysis in subjects consuming a 30% fat diet. This unique mechanism of action appears to teach patients how to reduce their intake of fat due to fecal leakage of unabsorbed fat if they exceed the 30% limitation on fat calories. In a five-center study in the United Kingdom, 228 obese adult subjects were randomly assigned to receive orlistat, 120 mg three times daily, versus placebo after run-in diet of 30% fat designed to produce an energy deficit of 600 kcal per day (298). After 1 year of treatment, 28% of the orlistat group lost at least 10% of body weight, compared with 17% of the placebo group (p = .04). Orlistat-treated subjects had significant decreases in LDL-C levels and in the ratio of LDL-C to HDL-C. More gastrointestinal events occurred in the orlistat group, but these were mild and transient. After 1 year, the decrease in vitamin E and beta-carotene levels was significantly greater in orlistat-treated patients than in the placebo group, and fat-soluble vitamins were given to supplement the diet of subjects in the orlistat group. In summary, both sibutramine and orlistat can produce and maintain weight loss over the course of a 12-month period that is greater than that obtained with placebo.

Surgery for obesity is becoming increasingly common in the United States, with the number of operations growing to approximately 40,000 in the year 2000 (299). This is results of the recognition that, if left untreated, patients who are the most obese (BMI greater than 40) have only a 1 in 7 chance of reaching their normal life expectancy and of increased acceptability of current surgical techniques (300). One current surgery involves the gastric bypass, in which a partition is created across the upper stomach by using surgical staples. Another way to limit food intake is to place a constricting ring around the fundus of the stomach, a procedure known as “gastric banding.” Approximately 80% of the patients who undergo these surgeries are women. The complications of gastric bypass are much less severe than those of the older jejunoileal intestinal bypass procedure, which is no longer performed due to the high morbidity and mortality associated with it. Laparoscopic techniques hold the promise of reducing the morbidity seen with these procedures but require special training and should be performed by practitioners who are experienced in this technique.

The selection criteria for obesity surgery include a BMI greater than 40 or of 35 to 40 in a patient with serious comorbidity that is treatable by weight loss (301). Other criteria are a minimum of 5 years’ duration of obesity, a history of conservative treatment that failed, no history of alcohol misuse or major psychiatric illness, and age between 18 and 55, with an acceptable operative risk. Women are asked to avoid becoming pregnant within 2 years of the operation. The surgery must be performed in a multidisciplinary environment with a team that includes dietitians or specialist nurses, physicians, anesthesiologists, radiologists, and psychologists experienced with the special problems that are seen in these patients.

CONCLUSIONS

What diet can cardiologists recommend at present? For those with coronary disease or who are greatly at risk for coronary disease, a healthy AHA diet is inadequate. A therapeutic diet that is nutritionally adequate and contains from 25% to 35% of calories as fat is recommended, but less than 7% of calories should come from saturated fat and intake of dietary cholesterol should be less than 200 mg per day. There should be at least five servings of fruits and vegetables daily, along with nonfat dairy products and salt restriction, if the patient is hypertensive. Whether the patient prefers an Asian regimen with more-complex carbohydrates or a Mediterranean-type regimen with more olive or canola oil is best decided on a case-by-case basis. Two servings of fatty fish per week should be recommended. For individuals who have experienced MI and cannot eat fish, consideration should be given to use of approximately 875 mg of omega-3 fatty acids as a fish oil capsule. Sugar calories are “empty” calories and should be eliminated from the diet. Because weight reduction is given high priority in the overweight heart patient, calories in excess of energy expenditure must be discouraged. An alcoholic drink with dinner is not prohibited, and moderate alcohol consumption may prove to be salutary. Nonetheless, as noted earlier, the negative effects seen in individuals who cannot limit alcohol consumption and in special circumstances (e.g., pregnancy) should make physicians wary about casual, global endorsement of alcoholic drinking to improve risk for CAD.

Although some patients may do well with highly restricted low-fat diets (as recommended by Ornish and Pritikin), there are no available data to show that this is the preferred nutritional choice for the patient with CAD. Nonetheless, these programs have taught us the value of a real commitment to a low-fat diet. As is seen even with drug therapy, individuals who adhere most consistently to a therapeutic regimen often get the best results (10). A possible danger of advising a very-low-fat regimen to patients who do not receive adequate instruction is the adoption of a dietary regimen that is too low in protein and too high in carbohydrates. If detailed individualized instruction is provided and there is a comprehensive approach to lifestyle changes, the dietary and lifestyle changes achieved can be impressive in the short term (302). Certainly, when noninvasive testing such as PET can monitor the efficacy of these regimens, the potential for improvement in coronary status can motivate patients considerably (301,303). Most often, surrogates such as improved risk factors (and possibly markers of subclinical disease) should provide the reassurance that patients often require to continue with these regimens. In addition, we need further studies of the Mediterranean-type diet used in the Lyon Trial (107). We need to understand whether the crucial intervention was the increase in omega-3 fatty acids, MUFAs, or both together with the low–saturated fat, low-cholesterol, low-fiber regimen that produced the striking results.

The growing weight of evidence suggests that lifestyle changes should be recommended to the coronary patient that encourage the avoidance of excess calories and promote regular exercise to reduce the likelihood of excessive weight gain. These are crucial supplements to dietary advice. Also helpful would be the presence of a registered dietitian to help the patient learn how to deal with external cues from the environment and to develop important skills such as label reading, wise restaurant menu selections, and recipe modification. This cannot be emphasized enough; individualized recommendations for lifestyle change and feedback are crucial to obtaining good results. Many excellent books on eating a healthier diet are available. Sources such as the AHA; the National Heart, Lung, and Blood Institute; and the American Dietetic Association should be consulted (by phone or through the Internet) to obtain help.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Several major controversies need to be resolved. The first is whether we should adopt the Mediterranean diet pyramid (*e*Fig. 2.1.2) instead of our current pyramid for primary prevention of CAD. As noted in this chapter, there are aspects of the Mediterranean-type diet that are particularly helpful for certain patients. However,

although the potential cardioprotective effects associated with a diet supplemented with omega-3 fatty acids and oleic acid are exciting to contemplate, their efficacy needs to be explored with more data from clinical trials.

Many physicians are under the false impression that basic nutrition principles do not work in clinical practice. Well-meaning but poorly reinforced suggestions about diet are certainly likely to fail. As noted in earlier sections of this chapter, failure is much less likely when individualized counseling and follow-up are provided. Results can occasionally be dramatic. In a recent small study involving healthy, motivated individuals that was designed to determine whether use of the Dietary Guidelines for Americans and the Food Guide Pyramid, combined with exercise training, could result in significant reductions in cardiovascular risk compared with a regimen of exercise therapy alone, subjects randomly assigned to the diet and exercise group fared better than those assigned to exercise alone (302). In the half of the group that received individualized dietary counseling using the Food Guide Pyramid as a primary educational tool, the percentage of energy intake from fat decreased from 39% to 23% (*e*Fig. 2.1.3). This was associated with significant reductions in BMI, total cholesterol levels, and LDL-C levels, whereas no change was observed in the group who used exercise alone.

Another controversial aspect of medical nutritional therapy is whether patients with CAD require a very-low-fat diet. Again, the data supporting this approach are inadequate at present because of the highly selected nature of the patients who have been involved in studies of the effect of such diets. Although these patients have been able to make the major lifestyle changes required for these regimens, it is not clear that this is feasible for the population at large. In fact, diets with less than 15% fat are not likely to have wide appeal. For those with CAD, a diet markedly restricted in saturated fats is still the primary approach and retains the appropriate focus. Well-motivated patients should be encouraged to learn the basics of a vegetarian lifestyle and supplement their diets with small amounts of lean meat, fish, and skinless fowl. The use of exercise as an adjunct to diet cannot be stressed enough. The best diets will invariably be the ones that promote loss of excessive weight while augmenting the use of drugs to lower LDL-C and TG levels and to raise subnormal levels of HDL-C.

An important controversy that appears to be resolving is whether it is better to have a diet supplemented with fish, vegetables, and fruits as a supply of antioxidants, or to load up on a handful of pills each morning that contain megadoses of minerals and vitamins. The adverse experience with beta-carotene and the lack of data confirming cardiovascular benefit from vitamin E supplementation in large-scale clinical trials should make all cardiologists more cautious about the supplements they recommend for their patients. Physicians should remember that, although tempting, recommendation of interesting but unproved nutritional supplements may not work to a patient's advantage.

A word of caution should be given about "fad diets" that are presented to cardiologists by their patients. Many diets have had glowing testimonials in the short term only to fall short of the mark in the long term. In addition, at the extremes of the life cycle, children and the elderly are likely to do poorly with dietary plans that may not have the proper nutritional balance for their age group. This can lead to unwanted nutritional deficiencies. Many patients look for endorsement because they feel the most important hurdle is getting started on weight loss. Actually, the most formidable hurdle is *maintaining* weight loss. As a general rule, diets that promise dramatic short-term weight loss fail to teach our patients the proper behaviors that are needed for long-term weight maintenance. Should it be surprising that so many regain lost weight and become even heavier?

A final controversy relates to the treatment of obesity. As the prevalence of obesity increases, its impact will be seen in cardiology practices. As noted earlier, the increase in insulin resistance with accompanying dyslipidemia, hypertension, and glucose intolerance (i.e., the metabolic syndrome) greatly increases coronary risk. The risk factors in turn magnify the negative effects of obesity on cardiac status. Moreover, for individuals with CAD, obesity limits or adversely affects the accuracy of diagnostic procedures. Although more vigorous attempts at adhering to dietary recommendations under the watchful eye of a registered dietitian are very useful, they have not proven as productive as might be wished. The current antiobesity drugs may be useful if 5% to 10% weight loss is required to improve risk-factor status. I do not recommend sibutramine in patients with CHD, because of its small but definite effects on blood pressure and heart rate. Further clinical trials of the newer generations of obesity drugs are needed to determine their proper place in both primary and secondary prevention of CAD. More widespread use of surgical techniques by qualified surgeons with appropriate multidisciplinary support may prove most helpful to severely obese patients. Given the high recidivism rate in weight-loss programs, the focus for the obese patient should be on learning new behaviors, such as dietary changes, exercise, and stress management. Increasing social support may be extremely helpful in this regard. Most important, the cardiologist should use every opportunity to endorse prevention of obesity through regular exercise and diet among individuals who are just beginning to increase their weight status as they age. Given the difficulty of successfully treating obesity, prevention of obesity should remain a high priority for public policy. Physicians should play a role as well and try to anticipate the expected weight gain from patients who stop smoking or start medications such as steroids, antidepressants, and antidiabetic drugs. These patients constitute a high-risk group to which heightened attention should be given.

THE FUTURE

As we approach the year 2010, the United States is well on its way to attaining an even lower overall serum cholesterol level through improved diet. The ongoing change in health care delivery toward a system of managed care has the potential to improve the nutritional health of the population through innovative, low-cost nutritional programs. The ability to document improved outcomes associated with such endeavors is an important task that lies ahead. Finally, exciting advances in medical genetics hold the promise of more-targeted nutritional advice, not only for the general population, but particularly for those at high risk for heart disease.

OVERVIEW

Lipid disorders are common and are an important risk factor for coronary heart disease (CHD) and all types of atherosclerotic cardiovascular disease (ASCVD). Intervention with diet and drugs to reduce low-density lipoprotein (LDL) cholesterol has been proven to decrease the risk of subsequent cardiovascular events, including the total mortality. In patients who have established ASCVD or are at a high risk for developing it, treatment to reduce LDL cholesterol is effective not only when the LDL cholesterol level is elevated, but also when the cholesterol level is average. On the basis of a wealth of clinical trial data, it is widely agreed that virtually all patients with ASCVD should be treated with lipid-lowering drug therapy to reduce the risk of subsequent cardiovascular events. However, sudden cardiac death at the time of the first myocardial infarction (MI) is common, and, therefore, waiting to reduce cholesterol until symptoms of CHD have developed is not an acceptable strategy. Drug therapy to reduce cholesterol in primary prevention has also been shown to reduce cardiovascular events, even when LDL cholesterol levels are only moderately elevated. Thus, the major challenge in primary prevention is to perform an accurate risk assessment so that high-risk patients can be treated with an appropriate level of aggressive drug therapy, and low-risk patients can avoid drug therapy. Traditional risk factors are useful but do not always permit accurate risk assessment; additional tests to assess cardiovascular risk, such as laboratory tests and noninvasive imaging tests of subclinical atherosclerosis, have a role to play. It is likely that those individuals at highest risk for developing premature CHD will be able to be prospectively identified. Cholesterol reduction is a cornerstone of cardiovascular risk reduction. Strategies to achieve cholesterol reduction must include both broad-based public health measures oriented around diet and lifestyle and highly focused, aggressive intervention targeted toward those at highest risk for developing premature CHD.

GLOSSARY

Apolipoprotein: Major protein component of lipoproteins; apolipoproteins have a variety of functions.

Cholesteryl ester transfer protein (CETP): Protein that transfers lipids among lipoproteins, especially cholesteryl ester from high-density lipoprotein to very low-density lipoprotein, in exchange for triglycerides.

Chylomicron: Intestinal triglyceride-rich lipoprotein; elevated when triglycerides are >1,000 mg per dL.

Hepatic lipase (HL): Endothelial-anchored enzyme in liver that is primarily responsible for hydrolysis of triglycerides and phospholipids in intermediate-density lipoprotein and high-density lipoprotein.

High-density lipoprotein (HDL): Small lipoprotein thought to participate in "reverse cholesterol transport"; levels are inversely associated with risk of coronary artery disease.

3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase: Rate-limiting enzyme in cholesterol biosynthesis; inhibition by statins results in reduction of plasma LDL-cholesterol levels.

Intermediate-density lipoprotein (IDL): Lipoprotein formed by hydrolysis of triglycerides in very low-density lipoprotein; elevated in type III hyperlipoproteinemia.

Lecithin-cholesterol acyltransferase (LCAT): Enzyme that converts free cholesterol to cholesteryl ester on high-density lipoprotein.

Lipoproteins: Complexes responsible for transporting lipids (cholesterol, triglyceride, phospholipids) within the blood.

Lipoprotein lipase (LPL): Endothelial-anchored enzyme primarily responsible for hydrolysis of chylomicron and very-low-density lipoprotein triglycerides, especially in muscle and adipose tissue.

Low-density lipoprotein (LDL): Major cholesterol-containing lipoprotein and major atherogenic lipoprotein.

Primary prevention: Treatment to prevent atherosclerosis and coronary artery disease events in persons who do not have evidence of coronary artery disease.

Secondary prevention: Treatment to prevent recurrent coronary artery disease events in persons who have documented coronary artery disease.

Very-low-density lipoprotein (VLDL): Major triglyceride-containing lipoprotein when fasting triglycerides are <1,000 mg per dL; made by the liver.

HISTORICAL PERSPECTIVE

Cholesterol was first postulated to be related to atherosclerosis when it was found to be a major component of advanced atherosclerotic plaques. The association between elevated serum cholesterol and atherosclerotic disease was first reported in the 1930s. Subsequent large epidemiologic studies such as the Seven Countries Study (1) and the Framingham Heart Study (2) confirmed the strong relationship between serum cholesterol and CHD. In the Multiple Risk Factor Intervention Trial, 356,222 men with no history of MI were screened and followed for the development of CHD over the course of 6 years. The relationship between serum cholesterol level and subsequent CHD was found to be continuous, graded, and strong (3). The Lipid Research Clinics Prevalence Study demonstrated in a 10-year follow-up that cholesterol level at baseline was strongly associated with CHD death in men who did and men who did not have CHD when they entered the study (4). In the Johns Hopkins Precursors Study, cholesterol levels determined in young men in their early twenties were predictive of the risk of developing CHD three to four decades later (5). In the Bogalusa Heart Study, aortic fatty streaks in young individuals (mean age, 18 years) were found to be strongly correlated with serum cholesterol level (6). These and many other epidemiologic and observational studies formed the basis of the “cholesterol hypothesis,” which states that the relationship between serum cholesterol and atherosclerosis is causal and that reduction of serum cholesterol reduces atherosclerotic disease.

The subfractionation of serum cholesterol into cholesterol contained within specific lipoproteins, such as LDLs and high-density lipoproteins (HDLs), was a major clinical advance. Risk for CHD was found to be strongly associated with LDL cholesterol levels. The seminal observation that HDL cholesterol levels were inversely associated with cardiovascular risk was made in the 1950s and rediscovered in the 1970s (7). Subsequent studies from many parts of the world have confirmed this observation (8) and have ultimately resulted in the use of HDL cholesterol levels as a key laboratory marker for the screening of cardiovascular risk in all adults (9).

The relationship between fasting serum triglycerides and cardiovascular risk has been confounded by the inverse association between triglycerides and HDL cholesterol, as well as by the association of triglycerides with other risk factors, such as diabetes mellitus and body mass. Earlier epidemiologic studies demonstrated that fasting triglycerides were not independently associated with cardiovascular risk. However, in the last several years, several prospective studies have indicated that triglyceride levels are an important independent predictor of risk (10). Although formal guidelines have not yet established the use of triglycerides as an independent risk factor, many clinicians now incorporate the fasting triglyceride level into a comprehensive cardiovascular risk assessment (see below).

LIPID-MODIFYING THERAPY AND EFFECTS ON ATHEROSCLEROSIS AND CARDIOVASCULAR EVENTS

Despite the wealth of epidemiologic and pathologic data linking serum cholesterol to atherosclerotic disease, proof of the “cholesterol hypothesis” required demonstration that reduction of cholesterol decreased atherosclerosis and clinical cardiovascular events. Over the past two decades, multiple trials have been reported that were designed to test this hypothesis, and more recent studies have been designed to test whether modification of HDL cholesterol and triglyceride levels would reduce atherosclerosis or cardiovascular risk. Many studies have assessed the impact of lipid-modifying therapy on a quantitative measure of atherosclerotic disease (as assessed by coronary angiography or carotid ultrasound) (*e*Table 3.0.1). Other, larger trials have been focused on the effect of lipid-modifying therapy on clinical cardiovascular events (nonfatal MI, CHD death, and total mortality rate) (Table 3.1). These studies encompass both secondary prevention trials (in patients with clinically established CHD) and primary prevention trials (in patients without established CHD).

TABLE 3.1 CLINICAL TRIALS OF CHOLESTEROL REDUCTION WITH CLINICAL EVENTS AS THE PRIMARY END POINT

Trials Using Quantitation of Atherosclerotic Disease as the Primary End Point

Quantitative Coronary Angiography

A large number of angiographic trials have been performed that address whether treatment to lower cholesterol or modify serum lipids influences the course of angiographic coronary disease (*e*Table 3.0.1). These trials have consistently demonstrated that cholesterol reduction resulted in slowing of the progression of coronary disease compared with the rate of progression in a control group. Some trials have even demonstrated modest regression of coronary atherosclerotic disease in a subset of the treated subjects. Although the results were statistically significant, the magnitude of the differences between treated and control groups in these studies has generally been rather small and of uncertain clinical significance. However, many of these studies have subsequently reported their secondary endpoint clinical cardiovascular event rates. In most trials, a substantial reduction in clinical events was seen in the treated group that was out of proportion to the small quantitative

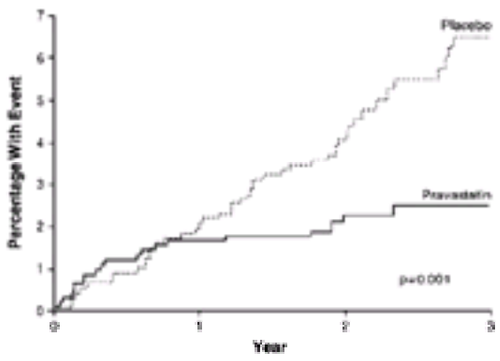
changes in luminal diameter of lesions. This consistent angiographic-clinical dissociation has led to the concept of “plaque stabilization,” in which cholesterol reduction alters the vulnerable plaque in a way that may not substantially change its angiographic stenosis but nevertheless makes it substantially less likely to rupture and cause an acute coronary event (11). The mechanisms by which cholesterol reduction reduces the likelihood of acute coronary events are not well understood but may include lipid depletion of the core of the lesion, stabilization of the endothelium, inhibition of platelets, and effects on vascular smooth muscle cell behavior (11,12).

Carotid Ultrasonography

Several trials have been performed that address the question of whether cholesterol reduction influences the progression of carotid atherosclerosis as assessed by B-mode ultrasonography for quantitation of the intimal-medial thickness (IMT) (eTable 3.0.1). All studies demonstrated a statistically significant effect of treatment on the primary end point of quantitative carotid intimal thickening. Interestingly, as noted in the coronary angiographic studies, secondary endpoint cardiovascular events were also substantially reduced in these trials (although the total number of events was relatively small).

Pooled Analysis

A pooled analysis of four atherosclerosis trials using pravastatin was prospectively planned and subsequently performed (13). These four trials (two involving coronary angiography and two involving carotid ultrasound) included a total of 1,891 subjects, all of whom had some evidence of atherosclerosis and elevated cholesterol levels, who were followed for 2 to 3 years. In this pooled analysis, the major end point was the combined end point of nonfatal or fatal MI. A total of 46 events in the placebo group and 21 events in the pravastatin group were reported, resulting in a 62% reduction in relative risk of nonfatal or fatal MI after 2 to 3 years of treatment (p = .001) (eFig. 3.0.1).



***e*FIGURE 3.0.1** Rate of nonfatal or fatal myocardial infarction in the pooled analysis of four pravastatin atherosclerosis trials. (From Byington RP, Jukema W, Salonen JT, et al. Reduction in cardiovascular events during pravastatin therapy: pooled analysis of clinical events of the pravastatin atherosclerosis intervention program. *Circulation* 1995;92:2419–2425.)

Taken together, these trials indicate that cholesterol reduction has a quantitative effect on the progression and even regression of atherosclerosis, and that the reduction in clinical cardiovascular events is disproportionately greater than the modest changes in measurable atherosclerosis.

Trials Using Clinical Events as the Primary End Point

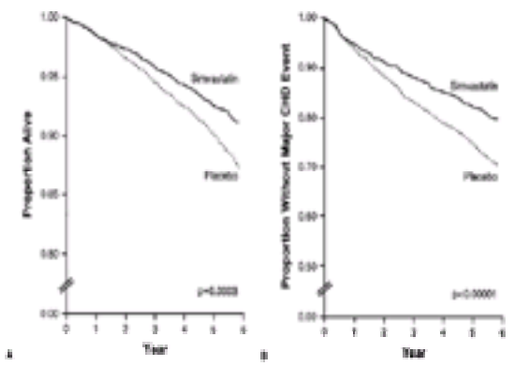
Early Clinical Trials: Niacin, Bile Acid Sequestrants, and Partial Ileal Bypass

The early clinical trials used niacin, bile acid sequestrants, and even the surgical approach of partial ileal bypass to reduce serum cholesterol levels (Table 3.1). The Coronary Drug Project demonstrated a modest benefit of niacin in reducing nonfatal MI after 6 years of treatment (14) and in reducing the total mortality rate after 15 years of follow-up (15). The Program on the Surgical Control of the Hyperlipidemias trial used partial ileal bypass surgery to reduce LDL cholesterol levels and demonstrated a significant 35% relative reduction in fatal CHD and nonfatal MI, although no significant reduction was seen in the total mortality rate (the primary end point of the trial) (16). In the Lipid Research Clinics Coronary Primary Prevention Trial, which studied the effect of cholestyramine administration in hypercholesterolemic men (17,18), combined fatal CHD and nonfatal MI (the primary end point) was reduced by 19%, but the total mortality rate was not reduced (68 deaths among patients receiving cholestyramine vs. 71 deaths among patients receiving placebo). A higher noncardiovascular mortality rate was seen in patients who were treated with cholestyramine (36 deaths) than in patients who received placebo (27 deaths), mostly because of a higher number of suicides and violent deaths among patients treated with cholestyramine (11 vs. 4 deaths). Extension of the follow-up period to a total of 13.4 years (19) demonstrated that the total number of deaths in the group of patients receiving cholestyramine (143 deaths) was not significantly different from that in the control group (156 deaths).

3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Inhibitor (Statin) Trials

Secondary Prevention

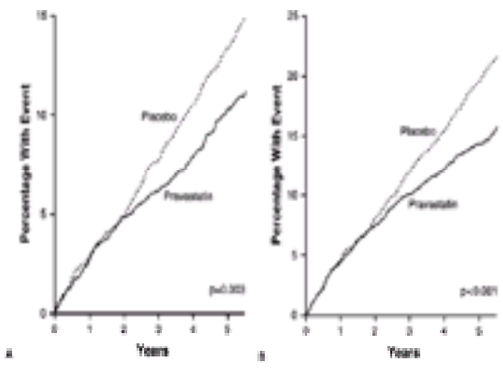
Five major clinical outcome trials with 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) performed during the 1990s definitively established that reduction of LDL cholesterol reduced cardiovascular risk in both secondary and primary prevention (Table 3.1). Three of these trials were secondary prevention trials, and two were primary prevention trials. The Scandinavian Simvastatin Survival Study (4S) (20) was designed to address the question of whether cholesterol reduction with simvastatin in persons with CHD and elevated cholesterol would reduce the total mortality rate (the primary end point). A total of 4,444 patients with angina or previous MI whose total cholesterol levels were between 212 and 310 mg per dL were randomized to placebo or simvastatin. The simvastatin dose was titrated to reduce the total cholesterol level to <200 mg per dL. Subjects were followed for a mean of 5.4 years. One hundred and eighty-nine deaths occurred in the group receiving placebo, and 111 deaths occurred in the group receiving simvastatin, resulting in a highly significant 30% relative reduction in the total mortality rate (p <.00001) (eFig 3.0.2A). The relative risk of a major coronary event (the secondary end point) such as CHD death or MI was reduced by 44% (p <.00001) (eFig 3.0.2B). The number of revascularization procedures such as coronary bypass surgery and angioplasty also dropped significantly, by 34%. An economic analysis based on the 4S study concluded that in the United States, the reduction in hospital costs alone as a result of the treatment would virtually offset the cost of the medication (21). Importantly, the reduction in risk was not only seen among subjects who had the highest cholesterol levels; the quartile with the lowest LDL cholesterol levels at baseline had proportionately as much benefit from treatment as the highest quartile (22).



***e*FIGURE 3.0.2** Proportion of subjects with all-cause mortality **(A)** and major coronary heart disease events **(B)** in the Scandinavian Simvastatin Survival Study involving patients with coronary heart disease (CHD) and elevated cholesterol levels. [From the Scandinavian Simvastatin Survival Study Group. Randomized trial of cholesterol lowering in 4444 patients with coronary heart disease: the Scandinavian Simvastatin Survival Study (4S). *Lancet* 1994;344:1383–1389.]

This issue is important, because the majority of patients with CHD do not have particularly elevated cholesterol levels; in fact, approximately 35% of all persons with

CHD have total cholesterol levels <200 mg per dL (23). Therefore, another major trial, the Cholesterol and Recurrent Events study (24), addressed the previously unanswered question of whether patients who had experienced MI and who had average cholesterol levels would benefit from further cholesterol reduction with pravastatin. In this study, 4,159 patients who had experienced MI 3 to 20 months before the trial and had total cholesterol levels <240 mg per dL were randomly assigned to receive placebo or pravastatin, 40 mg daily, and followed for an average of 5 years. The mean total cholesterol level was 209 mg per dL in each group, and the mean LDL cholesterol level was only 139 mg per dL (range, 115 to 174 mg per dL). After 5 years, 274 subjects in the placebo group had nonfatal MI or CHD death (the primary end point), compared with 212 subjects in the group of patients treated with pravastatin, resulting in a significant 24% reduction in relative risk (p = .003) (eFig 3.0.3A). Revascularization procedures were reduced by 27% (p <.001) (eFig. 3.0.3B). These results demonstrated that the benefit of cholesterol-lowering therapy extends even to CHD patients who have average cholesterol levels.



***e*FIGURE 3.0.3** Rate of fatal coronary artery disease or nonfatal myocardial infarction **(A)** and revascularization procedures **(B)** in the Cholesterol and Recurrent Events Study in patients with myocardial infarction and average cholesterol levels. (From Sacks FM, Pfeffer MA, Moye L, et al. The effect of pravastatin on coronary events after myocardial infarction in patients with average cholesterol levels. *N Engl J Med* 1996;335:1001–1009.)

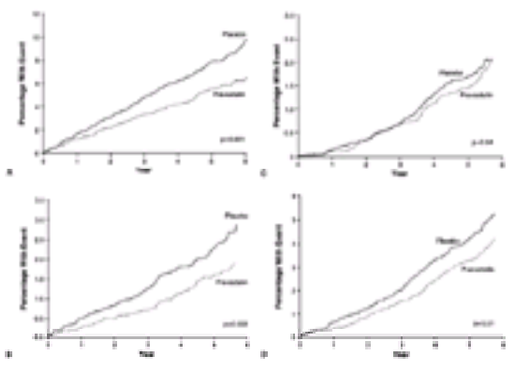
The Long-Term Intervention with Pravastatin in Ischaemic Disease Study (LIPID) (25) was the largest secondary prevention study performed to date. It included 9,014 patients aged 31 to 75 years who presented with either acute MI or unstable angina and who had baseline cholesterol levels spanning the wide range of 155 to 271 mg per dL. Subjects were randomly assigned to receive placebo or pravastatin, 40 mg daily, and followed for 6 years. Treatment with pravastatin significantly reduced the CHD mortality rate (the primary end point) by 24% (p <.001) and the total mortality rate by 22% (p <0.001). The study was terminated early by the data and safety monitoring committee because of the highly significant difference in total mortality between the two groups. The occurrence of revascularization was reduced by 20%, and the occurrence of stroke of any type was reduced by 19%.

These three studies definitively established the efficacy of statin therapy in reducing cardiovascular events and the total mortality rate in patients who had established CHD over a very wide range of baseline LDL cholesterol levels. Not only is cholesterol-lowering drug therapy clinically effective in secondary prevention, it is cost-effective as well. Aggressive cholesterol reduction in patients with patients with CHD or other ASCVD is now the standard of care, as agreed on in a joint statement issued by the American Heart Association and the American College of Cardiology (26). The majority of patients with ASCVD should be considered candidates for lipid-lowering drug therapy. Current debate in secondary prevention centers around not whether to treat, but how far to reduce the LDL cholesterol level (27). Studies designed to address this issue are currently under way.

All of the statin trials reviewed earlier excluded patients who were within 3 to 6 months of an acute coronary event. The LIPID trial was, in fact, the only secondary-prevention trial to include patients who had presented with unstable angina. In LIPID, the relative risk reduction for total mortality with pravastatin therapy was 20.6% among patients who had experienced MI and 26.3% among patients who had experienced unstable angina, suggesting a trend for even greater benefit in those patients who presented with unstable angina (28). In patients in LIPID who had previous unstable angina, the CHD mortality rate, the total mortality rate, the incidence of MI, the need for coronary revascularization, the number of admissions to the hospital, and the number of days spent in the hospital were all significantly lower in the group of patients receiving pravastatin. One question of substantial clinical interest is whether patients presenting with acute coronary syndromes would benefit from immediate initiation of statin therapy. In a small study called the Randomized Lipid-Coronary Artery Disease Study, patients were randomly assigned, an average of 6 days after presenting with an acute coronary syndrome, to receive pravastatin, 40 mg daily (combined, when necessary, with cholestyramine and/or nicotinic acid to achieve LDL cholesterol levels <130 mg per dL), or usual care (29). After 2 years, 52% of patients in the group receiving usual care but only 23% of patients in the group being aggressively treated experienced a recurrent cardiovascular event (p = .005). In a larger study called the Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering Study, patients who presented with acute coronary syndromes and did not undergo revascularization were randomly assigned to receive immediate therapy with atorvastatin, 80 mg, or placebo and followed for 4 months (30). A 16% reduction in recurrent coronary events was associated with immediate statin therapy, a difference that barely achieved statistical significance (p = .048). Additional studies that include patients undergoing revascularization are under way that also address the important question of the benefit of immediate initiation of statin therapy.

Primary Prevention

Primary prevention of CHD is also important, because approximately one-fourth to one-third of first MIs result in death (31), precluding the opportunity for secondary prevention. Nevertheless, the use of drug therapy in primary prevention has been controversial; before the mid-1990s, relatively few data were available that demonstrated clinical benefit. The West of Scotland Coronary Prevention Study (32) was a landmark trial in primary prevention of CHD. This study involved 6,595 healthy Scottish men aged 45 to 64 years, with total cholesterol levels >252 mg per dL and LDL cholesterol levels of 174 to 232 mg per dL. Although none of the study subjects had documented CHD, 5% had positive results of a Rose questionnaire indicating probable angina. Subjects were randomly assigned to receive pravastatin, 40 mg per day, or placebo and were followed for an average of 5 years. The primary end point of the study was nonfatal MI or CHD death. Two hundred and forty-eight definite events were reported in the group of patients receiving placebo (7.9% of the subjects) and 174 events in the group receiving pravastatin (5.5% of the subjects), resulting in a 31% reduction in relative risk of nonfatal MI or CHD death (p <.001) (eFig. 3.0.4A). In addition, a significant 32% reduction in CHD death (p <.033) (eFig. 3.0.4B) and a 37% reduction in revascularization procedures (p <.009) were seen. Importantly, no significant difference was found in the noncardiovascular mortality rate (eFig. 3.0.4C), indicating that cholesterol reduction with pravastatin did not increase the risk of death from other causes. In fact, the relative risk of death from any cause (total mortality rate) was reduced by 22% among patients treated with pravastatin (p = .051) during the 5-year period of the trial (eFig. 3.0.4D). This trial clearly established that drug therapy for hypercholesterolemia is an effective method of decreasing risk of cardiovascular events in persons who do not have prior evidence of CHD.



***e*FIGURE 3.0.4** Rates of nonfatal myocardial infarction or coronary artery disease death **(A)**, cardiovascular mortality **(B)**, noncardiovascular mortality **(C)**, and all-cause mortality **(D)** in the West of Scotland Coronary Prevention Study in men without myocardial infarction and with elevated cholesterol levels. (From Shepherd J, Cobbe SM, Ford I, et al. Prevention of coronary heart disease with pravastatin in men with hypercholesterolemia. West of Scotland Coronary Prevention Study Group. *N Engl J Med* 1995;333:1301–1307.)

The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) extended these findings to a population with modestly elevated to average cholesterol levels (33). A total of 6,608 men and women with LDL cholesterol levels of 130 to 190 mg per dL and HDL cholesterol levels <45 mg per dL in men and <47 mg per dL in women were randomly assigned to receive lovastatin, 20 mg, or placebo and were followed for an average of 5.2 years. The dose of lovastatin was

titrated to 40 mg in an attempt to reduce LDL cholesterol levels to <100 mg per dL. A 37% relative risk reduction was seen in the primary end point of combined cardiovascular events in the group of patients who were treated with lovastatin. Interestingly, only 17% of the subjects in this trial would have met National Cholesterol Education Program Adult Treatment Panel II (NCEP-ATPII) 1993 guidelines for drug therapy. Therefore, the major clinical challenge in the use of drug therapy to reduce cholesterol levels in primary prevention of CHD is the accurate identification of individuals who are likely to develop clinical CHD and who are therefore most likely to benefit from drug therapy.

Pooled Analyses

Previous trials have included insufficient numbers of coronary events to address definitively the effect of lipid-modifying therapy on CHD in subgroups of patients with varying baseline characteristics. The data from three large randomized trials of pravastatin that involved 19,768 patients and 2,194 primary end points (coronary death or nonfatal MI) were pooled and analyzed with the use of a prospectively defined protocol (34). Pravastatin significantly reduced relative risk in patients regardless of age, sex, smoking habits, and presence of diabetes mellitus or hypertension. Relative risk reduction was significant in predefined categories of baseline lipid concentrations and was similar throughout most of the baseline LDL cholesterol range (125 to 212 mg per dL). Therefore, treatment is effective in reducing CHD events in patients with high- or low-risk factor status across a wide range of pretreatment lipid concentrations.

Fibrate Trials

Fibrates have been used as lipid-lowering drugs for several decades. They are particularly effective in reducing triglyceride levels and have modest effectiveness in reducing cholesterol levels and raising HDL cholesterol levels (35). Relatively few clinical endpoint trials examining the use of fibrates have been published. In the World Health Organization cooperative trial using clofibrate to treat hypercholesterolemic men (36), a 25% reduction was seen in relative risk of nonfatal MI (the primary end point) after 5 years, but a substantial 47% increase in noncardiovascular deaths was also found. Extension of the follow-up period to 13 years did not reveal a persistent effect of the drug on the excess mortality rate (37). The Helsinki Heart Study (38) treated men who had elevated non-HDL cholesterol levels, >200 mg per dL, with gemfibrozil and demonstrated a significant 34% reduction in combined fatal and nonfatal MI (the primary end point) but no difference in the total mortality rate (45 deaths among patients receiving gemfibrozil and 42 deaths in the control group). A small trend toward an increase in the noncardiovascular mortality rate was seen (31 vs. 23 deaths, respectively), which was largely due to a difference in accidental and violent death (10 vs. 4 deaths, respectively). Extension of the follow-up period to 8.5 years (39) demonstrated an increased mortality rate in the group treated with gemfibrozil (101 deaths) compared to the group receiving placebo (83 deaths) that was not statistically significant (p = .19) and was due to a small increase in cancer deaths among patients receiving gemfibrozil. Neither of these trials were designed with adequate power to assess the impact of fibrates on the total mortality rate. Nevertheless, the lack of effect on the total mortality rate and the small trends toward an increased noncardiovascular mortality rate resulted in uncertainty about the broad use of fibrates for cardiovascular risk reduction in hypercholesterolemic patients.

Two trials of fibrates in the late 1990s provided more data but also generated more questions. The Veteran Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) tested the benefit of gemfibrozil therapy in patients who had CHD and reasonably well-controlled LDL cholesterol levels but low HDL cholesterol levels (40). Two thousand five hundred and thirty-one patients with CHD, low levels of HDL (mean, 32 mg per dL), low LDL cholesterol levels (mean, 112 mg per dL), and triglyceride levels <300 mg per dL were randomly assigned to receive treatment with a sustained-release gemfibrozil formulation (1,200 mg daily) or placebo and followed for an average of 5.1 years. Gemfibrozil therapy was associated with a significant 22% reduction in the primary end point (nonfatal MI and coronary death) compared with placebo. Gemfibrozil resulted in a 6% increase in HDL cholesterol levels, a 31% decrease in triglyceride levels, and no change in LDL cholesterol levels. This important study suggests that lipid-modifying drug therapy using fibrates in patients with CHD and low LDL and HDL cholesterol levels reduces cardiovascular events.

In contrast, the Bezafibrate Infarction Prevention (BIP) trial involved 3,090 patients with established CHD, total cholesterol levels of 180 to 250 mg per dL, HDL cholesterol levels <45 mg per dL, triglyceride levels <300 mg per dL, and LDL cholesterol levels <180 mg per dL who were randomly assigned to receive either bezafibrate, 400 mg daily, or placebo and followed for a mean of 6.2 years (41). The primary end point was fatal or nonfatal MI or sudden death. Bezafibrate therapy was associated with a reduction in the primary end point of only 7.3%, which was not statistically significant (p = .24). A post hoc analysis in the subgroup with high baseline triglyceride levels (>200 mg per dL) suggested a reduction in events of 39% (p = .02).

These trials differed in a number of important ways, including the agent used and the mean baseline LDL cholesterol levels, which in BIP were 150 mg per dL and in VA-HIT were only 111 mg per dL. A reasonable conclusion is that fibrates are effective as monotherapy in reducing events in secondary prevention if the LDL cholesterol is low, but not if it is elevated. A number of additional studies are under way that address the role of fibrates in reducing cardiovascular events, both as monotherapy and in combination with statins.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF LIPOPROTEIN METABOLISM AND RELATIONSHIP TO ATHEROSCLEROSIS

Clinical management of patients with lipid disorders requires a general working knowledge of normal lipoprotein metabolism (42). Lipoproteins are large macromolecular complexes that transport cholesterol and triglycerides within the blood. They contain a neutral lipid core consisting of triglycerides and cholesteryl esters that is surrounded by phospholipids and specialized proteins known as *apolipoproteins*. The five major families of lipoproteins are chylomicrons, VLDLs, intermediate-density lipoproteins (IDLs), LDLs, and HDLs. Chylomicrons are the largest and most lipid-rich lipoproteins, whereas HDLs are the smallest lipoproteins and contain the least amount of lipid. The major metabolic pathways of lipoproteins are shown in Figure 3.1,Figure 3.2, and Figure 3.3 and described in detail in the accompanying legends.

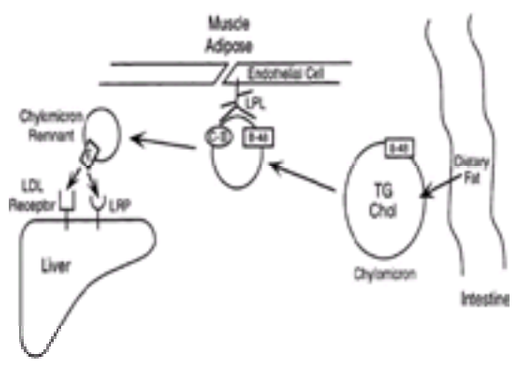


FIGURE 3.1 Exogenous pathway of lipid transport. Dietary fat is absorbed into chylomicrons, which contain the major structural apolipoprotein B-48. Chylomicrons bind to lipoprotein lipase (LPL) on the luminal surface of the capillary endothelium of tissues, especially muscle and adipose tissue. The LPL hydrolyzes the triglycerides [apolipoprotein C-II (C-II) on the chylomicron surface is a required cofactor for LPL]. The free fatty acids enter the tissue to be used for energy (muscle) or storage (adipose), and the triglyceride-depleted chylomicron remnant is released. Chylomicron remnants are taken up by the liver by binding of apolipoprotein E (E) to the low-density lipoprotein (LDL) receptor and the LDL receptor–related protein (LRP). TG Chol, triglyceride cholesterol.

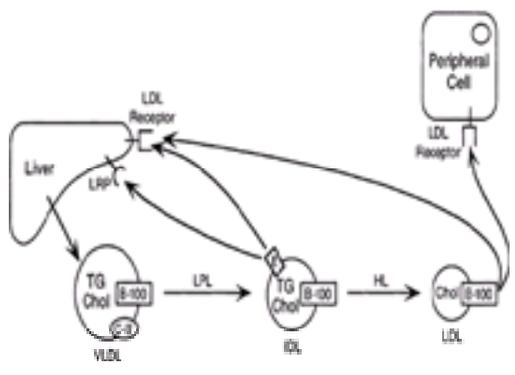

FIGURE 3.2 Endogenous pathway of lipid transport. The liver synthesizes triglycerides and cholesteryl esters and packages them into very-low-density lipoproteins (VLDLs), which contain the major structural apolipoprotein B-100. VLDLs are hydrolyzed by lipoprotein lipase (LPL) to form intermediate-density lipoproteins (IDL). IDLs can be taken up by the liver via binding of apolipoprotein E (E) to the LDL receptor or LDL receptor–related protein (LRP). Alternatively, the triglyceride and

phospholipid in IDL can be hydrolyzed by hepatic lipase (HL) within the hepatic sinusoids to form LDL. LDL can be taken up by peripheral cells or by the liver through the binding of apolipoprotein B-100 to the LDL receptor. C-II, apolipoprotein C-II; TG Chol, triglyceride cholesterol.

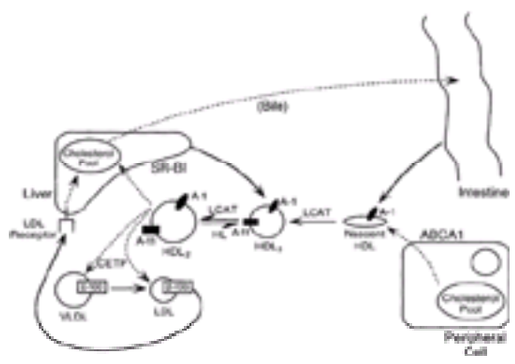

FIGURE 3.3 High-density lipoprotein (HDL) metabolism and reverse cholesterol transport. HDL and its major apolipoprotein, apolipoprotein A-I, are synthesized by both the intestine and the liver. A second major HDL protein, apolipoprotein A-II, is made only by the liver. Nascent HDL interacts with peripheral cells to facilitate the removal of excess free cholesterol through a process that is facilitated by the cellular protein ABCA1. Some of the acquired free cholesterol is esterified to cholesteryl ester on the HDL particle by the action of the enzyme lecithin-cholesterol acyltransferase (LCAT), and the nascent HDL particle becomes the larger HDL3. HDL acquires further cholesteryl ester by continued LCAT action and eventually becomes the even larger HDL2. HDL2 can selectively transfer both cholesteryl ester and free cholesterol to the liver via an HDL receptor in the liver called *scavenger receptor BI*. Cholesteryl esters can also be transferred from HDL2 to apolipoprotein B–containing lipoproteins such as very-low-density lipoproteins (VLDLs) and LDLs via the action of the cholesteryl ester transfer protein (CETP) and then returned to the liver by hepatic uptake of LDL. HDL2 triglycerides and phospholipids can be hydrolyzed by hepatic lipase (HL) to remodel HDL2 to HDL3. Cholesterol derived from HDL contributes to the hepatic cholesterol pool used for bile acid synthesis, and the cholesterol is eventually excreted into the bile and feces as bile acid or free cholesterol. Solid lines indicate the metabolism of the lipoprotein particles, and broken lines indicate the flux of cholesterol independent of lipoprotein particle metabolism.

Apolipoproteins are required for the structural integrity of lipoproteins and direct their metabolic interactions with enzymes, lipid transport proteins, and cell surface receptors (*e*Table 3.1.1). Apolipoprotein A-I (apoA-I) is a major component of all HDL particles and serves as a marker for this lipoprotein family. In contrast, apolipoprotein B (apoB) is the major apolipoprotein for all the remaining non-HDL lipoproteins. There are two forms of apoB, apoB-48 and apoB-100, both of which are derived from the same gene. In the liver, the apoB messenger RNA is translated to produce the larger apoB-100, which is found in lipoproteins derived from the liver (VLDL, IDL, LDL). However, in the intestine, the apoB messenger RNA is “edited” by a complex that introduces a stop codon sequence slightly before the midpoint of the coding sequence, resulting in the synthesis of a smaller protein (apoB-48), which is then found in lipoproteins derived from the intestine (chylomicrons).

***e*TABLE 3.1.1** CHARACTERISTICS OF MAJOR APOLIPOPROTEINS

Apolipoprotein	Lipoprotein association	Primary source	Functions
ApoA-I	HDL	Intestine, liver	Structural protein for HDL, activator of LCAT
ApoA-II	HDL	Liver	Unknown
ApoA-IV	HDL, CM, VLDL	Intestine	Unknown
ApoB-48	CM	Intestine	CM synthesis and secretion
ApoB-100	VLDL, IDL, LDL, Lp(a)	Liver	VLDL synthesis and secretion, ligand for binding to LDL receptor
ApoC-I	CM, VLDL, HDL	Liver	Unknown
ApoC-II	CM, VLDL, HDL	Liver	Cofactor for LPL
ApoC-III	CM, VLDL, HDL	Liver	Inhibitor of lipoprotein binding to receptors
ApoE	CM, IDL, HDL	Liver	Ligand for binding to LDL receptor and LRP
Apo(a)	Lp(a)	Liver	Unknown

CM, chylomicron; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); LPL, lipoprotein lipase; LRP, low-density lipoprotein receptor–related protein; VLDL, very-low-density lipoprotein.

Lipoprotein receptors are a class of cell surface proteins that bind lipoproteins. The known lipoprotein receptors bind regions of apolipoproteins on the lipoprotein particles. The best-understood lipoprotein receptor is the LDL receptor, which is responsible for catabolizing both chylomicron and VLDL remnants as well as LDL (43). The LDL receptor binds apolipoprotein E and apoB and has sometimes been called the “apoB/E receptor.” The level of LDL receptor expression in the liver plays a major role in regulating the plasma level of cholesterol (43). The LDL receptor–related protein (LRP) has a variety of ligands, including apoE (44). It serves as a second pathway for clearance of apoE-containing chylomicron and VLDL remnants, especially in the deficiency of LDL receptors (45). The VLDL receptor is expressed in several extrahepatic tissues and may play a role in the delivery of fat to peripheral cells (44). The scavenger receptor binds modified or oxidized LDL (in addition to other ligands) and is thought to play a role in the development of the macrophage into the foam cell (46). Several other types of lipoprotein receptors have been postulated, but none has been convincingly demonstrated to play a role in lipoprotein metabolism or atherosclerosis.

Lipid-modifying enzymes and lipid transport proteins play a major role in lipoprotein metabolism and potentially in atherosclerosis. Lipoprotein lipase (LPL) is an enzyme that hydrolyzes triglycerides in chylomicrons and VLDL. It is bound to the surface of the capillary endothelium, especially in muscle and adipose tissue, and binds to the chylomicrons as they traverse the capillary bed. Apolipoprotein C-II (apoC-II), found on the chylomicrons, serves as a required cofactor for LPL. The free fatty acids generated by triglyceride hydrolysis enter the tissue to serve as a source of energy or fat storage, and the resulting chylomicron remnant is released and is eventually taken up by the liver. Hepatic lipase (HL) is found primarily on the endothelium of the hepatic sinusoids. HL has both triglyceride and phospholipid hydrolytic activity. One major substrate for HL is IDL, possibly resulting in conversion to LDL or in some cases promoting the catabolism of IDL. The other major substrate for HL is HDL, in which the phospholipid hydrolysis results in conversion to smaller HDL particles that may be more rapidly catabolized. Lecithin-cholesterol acyltransferase (LCAT) converts free cholesterol to cholesteryl ester on lipoproteins (especially HDL) by transferring fatty acids from phospholipids to cholesterol (47). One major role of LCAT is thought to be the esterification of free cholesterol that is acquired by HDL from cells, thus creating a gradient for free cholesterol and enhancing further cholesterol efflux from cells. The cholesteryl ester transfer protein (CETP) transfers cholesteryl esters and other lipids among lipoproteins (48). One major role of CETP is thought to be the transfer of cholesteryl esters from HDL (formed as a result of LCAT activity) to VLDL and IDL in exchange for triglycerides. This may be a major pathway by which cholesterol obtained from cells by HDL is eventually returned to the liver in a process that has been termed “reverse cholesterol transport.” However, some cholesteryl esters are transferred by CETP to VLDL and LDL, and therefore CETP could promote atherogenesis; the relationship of CETP to atherosclerosis remains uncertain. The phospholipid transfer protein transfers phospholipids among lipoproteins (48), although its role in lipoprotein metabolism and atherosclerosis has not yet been fully elucidated. These lipoprotein-modifying enzymes and lipid transport enzymes act in concert to modulate lipoprotein metabolism and probably have important effects on atherosclerosis.

Disorders of lipoprotein metabolism involve perturbations that cause elevation of triglyceride and/or cholesterol levels, reduction of HDL cholesterol levels, or alteration of properties of lipoproteins, such as their size or composition. These perturbations can be genetic (primary) or may occur as a result of other diseases, conditions, or drugs (secondary). Many (but not all) lipoprotein disorders have as their most important clinical consequence the increased risk of premature ASCVD. The next section of this chapter focuses specifically on the identification and diagnosis of specific lipid disorders, and the subsequent section focuses on the management of lipid disorders, especially with regard to the prevention of atherosclerosis and its associated clinical events.

The mechanisms by which elevated serum cholesterol promotes atherosclerosis has been a subject of intensive research for decades. Much of this work has traditionally focused on the mechanisms by which lipoproteins promote foam-cell formation. *In vitro* studies by several investigators demonstrated that native LDL is not taken up by macrophages in culture and does not promote their conversion to foam cells. However, modification or oxidation of the LDL was demonstrated to result in cholesterol loading and foam-cell formation. This led to the “oxidized LDL hypothesis,” which states that LDL must be oxidized before it becomes atherogenic, and a large body of research has supported this general concept (49). Observational data suggest that intake of antioxidant vitamins is associated with decreased incidence of ASCVD. However, controlled clinical trials have not yet conclusively proven the hypothesis that inhibition of LDL oxidation reduces progression of atherosclerosis or risk of clinical cardiovascular events (see below). It is not certain that oxidation is required for all of the atherogenic effects of lipoproteins to take place. For example, some evidence suggests that certain lipoproteins, such as remnant lipoproteins, may promote foam-cell formation without prior modification or oxidation (50). In addition, LDL and other lipoproteins are likely to have other atherosclerosis-promoting effects that are distinct from foam-cell formation and may not require oxidation, such as effects on endothelial function, platelets, and smooth muscle cells (51). For example, cholesterol reduction has beneficial effects on coronary endothelial function (52,53) that may be at least partially independent of LDL oxidation. However, dissection of these mechanisms remains an active area of basic and clinical

research.

Although the epidemiologic inverse association of HDL cholesterol with CHD is well established, the mechanistic relationship of HDL metabolism to atherogenesis is not well understood (48). The leading hypothesis for decades has been the “reverse cholesterol transport hypothesis,” in which HDL removes excess cholesterol from cells within the arterial wall and returns it to the liver for excretion in the bile. Although this process occurs in tissues throughout the body, its direct relationship to HDL metabolism and atherogenesis remains uncertain. Even if reverse cholesterol transport is one mechanism by which HDL retards atherosclerosis, HDL may work by other mechanisms as well. For example, HDL has been demonstrated *in vitro* to inhibit LDL oxidation, stabilize prostacyclin, and inhibit endothelial adhesion molecule expression (48). Finally, it has been proposed that the HDL cholesterol level may simply be a good marker for other disorders associated with increased cardiovascular risk, such as the metabolic syndrome and abnormal postprandial lipemia, and may not be directly associated with inhibiting atherogenesis (48). Active research is ongoing in these important areas.

SECONDARY DISORDERS OF LIPOPROTEIN METABOLISM

Lipid disorders can be grouped into primary disorders (genetic or inherited) and secondary disorders (caused by disease or environmental factors). Clinically, it is useful to consider and exclude secondary causes. Some of the most important secondary causes of hyperlipidemia are reviewed here and listed in Table 3.2.

Disorder	Cholesterol	Triglycerides	HDL
Metabolic/endocrine			
Hypothyroidism	++	N	N
Diabetes mellitus, type II	+	++	−
Cushing's syndrome	+	++	−
Renal			
End-stage renal disease	+	+	−
Nephrotic syndrome	++	++	−
Hepatic			
Obstructive liver disease	++	N	−
Primary biliary cirrhosis	++	N	+
Drugs			
Alcohol	N	++	+
Thiazide diuretics	N	+	−
Beta-blockers	N	+	−
Cyclosporin	++	N	N
Isotretinoin and etretinate	N	++	−
HIV protease inhibitors	+	++	−

−, decreased; +, increased; ++, substantially increased; HDL, high density lipoprotein; HIV, human immunodeficiency virus; N, not affected.

TABLE 3.2 SELECTED DISORDERS ASSOCIATED WITH SECONDARY HYPERLIPIDEMIA

Hypothyroidism

Hypothyroidism causes elevated LDL cholesterol levels primarily because of down-regulation of the LDL receptor (54). Because hypothyroidism can be subtle in its clinical presentation, patients presenting with hypercholesterolemia should be screened with a thyroid-stimulating hormone to rule out hypothyroidism. Thyroid replacement therapy usually results in resolution of the hypercholesterolemia. Hypothyroid patients who remain hypercholesterolemic after adequate replacement probably have an underlying lipoprotein disorder and may require lipid-lowering drug therapy.

Diabetes Mellitus

Several forms of hyperlipidemia are recognized clinically in patients with diabetes mellitus (55,56). Patients with type I diabetes mellitus who are under adequate glycemic control do not usually have hyperlipidemia, and the presence of hyperlipidemia in such patients suggests the presence of an underlying genetic lipoprotein abnormality. In contrast, patients with type II diabetes mellitus frequently have associated hyperlipidemia. Insulin resistance results in impaired capacity to catabolize chylomicrons and VLDL, as well as excess hepatic triglyceride and VLDL production (57). Type II diabetes mellitus and even glucose intolerance are often associated with a constellation of lipid abnormalities, including elevated triglyceride and VLDL cholesterol levels, increased small, dense LDL levels, and decreased HDL cholesterol levels. These lipid abnormalities are also common in persons with impaired glucose tolerance and insulin resistance in whom frank diabetes is not present. Occasionally, the triglyceride levels may be extremely elevated (>1,000 mg per dL) and predispose the patient to acute pancreatitis. Significant elevation of LDL cholesterol levels in the diabetic patient often suggests the presence of an additional lipoprotein abnormality. All patients who present with hyperlipidemia should be screened for diabetes using a fasting glucose test. Aggressive control of diabetes often results in improved control of hyperlipidemia. Furthermore, hyperlipidemia is a major risk factor for diabetic patients, and lipid disorders in patients with diabetes should be aggressively treated to decrease the risk of ASCVD (55).

Renal Diseases

Chronic renal insufficiency and especially end-stage renal disease are often associated with moderate hypertriglyceridemia caused by a defect in triglyceride lipolysis and remnant clearance (54). Nephrotic syndrome is associated with a more pronounced hyperlipidemia involving both elevated triglyceride and cholesterol levels caused by hepatic overproduction of VLDL (58). Both types of renal disease should be considered and excluded when they are suspected in patients who present with hyperlipidemia. Resolution of the nephrotic syndrome improves the lipid profile, but patients with chronic nephrotic syndrome often require lipid-lowering drug therapy. Although the lipid abnormalities in end-stage renal disease are more modest, cardiovascular risk is high, and lipid-modifying drug therapy should be seriously considered. It has been suggested that lipid-lowering therapy could slow the progression of chronic renal insufficiency (59), but clinical trials have not yet been performed to test this hypothesis.

Alcohol Consumption

Alcohol intake often exacerbates hyperlipidemia, but its effects are highly variable (60). The greatest effects of alcohol are on triglyceride levels. Alcohol consumption inhibits oxidation of free fatty acids by the liver, which stimulates hepatic triglyceride synthesis and secretion of VLDL. The usual lipoprotein pattern associated with alcohol consumption is moderate hypertriglyceridemia, although it can raise total and LDL cholesterol levels as well. Regular alcohol use also raises the HDL cholesterol level by a mechanism that is not completely understood. Patients with hyperlipidemia who drink alcohol regularly should be advised to reduce their alcohol intake.

Drug Use

Several drugs are known to influence plasma lipid levels; these are listed in Table 3.2. Retinoids such as isotretinoin and etretinate, used for acne, are known to induce substantial hypertriglyceridemia in susceptible persons. Immunosuppressive therapy used in the posttransplantation setting is well known to cause hypercholesterolemia and hypertriglyceridemia. Finally, since the introduction of the protease inhibitors for therapy for human immunodeficiency virus, it has been recognized that many of these patients develop hyperlipidemia, which appears to result from a complex and poorly understood interaction between the disease and the effect of the drugs.

PRIMARY (INHERITED) DISORDERS OF LIPOPROTEIN METABOLISM

The classification of lipoprotein disorders is useful as a guide to accurate diagnosis and effective treatment. The Frederickson and Levy classification (Table 3.3) is based on the type of lipoprotein that is elevated. This classification system has been used for several decades. It is now gradually being replaced by a classification based on the understanding of the molecular etiology and pathophysiology of the lipoprotein disorders (Table 3.4). In this section, lipoprotein disorders are presented in a way intended to facilitate a practical clinical approach. This approach is based on classifying patients first according to triglyceride levels and can lead to a more rational approach to differential diagnosis and choice of appropriate therapy.

Phenotype	Lipoprotein	Triglyceride	Cholesterol	Xanthomas	Pancreatitis	Atherosclerosis	Molecular defects
I	CM	+++	+++	Eruptive	+++	0	LPL, apolipoprotein C-II
IIa	LDL	N	++	Tendon	0	+++	LDL receptor, apolipoprotein B-100
IIb	LDL and VLDL	+	+	None	0	+++	Unknown
III	Remnants	+	++	Palmar and tuberoeruptive	0	++	Apolipoprotein E
IV	VLDL	++	+	None	0	±	Unknown
V	CM and VLDL	+++	+++	Eruptive	+++	±	Unknown

+, mildly elevated; ++, moderately elevated; +++, severely elevated; CM, chylomicron; LDL, low-density lipoprotein; LPL, lipoprotein lipase; N, not affected; VLDL, very-low-density lipoprotein; 0, minimal to no risk.

TABLE 3.3 FREDERICKSON AND LEVY CLASSIFICATION OF LIPOPROTEIN PHENOTYPES

Genetic disorder	Molecular defect	Lipoproteins elevated	Lipoprotein phenotype	Clinical findings	Genetic transmission	Estimated incidence
Familial chylomicronemia syndrome	LPL deficiency, apolipoprotein C-II deficiency	Chylomicrons	Type I	Eruptive xanthomas, hepatosplenomegaly, pancreatitis	Autosomal recessive	Rare
Familial dysbetalipoproteinemia	Abnormal apolipoprotein E (i.e., E2/2)	Chylomicron and VLDL remnants	Type III	Palmar and tuberoeruptive xanthomas, premature atherosclerosis	Autosomal recessive or autosomal codominant	1/5,000
Familial combined hyperlipidemia	Unknown	VLDL and LDL	Type IIb, sometimes IIa or IV, rarely V	Premature atherosclerosis	Autosomal dominant	1/200
Familial hypertriglyceridemia	Unknown	VLDL, occasionally chylomicrons	Type IV, occasionally V	Usually none	Autosomal dominant	1/500
Familial hepatic lipase deficiency	Hepatic lipase	VLDL remnants	Type III deficiency	Premature atherosclerosis	Autosomal recessive	Rare
Familial hypercholesterolemia	LDL receptor	LDL	Type IIa	Tendon xanthomas, premature atherosclerosis	Autosomal codominant	1/500
Familial defective apolipoprotein B-100	Abnormal apolipoprotein B-100 (i.e., $Arg_{3500} \rightarrow Gln$)	LDL	Type IIa	Tendon xanthomas, premature atherosclerosis	Autosomal codominant	1/700

Arg, arginine; Gln, glutamine; LDL, low-density lipoprotein; LPL, lipoprotein lipase; VLDL, very low-density lipoprotein.

TABLE 3.4 PRIMARY LIPID DISORDERS

Disorders Associated with Triglyceride Levels >1,000 mg per dL

Severe hypertriglyceridemia (fasting triglyceride levels >1,000 mg per dL) is virtually always an indication of hyperchylomicronemia in the fasting state and points to an underlying genetic predisposition, often exacerbated by another medical condition or a hormonal or environmental factor. The major clinical complication of severe hypertriglyceridemia is acute pancreatitis, and initial treatment is focused on decreasing the triglycerides below 1,000 mg per dL to prevent this serious complication. In addition, some but not all patients with severe hypertriglyceridemia are at risk for premature ASCVD and require more aggressive therapy, even after triglyceride levels have been decreased below the 1,000 mg per dL threshold.

Familial Chylomicronemia Syndrome: Lipoprotein Lipase Deficiency and Apolipoprotein C-II Deficiency

The familial chylomicronemia syndrome (61) is characterized by presentation in childhood with acute pancreatitis and triglyceride levels >1,000 mg per dL. Recurrent abdominal pain is a common feature in children with this disorder. On physical examination, eruptive xanthomas (small papular lesions that occur in showers on the buttocks and back) are often seen. Lipemia retinalis (a pale appearance to the retinal veins) is a clue to the existence of severe hypertriglyceridemia, and hepatosplenomegaly caused by ingestion of chylomicrons by the reticuloendothelial system is often found. Premature ASCVD is not a feature of this disease.

Eruptive xanthoma. Bulbous cutaneous eruptions associated with hyperlipidemia.

Two different genetic defects can cause the familial chylomicronemia syndrome: LPL deficiency and apoC-II deficiency (Table 3.4). The hydrolysis of triglycerides in chylomicrons requires the action of LPL in tissue capillary beds, and apoC-II is a required cofactor for the activation of LPL (Fig. 3.1). Mutations in either the LPL gene or the apoC-II gene result in functional deficiency of LPL, inability to hydrolyze triglycerides in chylomicrons, and consequent massive hyperchylomicronemia. The disorder is autosomal recessive, meaning that both alleles of the LPL or apoC-II gene must be affected for the disorder to be present. Therefore, the parents of children with this disorder generally have normal or near normal triglyceride levels. Both are rare disorders, but of the two, LPL deficiency is much more common (approximately 1 case in 1 million persons) than apoC-II deficiency.

The diagnosis of the familial hyperchylomicronemia syndrome is usually made based on clinical presentation and some key laboratory features. The plasma is often lactescent, and after overnight refrigeration, a cake of chylomicrons forms on the surface. Triglyceride levels are >1,000 mg per dL and may be 10,000 mg per dL. Total cholesterol levels are also elevated, due to the presence of cholesterol in chylomicrons. Lipoprotein electrophoresis demonstrates markedly elevated chylomicrons at the origin but is not essential for making the diagnosis. The diagnosis of LPL and apoC-II deficiency can be confirmed at specialized centers by the quantitation of LPL activity in the plasma after intravenous heparin injection (postheparin lipolytic activity). Patients with suspected familial chylomicronemia syndrome should be referred to a specialized lipid center for diagnosis and management of the disorder.

The mainstay of therapy for familial chylomicronemia syndrome is restriction of total dietary fat. Consultation with a registered dietitian familiar with this disorder is essential. Caloric supplementation with medium-chain triglycerides, which are absorbed directly into the portal vein and therefore do not promote chylomicron formation, can be useful. If dietary fat restriction alone is not successful, some patients may respond to a cautious trial of fish oils (62). For patients with apoC-II deficiency, an attack of acute pancreatitis can be treated with infusion of fresh-frozen plasma to provide apoC-II in an attempt to clear severe hypertriglyceridemia and promote resolution of the pancreatitis.

Type V Hyperlipoproteinemia

Type V hyperlipoproteinemia (HLP) is a common diagnosis which continues to use the nomenclature of the Frederickson classification system. The label “type V hyperlipoproteinemia” is generally used to describe the disorder of an adult in whom triglyceride levels are >1,000 mg per dL and who does not have known familial chylomicronemia syndrome caused by LPL or apoC-II deficiency (see above). Type V HLP is also associated with risk of acute pancreatitis, which can be the initial presentation of this syndrome and is the major criterion for aggressive treatment of this condition. Type V HLP can also be associated with increased risk of

cardiovascular disease, although some patients with type V HLP do not appear to be at significantly increased risk.

Most but not all patients with type V HLP have a family history of hypertriglyceridemia, although specific genetic mutations causing type V HLP have not yet been identified. Type II diabetes mellitus or glucose intolerance frequently accompanies type V HLP, but type V HLP also occurs in people who have normal glucose tolerance. Some patients with nephrotic syndrome can develop severe hypertriglyceridemia. Estrogen replacement therapy can exacerbate moderate hypertriglyceridemia and lead to a more severe type V HLP, as can heavy alcohol consumption. Finally, treatment with isotretinoin or etretinate sometimes causes severe hypertriglyceridemia. Rarely, patients with familial dysbetalipoproteinemia (type III hyperlipidemia; see below) due to a mutation in apoE can have triglyceride levels >1,000 mg per dL, particularly if another factor is superimposed on the apoE mutation. The diagnostic evaluation of an adult patient presenting with triglyceride levels >1,000 mg per dL should be focused on a search for underlying predisposing factors and an attempt to establish a history of complications (pancreatitis and cardiovascular disease). A comprehensive personal and family history should be obtained, and all medications should be reviewed. On physical examination, lipemia retinalis and tiny eruptive xanthomas on the back or buttocks are the most specific findings for type V HLP. In contrast, larger tuberoeruptive xanthomas on the elbows or knees or palmar xanthomas (orange coloration to the creases of the palms) are more suggestive of familial dysbetalipoproteinemia (see Familial Dysbetalipoproteinemia, later). Diabetes and renal disease should always be excluded as potential contributing factors. No specific laboratory tests are required for the diagnosis of type V HLP except possibly lipoprotein centrifugation to exclude familial dysbetalipoproteinemia.

The management of type V HLP is first targeted at decreasing triglycerides to reduce the risk of pancreatitis, followed by further lipid lowering depending on the presence of CHD or other risk factors for cardiovascular disease. Women who are taking estrogens and patients taking isotretinoin or etretinate should be encouraged to discontinue these medications if triglyceride levels are >1,000 mg per dL. Diabetes mellitus should be controlled as optimally as possible. Metformin is a useful agent in the treatment of type II diabetes mellitus associated with severe hypertriglyceridemia, because it improves control of diabetes and also has a direct effect in lowering triglyceride levels. Patients should be referred to a registered dietitian for dietary counseling. In general, dietary management includes restriction of total fat as well as simple sugars in the diet. Alcohol should be avoided. Regular aerobic exercise can have a significant impact on triglyceride levels and should be actively encouraged. If the patient is overweight, weight loss can help to decrease triglyceride levels as well.

When fasting triglyceride levels remain >1,000 mg per dL despite institution of appropriate dietary and lifestyle measures and control of secondary causes, drug therapy must be considered to decrease the risk of acute pancreatitis. Drug therapy is usually straightforward, although a subset of patients is remarkably resistant to treatment. Three major drug classes should be considered for treatment of very high triglyceride levels: fibrates, nicotinic acid, and fish oils (see below). In practice, fibrates are generally recommended as the first-line agent. Nicotinic acid or fish oils should be considered for patients who fail to respond adequately to fibrates.

Frequently, patients remain significantly hypercholesterolemic after triglyceride levels are adequately controlled. This raises the difficult question of whether a second medication is needed to better control the LDL cholesterol levels. The NCEP guidelines are useful in making decisions about whether to institute further drug therapy in this setting (9). In patients who have CHD or diabetes mellitus or are at high risk for the development of CHD, who continue to have an LDL cholesterol level >130 mg per dL, most specialists recommend consideration of a second drug (usually a statin). Although it is important to recognize that an increased risk of myopathy is associated with this combination, it can be minimized by careful patient selection and by advising the patient to call the physician immediately in the event of generalized muscle pain.

Disorders Associated with Triglyceride Levels of 200 to 1,000 mg per dL

Fasting triglyceride levels <1,000 mg per dL are not generally associated with risk of acute pancreatitis. Therefore, the significance of elevated triglyceride levels of 200 to 1,000 mg per dL is their potential association with risk of ASCVD. There has been increasing recognition of the importance of elevated fasting triglycerides in this range as an independent cardiovascular risk factor (10). The major primary causes of elevated triglycerides of 200 to 1,000 mg per dL are familial hypertriglyceridemia (FHGT), familial dysbetalipoproteinemia (type III hyperlipidemia), and familial combined hyperlipidemia (FCHL). It is important to differentiate among them, because familial dysbetalipoproteinemia and FCHL are both definitely associated with increased risk of premature atherosclerosis, whereas the risk associated with FHGT is variable. The clinical approach to a patient with triglyceride levels of 200 to 1,000 mg per dL generally involves ruling out secondary causes (and, when they are found, treating them), differentiating among major primary causes, assessing the patient for the presence of ASCVD and other cardiovascular risk factors, and managing the lipid disorder based on the clinical assessment of cardiovascular risk. Because no clinical endpoint trials based on treatment of hypertriglyceridemia have been carried out and no formal guidelines for the clinical management of patients with hypertriglyceridemia are available, the clinical approach to reducing cardiovascular risk is focused on decreasing LDL cholesterol levels. However, elevated triglyceride levels can make the determination of the LDL cholesterol level difficult; can be associated with increased risk, even in the presence of a normal LDL cholesterol level; and can complicate the therapeutic approach.

Familial Hypertriglyceridemia

FHTG is a relatively common disorder characterized by moderately elevated triglyceride levels, usually with an average or only moderately elevated total cholesterol level. FHTG occurs in approximately 1 in 500 persons. It is inherited as an autosomal dominant trait but is not usually expressed until adulthood. The molecular etiology is unknown. In patients with FHTG, the VLDL level is elevated because of increased production, impaired catabolism, or a combination of the two. The LDL cholesterol level is generally not increased in patients with this disorder. Increased intake of simple carbohydrates, a sedentary lifestyle, obesity, insulin resistance, alcohol use, and estrogens can all exacerbate hypertriglyceridemia.

The diagnosis is suggested by elevated triglyceride levels (200 to 1,000 mg per dL) with normal or only mildly increased cholesterol levels (<240 mg per dL) and almost always a low HDL cholesterol level. A history of hypertriglyceridemia in at least one first-degree relative of the patient is useful in making the diagnosis. It is important to consider and rule out secondary causes of hypertriglyceridemia. In the differential diagnosis, both familial dysbetalipoproteinemia (type III HLP) and FCHL should be considered. This is not simply an academic exercise; these two conditions are associated with a significantly increased risk of ASCVD, whereas FHTG often is not. The total cholesterol level relative to the triglyceride level is usually lower in FHTG, compared with that in familial dysbetalipoproteinemia and FCHL, and the plasma apoB level is usually lower in FHTG than in the other two conditions. Determination of lipoprotein particle size using NMR reveals an increase in VLDL as the major lipoprotein abnormality.

Therapy for FHTG should begin with diet and lifestyle changes. Intake of simple carbohydrates should be reduced. Regular aerobic exercise can be very effective in decreasing triglyceride levels, as can weight loss. Alcohol use should be discouraged. Diabetes mellitus should be aggressively controlled. Lipid-lowering drug therapy can often be avoided if appropriate diet and lifestyle changes are made. However, drug therapy should be considered for patients who have triglyceride levels higher than 400 to 600 mg per dL after an adequate trial of diet and exercise changes. A fibrate is a reasonable choice as a first-line drug for FHTG, and niacin can also be considered in this condition.

Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia)

Familial dysbetalipoproteinemia is also commonly called *type III hyperlipidemia* (63). It is the best understood of the genetic lipid disorders that cause moderate elevation of triglyceride levels and can usually be definitively diagnosed based on a combination of clinical and laboratory parameters. Patients with familial dysbetalipoproteinemia usually present in adulthood with distinctive xanthomas or premature atherosclerosis, or asymptomatic hyperlipidemia is discovered on routine screening. Two types of xanthomas are seen in patients with familial dysbetalipoproteinemia. Tuberoeruptive xanthomas begin as clusters of small papules on the elbows, knees, or buttocks and can grow to the size of small grapes. Palmar xanthoma, orange-yellow discoloration of the creases of the palms and wrists, may also be present. Either of these xanthomas is highly suggestive of familial dysbetalipoproteinemia. Premature ASCVD is often seen in this disorder. Compared with other lipid disorders, peripheral vascular disease is particularly common in patients with familial dysbetalipoproteinemia.

The pattern of hyperlipidemia can be another clue to the diagnosis of familial dysbetalipoproteinemia. Patients generally have both hypertriglyceridemia and hypercholesterolemia, and in contrast to most other lipid disorders, the cholesterol and triglyceride levels are often elevated to a relatively similar degree. In addition, the HDL cholesterol level is often relatively normal, in contrast to most hypertriglyceridemic conditions, in which the HDL cholesterol level is usually reduced. Hyperlipidemia can be relatively mild or very severe, depending on the presence of other metabolic conditions and unknown factors.

Familial dysbetalipoproteinemia is caused by mutations in the gene for apoE (63,64). ApoE is present on chylomicron and VLDL remnants and mediates their removal from the plasma by binding to receptors in the liver (Fig. 3.1 and Fig. 3.2). Defective apoE is impaired in its ability to bind to these receptors, resulting in accumulation of chylomicron and VLDL remnants in the plasma. The most common form of familial dysbetalipoproteinemia is related to a common polymorphism of apoE. The “normal” form of apoE is known as *apoE3*, but another form, called *apoE2*, has an allele frequency of approximately 7%. The apoE2 protein, which differs from apoE3 by a single amino acid, does not bind adequately to lipoprotein receptors, resulting in defective removal of chylomicron and VLDL remnants. Homozygosity for the E2 allele (the E2/E2 genotype) is the most common cause of familial dysbetalipoproteinemia. However, most persons with the apoE2/E2 genotype do not have familial dysbetalipoproteinemia; development of this disorder appears to require an additional factor. Some of these factors include obesity, diabetes mellitus, hypothyroidism, renal disease, and alcohol use, but many patients with familial dysbetalipoproteinemia do not have an obvious predisposing factor other than the E2/E2 genotype. Another common variant of apoE, known as *apoE4*, has an allele frequency of approximately 14%. Although it is associated with elevated LDL cholesterol levels and increased risk of both CHD and Alzheimer’s disease (65), the common apoE4 allele is not associated with familial dysbetalipoproteinemia.

Because familial dysbetalipoproteinemia is treated somewhat differently from other lipid disorders, it is important to consider this diagnosis and confirm it when it is suspected. The diagnosis can be made with reasonable confidence by one of three methods. The traditional approach is to use lipoprotein electrophoresis, which demonstrates a broad beta band due to the presence of remnant lipoproteins but is expensive and not always definitive. In a second, and preferred, method, often referred to as a "beta quantification," plasma is subjected to ultracentrifugation and the cholesterol level is measured in the VLDL fraction. Because this disorder is associated with increased numbers of VLDL remnants that are rich in cholesterol relative to triglycerides, an elevated ratio of VLDL cholesterol:triglycerides of >0.3 confirms the diagnosis. A third approach is to perform lipoprotein analysis using NMR, which reveals a substantial increase in IDL sized particles. Finally, the apoE2/E2 pattern can be determined by using protein methods (apoE phenotype) or DNA-based methods (apoE genotype). The finding of an apoE2/E2 pattern by phenotyping or genotyping in a patient in whom familial dysbetalipoproteinemia is suspected confirms the diagnosis.

The absence of the apoE2/2 genotype decreases the likelihood but does not absolutely rule out the diagnosis of familial dysbetalipoproteinemia, because mutations in apoE other than E2 can also cause this condition (66). These mutations, which are much less common than apoE2, generally result in the synthesis of an apoE protein that is severely defective in its ability to bind to lipoprotein receptors. Often the inheritance of only one mutant allele is adequate to cause familial dysbetalipoproteinemia; hence the term "dominant type III hyperlipoproteinemia." Several different mutations in the apoE gene, all in the region of the protein that binds to the receptors, have been described in kindreds with this dominant form of the disease (66). Finally, several families have complete deficiency of apoE, which causes a severe form of familial dysbetalipoproteinemia (63).

Because familial dysbetalipoproteinemia is associated with increased risk of premature ASCVD, it should be actively treated. General therapeutic measures include decreased intake of dietary fat, regular aerobic exercise, weight loss (if required), and discontinuance of alcohol use. Postmenopausal women who have familial dysbetalipoproteinemia respond very favorably to estrogen replacement therapy. Although estrogens generally elevate triglyceride levels, familial dysbetalipoproteinemia is unusual in that estrogen replacement often decreases the triglyceride levels. Fibrates and niacin are each very effective in the treatment of familial dysbetalipoproteinemia. HMG-CoA reductase inhibitors have also been used with success, but they may be somewhat less effective than in other forms of hyperlipidemia.

Familial Combined Hyperlipidemia

FCHL is the most common primary lipid disorder, occurring in approximately 1 in 200 persons. Approximately 20% of patients with CHD who are younger than 60 years have FCHL (67). FCHL is characterized by a mixed dyslipidemia, usually associated with moderately elevated fasting triglycerides, moderately elevated cholesterol, and reduced HDL cholesterol. In most cases, at least one first-degree relative also has hyperlipidemia, and there is often a family history of premature CHD as well. Xanthomas are not generally seen in patients with this disorder. Visceral obesity, glucose intolerance, insulin resistance, hypertension, and hyperuricemia are sometimes associated with FCHL. Patients with FCHL almost always have a significantly elevated plasma level of apoB that is disproportionate to the LDL cholesterol level (68). This indicates the presence of small, dense LDL particles, which are characteristic of this syndrome and are considered to be highly atherogenic. The term "hyperapobetalipoproteinemia" has been used to describe the syndrome of elevated apoB with normal lipid levels, and that disorder is probably a subset of FCHL. FCHL is inherited as an autosomal dominant trait and can be expressed in childhood, but it sometimes is not fully expressed until adulthood.

The genetic basis of FCHL is not known. Studies of lipoprotein metabolism in carefully selected individuals have indicated that hepatic overproduction of VLDL is a common metabolic basis of this condition (68). It has been suggested that a subset of patients with the FCHL phenotype may be heterozygous for LPL deficiency, but LPL mutations are probably not a common cause of FCHL (69). It is likely that more than one genetic etiology of the FCHL phenotype exists (70).

The diagnosis of FCHL is suggested by the presence of a mixed hyperlipidemia with fasting triglyceride levels of 200 to 800 mg per dL, cholesterol levels of 200 to 400 mg per dL, and decreased HDL cholesterol levels in the absence of secondary causes of hyperlipidemia. A family history of hyperlipidemia and premature coronary disease is often present and supports the diagnosis. The finding of an apoB level that is elevated relative to the LDL cholesterol level suggests increased levels of small, dense LDL. The size and concentration of LDL can be determined using an NMR technique, which helps confirm the diagnosis and assists in decisions regarding therapy.

Because individuals with FCHL are at significantly increased risk of premature CHD, they should be treated aggressively. Decreased dietary intake of saturated fat and simple carbohydrates, regular aerobic exercise, and weight loss can all have beneficial effects on the lipid profile. However, many patients with FCHL require lipid-lowering drug therapy for adequate control. HMG-CoA reductase inhibitors (statins) are effective in lowering LDL cholesterol and apoB levels. Nicotinic acid decreases both LDL cholesterol and triglyceride levels and raises the HDL cholesterol level, and it is often used in combination with statins for this condition (71).

Hepatic Lipase Deficiency

HL deficiency is a very rare autosomal recessive disorder characterized by a mixed hyperlipidemia and the accumulation of lipoprotein remnants in plasma (72). HL hydrolyzes triglycerides and phospholipids in VLDL remnants and IDL and promotes their conversion to LDL (Fig. 3.2). Genetic deficiency of HL impairs the metabolism of VLDL remnants and IDL and results in their accumulation in the plasma. HL also metabolizes HDL lipids, so levels of HDL cholesterol are often slightly elevated in HL deficiency. The diagnosis of HL deficiency is suggested by a mixed hyperlipidemia with elevation in both triglyceride and cholesterol levels but an HDL cholesterol level that is normal or elevated rather than low. Familial dysbetalipoproteinemia should be excluded by apoE genotyping. Measurements of HL can be made in postheparin plasma by specialized laboratories. The association of HL deficiency with atherosclerosis is uncertain, but patients should be treated for hyperlipidemia with an approach similar to that used for familial dysbetalipoproteinemia. Acquired (usually partial) defects in HL can be seen in hypothyroidism, chronic renal insufficiency, and chronic liver disease.

Disorders Associated with Triglyceride Levels <200 mg per dL

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is caused by mutations in the gene for the LDL receptor that prevent its appearance on the cell surface or impair its ability to bind and internalize LDL (73). More than 200 different mutations in the LDL receptor have been described in patients with FH (74). FH is an autosomal codominant disorder, meaning that heterozygotes have hypercholesterolemia but homozygotes have even more severe hypercholesterolemia. The presence of one mutant LDL receptor allele results in the production of only approximately one-half the normal number of LDL receptors, whereas the presence of two mutant alleles severely reduces or eliminates functional LDL receptors. The reduction in functional hepatic LDL receptors leads to reduced clearance of plasma LDL by the liver and substantial elevations in LDL cholesterol. Elevated LDL cholesterol levels lead directly to the major complication of this condition, premature ASCVD.

Heterozygous FH occurs in approximately 1 in 500 persons in North America and worldwide, making it one of the most common single gene disorders. It is characterized by elevated LDL cholesterol levels (usually 200 to 400 mg per dL) with normal triglyceride levels and a family history of hypercholesterolemia or premature cardiovascular disease. The finding of tendon xanthomas is virtually diagnostic of FH (although these can also been seen in another disorder, as discussed later). Tendon xanthomas are most easily recognized within the Achilles tendons, where they cause thickening and irregularity. Another common location for tendon xanthomas is the digit extensor tendons of the metacarpophalangeal joints on the dorsa of the hands. Premature arcus corneae is frequently seen in patients with heterozygous FH. There is no definitive diagnostic test for heterozygous FH; the disorder is diagnosed on clinical grounds.

Heterozygous FH is strongly associated with premature ASCVD, especially CHD. Therefore, patients should be aggressively treated to lower the LDL cholesterol level. Most heterozygous FH patients require lipid-lowering drug therapy. Statins are especially effective in treatment of heterozygous FH, inducing up-regulation of the normal LDL receptor allele in the liver. If further lowering of the LDL level is required, the addition of a bile acid sequestrant to the statin is often beneficial. Niacin is also effective in FH and is often used in combination with statins and resins. The combination of all three drug classes (statin, resin, and niacin) is sometimes required to achieve LDL cholesterol level goals. If combination drug therapy is not tolerated or fails to adequately control the cholesterol levels, LDL apheresis should be considered (75) (see below).

Homozygous FH is caused by the inheritance of two mutant LDL receptor alleles, which results in the production of few or no LDL receptors and a severe defect in the catabolism of LDL. Homozygous FH occurs in approximately 1 in 1 million persons worldwide and is a much more severe clinical disorder than heterozygous FH. Patients with homozygous FH are often classified into one of two groups, based on the amount of LDL receptor activity measured in their skin fibroblasts: "Receptor negative" patients have <2% of normal LDL receptor activity, whereas "receptor defective" patients have 2% to 25% of normal LDL receptor activity (73). This classification is important, because LDL receptor–defective patients have a much better prognosis than LDL receptor–negative patients. LDL receptor–defective patients sometimes have small responses to drug therapy and can survive into the third decade of life and even beyond. In contrast, survival of the untreated LDL receptor–negative patient with homozygous FH into the third decade of life is very unusual. Clinical heterogeneity among homozygous FH patients is due to the significant genetic heterogeneity of the LDL receptor gene mutations (74).

Patients with homozygous FH usually present in childhood with cutaneous xanthomas on the hands, wrists, elbows, knees, heels, or buttocks. Some patients with

homozygous FH do not have cutaneous xanthomas but develop tuberous or tendon xanthomas on the elbows, knees, or Achilles tendons as older children or adolescents. Some degree of arcus corneae is usually present. Total cholesterol levels are usually >500 mg per dL and can be as high as 1,200 mg per dL. The devastating complication of homozygous FH is accelerated atherosclerosis, which can result in clinical sequelae even in childhood. Atherosclerosis often develops first in the aortic root and can cause aortic valvular or supravalvular stenosis. It frequently extends into the coronary ostia, which can develop significant stenoses. Carotid and femoral disease usually occurs somewhat later; the presence of femoral bruits has been reported to be a poor prognostic sign. Children with homozygous FH often develop symptoms of vascular disease before puberty, but symptoms can be atypical or go unreported, and sudden death is common. Untreated LDL receptor–negative patients with homozygous FH rarely survive beyond the second decade. LDL receptor–defective patients have a better prognosis but invariably develop clinical ASCVD by the age of 30 years and often much sooner.

A child who has severe hypercholesterolemia, relatively normal triglyceride levels, and cutaneous or tendon xanthomas should be suspected of having homozygous FH. The biologic parents and other relatives should be tested for hypercholesterolemia. A diagnosis of homozygous FH can be confirmed at specialized centers through assay of the LDL receptor activity on the skin fibroblasts after a skin biopsy is performed. Obstructive liver disease should be excluded by appropriate tests if its presence is suspected. Patients in whom homozygous FH is suspected should be referred to a specialized center. Drug therapy including a statin and a bile acid sequestrant should be tried. Atorvastatin, a new long-acting, potent statin, has been reported to have greater efficacy in homozygous FH than other statins and should be considered. Liver transplantation is effective in decreasing LDL cholesterol levels but is associated with the substantial risks of surgery and long-term immunosuppression. The treatment of choice for homozygous FH is LDL apheresis, which can promote regression of xanthomas and retard progression of atherosclerosis (76,77). The age at which LDL apheresis should be initiated is uncertain. Venous access is often problematic in young children, and central venous catheters can promote infections, which are especially risky, given the frequent aortic valvular and supravalvular flow disturbances. It is generally recommended that initiation of LDL apheresis be delayed until the patient is approximately 5 years old, except when evidence of ASCVD is present.

Because of its well-understood pathophysiology, serious consequences, and poor options for treatment, homozygous FH is a model for the development of somatic liver-directed gene therapy. Five patients with homozygous FH were treated in a gene therapy protocol involving *ex vivo* reconstitution of the LDL receptor gene into autologous hepatocytes with subsequent reimplantation (78). At 4 months, all patients had evidence of LDL receptor transgene expression by liver biopsy. LDL cholesterol levels were decreased in two patients by 17% and 22%, but in the other three patients, LDL cholesterol levels were essentially unchanged. Metabolic turnover studies in three patients documented an increased rate of LDL catabolism in the patient whose LDL cholesterol level decreased by 22% but no substantial difference in LDL kinetics in two of the patients whose LDL cholesterol levels showed little change (78). Although this pilot protocol demonstrated the feasibility of somatic gene transfer and expression of the LDL receptor in humans and some impact on LDL cholesterol levels and metabolism, future gene therapy trials await further improvements in technology. In the future, even low-level expression of the LDL receptor in an LDL receptor–negative FH patient could have the potential for substantial clinical benefit to the patient once it is combined with potent cholesterol-lowering drugs.

Familial Defective Apolipoprotein B-100

Familial defective apoB-100 (FDB) resembles heterozygous FH clinically. It is characterized by elevated LDL cholesterol levels with normal triglyceride levels, possible tendon xanthomas, and increased risk of premature ASCVD (79). In contrast to FH, FDB is caused by mutations in the receptor-binding region of apoB-100, the ligand for the LDL receptor, which impairs its binding and delays the clearance of LDL from the blood. The most common mutation that causes FDB is a substitution of glutamine for arginine at position 3500 in apoB-100 (79). However, other mutations have been reported that have a similar effect on binding of apoB to the LDL receptor. FDB is a dominantly inherited disorder and occurs in approximately 1 in 700 persons in Europe and North America.

Patients who have FDB clinically resemble those with heterozygous FH, and these disorders cannot be differentiated on purely clinical grounds. The apoB mutation can be detected in specialized laboratories so that a specific diagnosis of FDB can be made. However, there is no compelling reason to make a specific molecular diagnosis, because the clinical management of patients with FDB is similar to that of patients with heterozygous FH. If future therapies are found that are more effective in one condition than in the other, molecular diagnosis could be indicated to guide specific therapy.

Polygenic Hypercholesterolemia

Most forms of hypercholesterolemia are not single-gene disorders, but rather are caused by a complex interaction of several genetic and environmental factors. For example, genetic differences in cholesterol absorption, cholesterol synthesis, or rates of bile acid synthesis may result in very different cholesterol levels in people challenged with a diet rich in fat. Polygenic hypercholesterolemia is characterized by a cholesterol level exceeding the 95th percentile for age and gender, with triglyceride levels that are usually relatively normal. In polygenic hypercholesterolemia, LDL cholesterol levels are usually not as elevated as they are in heterozygous FH and FDB, and tendon xanthomas are not observed. In the differentiation of polygenic hypercholesterolemia from the these single-gene disorders, family studies are useful. Only approximately 7% of first-degree relatives of patients with polygenic hypercholesterolemia are hypercholesterolemic, whereas approximately one-half of the relatives of patients with FCHL, heterozygous FH, and FDB have dyslipidemia. Treatment of polygenic hypercholesterolemia follows the same guidelines as the approach to any patient with hypercholesterolemia.

DISORDERS OF HIGH-DENSITY LIPOPROTEIN METABOLISM

HDL cholesterol levels are inversely associated with CHD, independent of LDL cholesterol levels. The National Cholesterol Education Program recommends that all adults older than 20 years should be screened not only for total cholesterol levels, but also for HDL cholesterol levels. As a result of screening, patients with low HDL cholesterol levels are frequently identified. However, formal guidelines for the approach to the patient with a low HDL cholesterol level have not yet been developed. Many causes of low HDL cholesterol are secondary to other factors. Cigarette smoking, obesity, and physical inactivity contribute to a low HDL cholesterol. Type II diabetes mellitus, end-stage renal disease, and hypertriglyceridemia from any cause are all associated with low HDL. Beta-blockers, thiazide diuretics, androgens, and progestins can all reduce HDL cholesterol levels. Importantly, a low-fat diet often results in a low level of HDL cholesterol; for example, most vegetarians have low levels of HDL cholesterol. In this case, the low HDL is not considered to be associated with an increased risk of CHD, because persons who eat low-fat diets are at substantially reduced risk of premature CHD. However, many persons with low HDL cholesterol levels have a genetic cause for the low HDL cholesterol. Only a few of the genes responsible for inherited syndromes associated with low HDL levels have been identified (*e*Table 3.4.1).

***e*TABLE 3.4.1** GENETIC DISORDERS ASSOCIATED WITH LOW HIGH-DENSITY LIPOPROTEIN (HDL) CHOLESTEROL LEVELS

Genetic disorder	Molecular defect	Metabolic abnormalities	Lipoprotein findings	Clinical findings	Premature atherosclerosis	Genetic transmission
Familial apoA-I deficiency	ApoA-I absence	Absent apoA-I biosynthesis	HDL <5 mg/dL, TG normal	Planar xanthomas, corneal opacities	++	Autosomal codominant
Familial apoA-I structural mutants	Abnormal apoA-I	Rapid apoA-I catabolism	HDL 15–30 mg/dL, TG normal or increased	Often none; sometimes corneal opacities	No	Autosomal dominant
Familial LCAT deficiency	LCAT deficiency (complete)	Rapid HDL catabolism	HDL <10 mg/dL, TG increased	Corneal opacities, anemia, proteinuria, renal insufficiency	No	Autosomal recessive
Fish-eye disease	LCAT deficiency (partial)	Rapid HDL catabolism	HDL <10 mg/dL, TG normal or increased	Corneal opacities	No	Autosomal recessive
Tangier disease	ABCA1 mutants	Very rapid HDL catabolism	HDL <5 mg/dL, TG usually increased	Corneal opacities; enlarged, orange tonsils; hepatosplenomegaly; peripheral neuropathy	+	Autosomal codominant
Familial hypoalphalipoproteinemia	Unknown	Usually rapid HDL catabolism	HDL 15–35 mg/dL, TG normal	Often none; sometimes corneal opacities	No to ++	Autosomal dominant

+, moderately increased risk of premature atherosclerosis; ++, markedly increased risk of premature atherosclerosis; ApoA-I, apolipoprotein A-I; LCAT, lecithin-cholesterol acyltransferase; TG, triglycerides.

Primary Disorders That Cause Low High-Density Lipoprotein Cholesterol Levels

Familial Apolipoprotein A-I Deficiency and Structural Apolipoprotein A-I Mutations

Complete genetic deficiency of apoA-I due to deletions of the apoA-I gene or nonsense mutations that prevent the biosynthesis of apoA-I protein result in a virtually absence of plasma HDL (80,81 and 82). The rare patients with this syndrome have corneal opacities and sometimes cutaneous or planar xanthomas. The risk of premature cardiovascular disease in patients with apoA-I deficiency is increased, but onset of CHD symptoms in these kindreds has varied from the third to the seventh decade of life. Mutations in the apoA-I coding sequence have been described in association with low levels of HDL cholesterol (usually 15 to 30 mg per dL) but are a very rare cause of low HDL cholesterol levels in the general population (83). The first of these mutants to be described was apoA-I_{Milano}, which was not found to be associated with increased risk of premature CHD, despite the low levels of HDL cholesterol seen in persons who bear this mutation. Increased premature

cardiovascular disease has not been reported in any kindred with an apoA-I mutation causing low HDL levels, suggesting that the mechanism that causes the low HDL levels may be an important determinant of the associated CHD risk. Most of these individuals do not appear to have clinical sequelae, other than corneal opacities, that are related to the apoA-I mutations. Interestingly, a few apoA-I mutations have been described in association with systemic amyloidosis, and the mutant apoA-I has been found as a component of the amyloid plaque.

Familial Lecithin-Cholesterol Acyltransferase Deficiency and Fish-Eye Disease

HDL facilitates the removal of unesterified cholesterol from cells, after which the cholesterol is esterified by the lipoprotein-associated enzyme LCAT (Fig. 3.3). Two general types of genetic LCAT deficiency have been described in humans: complete deficiency (also called *classic LCAT deficiency*) and partial deficiency (also called *fish-eye disease*) (84). Progressive corneal opacification, very low plasma levels of HDL cholesterol (usually <10 mg per dL), and variable hypertriglyceridemia are characteristic of both types. In partial LCAT deficiency, there are no other known clinical sequelae. In contrast, complete (classic) LCAT deficiency is characterized by anemia and progressive proteinuria and renal insufficiency. The diagnosis of LCAT deficiency can be made in specialized laboratories by quantitation of LCAT and cholesterol esterification activity in the plasma. Several different mutations in the LCAT gene have been described in patients with fish-eye disease and classic LCAT deficiency. Remarkably, despite the extremely low levels of HDL cholesterol and apoA-I that are seen in these patients, there is no apparent increased risk of premature ASCVD in either complete or partial LCAT deficiency. This demonstrates once again that the relationship between low HDL cholesterol levels and increased risk of CHD is complex and depends in part on the specific cause of the low HDL levels.

Tangier Disease

Tangier disease is a very rare disorder associated with accumulation of cholesterol in the reticuloendothelial system, resulting in hepatosplenomegaly, intestinal mucosal abnormalities, and pathognomonic enlarged orange tonsils (85). Intermittent peripheral neuropathy can also be seen that is caused by cholesterol accumulation in Schwann cells. Patients with Tangier disease have HDL cholesterol levels <5 mg per dL and extremely low levels of apoA-I because of their markedly accelerated HDL catabolism. Tangier disease is caused by mutations in the gene encoding ABCA1, a cellular transporter that facilitates the efflux of unesterified cholesterol and phospholipids from cells to apoA-I as an acceptor (86). Tangier disease is associated with increased risk of premature ASCVD, but this risk does not seem to be proportional to the markedly decreased HDL cholesterol and apoA-I levels. Tangier disease is an autosomal codominant disease; obligate heterozygotes have moderately reduced HDL cholesterol levels but no evidence of reticuloendothelial cholesterol accumulation. The risk of premature atherosclerosis in obligate heterozygotes is also be increased. Importantly, a substantial number of persons with low HDL cholesterol levels may have mutations in ABCA1 (87).

Primary Hypoalphalipoproteinemia

The most common inherited syndrome associated with low HDL levels is termed *primary hypoalphalipoproteinemia* or *familial hypoalphalipoproteinemia* (88,89). It is defined as an HDL cholesterol level below the 10th percentile in the setting of relatively normal cholesterol and triglyceride levels, no apparent secondary causes of the low HDL level, and no clinical signs of LCAT deficiency or Tangier disease. This syndrome is often referred to as *isolated low HDL*. A family history of low HDL cholesterol levels facilitates the diagnosis of an inherited condition, which usually follows an autosomal dominant pattern. The genetic etiology of this syndrome is unknown, although the metabolic etiology appears to be primarily accelerated catabolism of HDL and its apolipoproteins (47,90). Several kindreds with this syndrome have been described in association with an increased incidence of premature ASCVD (89), but other families have been described in which there was no evidence of increased ASCVD (91). Therefore, the direct relationship of primary hypoalphalipoproteinemia to premature CHD is uncertain and may depend on the specific nature of the gene defect or the metabolic cause of the low HDL cholesterol level.

SCREENING AND MANAGEMENT OF PATIENTS WITH LIPID DISORDERS

Screening

A general approach to the screening and management of hyperlipidemia has been developed by an expert panel convened by the NCEP of the National Institutes of Health, and the original recommendations (92) underwent one revision in 1993 and another revision in 2001 (9). These guidelines have been widely endorsed by other professional organizations, including the American Heart Association and the American College of Cardiology (26). Alternative screening guidelines issued by the American College of Physicians (93,94) were based on a number of tenuous assumptions and have not been widely accepted.

All adults older than 20 years should be screened through measurement of fasting total, LDL cholesterol, HDL cholesterol, and triglyceride levels. The initial classification according to the NCEP-ATPIII guidelines is described in Table 3.5.

Cholesterol (mg/dL)	Classification
Total	
<200	Desirable
200–239	Borderline high
≥240	High
LDL	
<100	Optimal
100–129	Near or above optimal
130–159	Borderline high
160–189	High
≥190	Very high
HDL	
<40	Low
≥60	High

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

TABLE 3.5 CLASSIFICATION BASED ON TOTAL, LDL, AND HDL CHOLESTEROL LEVELS

The LDL cholesterol is usually estimated from the other lipid values using the following equation: LDL cholesterol = total cholesterol – (triglycerides/5) – HDL cholesterol. (Because VLDL usually contains triglyceride and cholesterol in a ratio of approximately 5:1, “triglycerides/5” is an estimate of the VLDL cholesterol). This formula is reasonably accurate if test results are obtained from fasting plasma and if the triglyceride level is less than 400 mg per dL. The determination of LDL cholesterol levels in patients who have triglyceride levels >400 mg per dL usually requires application of ultracentrifugal techniques in specialized laboratories, although direct assays for LDL measurement have recently become available. All further evaluation and treatment is based on other cardiovascular risk factors (Table 3.6) and the LDL cholesterol level (Table 3.7).

Age
Men ≥45 yr
Women ≥55 yr
Family history of premature CHD (CHD in male first-degree relative ≤55 yr or female first-degree relative ≤65 yr)
Cigarette smoking
Hypertension
Low high-density lipoprotein cholesterol[a]

CHD, coronary heart disease.
[a]If the high-density lipoprotein cholesterol is ≥60 mg/dL, subtract one risk factor.
Note: Diabetes mellitus is considered a CHD risk equivalent; see Table 3.7.

TABLE 3.6 MAJOR CARDIOVASCULAR RISK FACTORS TO CONSIDER IN THE TREATMENT OF LOW-DENSITY LIPOPROTEIN CHOLESTEROL

Risk category	LDL-C Goal (mg/dL)	Lifestyle therapy (mg/dL)	Drug therapy (mg/dL)
CHD or CHD risk equivalent (10-yr risk >20%)	<100	≥100	≥130 (100–129 optional)
2+ risk factors (10-yr risk 10–20%)	<130	≥130	≥130
2+ risk factors (10-yr risk <10%)	<130	≥130	≥160
0–1 risk factors	<160	≥160	≥190 (160–189 optional)

CHD, coronary heart disease.

TABLE 3.7 LOW-DENSITY LIPOPROTEIN CHOLESTEROL (LDL-C) GOALS AND CUTPOINTS FOR THERAPY

Diagnosis and Classification of Lipid Disorders

Most patients with hyperlipidemia have a primary or genetic cause for the lipid disorder. However, the clinician should always first consider whether a secondary medical disorder could be causing or contributing to the hyperlipidemia. Treatment of the underlying medical condition can often result in substantial improvement in the lipid profile and obviate the need for therapy directed at the lipids themselves. Once secondary causes have been considered, the fasting triglyceride level can be used as an initial method of stratifying patients. This approach guides both the initial diagnostic evaluation and the selection of the most effective therapy. It is important to consider the differential diagnosis of hyperlipidemia before treatment is started, because the inherited disorders discussed earlier are associated with different risks of developing CHD, different responses to drug therapy, and differences in family and genetic history.

Although extremely elevated triglyceride levels (>1,000 mg per dL) are associated with a risk of acute pancreatitis, the most important clinical consequence of lipid disorders is ASCVD, including coronary, cerebrovascular, and peripheral vascular disease. The clinical approach to a patient with a lipid disorder is significantly influenced by the presence of established ASCVD and other risk factors. Treatment of hyperlipidemia in patients with ASCVD is called *secondary prevention*, whereas treatment in patients without established ASCVD is known as *primary prevention*.

Management of lipid disorders should be based, whenever possible, on clinical trials that indicate the benefit of treatment in decreasing the risk of cardiovascular morbidity and death, although reasonable extrapolation of these data to specific subgroups is sometimes required (95). LDL cholesterol levels are strongly associated with increased risk of cardiovascular disease, and abundant data exist to show that treatment aimed at lowering LDL levels decreases the risk of clinical cardiovascular events in both secondary and primary prevention (51). Elevated triglyceride levels are also associated with increased risk of cardiovascular disease, but this relationship weakens considerably when statistical corrections are made for LDL and HDL cholesterol levels (96). Furthermore, no trials have been performed specifically to determine whether treatment to decrease triglyceride levels decreases the risk of cardiovascular disease. HDL cholesterol levels are inversely associated with cardiovascular disease, but no clinical trial data exist to date indicating that treatment aimed at elevating HDL levels leads to decreased risk of cardiovascular disease events. However, elevated triglyceride levels, decreased HDL cholesterol levels, or both are important clues to the existence of a lipid disorder and can help to identify individuals who may be at higher risk of cardiovascular disease and therefore are candidates for more aggressive therapy aimed at lowering the LDL cholesterol level. The clinical management of lipid disorders is a major component of an overall strategy directed toward the treatment or prevention of complications related to ASCVD. Some general guidelines for the nonpharmacologic management of patients with lipid disorders are given in the next section.

General Issues in the Nonpharmacologic Management of Lipid Disorders

Identify and Treat Secondary Causes of Hyperlipidemia

Secondary causes of hypercholesterolemia should be considered and excluded with appropriate laboratory testing. Many lipid experts recommend routine screening of all hyperlipidemic patients with a thyroid stimulating hormone to exclude hypothyroidism. Treatment of hypothyroidism usually results in substantial improvement in hypercholesterolemia. A fasting glucose level should always be obtained in the initial workup of a patient with hyperlipidemia. Diabetes mellitus should be controlled as effectively as possible, which often results in substantial improvement in hyperlipidemia. Nephrotic syndrome and chronic renal insufficiency should be excluded if they are clinically suspected. Patients with hyperlipidemia, especially hypertriglyceridemia, who drink alcohol should be encouraged to decrease their intake. Sedentary lifestyle, obesity, and smoking are all associated with low HDL cholesterol levels.

Counsel Patients on an Appropriate Diet

Dietary modification is an important component of the effective management of patients with lipid disorders. It is important for the physician to make a general assessment of the patient's diet, to provide suggestions for improvement, and to recognize whether a patient may benefit from referral to a dietitian for more intensive counseling. The dietary approach depends on the type of hyperlipidemia. For predominant hypercholesterolemia, the major approach is restriction of saturated fat intake. For moderate hypertriglyceridemia, it is also important to restrict intake of simple sugars. For severe hypertriglyceridemia reflecting hyperchylomicronemia, restriction of total fat intake is critical.

To lower the LDL cholesterol level by diet modification, restricting the intake of saturated fats and cholesterol is necessary. The most widely used diet is the "step I diet" developed by the American Heart Association (Table 3.8). If possible, the patient should receive specific instruction in the diet from a dietitian or qualified professional. Periodic review of the diet may be needed to reinforce the need for its continued use. Responses to a step I diet vary widely among individuals, and it can be difficult to predict which persons are most likely to benefit from dietary intervention. However, the majority of patients has relatively modest (<10%) decreases in LDL cholesterol levels on a step I diet. If therapeutic goals for LDL cholesterol are not reached after 3 to 6 months on a step I diet, the patient may be referred to a registered dietitian for more detailed dietary instruction, including the introduction of a step II diet, which is further restricted in total and saturated fat (Table 3.7). Patients with established ASCVD should be instructed on how to maintain a step II diet from the first. Almost all persons experience a decrease in HDL cholesterol levels when they decrease the amount of total and saturated fat in their diets. Patients should be reassured that a low-fat diet is beneficial in terms of reducing overall cardiovascular risk. For patients with hypertriglyceridemia, dietary counseling should also include restriction of simple sugar intake. Treatment of severe hypertriglyceridemia (triglyceride levels >1,000 mg per dL) includes restriction of all fat intake, both saturated and unsaturated.

Dietary constituent	Step I diet	Step II diet
Total fat	<30% of total calories	<30% of total calories
Saturated fatty acids	<10% of total calories	<7% of total calories
Polyunsaturated fatty acids	<10% of total calories	<10% of total calories
Monounsaturated fatty acids	10–15% of total calories	10–15% of total calories
Carbohydrates	50–60% of total calories	50–60% of total calories
Protein	15–20% of total calories	15–20% of total calories
Cholesterol	<300 mg/day	<200 mg/day
Total calories	As required to achieve and maintain desired body weight	As required to achieve and maintain desired body weight

TABLE 3.8 DIETARY GUIDELINES FOR MANAGING HYPERCHOLESTEROLEMIA

Certain types of foods and dietary additives can be used to modestly reduce cholesterol levels and in some cases obviate the need for drug therapy. Plant stanol esters were shown to reduce LDL cholesterol levels in randomized controlled trials when the esters are taken three times per day (97); are not absorbed; and are available in a variety of foods, such as spreads, salad dressings, and snack bars under the trade label Benecol. Plant sterol esters also can reduce LDL cholesterol but have not been as extensively studied, and they can be absorbed, so they are not as desirable an option. Chinese red yeast rice has been shown to reduce LDL cholesterol levels and is known to contain small amounts of lovastatin, which probably accounts for its modest cholesterol-lowering properties. Addition of psyllium to the diet can reduce cholesterol levels. Soy protein has been shown to reduce cholesterol levels. Certain types of nuts, such as walnuts, have been shown to reduce cholesterol

levels, but this approach requires the daily consumption of a very large amount of nuts and is not practical. Despite some enthusiasm, controlled trials of garlic have not demonstrated a significant cholesterol-lowering effect. Other herbal approaches, such as gugulipid, are interesting but require further study. No controlled studies have been carried out that combined several of these nonpharmacologic options to address their additive or synergistic effects.

Encourage Regular Aerobic Exercise

Regular aerobic exercise can have a positive effect on lipids. Elevated triglyceride levels are especially sensitive to aerobic exercise, and persons with hypertriglyceridemia can substantially lower their triglyceride levels by initiating an exercise program. The effect of exercise on LDL cholesterol levels is more modest. Although aerobic exercise is widely believed to raise HDL cholesterol levels, the effects on HDL are relatively modest in most individuals. Patients should also be reminded that aerobic exercise has cardiovascular benefits that extend well beyond its effect on lipid levels (98).

Encourage the Patient to Achieve and Maintain an Appropriate Weight

Obesity is often associated with dyslipidemia, especially with elevated triglyceride levels, low HDL cholesterol levels, and small, dense LDL levels. In individuals who are overweight, weight loss can have a significant favorable impact on the lipid profile and should be actively encouraged. In addition to providing counseling on other dietary issues, a dietitian should advise patients about the caloric restriction necessary for effective weight loss.

Consider Hormone Replacement Therapy in Postmenopausal Women

The effects of hormone replacement therapy (HRT) on lipid metabolism are complex (99). HRT generally decreases LDL cholesterol levels and modestly increases HDL cholesterol levels. However, HRT raises triglyceride levels, and, in women with underlying triglyceride disorders, can precipitate severe hyperchylomicronemia and acute pancreatitis. Therefore, HRT is relatively contraindicated in women with triglyceride levels >500 mg per dL, until the triglyceride levels are better controlled. When triglyceride levels are between 250 and 500 mg per dL, estrogens can be administered cautiously, but triglyceride levels should be monitored carefully. One exception to this rule is in women with type III HLP, in whom estrogen replacement can substantially improve the lipid profile, including the triglyceride levels. HRT also decreases levels of lipoprotein (a) [Lp(a)] in women (100).

The relationship of HRT to cardiovascular risk has been the topic of substantial debate. On the basis of observational data, HRT was believed to confer substantial cardiovascular benefit associated with an approximately 50% reduction in clinical cardiovascular disease events (101). However, randomized controlled trials with estrogen replacement have not duplicated the positive results seen in observational studies. Both the Heart and Estrogen/Progestin Study clinical outcome trial (102) and an angiographic study (103) have failed to show a benefit of combination estrogen/progestin HRT in secondary prevention. Therefore, prospective studies do not support a role for HRT in the secondary prevention of cardiovascular disease, at least over the short to medium term. However, many experts feel that estrogen replacement may still have a clinical role, especially in primary prevention. Understanding of the long-term role of HRT and the effect of HRT in primary prevention of cardiovascular disease awaits the results of ongoing studies, including the Women's Health Initiative Study of >50,000 asymptomatic postmenopausal women (104).

Drug Therapy for Lipid Disorders

Deciding to Initiate Drug Therapy for Dyslipidemia

The decision to use drug therapy is highly dependent on whether established CHD is present and, if it is not, on the global cardiovascular risk of the patient. Drug therapy for hypercholesterolemia in patients with established CHD is well supported by clinical trial data. Randomized controlled clinical trials have demonstrated conclusively that lowering LDL cholesterol levels in patients with established CHD reduces not only cardiovascular events and CHD mortality rates but also the total mortality rate after only 5 years. Even patients with CHD who have average LDL cholesterol levels benefit from treatment. Drug treatment to lower LDL cholesterol levels in patients with CHD is also highly cost-effective (21,105). Current guidelines (9) call for drug therapy in all patients who have established CHD and LDL cholesterol levels >130 mg per dL (9,26), with consideration given to treating patients with LDL cholesterol levels 100 to 130 mg per dL (Table 3.7). Based on these guidelines, the majority of patients with established CHD should be treated with cholesterol-lowering drug therapy. Nevertheless, it has been estimated that at least 50% of patients who have CHD are not receiving cholesterol-lowering drug therapy (106).

The decision to initiate lipid-lowering drug therapy in primary prevention is more difficult. However, data now exist that demonstrate a substantial benefit with drug therapy, even in individuals without preexisting CHD. Therefore, persons at high risk for the development of cardiovascular disease are excellent candidates for lipid-modifying drug therapy. For example, patients with diabetes mellitus have a level of absolute cardiovascular risk that is similar to that of patients with established CHD (107). Therefore, lipid disorders in diabetic patients should be treated as aggressively as in patients with established CHD; the NCEP, the American Heart Association, the American College of Cardiology, and the American Diabetes Association all have endorsed this view. Absolute global cardiovascular risk can be quantitated using a simple approach based on the Framingham Heart Study database (108) and used as a guide in the decision about whether to initiate cholesterol-lowering drug therapy. A 10-year risk of less than 20% should be considered a "CHD risk equivalent," and such patients should be treated like those with CHD or diabetes targeting the LDL to <100 mg per dL (Table 3.7). Drug therapy should be used for most individuals who have markedly elevated LDL cholesterol levels (>190 mg per dL), even if the short-term absolute risk is not particularly elevated. However, it is often difficult to decide whether to initiate drug therapy in patients who have LDL cholesterol levels that are in the gray zone between 130 and 190 mg per dL. Although it is desirable to avoid drug treatment in patients who are unlikely to develop CHD, a very high proportion of patients who eventually develop CHD have LDL cholesterol levels in this range (23). Therefore, the use of certain blood and vascular imaging tests may be useful in helping to refine the risk assessment, and therefore the decision about drug therapy (see below). In persons considered to be at low risk, the emphasis should remain primarily on dietary and lifestyle modification.

In certain patients, drug therapy should be targeted initially toward reduction of triglyceride levels rather than the LDL cholesterol level. For example, when triglyceride levels are >1,000 mg per dL, the patient has a primary triglyceride disorder and should be treated with drug therapy to prevent acute pancreatitis. When triglyceride levels are 400 to 1,000 mg per dL, the decision to use drug therapy depends on the assessment of cardiovascular risk; however, if drug therapy is used, it should usually be targeted first at reducing the triglyceride levels, because cholesterol reduction is difficult in the setting of substantially elevated triglycerides. Importantly, all of the five major clinical endpoint trials with statins have excluded persons with triglyceride levels >350 to 450 mg per dL. Therefore, no data are available regarding the effectiveness of statins in reducing cardiovascular risk in persons with triglyceride levels greater than approximately 400 mg per dL. If the triglyceride levels are <400 mg per dL, the initial emphasis in treatment should be on reduction of the LDL cholesterol level, not the triglyceride levels.

In general, a low level of HDL cholesterol justifies the use of more aggressive therapy to decrease an elevated LDL cholesterol level. In AFCAPS/TexCAPS, subjects were recruited in part on the basis of relatively low HDL cholesterol levels, and individuals with the lowest HDL cholesterol levels at baseline had the highest relative risk reduction with lovastatin therapy (109). Drug therapy targeted primarily toward raising HDL cholesterol is a potentially important strategy for reducing cardiovascular events. The VA-HIT study has provided data to support the initiation of pharmacologic therapy in patients in whom LDL cholesterol levels are controlled but HDL cholesterol levels are low. More data are required before broad recommendations are made about the use of drug therapy targeted specifically toward raising HDL cholesterol levels to prevent cardiovascular events.

Choosing a Lipid-Lowering Drug

Once the decision to initiate drug therapy has been made, the drug must be chosen. A summary of the major drugs for treating dyslipidemia is provided in Table 3.9, and the major classes of drugs are discussed here.

Drug	Major indications	Starting dose	Maximal dose	Mechanism	Common side effects
HMG-CoA reductase inhibitors	Elevated LDL			Inhibit cholesterol synthesis and up-regulate LDL receptors in liver	Myositis, arthralgias, GI upset, elevated liver function tests
Lovastatin		20 mg daily	80 mg daily		
Pravastatin		10 mg qhs	40 mg qhs		
Simvastatin		10 mg qhs	40 mg qhs		
Fluvastatin		20 mg qhs	40 mg qhs		
Atorvastatin		20 mg qhs	80 mg qhs		
Cerivastatin		0.2 mg qhs	0.8 mg qhs		
Bile acid sequestrants	Elevated LDL			Promote bile acid excretion and increase LDL receptors in liver	Bloating, constipation, flatus, elevated triglycerides
Cholestyramine		4 g daily	As tolerated		
Colestipol		5 g daily	As tolerated		
Colesevelam		3.75 g daily	As tolerated		
Nicotinic acid	Elevated LDL and triglycerides, low HDL			Decrease VLDL synthesis	Cutaneous flushing, GI upset, elevated glucose, uric acid, transaminases
Immediate-release		100 mg t.i.d.	1,000 mg t.i.d.		
Sustained-release (Niaspan)		500 mg qhs	2,000 mg qhs		
Fibric acid derivatives	Elevated triglycerides			Stimulate lipoprotein lipase; may decrease VLDL synthesis	Myositis, GI upset, gallstones
Gemfibrozil		600 mg b.i.d.	600 mg b.i.d.		
Fenofibrate		200 mg qd	200 mg qd		
Fish oils	Elevated triglycerides	1 g daily	12 g daily	Decrease triglyceride synthesis	Diarrhea, GI upset, fishy odor to breath

GI, gastrointestinal; HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein.

TABLE 3.9 MAJOR DRUGS USED FOR THE TREATMENT OF HYPERLIPIDEMIA

3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Inhibitors (Statins)

HMG-CoA reductase is the rate-limiting step in cholesterol biosynthesis, and inhibition of this enzyme decreases cholesterol synthesis. There are six HMG-CoA reductase inhibitors currently available: lovastatin (Mevacor), pravastatin (Pravachol), simvastatin (Zocor), fluvastatin (Lescol), atorvastatin (Lipitor), and cerivastatin (Baycol). By inhibiting cholesterol biosynthesis, these drugs lead to increased hepatic LDL receptor expression and in some situations to decreased hepatic production of VLDL as well. Their major effect is reduction of LDL cholesterol, which they do in a dose-dependent fashion. There is wide interindividual variation in the initial response to statins, but once a patient is on a statin, the doubling of the statin dose produces a very predictable 6% further reduction in LDL cholesterol (110). Statins also reduce triglyceride levels in a dose-dependent fashion that is proportional to their effect in decreasing LDL cholesterol levels. Statins have a modest effect in increasing HDL cholesterol levels by 5% to 10% that is not dose dependent. As was reviewed earlier, considerable evidence of efficacy of statins in reducing the risk of clinical cardiovascular events is now available.

Patient acceptance of these drugs is high, because they can be taken in tablet form once a day and are generally well tolerated. Potential side effects include gastrointestinal upset, headaches, sleep disturbance, fatigue, and muscle or joint pains. Severe myopathy and even rhabdomyolysis have been reported with HMG-CoA reductase inhibitors, but these side effects are very rare. The risk of statin-associated myopathy is increased by the administration of drugs that interfere with the cytochrome P450 metabolism of statins, such as erythromycin, and related antibiotics, antifungal agents, immunosuppressive drugs, and fibrates. Severe myopathy can usually be avoided by carefully selecting the patients who will receive treatment with statins, by avoiding interacting drugs, and by informing patients of the potential of severe myopathy and advising immediate discontinuance of the drug in the event of new generalized muscle pain. Serum creatine kinase (CK) levels need not be monitored on a routine basis, because an elevated serum CK level in the absence of symptoms does not predict the development of myopathy and does not suggest the need for discontinuing the drug. The serum CK level can be measured in a patient who is taking a statin and complains of muscle pain, but a normal level does not exclude the possibility that the symptoms are caused by the drug. By convention, liver transaminases (alanine aminotransferase and aspartate aminotransferase) are monitored in patients taking statins (for example, 8 weeks after initiation of the drug and every 6 months thereafter). Other liver function tests, such as those for alkaline phosphatase and gamma glutamyl transpeptidase, are not useful and need not be used to monitor the patient. Substantial elevation (more than three times normal levels) in transaminases is relatively rare, and mild to moderate elevation (one to three times normal levels) in transaminases in the absence of symptoms need not mandate discontinuation of the medication. Severe clinical hepatitis associated with statins is exceedingly rare, if it occurs at all, and the trend is toward less-frequent monitoring of transaminases in patients taking statins.

A careful review of the five major trials with statins indicates a high level of safety (111). These five trials included a total of more than 30,000 subjects, one-half of whom were treated with active statin therapy for an average of 5 to 6 years. A review of this experience demonstrates that the incidence of suicide and fatal trauma did not differ between the patients being treated with statin and those receiving placebo. Likewise, the incidence of cancer did not differ between the two groups.

Bile Acid Sequestrants (Resins)

Bile acid sequestrants include cholestyramine (Questran), colestipol (Colestid), and colesevelam (WelChol). They bind bile acids in the intestine, interrupt their enterohepatic circulation, and accelerate the loss of bile acids in the stool. To maintain an adequate bile acid pool, the liver diverts cholesterol to bile acid synthesis. The decreased intracellular cholesterol content results in up-regulation of the hepatic LDL receptor and enhanced LDL clearance from the plasma. Bile acid sequestrants primarily reduce LDL cholesterol levels and should not be prescribed for patients with triglyceride levels higher than approximately 300 mg per dL, because this exacerbates hypertriglyceridemia. The bile acid sequestrants are very safe drugs that are not systemically absorbed. However, cholestyramine and colestipol are insoluble resins that must be suspended in liquid and are therefore often inconvenient and unpleasant to take. Colestipol is also available in large tablets, but multiple tablets must be taken each day to achieve a substantial effect. The newest bile acid sequestrant, colesevelam, was designed to combat the limitations of the traditional resins by providing a molecule able to bind a larger number of bile acids. Colesevelam is available in smaller tablets than colestipol, and because it binds more bile acids per molecule, fewer tablets are required each day to achieve the desired effect. Most side effects of resins are limited to the gastrointestinal tract; bloating and constipation can occur and are ultimately dose limiting. In addition, bile acid sequestrants may bind some other drugs (e.g., digoxin and warfarin) and interfere with their absorption, so that other medications must be taken 1 hour before or 4 hours after the bile acid sequestrants are taken.

Bile acid sequestrants can be useful in young, highly motivated patients with moderate hypercholesterolemia who wish to avoid systemic drug therapy. These are also the cholesterol-lowering drug of choice in children and in women who are pregnant, could become pregnant, or are lactating. Bile acid sequestrants are especially effective in combination therapy, and their major clinical role has evolved to use in combination with HMG-CoA reductase inhibitors, with which they are synergistic in the reduction of LDL cholesterol.

Nicotinic Acid (Niacin)

Nicotinic acid, or niacin, is a B-complex vitamin that in high doses is a lipid-lowering drug. Niacin reduces triglyceride and LDL cholesterol levels and is the most effective of the available lipid-modifying drugs in raising HDL cholesterol. Niacin is also the only lipid-lowering drug currently available that decreases Lp(a) levels (34,35,36 and 37). Its safety and efficacy were documented in the Coronary Drug Project, which demonstrated a modest benefit to the use of niacin to reduce nonfatal MI after 6 years of treatment (14) and a decrease in the total mortality rate after 15 years of follow-up (15).

The use of immediate-release crystalline niacin has been limited by the occurrence of cutaneous flushing. However, with proper administration and patient education, flushing can be minimized. The starting dose of immediate-release niacin should usually be 100 mg three times per day and always at the end of meals. Food delays the absorption and makes it much easier to tolerate with less flushing. Patients should be told to expect some flushing initially but that it will improve quickly with continued administration. Every 4 to 7 days, the dosage should be increased by 100 mg per dose, eventually reaching 500 mg three times per day. After 1 month of treatment with this dose, lipid and other pertinent levels (e.g., glucose, uric acid, and liver transaminases) should be measured. It is frequently necessary to increase the dose to 3 g per day to achieve a substantial beneficial effect on lipid levels. Rarely, immediate-release niacin is used in doses of up to 4.5 g per day. Despite adherence to the dosing protocol, some patients may continue to have flushing with certain doses (often the morning dose) and may benefit from taking aspirin 30 minutes before the niacin.

Sustained-release forms of niacin are associated with less flushing and therefore are better tolerated. However, the use of over-the-counter sustained-release niacin preparations, which are usually administered twice a day, has been limited because of several cases of severe hepatotoxicity. Niaspan is a prescription sustained-release niacin that is administered once daily at bedtime. Niaspan is better tolerated than immediate-release crystalline niacin and is probably safer than over-the-counter sustained-release niacin because of its pharmacokinetics, the once-a-day dosing, and superior quality control. In one study, Niaspan decreased triglyceride levels by 29% and increased HDL cholesterol levels by 26% at a dose of 2 g (112). Niaspan has also been directly compared to gemfibrozil and had a significantly greater effect on HDL cholesterol levels (increase of 26%), compared with 1,200 mg of gemfibrozil (increase of 13%), although gemfibrozil had a more pronounced effect on triglyceride levels (decrease of 40%) than Niaspan (decrease of 29%) (113).

Use of niacin can be limited by side effects other than flushing. It has been associated with elevation in uric acid and precipitation of gouty attacks and can also exacerbate peptic ulcer disease and symptoms of gastroesophageal reflux. Mild elevations in transaminases occur in as many as 15% of treated patients, but these elevations rarely require cessation of treatment with the medication. Niacin potentiates the effect of warfarin and should be used cautiously for patients taking warfarin. Acanthosis nigricans, a dark-colored, coarse skin lesion, is a rare side effect of niacin that is not dangerous but can be bothersome.

Niacin can elevate fasting glucose in patients with diabetes and therefore has traditionally been avoided in the treatment regimens of these patients. However, the Arterial Disease Multiple Intervention Trial confirmed the benefits of short-acting niacin and extended the safety and efficacy of this therapy to patients with diabetes (114). In this study, niacin given at an average dose of 2,500 mg per day resulted an increase in HDL cholesterol of 29% and a decrease in triglycerides of 25% in patients with and without diabetes. Interestingly, although patients with diabetes who were treated with niacin had a small increase in fasting glucose, their glycosylated hemoglobin levels did not change from baseline but were 0.3% higher than those in patients with diabetes who received placebo. No changes in hypoglycemic agents were required during the 48-week follow-up period.

Successful therapy with niacin requires careful education and motivation on the part of the patient. Its advantages are its low cost, long-term safety, and efficacy in treatment of combined hyperlipidemia and in raising HDL cholesterol levels. It is particularly useful in the secondary prevention of CHD in motivated patients who have combined hyperlipidemia and low HDL levels. Niacin can also be used successfully in combination with bile acid sequestrants and statins. In particular, patients already receiving a statin who require further LDL cholesterol reduction, in whom triglyceride levels remain elevated, or who have low HDL cholesterol levels can benefit substantially from the addition of niacin to treatment regimen (71).

Fibric Acid Derivatives (Fibrates)

Fibric acid derivatives, or fibrates, are agonists of peroxisome proliferator–activated receptor-a, a nuclear hormone receptor involved in metabolic regulation (35). This

class includes clofibrate (Atromid-S), gemfibrozil (Lopid), fenofibrate (TriCor), and bezafibrate (not available in the United States). Fibrates work by activating peroxisome proliferator–activated receptor-a to stimulate LPL activity (enhancing triglyceride hydrolysis), reduce apoC-III synthesis (enhancing lipoprotein remnant clearance), and possibly reduce VLDL production. Fibrates decrease triglyceride levels effectively (up to 40%) and generally increase HDL cholesterol levels modestly (up to 15%), but they have less ability to decrease LDL cholesterol levels.

The most straightforward clinical role of fibrates is in the treatment of severe hypertriglyceridemia to prevent acute pancreatitis. They are also highly effective in patients who have type III HLP. Fibrates are first-line agents for individuals with triglyceride levels >400 to 600 mg per dL who need drug therapy. The role of fibrates in the treatment of dyslipidemia for prevention of cardiovascular disease is supported by the Helsinki Heart Study and the more recent VA-HIT trial. Additional clinical endpoint trials with fibrates are under way.

Fibrates are generally well tolerated; the most common side effect is dyspepsia, which occurred in 6% more patients receiving treatment with fibrates than patients receiving placebo in the VA-HIT study. Myopathy has occurred, but in the absence of treatment with other drugs, it is very rare. In both the VA-HIT and BIP studies no statistically different occurrence of muscle complaints was seen between the group of patients receiving fibrates and those receiving placebo. Elevated results of liver function tests can also occur, but the frequency of elevations in transaminases more than three times the upper limit of normal was no different among patients receiving fibrates than those receiving placebo in both the VA-HIT and the BIP trials. Fibrates have also been associated with an increased risk of gallstones, but this was not seen in VA-HIT over the course of 5 years. Fibrates can potentiate the effect of warfarin and interact with certain oral hypoglycemic agents. In the World Health Organization study (37), clofibrate was associated with an increase in gastrointestinal tumors and in the total mortality rate, and therefore clofibrate is rarely used.

Omega-3 Fatty Acids (Fish Oils)

W-3 Polyunsaturated fatty acids (**W**-3 PUFAs) are useful tools in the management of severe hypertriglyceridemia. **W**-3 PUFAs are found naturally in high concentrations in fish and in flax seeds, and their use in the form of concentrated fish-oil capsules has been at the center of active investigation. Both epidemiologic and experimental studies have demonstrated the benefit of dietary fish intake and concentrated fish oils in the management of CHD (115). Most of the attention has been focused on the two active molecules in fish oil, eicosapentanoic acid (EPA) and decohexanoic acid (DHA).

W-3 PUFAs in doses of 3 to 6 g per day consistently decrease fasting and postprandial triglyceride levels (116). Fish oils are useful as a third-line therapy for patients who have severe hypertriglyceridemia that is resistant to fibrates and niacin or who are intolerant of these drugs. At least 6 g per day is usually required for a substantial effect, and many patients require 9 to 12 g per day. Fish oils should not be used to treat hypercholesterolemia and have been reported to raise LDL cholesterol levels. Interestingly, a large randomized controlled trial demonstrated that one fish-oil capsule daily was associated with a significant reduction in cardiovascular events (117).

In general, supplemental **W**-3 PUFAs are well tolerated, with patients reporting dyspepsia and a fishy aftertaste at doses of more than 3 g per day. Despite concerns, large trials have not reported increased bleeding. Supplemental **W**-3 PUFAs have been studied in a wide range of populations, including postmenopausal women who are receiving HRT, patients with diabetes, and patients who are already receiving statins and antiplatelet agents. The U.S. Food and Drug Administration (FDA) has decided that up to 3 g daily of EPA and DHA is “generally regarded as safe.” What limits the generalized use of **W**-3 PUFAs is the large number of capsules that must be ingested. Because most commercially available fish-oil preparations in the United States contain 30% to 50% EPA and DHA, patients have to take at least two to three tablets (1 g) three times daily to get the desired decrease in triglyceride levels. Fish-oil supplements are best used in patients with primary triglyceride abnormalities who cannot tolerate or chose not to take fibrates or niacin. Fish-oil supplements can also be used in combination with fibrates, niacin, or statins in patients who do not reach target triglyceride levels during treatment with those drugs.

Combination Drug Therapy

Some patients with dyslipidemia may require therapy with more than one drug. Patients with FH often have difficulty achieving LDL cholesterol goals with a statin alone but respond very well to the addition of a bile acid sequestrant. In some cases, the addition of niacin to this regimen is required for further decreases in LDL levels (71). Patients with FCHL can often reach their LDL cholesterol goal with a statin alone but frequently have persistent moderate hypertriglyceridemia, low HDL cholesterol levels, or both. In this situation, the addition of niacin to the statin can be highly effective in reducing the triglycerides and increasing the level of HDL cholesterol (71,118). Many patients with triglyceride levels higher than 400 to 600 mg per dL require initial therapy with a fibrate to decrease the triglyceride levels, but once the triglycerides are reduced, the LDL cholesterol often remains elevated. In this situation, the addition of a statin to the fibrate is effective in decreasing the level of LDL cholesterol. Although the risk of myopathy with this combination is a concern, it can be minimized with appropriate patient selection and education (118). Patients should be told of the potential for myopathy and advised to stop the medication and call their physician in the event of unexplained or generalized muscle pain. Practicing physicians are encouraged to consider combination therapy in appropriate high-risk patients or consider referring patients who may benefit from such therapy to a specialized lipid center.

Approaches to Reducing Cholesterol When Drugs Are Not Tolerated or Are Ineffective

Some patients cannot tolerate any of the existing lipid-lowering drugs at the doses required for adequate control of their lipid levels. A larger group of patients, most of whom have genetic lipid disorders, remain significantly hypercholesterolemic despite combination drug therapy. These patients, many of whom already have established CHD, are at high risk for disease progression and clinical events and should be referred to a specialized lipid center. The approaches discussed in the next sections have been used or are being developed for use in such patients.

Partial Ileal Bypass

Partial ileal bypass was developed as a surgical procedure to decrease LDL cholesterol levels in the 1960s (119). Like the mechanism of the bile acid sequestrants, partial ileal bypass interrupts the enterohepatic circulation of bile acids, resulting in up-regulation of the hepatic LDL receptor. One controlled trial of partial ileal bypass in moderately hypercholesterolemic patients who had established CHD demonstrated a 38% decrease in LDL cholesterol and a 35% decrease in the combined end point of nonfatal MI and CHD death (16). The procedure is ineffective in patients with homozygous FH (73), probably because partial ileal bypass works by up-regulating the LDL receptor (which is absent in homozygous FH). Partial ileal bypass has not been proven to be effective in patients with severe hypercholesterolemia who did not respond adequately to HMG-CoA reductase inhibitors. Diarrhea is a common side effect of this procedure, and the incidence of kidney stones, gallstones, and intestinal obstruction increases in patients who have undergone the surgery. The clinical usefulness of partial ileal bypass is limited to treatment of hypercholesterolemic patients who have established CHD, are unable to tolerate standard lipid-lowering medications, and do not wish to undergo LDL apheresis.

Low-Density Lipoprotein Apheresis or Plasma Exchange

The preferred option for management of patients who have refractory or drug-resistant hypercholesterolemia is LDL apheresis (or, if LDL apheresis is not available, plasma exchange). Plasma exchange involves removing a large volume of plasma and replacing it with an albumin/saline solution. It results in acute reduction in plasma cholesterol levels and has been used for decades on a repetitive basis for the management of severe hypercholesterolemia (120). However, plasma exchange also removes all other plasma constituents, such as HDL cholesterol and other plasma proteins, and is often associated with fatigue and other systemic symptoms. In 1996, the FDA approved a device for selective LDL apheresis (Kaneka) as an alternative to plasma exchange. In this approach, the patient’s plasma is passed over dextran sulfate columns that selectively remove LDL, and then the LDL-depleted plasma is returned to the patient (121). More recently, another device (Braun) that uses heparin columns was also approved by the FDA. Both methods are in use in many countries around the world. In contrast to plasma exchange, LDL apheresis does not decrease the levels of HDL cholesterol or other plasma constituents and is often better tolerated by patients. Clinical trials have indicated that LDL apheresis can retard progression or cause regression of CHD in patients who have severe drug-resistant hypercholesterolemia (76,77) and have even suggested a decrease in clinical cardiovascular events (77). Patients on maximally tolerated combination drug therapy who have CHD and an LDL cholesterol level >200 mg per dL or no CHD and an LDL cholesterol level >300 mg per dL are considered candidates for LDL apheresis (75). The procedure is usually performed every 2 weeks, although some patients with very severe hypercholesterolemia may benefit from undergoing the procedure every week. LDL apheresis is safe, but it requires a major time commitment on the part of the patient and a substantial expense on the part of the insurer. Nevertheless, it is considered the therapy of choice for patients with severe refractory hypercholesterolemia, and these patients should be referred to a specialized lipid center for management of their condition, including consideration of LDL apheresis.

Future Developments in the Treatment of Dyslipidemia

Small molecules that target new molecular pathways are under development for use in therapy for dyslipidemia. One example is a molecule that inhibits the intestinal bile acid transporter. These molecules inhibit the reuptake of bile acids by the intestine and therefore result in LDL receptor up-regulation and reduction of LDL cholesterol. They are expected to be particularly effective in combination with statins. Somatic gene therapy is a logical treatment of the future for patients with major genetic lipid disorders who cannot be treated adequately with available drugs (122). Homozygous FH due to deficiency of LDL receptors has been a disease model for the development of liver-directed somatic gene therapy, and a pilot clinical trial involving five patients has been completed (123). However, the development of effective

gene therapy for severe genetic dyslipidemias requires advances in the technology of gene delivery and expression.

Approach to the Patient with Low High-Density Lipoprotein Cholesterol

Many individuals are found to have a low HDL cholesterol level during routine lipid screening. The finding of a low HDL cholesterol level can be useful when it is recognized as an independent risk factor in the assessment of CHD risk and in the clinical management of LDL cholesterol levels that are in the gray zone. However, no formal guidelines have been developed specifically for the classification and management of patients with isolated findings of low levels of HDL cholesterol.

Secondary causes of low HDL levels should always be considered. Specifically, the patient should be asked about medications, smoking habits, dietary patterns, and physical activity. Decreased HDL cholesterol levels in patients with substantially elevated triglyceride levels (>500 mg per dL) are common and should not be directly addressed until the triglyceride levels have been reduced. Once secondary causes and hypertriglyceridemia are excluded, the differential diagnosis and management of low HDL cholesterol can be divided into moderately decreased HDL cholesterol levels (20 to 35 mg per dL) and severely decreased HDL levels (<20 mg per dL). Severely decreased HDL cholesterol levels <20 mg per dL accompanied by triglyceride levels <400 mg per dL usually indicate the presence of a specific genetic etiology for the condition, such as mutations in apoA-I, LCAT deficiency, or Tangier disease. A patient in whom one of these diagnoses is suspected should be referred to a specialized lipid center for further evaluation.

No formal clinical practice guidelines are available for the management of the condition of patients with isolated low HDL cholesterol. However, some general guidelines can be proposed. Secondary factors should be sought and corrected when possible. Smoking should be discontinued, obese persons should be encouraged to lose weight, and sedentary persons should be encouraged to exercise. HRT can substantially raise HDL cholesterol and should be considered in postmenopausal women. When possible, medications associated with reduced HDL cholesterol should be discontinued. Diabetes mellitus should be optimally controlled. Isolated low HDL cholesterol levels that are not a result of a secondary factor or a very low-fat diet are often associated with modestly elevated LDL cholesterol levels. In this situation, a finding of decreased HDL cholesterol levels is useful clinically as an additional independent cardiovascular risk factor supporting the use of drug therapy to reduce a slightly increased or even average LDL cholesterol level. If the LDL cholesterol level is well controlled, it can be difficult to decide whether pharmacologic intervention should be used to raise an isolated finding of a low HDL cholesterol level. In individuals with established ASCVD, drug therapy may be a reasonable approach, especially in light of the results of the VA-HIT study. In healthy individuals, no published clinical trials have demonstrated any benefit from treatment targeted specifically at increasing the level of HDL cholesterol. Every effort should be made to assess the risk of future CHD in patients with isolated findings of low HDL cholesterol levels so that appropriate clinical decisions about medical management can be made. In high-risk individuals, drug therapy targeted toward HDL cholesterol could be reasonably considered.

Statins increase HDL cholesterol levels modestly, by approximately 5% to 10%, and are not generally regarded as HDL cholesterol–raising drugs. Fibrates also increase HDL cholesterol modestly, by approximately 5% to 15%, but are most effective when triglyceride levels are elevated. Change in HDL in response to fibrate therapy is relatively slight in many patients who have low HDL cholesterol and normal triglyceride levels. Niacin is the most effective therapy targeted at increasing HDL cholesterol levels that is currently available; increases in HDL cholesterol levels up to approximately 30% have been seen. But some patients who have isolated findings of low HDL cholesterol levels do not even respond significantly to niacin therapy. New molecules designed to raise HDL cholesterol levels or promote reverse cholesterol transport are under active development.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The case for aggressive cholesterol reduction has become much stronger over the past few years as a number of new clinical studies have been published. These studies have contributed to the paradigm shift away from a focus on angiographic disease and degree of luminal stenosis and toward the concept of plaque stabilization in the prevention of acute coronary events. The enthusiasm for using aggressive lipid lowering to markedly reduce the burden of coronary morbidity and death has been apparent in a variety of editorials written by prominent scientists. Nobel laureates Drs. Michael Brown and Joseph Goldstein stated in an editorial in *Science* that “Exploitation of recent breakthroughs—proof of the cholesterol hypothesis, discovery of effective drugs, and better definition of genetic susceptibility factors—may well end coronary disease as a major public health threat early in the next century” (124). Dr. William Roberts, editor of the *American Journal of Cardiology*, has called the statin drugs “miracle drugs” that are to atherosclerosis “what penicillin was to infectious disease” (125). The purpose of this section will be to outline the issues, make practical suggestions based on current knowledge, and point out needs for future basic and clinical research.

Assessment of Cardiovascular Risk

It is widely agreed that drug therapy to reduce cholesterol is indicated in secondary prevention of clinical events and death in individuals with established CHD (26). Most experts also agree that drug therapy is indicated for primary prevention in certain high-risk individuals (such as diabetics and those with multiple risk factors) who have hypercholesterolemia that cannot be controlled adequately with diet and exercise. Therefore, in primary prevention, the major emphasis has turned to the more precise identification of high-risk individuals who are most likely to benefit from more aggressive therapy. It is now generally recognized that although traditional risk factors are reasonably good at predicting excess risk above the baseline for particular populations, they allow clinicians to predict only approximately 50% to 60% of the variation in absolute risk in individual patients (126). Therefore, factors that enhance predictive ability in an additive fashion over traditional risk factors would have considerable clinical usefulness, allowing better decisions to be made regarding the use of proven preventive therapies. Although traditional risk factors are useful in identifying some high-risk individuals, they identify only approximately one-half of the individuals who are destined to develop premature CHD. Therefore, there is great interest in the use of additional tests to identify high-risk individuals. Such information has immediate implications with regard to decisions about the use and intensity of lipid-lowering drug therapy. Those individuals at the highest risk for future CHD will benefit the most from aggressive lipid-lowering drug therapy (127). This section will briefly review some of the tests that have been proposed and are being used for the purpose of cardiovascular risk assessment.

Low-Density Lipoprotein Particle Concentration and Size

A given level of LDL cholesterol could be caused by a small number of large LDL particles or a large number of small LDL particles. A large body of epidemiologic data indicates that the latter is associated with substantially greater cardiovascular risk than the former. Therefore, determination of LDL particle concentration and size could potentially be used to aid the diagnosis of lipid disorders and to refine the identification of individuals at risk for premature CHD, who therefore deserve more aggressive therapy (128). ApoB is the major protein component of LDL, and each LDL particle has one molecule of apoB per particle. Thus, the apoB concentration is an indirect measure of the number of LDL particles. Although epidemiologic studies have been conflicting, apoB levels are probably predictive of CHD risk independent of LDL cholesterol levels (128,129). Assays to measure apoB have not yet been fully standardized. An NMR imaging–based method has become the gold standard for the quantitation of LDL particle size and LDL particle number (130). Some clinicians choose to use this test, which is FDA-approved and commercially available, to assist them in the treatment of patients with LDL cholesterol levels that are in a borderline range. The finding of an increased concentration of small, dense LDL particles could reasonably lead to the initiation of drug therapy, even if the LDL cholesterol level itself were not significantly elevated.

Lipoprotein(a)

Lp(a) is similar to LDL, but it is characterized by the presence of an additional protein called “apolipoprotein(a)” (131). Lp(a) levels are highly genetically determined, and the gene for apolipoprotein(a) is the major genetic factor controlling the plasma levels of Lp(a). A large number of epidemiologic and observational studies have indicated that Lp(a) levels are associated with premature ASCVD, independent of LDL cholesterol levels (131). A recent prospective study of the Framingham offspring cohort confirmed that the relative risk for premature CHD was increased in the presence of an elevated Lp(a) level (132). The mechanism by which Lp(a) promotes cardiovascular disease is not well understood, although it may inhibit activation of plasminogen to plasmin. Elevated Lp(a) levels may not have the same significance in all ethic groups; in studies of African-Americans, Lp(a) levels have not been associated with CHD. In contrast, elevated levels of Lp(a) are common in Asian Indians who have premature CHD and may play an important role in the early CHD often seen in this population. End-stage renal disease is strongly associated with elevated levels of Lp(a), which may play a role in the cardiovascular disease common in patients with such disease. Lp(a) levels increase in women after menopause and can be reduced with HRT. Some data suggest that an elevated Lp(a) level invites less risk after decrease of an elevated LDL cholesterol level (133). Therefore, an elevated Lp(a) level should be considered in decisions about whether to initiate drug therapy aimed at lowering the LDL cholesterol level. Although there is no proof that reducing levels of Lp(a) reduces the risk of cardiovascular disease, niacin is the only lipid-lowering drug that consistently lowers the Lp(a) level, and it should probably receive extra consideration as a treatment in the hypercholesterolemic patient who has an elevated Lp(a) level. Finally, postmenopausal women with elevated Lp(a) levels should receive special consideration for estrogen replacement therapy. However, the major emphasis in the setting of an elevated Lp(a) should remain on reduction of the LDL cholesterol level.

Homocysteine

Homocysteine levels have a continuous graded relationship with all types of ASCVD (134). This association is independent of known risk factors, and the mechanism has not yet been established. Homocysteine levels are inversely associated with folic acid intake and serum folate levels (135). Therefore, in addition to providing evidence of higher CHD risk, an elevated serum homocysteine level may have therapeutic implications with regard to folic acid supplementation. Randomized controlled clinical trials of the use of folic acid supplementation to lower homocysteine levels in the prevention of CHD are under way, but results have not yet been

reported.

Inflammatory Markers

There has been increasing interest in the concept of atherosclerosis as an inflammatory disease (136). This concept has been fueled by the finding that serum markers of inflammation predict future cardiovascular events (137,138). The most-studied marker has been the high-sensitivity C-reactive protein, which has been found to be associated with increased cardiovascular risk in multiple prospective studies. Other inflammatory markers that have also been found to be predictive of risk include interleukin-6, serum amyloid A, and soluble intercellular adhesion molecule 1 (139). In a head-to-head comparison of different serum-based markers, inflammatory markers were clearly additive to lipid markers in predicting future cardiovascular risk (140). The clinical use of certain markers, such as high-sensitivity C-reactive protein, in selected patients for improvement of cardiovascular risk assessment may be reasonable.

Fibrinogen

Fibrinogen levels have been found to have a significant association with premature CHD in several studies (141). The mechanism by which fibrinogen promotes CHD is not well understood but may involve at least in part its effects on plasma viscosity.

Genetic Polymorphisms

Genetic variation plays a role in determining cardiovascular risk. A variety of single-nucleotide polymorphisms in different candidate genes have been reported to be associated with CHD in univariate analyses. In theory, a panel of a large number of single-nucleotide polymorphisms could be used to predict future cardiovascular risk. This type of panel is not yet ready for use in clinical decision-making but is under active study.

Noninvasive Vascular Imaging

In theory, the use of noninvasive tests to examine vascular beds for presence of atherosclerotic plaque before the development of symptoms is an attractive way of identifying high-risk individuals who may be candidates for more aggressive therapy to reduce LDL cholesterol levels (142). Several different modalities are under development and clinical investigation with regard to this concept. Because acute coronary events are frequently caused by lesions that represent <50% stenosis of the vessel, the goal in identifying individuals at high risk for coronary events is not to identify those with significant coronary stenoses (as for exercise testing), but rather to identify individuals who are at higher statistical risk of developing vulnerable coronary lesions and having acute coronary events. Therefore, the most promising methods are likely to be those that sensitively and specifically detect and quantitate atherosclerosis. B-mode carotid ultrasound can be used to quantitate carotid IMT in asymptomatic individuals, and this technique has been used to demonstrate that lowering lipid levels can retard the progression of intimal thickening in comparison with that in control patients (143,144 and 145). Prospective studies based on large populations, such as the Atherosclerosis Risk in Communities (ARIC) study and Cardiovascular Health Study (CHS), have shown that carotid IMT is predictive of future coronary events, independent of known cardiovascular risk factors. Another marker for coronary atherosclerotic plaque is coronary calcification (146). Electron-beam tomography can detect and quantitate coronary calcification as a specific marker for atherosclerotic plaque (147). Coronary calcification is highly correlated with the extent of atherosclerotic disease on autopsy (148,149) and with the extent of angiographic coronary disease (147). Several prospective studies have indicated that the extent of coronary calcification is associated with the probability of a future coronary event (150). Therefore, both carotid IMT and coronary calcification could potentially be used as noninvasive methods for stratifying selected asymptomatic persons according to cardiovascular risk, to aid physicians in making more informed decisions regarding drug therapy for cholesterol reduction.

Use of Lipid-Lowering Drug Therapy in Underrepresented Subgroups

Women

Women have been traditionally underrepresented in lipid-lowering trials, although trials such as 4S, Cholesterol and Recurrent Events, LIPID, and AFCAPS/TexCAPS included women. Subgroup analyses have indicated that women are as likely as men to benefit from cholesterol reduction. On the basis of available data, women with CHD or diabetes or who have high cardiovascular risk should receive treatment as aggressive as that in men. Premenopausal women are, on average, at substantially lower risk of developing premature CHD than men of the same age, and therefore the threshold of LDL cholesterol levels for institution of drug therapy should probably be higher for women than for men. Nevertheless, in women at high risk, such as those with diabetes mellitus or strong family histories of premature CHD, it is appropriate to consider more aggressive therapy. HRT may be considered for postmenopausal women before initiation of lipid-lowering drug therapy, because estrogens can lower LDL cholesterol levels (as well as raise HDL cholesterol). Postmenopausal women who are not receiving estrogen replacement are at similar risk to that in men for developing CHD and therefore should be treated for hypercholesterolemia with a similar degree of intensity.

Elderly Individuals

Some secondary prevention trials have included patients as old as 75 years. Subgroup analyses have indicated that age is not a determinant of benefit from therapy and that patients in older age groups derive benefit similar to that in younger patients. Given the wealth of data demonstrating the benefit of cholesterol reduction in secondary prevention, it is rational to treat elderly persons with CHD as aggressively as younger persons with CHD. However, the decision to use cholesterol-lowering drug therapy should be influenced by the general health of the patient, the need for other medications, and the patient's ability to tolerate the lipid-lowering medication. Primary prevention of CHD using cholesterol-lowering drugs is a more difficult issue in elderly patients. The West of Scotland study included patients as old as 64 years; a subgroup analysis of patients older than 55 years indicated a significant reduction in MI and CHD death, similar to that seen in the group of patients younger than 55 years (32). The approach to hypercholesterolemia in elderly persons without CHD should probably be influenced primarily by the general health and vigor of the patients as well as by their degree of interest in being treated aggressively. For example, a healthy, active 80-year-old with an elevated LDL cholesterol level who wants to do everything possible to prevent his or her first MI should not be denied drug therapy simply on the basis of age.

Role of Antioxidants in Reduction of Risk of Coronary Heart Disease

The Probucol Quantitative Regression Swedish Trial used probucol as an antioxidant to treat patients who had femoral atherosclerosis. No difference was seen between the group of patients who were treated with probucol and the control group with regard to the extent of femoral atherosclerosis (151). Two large trials failed to demonstrate any effect on cardiovascular disease from beta carotene supplementation with relatively low doses of either 50 mg every other day (152) or 30 mg daily (153). The Cambridge Heart Antioxidant Study compared the use of two different doses of vitamin E supplementation (400 and 800 IU per day) to placebo in 2,002 patients with established CHD (154). The analysis was performed by pooling the two different treatment groups and comparing them to the placebo group. Combined CHD death and nonfatal MI (the primary end point) was significantly reduced (by 47%; $p < .005$) in the groups treated with vitamin E. This difference was entirely due to a reduction in nonfatal MI (14 events in the group of patients receiving treatment vs. 41 events in the control group). Although the trial was not powered to address the total mortality rate, the rate was actually increased in the group of patients receiving vitamin E (36 deaths) compared with that in the control group (27 deaths). In the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico–Prevenzione Trial (117), 11,324 Italian subjects with recent MI (<3 months before enrollment) were randomly assigned to receive 300 mg per day of synthetic vitamin E, 1 g per day of **W**-3 PUFA, or both, or placebo in a 2-by-2 factorial design and followed for 3.5 years. The primary combined efficacy end points were death, nonfatal MI, and stroke. Treatment with **W**-3 PUFAs without vitamin E significantly lowered the risk of the primary end point. The Heart Outcomes Prevention Evaluation study (155) involved 9,541 subjects aged 55 years or older with both symptomatic and asymptomatic cardiovascular disease. Subjects were randomly assigned to receive naturally occurring vitamin E (400 IU) or placebo and followed for 4.5 years. This trial used a two-by-two factorial design that also involved the angiotensin-converting enzyme inhibitor ramipril. No clinical benefit or adverse events were noted in the group of patients treated with vitamin E. The Secondary Prevention with Antioxidants of Cardiovascular Disease in Endstage Renal Disease (SPACE) trial (156) investigated the effect of high-dose vitamin E supplementation on cardiovascular disease outcomes in hemodialysis patients with preexisting heart disease. One hundred and ninety-six hemodialysis patients aged 40 to 75 years were randomly assigned to receive 800 IU per day of vitamin E or placebo in a double-blind design. Patients were followed for approximately 17 months. The primary end points included fatal and nonfatal MI, ischemic stroke, peripheral vascular disease, and unstable angina. Secondary outcomes included cardiovascular mortality and total mortality rates. Results of this study demonstrated a highly significant reduction in the composite primary outcome measure that was chiefly attributable to a 70% reduction in acute MI. No effect on the total mortality rate or the cardiovascular mortality rate was seen. Therefore, although most of the results of vitamin E supplementation trials have been negative to date, the results of the SPACE trial suggest that patients who have elevated levels of oxidant stress may benefit from therapy with vitamin E. Additional clinical trials are under way that are examining the important question of whether antioxidant therapy will reduce cardiovascular events in both secondary and primary prevention.

THE FUTURE

Virtually all experts agree that cholesterol-lowering drugs are underused and that more frequent use will lead to even more impressive reductions in coronary events in the future. Nevertheless, many clinical issues remain unresolved in the treatment of lipid disorders. Although a thorough discussion of all of these issues is beyond the scope of this chapter, several are discussed here: (1) the use of additional diagnostic tests for determining CHD risk as a guide to intensity of lipid-lowering drug therapy in primary prevention, (2) the use of lipid-lowering drug therapy in particular subgroups underrepresented in clinical trials, and (3) the use of antioxidant therapies.

OVERVIEW

Physical activity results in increased exercise capacity and physical fitness, which may lead to many health benefits. Individuals who are more physically active appear to have lower rates of all-cause mortality, probably due to a decrease in chronic diseases, including coronary artery disease (CAD). This low rate may result from an improvement in cardiovascular risk factors, enhanced fibrinolysis, improved endothelial function, decreased sympathetic tone, and other as-yet-undetermined factors.

Regular endurance and resistance exercise leads to favorable alterations in the cardiovascular, musculoskeletal, and neurohumoral systems. These alterations result in a training effect that allows an individual to do increasing amounts of work at a lower heart rate and blood pressure. Such an effect is particularly desirable in patients with CAD, because it allows increased activity with less ischemia.

Current recommendations from the Centers for Disease Control and Prevention (CDC) (8) state that every American should participate in at least moderately intense physical activity for at least 30 minutes on most, if not all, days of the week. Unfortunately, too many Americans are sedentary and perform too little physical activity. This is especially true among racial minorities, low-income groups, the elderly, and women. It is important to educate the public regarding the benefits of physical activity and to help encourage more leisure-time exercise in underactive individuals.

GLOSSARY

Calorie: a unit of energy equal to the amount of heat required to raise the temperature of 1 kg of water 1°C.

- 1,000 cal = 1 kcal
- 5 kcal = 1 L oxygen consumed
- 7,000 kcal = 1 kg fat (2.2 lb)

Endurance exercise: Dynamic exercise involving high-repetition movements against low resistance. Endurance exercise also is called *isotonic exercise* because muscle shortening develops predominantly without much muscle tension. Examples include walking, jogging, swimming, and cycling. The term also is referred to as *aerobic exercise*.

Exercise: A form of physical activity; planned physical activity with the goal of achieving or preserving physical fitness.

Maximal oxygen uptake ($\dot{V}O_2$max): Maximal rate of oxygen consumption per minute. $\dot{V}O_2$max is a reliable, reproducible, and objective measure of physical fitness.

Metabolic equivalent (MET): One MET is equal to the amount of oxygen per minute required by the body during resting conditions.

1 MET = 3.5 mL oxygen/kg body weight/minute

Physical activity: Skeletal muscle contraction resulting in bodily movement that requires energy utilization.

Physical fitness: A set of attributes that enables an individual to perform physical activity.

Resistance exercise: Exercise involving low-repetition movements against a high resistance. An example is weightlifting.

Training effect: The ability to achieve a higher peak workrate and $\dot{V}O_2$max with lower heart-rate responses to submaximal levels of exercise compared with pretraining conditions.

Volume of oxygen ($\dot{V}O_2$): Amount of oxygen consumed per minute and expressed as the absolute value or as liters per kilogram of body weight per minute.

$\dot{V}O_2$ = stroke volume × heart rate × arteriovenous oxygen difference

Work: Force × distance.

Workrate: Work per unit of time.

INTRODUCTION

Physical Activity and Public Health

Nearly 60 million (approximately one of every four) persons in the United States have cardiovascular disease (CVD). Of these, 50 million suffer from hypertension, 12 million have CAD, and more than 4 million have suffered a stroke (1). Despite the declining mortality rate observed since 1950 and due to cardiovascular illness, 43% of all deaths are currently attributed to CVD. The morbidity and subsequent disability incurred from cardiovascular illness have far-reaching medical and socioeconomic implications and an estimated total cost of $327 billion in 2000. Thus, continued major efforts in preventing CVD are needed to reduce the overall incidence of atherosclerotic disease and stroke (1).

Physical inactivity is a risk factor for CVD. Regular exercise results in an increase in exercise capacity and lower myocardial oxygen demand, leading to cardiovascular benefits such as lower mortality rates and fewer symptoms of CAD (2,3 and 4). Moreover, the long-term cost-effectiveness of an unsupervised exercise training program has been estimated to be less than $12,000 per year of life saved for all individuals (5). The Surgeon General's report on physical activity and health (6) has summarized the findings of five national surveys by the CDC. The results indicate that too many American adults lead sedentary lifestyles, with only 14% of respondents reporting regular vigorous physical activity (i.e., activity performed at 50% of maximum cardiorespiratory capacity for 20 minutes at least three times per week). Approximately 25% of adults report regular moderate physical activity (i.e., activity performed at 3 to 6 METs for 30 minutes on most days of the week), and 25% participate in no leisure-time physical activity (6). More recent data from the National Health Interview Survey (7) estimate that 40% of American adults are sedentary.

Many factors contribute to physical inactivity in adults, but the most-cited reasons are lack of time and risk of injury. Although most Americans are aware that exercise is beneficial for good health, this knowledge does not strongly correlate with physical activity. Other important barriers are lack of companionship or encouragement and the absence of an appropriate environment for exercise (e.g., no available paths for walking or biking, poor weather, or dangerous neighborhood). Regular physical activity is more strongly associated with enjoyment of exercise, confidence in athletic ability, and participation in low to moderate levels of activity (8).

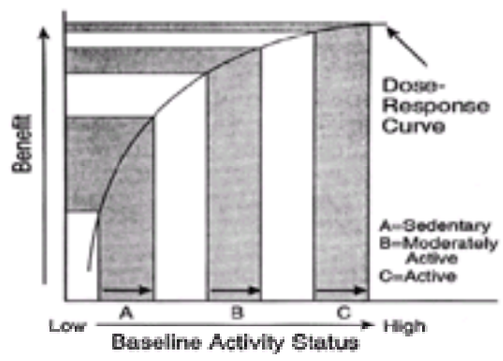
Organizations, including the CDC, the American College of Sports Medicine (ACSM) (8), and the American Heart Association (AHA) (9), have published consensus reports and recommendations for the promotion of physical activity in an attempt to increase the leisure-time activity of all Americans. In a joint statement (8), the CDC and ACSM recommend that all adults participate in at least 30 minutes of moderate-intensity exercise on most, if not all, days of the week. Moderate-intensity physical activity is achievable for most adults and can be accomplished with many routine activities such as walking briskly (i.e., 3 to 4 miles per hour) for 2 miles, biking at 10 miles per hour, swimming, house cleaning, lawn mowing, and gardening. These recommendations emphasize that the 30 minutes of activity can be obtained intermittently throughout the day in 10-minute increments or in one continuous session. Thus, physical activity can become part of the daily routine and may involve using stairs instead of an elevator, walking or biking instead of driving, calisthenics, or use of exercise equipment while watching television (8) (*e*Table 4.0.1). An increase in lifestyle physical activity can be as effective as participation in traditional, structured exercise in improving caloric expenditure, blood pressure, and cardiorespiratory fitness (10).

***e*TABLE 4.0.1** EFFORT INTENSITY FOR VARIOUS COMMONLY PERFORMED PHYSICAL ACTIVITIES

Light (<3.0 METs[a] or <4 kcal/min)	**Moderate (3.0–6.0 METs or 4–7 kcal/min)**	**Hard/vigorous (>6.0 METs or >7 kcal/min^{-1})**
Walking, slowly (strolling)(1–2 miles/h)	Walking, briskly (3–4 miles/h)	Walking, briskly uphill or with a load
Cycling, stationary (<50 W)	Cycling for pleasure or transportation (£10 miles/h)	Cycling, fast or racing (>10 miles/h)
Swimming, slow treading	Swimming, moderate effort	Swimming, fast treading or crawl
Conditioning exercise, light stretching	Conditioning exercise, general calisthenics, racket sports, table tennis	Conditioning exercise, stair ergometer, ski machine, racket sports, singles tennis, racquetball
Golf, power cart	Golf, pulling cart or carrying clubs	
Bowling		
Fishing, sitting	Fishing, standing/casting	Fishing in stream
Boating, power	Canoeing, leisurely (2.0–3.9 miles/h)	Canoeing, rapidly (³4 miles/h)
Home care, carpet sweeping	Home care, general cleaning	Moving furniture
Mowing lawn, riding mower	Mowing lawn, power mower	Mowing lawn, hand mower
Home repair, carpentry	Home repairs, painting	

MET, metabolic equivalent.
[a] 1 MET = 3.5 kcal/kg/min.
From Pate RR, Pratt M, Blair SN, et al. Physical activity and public health: a recommendation from the Centers for Disease Control and Prevention and the American College of Sports Medicine. *JAMA* 1995;273:402–407, with permission.

It is advised that individuals who are inactive should increase their physical activity gradually until they are moderately active for 30 minutes per day. Those who participate in light levels of exercise or who are irregularly active should attempt to exercise more regularly, at least at moderate levels. The beneficial effects depend on how active the individual is at baseline. For example, sedentary people will gain the most, followed by moderately active individuals, and then active individuals (8) (*e*Fig. 4.0.1).



***e*FIGURE 4.0.1** The relationship between baseline physical activity and health benefits is depicted. The greatest benefits are observed in patients who are least active and increase their physical activity. (From Pate RR, Pratt M, Blair SN, et al. Physical activity and public health: a recommendation from the Centers for Disease Control and Prevention and the American College of Sports Medicine. *JAMA* 1995;273:402–407, with permission.)

Physical Activity, Exercise, and Fitness

Physical activity, fitness, and exercise are related entities but have different definitions. The definitions described below are as defined in the Surgeon General's report on physical activity and health (6).

Physical Activity

Physical activity is skeletal muscle contraction resulting in bodily movement that requires energy use. Further classification can be based on mechanical and metabolic aspects of contraction. Mechanical properties relate to whether limb movement occurs and includes isometric contraction (i.e., muscle tension without limb movement) and isotonic contraction (i.e., limb movement without change in muscle tension). Metabolic properties of physical activity are divided into categories of aerobic contraction (i.e., energy derived in the presence of oxygen) and anaerobic contraction (i.e., energy derived in the absence of oxygen). Most activity involves a

combination of the above parameters (6).

The intensity of physical activity can be described as the energy required per unit of time for the performance of an activity and can be obtained by measuring the oxygen uptake required for the activity. This intensity can be expressed in units of oxygen, kilocalories (measure of heat), or kilojoules (measure of energy). In addition, intensity of activity can be expressed by measuring the force of muscle contraction and is expressed in pounds or kilograms. Alternatively, physical activity can be measured in relative terms by relating the amount of activity in relation to the individual's capacity and is usually expressed as a percentage, such as the percentage of $\dot{V}O_2$max or the percentage of maximum heart rate (6) (Table 4.1).

	Endurance-type activity					
	Relative intensity		Absolute intensity (METs) in healthy adults (age in yr)			
				Middle-aged		
Intensity	$\dot{V}O_2$max/heart rate reserve (%)	Maximum heart rate (%)	Young (20–39)	(40–64)	Old (65–74)	Very old (80+)
Very light	<25	<50	<3.0	<2.5	<2.0	≤1.25
Light	25–39	50–63	3.0–4.7	2.5–4.4	2.0–3.5	1.26–2.20
Moderate	40–59	64–76	4.8–7.1	4.5–5.9	3.6–4.7	2.30–2.95
Hard	60–84	77–93	7.2–10.1	6.0–8.4	4.8–6.7	3.00–4.25
Very hard	≥85	≥94	≥10.2	≥8.5	≥6.8	≥4.25
Maximal[a]	100	100	12.0	10.0	8.0	5.0

MET, metabolic equivalent; $\dot{V}O_2$max, maximal oxygen uptake.
[a]Based on 8 to 12 repetitions for persons <60 years old and 10 to 15 repetitions for persons >60 years old.
[b]Maximum values are mean values achieved during maximum exercise by healthy adults. Absolute intensity (METs) values are approximate mean values for men. Mean values for women are approximately 1 to 2 METs lower than those for men.
Adapted from U.S. Department of Health and Human Services. Physical activity and health: a report of the surgeon general. Atlanta: Center for Disease Control and Prevention, National Center for Chronic Disease Prevention and Promotion, 1996.

TABLE 4.1 CLASSIFICATION OF PHYSICAL ACTIVITY INTENSITY[a]

Physical Exercise

Physical exercise is a form of physical activity and is defined as planned physical activity with the goal of achieving or preserving physical fitness. *Exercise training* may be a more accurate term, because similar activity may be viewed as exercise by one person and not by others (6).

Physical Fitness

Physical fitness is a set of attributes that enables an individual to perform physical activity (8). Physical fitness is best assessed by measures of $\dot{V}O_2$max. Many studies estimate fitness levels by measurement of the peak workrate or MET level achieved during graded exercise tests. Numerous exercise training studies have evaluated the frequency, intensity, and duration of the training sessions. Based on these data, it appears that the most consistent benefit on $\dot{V}O_2$max is observed when exercise training is performed at least three to five times per week for 12 or more weeks at an intensity of approximately 60% of the maximum heart rate, or 50% of $\dot{V}O_2$max, for 20 to 60 minutes (11). Improvements in $\dot{V}O_2$max of 15% to 30% are usually achieved using the above guidelines (11). It also appears that intermittent activity can confer fitness benefits similar to those of continuous activity at similar exercise intensities and total duration (12).

Physical Activity Patterns in the United States

In the past, most physical activity was occupationally related. However, technological advances of the twentieth century have rendered many jobs less physically demanding; thus, exercise must now be obtained during leisure time. General awareness of the benefits of physical activity has increased over the past 30 years; however, data regarding trends before 1980 are limited. Several studies between 1988 and 1992 have addressed the patterns in adult Americans and are summarized in the 1996 Surgeon General's report on physical activity and health. The patterns of physical activity in American adults vary with regard to sex, age, ethnicity, socioeconomic status, education, and a variety of other social factors (6) (eTable 4.1.1). These data concur with those from the more recent National Health Interview Survey (7).

***e*TABLE 4.1.1** ACTIVITY PATTERNS AMONG VARIOUS DEMOGRAPHIC GROUPS IN THE UNITED STATES[a]

	No leisure-time physical activity	Regular, moderate physical activity	Regular, vigorous physical activity
Total	28.7	23.5	14.2
Males	26.5	24.9	12.6
Females	30.7	22.3	15.6
White	27.4	24.3	14.8
Black	38.4	17.6	9.4
Hispanic	34.8	23.4	11.9
<12 years education	28.7	17.0	8.0
College education	22.6	28.3	21.6
Income <$10,000	41.5	20.3	8.8
Income >$50,000	17.8	27.7	20.3
Employed	25.8	22.5	13.8
Unemployed	36.0	21.6	10.1
Married	28.5	22.5	15.3
Never married	22.4	28.1	11.0

[a]Values represent % of Americans over the age of 18 who participate in no physical activity, moderate physical activity, or vigorous physical activity.

When the surveys were analyzed according to gender, it appeared that more women than men were inactive, more men than women engaged in regular, moderate physical activity, and approximately an equal number of men and women exercised vigorously (6). According to age, adolescents are less active than children—an observation that is more pronounced in girls than boys. The percentage of physically inactive adults increases with age, with no leisure-time physical activity reported among 38% to 50% of people older than 75 years. Interestingly, vigorous activity increases with age in both men and women up to 74 years of age and then decreases after age 75 (6). This may be because the elderly have more leisure time or because activity that is considered moderate in middle age, such as walking, is considered vigorous in the elderly due to the diminished cardiorespiratory capacity that occurs with aging.

Approximately 16% of the United States population consists of racial minorities, and the impact of CVD among these individuals is now being realized (13). Levels of physical activity are lower in blacks and Hispanics compared with whites and lower in minority women compared with men of these groups. Whereas approximately 25% of whites are inactive, approximately 40% of minority women and 30% of minority men participate in no leisure-time physical activity (6). In addition, 25% of whites participate in moderate leisure-time physical activity, but only 21% of black men and 15% of black women are moderately active. The trend for Hispanics is similar to that for whites (6).

Groups reporting the lowest amounts of exercise are at highest risk for CVD. The estimated age-adjusted prevalence of CVD in adults for non-Hispanic whites is 30% for men and 24% for women; for non-Hispanic blacks, 41% for men and 40% for women; and for Mexican Americans, 29% for men and 27% for women (1).

Physical inactivity also appears to correlate with various socioeconomic factors. Participation in leisure-time physical activity is positively associated with higher education, higher income, employment status, and marriage (6). Evidence to date suggests that socioeconomic status is an important and independent factor in the etiology and progression of CVD. When socioeconomic status is characterized by the principal measures of education, occupation, and income, there appears to be a consistent, inverse relation between these indicators and CVD risk factors—primarily hypertension, obesity, cholesterol levels, and cigarette smoking (14). Keil et al. (15) have demonstrated that among men in the Charleston Heart Study, there were no differences in all-cause or cardiovascular mortality between black and white men when socioeconomic status was controlled. The pathophysiologic mechanisms linking socioeconomic status to CVD are unclear. In addition to the greater prevalence of risk factors in persons of lower socioeconomic status, issues of behavior, coping, and access to health care should also be considered.

Finally, physical activity varies with the geographic location and season of the year. Highest levels of inactivity are reported in the South and the lowest levels are

reported in the West. Americans are more physically active during the spring and summer months than during the winter (6).

PHYSICAL ACTIVITY AND HEALTH: EPIDEMIOLOGIC OBSERVATIONS AND BIOLOGIC MECHANISMS

All-Cause Mortality

Data accumulated over the past 50 years have confirmed the health benefits of exercise. Epidemiologic studies have shown that active individuals are at lower risk for developing many chronic diseases (8). In addition, all-cause mortality rates are higher in less active people than in those who are more active (16,17). A large-scale epidemiologic study involving 13,375 women and 17,265 men between the ages of 20 and 93 years reported a significant inverse association between leisure-time physical activity and all-cause mortality (18). Approximately 12% of deaths per year in the United States are associated with inactivity (19). The risk for all-cause mortality decreases among inactive individuals who become more physically active (20). Importantly, recent data from an evaluation of 5,209 men and women demonstrate that the performance of recent activity confers a reduction in all-cause mortality, whereas activity performed decades earlier without subsequent maintenance appears to have no long-term benefit (21).

Cardiovascular Disease

Many studies have demonstrated that regular exercise and physical activity prevent primary and secondary cardiac events. In one of the most well-known studies, male Harvard University alumni without a history of CVD were followed for 16 years (16). There was a 39% reduction in cardiovascular morbidity and a 24% reduction in cardiovascular mortality in subjects with exercise energy expenditures of more than 2,000 kcal per week. Oldridge et al. (4) performed a metaanalysis of ten randomized clinical trials that examined the effects of cardiac rehabilitation after myocardial infarction (MI). No differences in nonfatal MI were apparent; however, there was a 24% reduction in all-cause mortality and a 25% reduction in cardiovascular mortality among exercise rehabilitation patients compared with controls. Wannamethee et al. (22) have also demonstrated that in men with established CAD, an increase in leisure-time physical activity was associated with a significant reduction in all-cause mortality.

Several population-based studies show that incremental levels of regular physical activity are inversely proportional to long-term cardiovascular mortality when controlled for the presence of other risk factors in both men and women (2,8,16,20,23) (Fig. 4.1). Among male alumni, the risk of death became progressively lower as physical activity levels increased from 500 to 3,500 kcal per week of energy expended (16). Alumni who were initially inactive and later increased their activity levels demonstrated significantly reduced cardiovascular risk compared with those who remained inactive (20). Moreover, when measured by an exercise tolerance test, higher levels of physical fitness are associated with significantly reduced subsequent cardiovascular mortality among men and women (17,25). In the Nurses' Health Study (24,26), 73,029 women (aged 40 to 65 years) were followed for 4 years. Physical activity in women was inversely related to the risk for stroke and CAD. The largest benefit was seen between the lowest and second-lowest quintile groups, suggesting that the incremental value of exercise is greatest in the least-active subjects compared with the most-active subjects. In a general population of elderly men, the 10-year CVD and all-cause mortality rate was inversely related to increasing levels of physical activity (27).

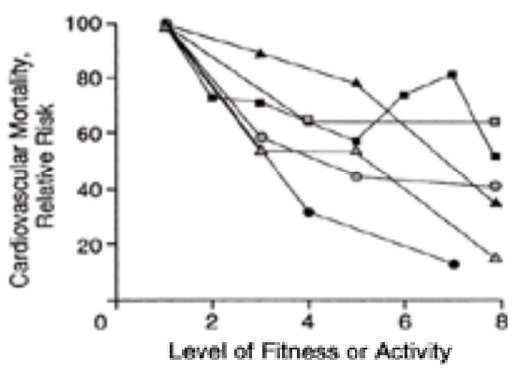


FIGURE 4.1 The relationship between physical activity or fitness and the relative risk for cardiovascular mortality. As fitness improves, the risk for cardiovascular death diminishes. ■, Paffenbarger et al. (1993); ▲, Morris et al. (1990); ●, Blair et al. (1989); □, Leon et al. (1987); △, Ekelund et al. (1988); ○, Sandvik et al. (1993). (From Pate RR, Pratt M, Blair SN, et al. Physical activity and public health: a recommendation from the Centers for Disease Control and Prevention and the American College of Sports Medicine. *JAMA* 1995;273:402–407, with permission.)

The relative risk of CAD in physically inactive subjects compared with active individuals is approximately 2.0 (2,8,9). Importantly, the relative risk for cardiovascular mortality in the least-fit or least-active individuals compared with the most-fit or most-active subjects approaches 6.0 (8,9,17). Paffenbarger et al. (20) have reported encouraging data that demonstrate that, when habitual physical activity levels are increased, subsequent mortality is decreased relative to those who remained physically inactive. These data strongly support the need to increase physical activity and fitness levels among both women and men, with the most mortality benefit to be derived by those who are the least fit.

The specific mechanisms by which physical activity reduces CAD mortality are not known. Exercise improves lipid profile, glucose tolerance, obesity, and elevated blood pressure. In a cross-sectional analysis of a large cohort of men and women, increasing levels of physical fitness assessed by maximal exercise treadmill testing were found to protect against elevations in most coronary heart disease (CHD) risk factors in persons with and without CAD (28). However, modification of atherosclerotic risk factors does not fully explain the benefits that have been observed. Other possible mechanisms—including effects on thrombosis, endothelial function, and autonomic tone—may play an important role (*e*Table 4.1.2).

***e*TABLE 4.1.2** PHYSICAL ACTIVITY AND REDUCED CARDIOVASCULAR RISK: BIOLOGIC MECHANISM
Lower blood pressure
Improved glucose tolerance
Reduced obesity
Improvement of lipid profile
Enhanced fibrinolysis
Improved endothelial function
Enhanced parasympathetic autonomic tone

Cardiovascular Risk Factors

Hypertension

Three cohort studies have demonstrated that regular physical activity prevents the development of hypertension. In the Harvard University alumni study (21), there was a 35% increased risk for the development of hypertension in sedentary versus active individuals. This risk was more pronounced in obese subjects. Blair and colleagues (30) found that, compared with physically-fit patients, subjects who were less fit had a relative risk of 1.5 for the development of hypertension. In a prospective study of Japanese men aged 35 to 60 years, Hayashi et al. (31) showed that milder forms of physical activity such as walking are associated with a reduction in the risk of developing hypertension. As a result of these and other studies, the National Institutes of Health now recommends regular physical activity for the prevention of hypertension (32).

In addition to preventing hypertension, regular exercise has also been found to lower blood pressure. In mildly hypertensive men, short-term physical activity decreases blood pressure for 8 to 12 hours after exercise, and average blood pressure is lower on exercise days than on nonexercise days (33). In severely hypertensive black men, moderate physical activity performed for 16 to 32 weeks results in a decrease in diastolic blood pressure that is sustained even after reduction in antihypertensive medications. In addition, a significant decrease in left ventricular (LV) hypertrophy has been reported as early as 16 weeks after the initiation of exercise (34).

Diabetes Mellitus

Physical activity has beneficial effects on glucose metabolism and insulin sensitivity, including increased sensitivity to insulin, decreased production of glucose by the liver, larger numbers of muscle cells that use more glucose than adipose tissue, and reduced obesity (35). In addition, there is evidence that regular exercise may

prevent the onset of diabetes mellitus. A study of male alumni from the University of Pennsylvania (36) found that for every 500 calories of energy expended per week participating in leisure-time physical activity, the age-adjusted risk for the development of type 2 diabetes mellitus decreased by 6%. Lynch et al. (37) found that men who participated in moderate physical activity for at least 40 minutes a week were at lower risk for developing type 2 diabetes. This risk reduction was even more pronounced in men at high risk for developing diabetes. In a population-based prospective study, men in the lowest level of cardiorespiratory fitness, as measured by maximal exercise treadmill time, had a 3.7-fold higher risk of developing diabetes compared with men in the highest fitness level (38). In a large prospective cohort study of women, the risk of developing type 2 diabetes was substantially decreased in women who either walked or exercised vigorously, as long as the total energy expenditure was the same (40). Among physically inactive men who already have type 2 diabetes, those with a low fitness level have higher all-cause mortality than those who exercise and are physically fit (39). However, the role of exercise in the prevention and treatment of type 1 diabetes mellitus is unclear.

Overweight and Obesity

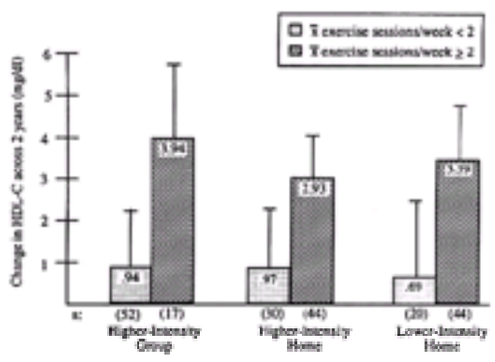
The prevalence of obesity has increased over the past 25 years, despite a reduction in fat intake. The most likely explanation for this national trend is an increase in total caloric intake, along with a reduction in physical activity (41). Using a body mass index of 25 or higher as “overweight” and a body mass index of 30 or higher as “obese,” nearly 106 million American adults age 20 and older are considered overweight (55 million men and 51 million women), and more than 43 million are considered obese (18 million men and 25 million women). In addition, an estimated 4.9 million children ages 6 to 17 are considered overweight (1).

Exercise training appears to be an important component for weight loss, although the effect of exercise is quite variable. Most controlled exercise training studies show only modest weight loss (approximately 2 to 3 kg) in the treated group versus the control group. When diet is added to exercise programs, the average weight loss is 8.5 kg (42,43). A well-controlled, 1-year randomized trial (44) that included 231 subjects demonstrated a significant 8.7-kg weight loss, most of which was body fat, in the exercise and diet intervention group and a significant 5.1-kg weight loss in the diet-only group. Those in the control group increased their weight by an average of 1.7 kg. Another randomized controlled trial involving 40 obese women demonstrated that moderate-intensity lifestyle activity combined with a low-fat diet resulted in favorable effects on weight loss, systolic blood pressure, and serum lipoprotein concentrations at 16 weeks and 1 year. Remarkably, the magnitude of benefit was similar to that observed in patients randomized to diet plus a structured program of aerobic exercise (45). These data strongly support the role of both exercise and diet in weight-loss programs.

Body composition and fat distribution are also linked to cardiovascular mortality (43) and are favorably affected by exercise. On average, exercise training programs reduce body fat by approximately 1.6% (42). Physically active men and women have a more favorable waist-hip ratio (p <0.9) than do sedentary individuals (46,47,48 and 49). Although significant, these changes are rather small, even after 1 year of diet and exercise (47). Importantly, physical activity appears to have favorable effects on lipoproteins, glucose metabolism, and blood pressure, even when weight loss is only modest (50).

Lipids

The effect of exercise on lipid levels has been an area of continued research. There is much variability in the results of exercise–lipid-lowering studies, at least in part due to the heterogeneity of the study methods, populations, exercise interventions, and the use of adjunctive interventions such as diet or pharmacologic lipid-lowering agents. A metaanalysis of 95 studies (51), most of which were not randomized controlled trials, concluded that exercise leads to a 6% reduction in total cholesterol, 10% in low-density lipoprotein cholesterol, and 13% in cholesterol/high-density lipoprotein cholesterol (HDL-C), and a 5% increase in HDL-C. The greatest changes in lipids were noted in patients who also lost weight during their exercise program. When body weight increased, lipid levels worsened. Intermediate changes were noted when body weight remained constant. It appears that the training intensities required to yield modest improvements in lipids are not as high as those that lead to improvements in fitness levels, as HDL appears to increase across a broad spectrum of exercise intensities (52,53) (eFig. 4.1.1). Moderate-intensity exercise (i.e., equivalent to briskly walking 10 miles per week), Step 2 AHA diet, and the combination of exercise plus diet were studied in a randomized controlled trial of postmenopausal women and middle-aged men. The most favorable changes in low-density lipoprotein (8% to 12% reduction) occurred among subjects in the diet and exercise group after 1 year. HDL levels decreased by 2% among women in the diet plus exercise groups, but among men there was a favorable increase of 2% (54).



***e*FIGURE 4.1.1** Graph depicts the relationship between the mean change in high-density lipoprotein cholesterol and frequency of exercise over a 2-year period of exercise training. Although the absolute change is small, the change was greater for subjects who exercised ³2 times per week compared with those who exercised <2 times per week, despite the intensity or location of exercise. HDL-C, high-density lipoprotein cholesterol. (From King AC, Haskell WL, Young DR, et al. Long-term effects of varying intensities and formats of physical activity on participation rates, fitness, and lipoproteins in men and women aged 50 to 65 years. *Circulation* 1995;91:2596–2604, with permission.)

In a study of 82 male and female patients with coronary disease, a 3-month exercise training program in conjunction with diet resulted in an 8% increase in HDL and a 22% decrease in triglycerides in subjects who had baseline triglyceride elevations. However, there was no significant improvement in body weight, low-density lipoprotein cholesterol, glucose level, or insulin level (55).

Few investigations of the effect of exercise on lipids and lipoproteins have been performed in women. Available prospective studies are contradictory (56,57 and 58). Because estrogen causes an increase in HDL-C (58), studies regarding women are also confounded by menopausal status and estrogen use, which are frequently not reported. A cross-sectional study examined the effects of vigorous exercise on HDL-C in female runners (59). HDL-C levels increased with increasing amounts of exercise and continued to rise, even in women who ran more than 64 km per week. For every additional kilometer run, the HDL-C increased by 0.133 to 0.200 mg/dL. This dose-response relation persisted in premenopausal and postmenopausal women, as well as in subjects on oral contraceptives and estrogen replacement therapy. Although these studies suggest an improvement in lipid profile with exercise training, the effects are quite modest. These improvements may have a favorable effect on cardiovascular risk; however, exercise is unlikely to normalize cholesterol levels in patients with true lipid disorders.

Thrombosis

Mounting evidence suggests that hemostatic parameters are important cardiovascular risk factors. Hemostasis is a balance between clot formation (thrombosis) and clot dissolution (fibrinolysis). This balance is especially important in CAD, in which the fibrinolytic system plays a protective role. The Framingham Study (60) has shown that elevated fibrinogen levels increase the risk for CAD in men and women between the ages of 47 and 59 years. In fact, patients in the upper tercile of fibrinogen levels had a two- to threefold higher incidence of CVD. Emerging evidence suggests that exercise training favorably affects the fibrinolytic system, which may help to explain the reduction in cardiac events observed in subjects who are more physically active. Strenuous endurance exercise for 6 months in healthy older patients (i.e., aged 60 to 82 years) resulted in a significant improvement in hemostatic parameters, a reduction in plasma fibrinogen levels of 13%, an increase in mean tissue-plasminogen activator (t-PA) of 39%, an increase in active t-PA of 141%, and a reduction of plasminogen activator inhibitor-1 of 58% (61). In contrast, younger patients (i.e., aged 24 to 30 years), whose baseline fibrinolytic variables were lower than the older group, had no significant change in fibrinogen, t-PA, or plasminogen activator inhibitor-1 activity. However, other studies have shown favorable effects of fibrinolytic enzymes after exercise training in younger subjects (62) and in patients after MI (63).

There is also evidence that acute and chronic exercise affect platelet activation. Platelet activation is important in the pathophysiologic mechanisms of unstable coronary syndromes and acute MI. Kestin et al. (64) studied the effects of treadmill exercise on platelet activation in sedentary and physically fit individuals. After acute strenuous exercise of similar duration and intensity, platelet activation and hyperreactivity were increased in sedentary subjects but remained unchanged in physically fit subjects. Rauramaa et al. (65) demonstrated that regular, moderate-intensity physical activity in middle-aged, overweight, mildly hypertensive men results in decreased platelet aggregation. After the 12-week exercise program, the study subjects demonstrated a 52% reduction in secondary platelet aggregation compared with a 17% decrease for the control group. Thus, it appears that, although acute exercise can lead to increased platelet activity, especially in sedentary individuals,

regular exercise may abolish or improve this response.

Inflammation

Growing evidence suggests that inflammation plays a role in atherosclerosis. In a recent study, serum levels of cytokines and C-reactive protein levels were measured in 52 volunteers in a 6-month, moderate-intensity exercise program who were at risk for ischemic heart disease. Atherogenic cytokine production fell significantly after the training period, as did levels of C-reactive protein (66).

Endothelial Function

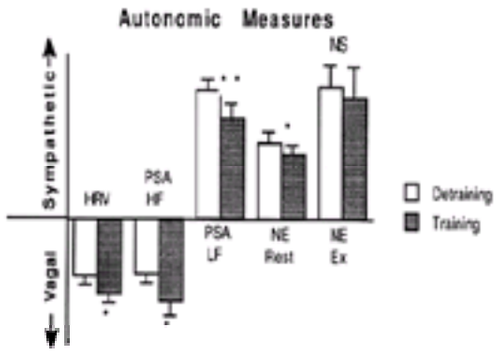
The vascular endothelium plays an important role in the regulation of arterial tone and local platelet aggregation, in part through the release of nitric oxide (NO) (67). NO produces vasodilation and inhibits platelet adhesion and aggregation by a guanylyl cyclase–dependent mechanism in vascular smooth-muscle cells and platelets. These effects are associated with an increase in platelet cyclic–guanosine monophosphate. Release of NO is stimulated by serotonin, thrombin, acetylcholine, and other receptor-dependent agonists (67). NO release is also stimulated by increased shear stress associated with acute and chronic increases in blood flow (68,69). Endothelium-dependent dilation is impaired in patients with coronary atherosclerosis or coronary risk factors, including hypercholesterolemia, diabetes mellitus, cigarette smoking, and hypertension (70,71 and 72). Patients with peripheral arterial disease have also been shown to have impaired endothelium-dependent vasodilation in the presence of cardiac risk factors (73). Convincing evidence exists that impaired NO action in atherosclerosis contributes to the pathophysiology of myocardial ischemia in patients with stable and unstable coronary syndromes (71,72,74).

An improvement in endothelial function in such patients has the potential to improve outcome. Growing evidence suggests that exercise improves endothelial function (75). Recent animal studies suggest that an important consequence of chronic exercise is an improvement in vasomotor function. This manifests by increased endothelium-dependent vasodilation in response to increased blood flow and clinically relevant NO agonists (76,77). High-resolution brachial artery ultrasound assessment of flow-mediated dilation has been used and validated as a model to evaluate endothelial function (78,79). Brachial artery diameter is measured at baseline and after reactive hyperemia produced by 5 minutes of cuff occlusion of the upper arm. Relative increases in diameter from baseline are used as measures of endothelium-dependent, flow-mediated dilation. Using this method, Clarkson et al. (80) showed that exercise training improved endothelium-dependent, flow-mediated dilation in young, healthy men. This effect was present in patients with and without CAD risk factors and was not related to lipid levels. Similar effects were demonstrated in patients with heart failure (HF) (81). Aging has been associated with a progressive decline in endothelium-dependent vasodilation, which may partially explain the increased risk of atherosclerosis in the elderly. A cross-sectional study of 68 healthy men demonstrated that regular aerobic exercise prevented this age-associated decline in endothelial function (82). A separate study suggests that the mechanism of the improvement in endothelial function in trained elderly athletes may be an increase in the availability of NO (83).

A seminal study by Hambrecht et al. (84) assessed whether exercise training affects endothelial function in the coronary circulation. In a randomized controlled trial, improvement in coronary endothelial function and coronary flow reserve in men with CAD was demonstrated. After 4 weeks of exercise training, significantly less coronary vasoconstriction in response to acetylcholine was observed.

Autonomic Function

The balance between sympathetic and parasympathetic activity modulates cardiovascular activity. Enhanced sympathetic nervous system activity, which may occur with aging, may be a risk factor for cardiac events. Heart-rate variability (HRV) is a well-accepted noninvasive technique for assessing autonomic tone. HRV increases with higher parasympathetic tone and decreases with sympathetic stimulation. Thus, higher HRV implies augmentation of parasympathetic tone, which may protect against cardiovascular morbidity and mortality. In healthy subjects, HRV appears to be related to exercise training. In a cross-sectional study, Goldsmith et al. (85) evaluated HRV in eight endurance-trained men and eight age-matched controls. Using 24-hour Holter monitors, they found that the standard deviation of the RR intervals, the average RR interval, and the high-frequency power were greater in the trained group, suggesting that exercise training increases parasympathetic tone. In another cross-sectional study, DeMeersman et al. (86) compared HRV in 72 male runners with sedentary age-matched controls. HRV was significantly higher in the physically fit patients, implying higher parasympathetic tone. Whether exercise affects autonomic tone in patients with CVD is unclear. Coats et al. (87,88) found that exercise training increased HRV in 17 patients with chronic HF (eFig. 4.1.2). However, in a recent randomized controlled trial of 25 men with new-onset LV dysfunction after MI, 2 months of high-intensity exercise training did not alter HRV at 1, 2, and 12 months compared with controls (89).



***e*FIGURE 4.1.2** Bar graph demonstrates the effect of exercise training and detraining on parameters of autonomic function. Training results in higher heart-rate variability (HRV) but lower spectral power of the low-frequency component of HRV (PSA LF) and norepinephrine (NE) spillover. This indicates higher vagal and lower sympathetic tone in exercise-trained subjects compared with detrained subjects. Ex, exercise; NS, not significant; PSA HF, spectral power of the high-frequency component of HRV. [From Coats AJS. Exercise rehabilitation in chronic heart failure. *J Am Coll Cardiol* 1993;22(Suppl A):172A–177A, with permission.]

Other markers of sympathetic tone, such as responses to various stressors, are influenced by physical training. In one study, 37 men with type A personalities were randomized to aerobic or weight-training programs for 12 weeks (90). The aerobic group showed improvement in functional capacity and lower sympathetic responses to a variety of mental stressors compared with the weightlifters. This response manifested as lower heart rate, rate-pressure product, diastolic blood pressure, and epinephrine levels in the aerobically trained individuals during the performance of mental arithmetic. Compared with sedentary individuals, subjects who exercise daily have been found to have lower norepinephrine spillover rates—a measure of sympathetic activity (91). These data suggest that regular aerobic exercise reduces sympathetic responses, which may be an important factor in reducing the risk for CAD. Whether these benefits extend to patients with CVD is unclear.

Mental Health and Quality of Life

There is evidence that physical activity improves psychological well-being; however, these data are less convincing than those regarding physical benefits. In general, exercise is associated with decreased anxiety and depression and an increased sense of well-being (92). Psychological benefits have also been found in cardiac patients who are more physically active (93). Several studies also have evaluated the effect of exercise on quality of life among patients with CVD. In a recent randomized controlled trial of moderate exercise training in patients with HF, measures of quality of life were significantly improved in patients who exercised (94).

PHYSIOLOGY OF EXERCISE

Types of Exercise

Most types of exercise involve endurance and resistance training. However, usually one type of training predominates. The physiologic responses to exercise lead to specific muscular, neurohumoral, and cardiovascular adaptations that depend, in part, on the type of exercise performed.

Endurance

Endurance (aerobic, dynamic) training consists of dynamic or isotonic exercise, which involves high-repetition movements against low resistance. Examples include walking, jogging, swimming, or cycling. Isotonic exercise implies that muscles shorten but maintain a constant tension, although tension does change to some degree during exercise (11). Endurance exercise involves rhythmic contraction and relaxation of working muscles. This results in increased blood flow to active muscles during

relaxation and increased venous return to the heart from the working muscles during contraction. Regular dynamic exercise is referred to as *endurance training*, because it results in improved functional capacity, enabling the individual to exercise for a longer duration or at a higher workrate.

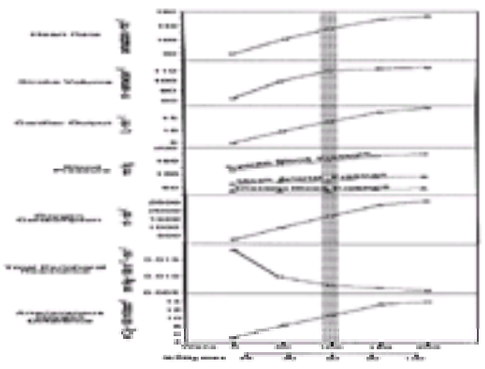
Resistance

Resistance training, also called *static exercise*, involves low-repetition movements against high resistance. This training may also be referred to as *isometric exercise*, because muscle tension develops predominantly without muscle shortening. An example of resistance training is weightlifting. The development of muscle tension during resistance training restricts blood flow during contraction. Regular resistance training leads to increased strength and is commonly referred to as *power* or *strength training*.

Cardiovascular Responses to Acute Exercise

Hemodynamic Changes

The cardiovascular system must respond in several ways to meet the demands of exercising muscles (95) (eFig. 4.1.3). The heart and peripheral blood vessels work together with neurohumoral stimuli and the muscle beds to increase oxygen supply to exercising muscles, clear byproducts of metabolism and heat produced by working muscles, and deliver neurohumoral substances to target tissues. The acute hemodynamic changes with exercise include increased $\dot{V}O_2$, heart rate, stroke volume, and systolic blood pressure. The amount that each of these parameters changes depends on which limbs are exercising (upper vs. lower), body position, and type of muscle contraction (isotonic vs. isometric).



***e*FIGURE 4.1.3** Cardiovascular and hemodynamic responses to acute exercise in the untrained subject. The shaded area represents the lactate threshold. Workrate is plotted along the x-axis. $\dot{V}O_2$max, maximal oxygen uptake. (From Durstine LJ, Pate RR, Branch JD. Cardiorespiratory responses to acute exercise. In: Durstine JL, King AC, Painter PL, et al., eds. *ACSM resource manual for guidelines for exercise testing and prescription*, 2nd ed. Philadelphia: Lea & Febiger, 1993:66–74, with permission.)

Contraction and relaxation of skeletal muscle are energy-dependent processes requiring the use of oxygen in the generation of adenosine 6-triphosphate. As a result, $\dot{V}O_2$—a measure of energy expenditure and oxygen use by exercising muscles—must increase from resting values. $\dot{V}O_2$ is linearly related to cardiac output (stroke volume × heart rate) and arteriovenous oxygen (AVO_2) difference (i.e., the amount of oxygen extracted from blood by peripheral tissues). Levels of $\dot{V}O_2$ 15 to 20 times higher than baseline can be attained during exercise due to augmented cardiac output or enhanced extraction of oxygen from the blood (96). The average resting AVO_2 difference is 5 mL/100 mL. During maximal exercise, enhanced oxygen extraction by exercising muscles can result in an increased AVO_2 difference up to 16 mL/100 mL (97). The $\dot{V}O_2$max of an individual is the best measurement of fitness and aerobic work capacity.

Cardiac output can augment four to five times from its baseline during endurance exercise and is influenced by body position, age, gender, fitness, and presence of cardiac disease. Higher cardiac output is the result of increased heart rate and stroke volume (97). As exercise increases, stroke volume increases until approximately 50% of maximum exercise capacity is reached, after which higher cardiac output is due to faster heart rate. The increase in stroke volume results from multiple neurohumoral stimuli, including sympathetic tone, epinephrine, and norepinephrine. In addition, endurance training results in augmented venous return from contracting muscles, leading to increased LV end diastolic volume. The greater stretching of the left ventricle results in increased stroke volume by 1.3 to 1.5 times baseline due to the Frank-Starling mechanism (97,98). Heart rate can increase 2.0 to 2.5 times baseline due to augmented sympathetic tone and diminished parasympathetic tone, in addition to increased epinephrine and norepinephrine (99).

Total peripheral resistance decreases during endurance exercise due to arteriolar vasodilation in exercising muscles. Vasodilation, which probably results from a decrease in local pH due to metabolic byproducts such as carbon dioxide and lactate, predominates over the vasoconstrictor effects of increased sympathetic tone. The net effect is a decrease in diastolic blood pressure—an indicator of peripheral resistance—and an increase in systolic blood pressure due to increased cardiac output (97). With resistance training, isometric contraction of skeletal muscle causes an increase in systolic and diastolic blood pressure, both of which fall abruptly during relaxation (100). This event results in increases in heart rate and blood pressure that are proportional to the intensity of contraction, size of the muscles involved, and duration of contraction (101).

The extent to which each of these hemodynamic parameters changes depends on body position and the specific muscle group that is being exercised. A comparison of dynamic arm and leg exercise can help to elucidate these differences. With submaximal dynamic arm exercise, there is less arteriolar dilation than with leg exercise because the muscle group is smaller. This characteristic results in higher total peripheral resistance due to vasodilation in the smaller vascular bed of the arm and vasoconstriction in the larger, nonexercising vascular bed. The increased total peripheral resistance, in turn, leads to a higher diastolic blood pressure than that seen with leg exercise. In addition, heart rate is faster during arm exercise due, in part, to differences in sympathetic tone. Arm exercise also leads to smaller increases in cardiac output because of lower volumes of blood returning to the heart from the smaller muscle mass of the arm (102). $\dot{V}O_2$max during arm exercise is approximately 70% of that during leg exercise (98), whereas, at a similar submaximal $\dot{V}O_2$, arm exercise requires lower workrates than does leg exercise.

Both age and gender have an effect on physiologic responses to exercise. Men can exercise to higher peak workrates and $\dot{V}O_2$ than can women. Peak workrates in older individuals are lower than in younger subjects. In addition, at matched workrates, $\dot{V}O_2$ is higher in older subjects (103,104).

Changes in Myocardial Oxygen Demand

As a result of increased oxygen demand by exercising muscles, the heart must augment stroke volume and heart rate, leading to an increase in blood pressure, LV contractility, and wall stress (98). These alterations, which increase with exercise, result in greater myocardial oxygen demand. A reliable estimate of myocardial oxygen demand is the rate-pressure product (i.e., the product of the heart rate and systolic blood pressure) (105). Coronary arteries respond to increased demand for oxygen by augmenting coronary blood flow, which is dependent on coronary perfusion pressure, the diameter of the coronary artery lumen, and distal coronary resistance. Coronary blood flow is controlled by neurohumoral stimuli and local endothelial factors—all of which regulate vasomotor tone. Neuromodulation of the coronary vasculature is regulated, in part, by the increase in sympathetic tone that occurs with exercise. The net effect of alpha- and beta-adrenergic stimulation in normal arteries is vasodilation. The endothelium produces various vasoactive substances that regulate vasomotor tone. Vasodilation in normal coronary arteries results from the release of NO and prostaglandins, which are produced in response to various stimuli such as increased flow and shear stress (68).

Myocardial responses to acute exercise in patients with CAD or reduced LV systolic function differ from responses of normal subjects. Luminal narrowing of the coronary artery results in a supply-demand mismatch for oxygenated blood during physical activity. This mismatch manifests as myocardial ischemia and myocardial dysfunction due to an inability of the coronary artery to deliver sufficient amounts of oxygenated blood to meet the increased oxygen demands of the heart. In patients with normal LV function, functional capacity may be limited by symptoms of angina. Myocardial dysfunction may lead to increased LV end diastolic pressure, resulting in dyspnea. Alternatively, diminished myocardial contractility may lead to a reduced cardiac output, thereby limiting the supply of oxygenated blood to exercising muscles and producing fatigue (99). Patients with reduced systolic function and HF have altered hemodynamic responses to exercise that may impair exercise tolerance. These individuals have reduced cardiac outputs with exercise due to a blunted heart-rate response and failure to increase stroke volume. As a result, systolic blood pressure is reduced; however, the total peripheral resistance is elevated. Thus, a smaller portion of the cardiac output reaches the exercising muscles, leading to

increased anaerobic metabolism and lactate production. The resulting acidosis causes muscle fatigue and discontinuation of exercise (99,106).

Responses to Exercise Training

Regular endurance or resistance training results in specific changes in the muscular, cardiovascular, and neurohumoral systems that lead to improvement in functional capacity and strength. These changes are referred to as the *training effect* and allow an individual to exercise to higher peak workrates with lower heart rates at each submaximal level of exercise.

Muscular Adaptations

Regular endurance training results in changes in skeletal muscle, including increases in mitochondria, myoglobin, capillary density, and metabolic enzymes (107). The increased mitochondrial number is specific to the muscle group exercised. For example, runners have more mitochondria in their lower-extremity muscles than in their arm muscles. Additional capillaries in skeletal muscle serve to aid in the exchange of nutrients and metabolic byproducts during exercise (108). Increased metabolic enzymes enhance a muscle's capacity for converting glycogen and fatty acids to adenosine 6-triphosphate. With endurance training, more energy is derived from fatty-acid metabolism, and glycogen stores are spared (107). As a result, less lactate is produced, and endurance is enhanced. The net effect of the changes in skeletal muscle is to promote aerobic metabolism, which, in turn, improves exercise capacity.

In contrast to endurance training, regular resistance training leads to muscle-cell hypertrophy due to increased synthesis of contractile proteins and connective tissue (109).

Cardiovascular Adaptations

Endurance training results in increased venous return to the heart, which leads to higher LV volumes. Resistance training exposes the patient to chronic increases in afterload due to increased total peripheral resistance and elevated blood pressure, yielding a greater LV wall thickness. These effects result in increased LV mass in both training groups. However, the LV mass–lean body mass ratio is elevated in the endurance trainer, whereas it is normal in the resistance trainer (110). The increase in LV mass in the resistance trainer is proportional to the increase in skeletal muscle mass.

Along with changes in myocardial mass, certain hemodynamic effects are observed from endurance and resistance training. Wall stress at rest in endurance trainers is normal; however, it is lower in resistance trainers due to increased wall thickness without ventricular dilation (111). Systolic function and fractional shortening at rest are normal in both groups. However, compared with nonathletes, stroke volume is increased due to greater end diastolic volumes (111,112). Despite increased LV wall thickening, diastolic function appears to be normal in both groups (113). A cross-sectional study comparing the effects of long-term training among distance runners and wheelchair athletes demonstrated that long-term arm exercise and leg exercise yield increases in LV volume and mass—although to a lesser degree in arm-trained athletes—compared with untrained control subjects (114).

The decline in $\dot{V}O_2$max (exercise capacity) seen with aging has also been shown to be attenuated by habitual exercise. A recent study (115) aimed to explain this observation and noted that, after exercise training, peak leg blood flow increased by 50%, although there was no change in peak cardiac output. This occurrence suggests that exercise yields a reversible deconditioning effect on the distribution of cardiac output to exercising muscle. In patients with CAD, there appears to be less ischemia for a given rate-pressure product after exercise training compared with that before training. Improvements in ischemic threshold manifest as less angina (116), ST-segment depression (117), and thallium defects (118) at the same levels of exercise. These findings suggest that exercise training improves myocardial oxygen supply in patients with CAD. The specific mechanisms responsible are unclear; however, possible explanations include improvement in endothelial function and vasomotor tone, decreased sympathetic tone, and alterations in blood rheology.

Neurohumoral Adaptations

Neurohumoral responses to exercise manifest as lower resting heart rate and reduced heart rate at any level of submaximal exercise. The diminished heart rate at rest and with exercise is due to increased resting parasympathetic tone and decreased sympathetic tone. Lower levels of circulating catecholamines are observed in trained versus untrained individuals (90,91), whereas the number and sensitivity of beta-adrenergic receptors appear unchanged with exercise training (119).

Detraining

Cessation of exercise training for as little as 3 weeks can lead to some loss of the training effect. This may be partially due to the reduction in LV size and stroke volume as a consequence of the absence of increased cardiac filling, which occurs with exercise (120). The lower preload results in less stretching of the myocardium and a lower stroke volume, according to the Frank-Starling mechanism.

PHYSICAL ACTIVITY AND EXERCISE: PRESCRIPTION FOR HEALTH AND FITNESS

Energy Expenditure

Major public health statements have generated recommendations regarding the amount of exercise and physical activity that should be performed each week to generate health benefits. It is important to note that these recommendations are based on studies performed almost exclusively on men, although recent years have witnessed an increasing number of studies performed on women.

Intensity, Frequency, and Duration of Physical Activity

The CDC, ACSM (8), and Surgeon General (6) recommend that adults exercise for 30 minutes at moderate-intensity levels on most, if not all, days of the week to achieve a weekly energy expenditure of at least 1,000 kcal. These statements stem from evidence stating that regular moderate physical activity provides many health benefits. In addition, these recommendations stress that physical activity can be accomplished in multiple short intervals—which may be more feasible for many individuals—rather than continuous 30-minute exercise sessions. Low-intensity exercise should be performed more frequently and for longer duration.

The CDC recommendations are based on data that suggest that the benefits of exercise are related to the total energy expenditure or dose measured in calories or duration of physical activity. Observational studies have shown that cardiovascular mortality decreases when duration of exercise increases from 15 to 47 minutes per day and when caloric expenditure increases from 500 to 2,000 calories per week (16). A recent study of 7,307 Harvard University alumni demonstrated that brief durations of physical activity—as short as 15 minutes—conferred as much of a reduction in CHD risk as longer sessions, as long as the total energy expenditure was equivalent (121). However, an important question remains regarding the intensity of physical activity required to incur a mortality benefit. Intensity can be defined in terms of reflecting the rate of energy expenditure during exercise (expressed in METs or kcal per minute) or the relative percentage of maximum aerobic capacity that is maintained during the exercise or activity (expressed in terms of percentage of maximum heart rate or percentage of $\dot{V}O_2$max achieved on exercise tests) (8). The data regarding exercise intensity are much less clear than those addressing dose. Lee et al. (122) have reported that only energy expended during vigorous activity (>6 METs) yielded a mortality benefit among Harvard University alumni. More recent data from this cohort similarly demonstrate that moderate activities (<6 METs) have no clear association with risk of CHD and that men older than 60 years with coronary risk factors who expended more than 1,000 kcal per week had less CHD risk, as did men without risk factors. The intensity of physical activity was associated with a 20% reduction in CHD risk (29). Conversely, walking also has been shown to reduce the incidence of coronary disease in a large sample of elderly subjects, with a proportionately lower incidence of CVD in men who walked more than 1.5 miles per day (29). One must consider however, that brisk walking in elderly persons may be at moderate-intensity relative to their peak exercise capacity but, in absolute terms, is <6 METs. Similarly, prospective data from the Nurses Health Study suggest that brisk walking (3 to 4 miles per hour; 2.5 to 4.5 METs), as well as vigorous exercise (>6 METs), is associated with a substantial reduction in the risk for CVD (124).

Training Modalities

Modalities for training can be categorized by the specific muscle groups that are exercised, such as arms, legs, or both. In addition, different modalities emphasize predominantly endurance or resistance exercises (*e*Table 4.1.3).

***e*TABLE 4.1.3** TYPES OF EXERCISE
Lower extremity
Endurance Walking
Jogging/running

	Climbing stairs
Resistance	Leg extension, curls, press
	Adductor/abductor
Upper extremity	
Endurance	Arm ergometry
Resistance	Biceps curls
	Triceps extension
	Bench/overhead press
	Lateral pull down/raises
	Bench-over/seated row
Combined upper and lower extremity	
Endurance	Rowing
	Cross-country ski machines
	Combined arm/leg cycle
	Swimming
	Aerobics

Endurance Lower-Extremity Exercise

Endurance leg exercise is the most common form of physical activity performed. Examples include walking, running, cycling, and climbing stairs. When calculating workrate (force × distance/time), it is important to take into consideration whether the activity is a weight-bearing exercise (walking or running) or a non–weight-bearing exercise (cycling). This consideration is due to the fact that during weight-bearing exercise, body weight is a major component of force; during non–weight-bearing exercise, body weight is supported and, consequently, is a much smaller component of force (125).

Walking

Walking is a common form of exercise that is highly feasible for the general population, because it does not require special equipment or the mastery of a new technique. Brisk walking (3 to 4 miles per hour) is considered moderate exercise for most individuals. A slower pace is frequently an adequate intensity for the elderly, because they have a lower maximum peak heart rate and $\dot{V}O_2$; thus, less exercise is needed to achieve a training effect. Walking is commonly prescribed in cardiac rehabilitation programs.

Individuals can walk indoors or outdoors. Exercise intensity can be regulated using a treadmill, because the speed and grade can be altered. It should be kept in mind that holding onto the handrail of a treadmill reduces the amount of work performed. Ideally, one should walk without holding the handrail or use it for balance only. Hand-held weights and elevations in grade can increase training intensity. A recent study in healthy volunteers compared energy expenditure at various perceived exertion levels for various indoor exercise machines (126). Although the results suggest that energy expenditure was highest with treadmill exercise compared with cross-country ski machines, rowing, stair-climbing machines, and stationary bicycles, additional studies are needed to confirm these results.

Jogging and Running

Jogging and running are higher-intensity forms of exercise than walking. As with walking, no special equipment or instruction is needed to begin. However, due to the higher impact, injuries are more common than with walking. Jogging on shock-absorbing surfaces can help to decrease the impact.

Stair-Climbing

Stair-climbing has become popular due to the advent of stair-climbing machines. Different intensities and exercise programs can be performed. In this type of exercise, holding onto the handrails decreases exercise intensity. Stair-climbing is used in many fitness programs and provides exercise diversity to prevent boredom.

Cycling

Cycling is another popular dynamic lower-extremity exercise. Stationary bicycles take up little space and are relatively inexpensive compared with other types of training equipment. These bicycles are ideal for individuals who are insecure on a treadmill or who have orthopedic or neurologic impairments that cause unsteady gait. The workrate is dependent on the force exerted on the flywheel, the resistance of which can be altered. Off-road cycling has become extremely popular. Unlike walking or jogging, cycling must be learned and involves muscle groups that are not usually required for everyday activity. As a result, the initial exercise capacity during cycling may be low, especially in the elderly.

Endurance Upper-Extremity Exercise

As previously discussed, the physiologic responses of endurance upper-extremity exercise are different from those of lower-extremity exercise in that the arms have a smaller muscle mass. Given the location of the arms, arm exercise often requires the use of other muscle groups (e.g., chest, back, legs, and buttocks) for stabilization. This requirement results in a curvilinear response of the $\dot{V}O_2$ with increasing workrates, leading to less predictable changes in heart rate and blood pressure (103). Consequently, the $\dot{V}O_2$ for any submaximal arm work exceeds that for leg work, resulting in expenditure of more calories for the amount of external work performed during arm exercise. Compared with leg exercise, arm exercise at matched submaximal workrates also leads to higher ventilation, blood pressure, heart rate, total peripheral vascular resistance, and cardiac output. The total peripheral resistance is higher with arm exercise than with lower-extremity exercise, because there is less vasodilation in the smaller vascular bed of the arm. The smaller muscle bed also results in less blood returning to the heart and, thus, smaller increases in cardiac output (102).

Arm Ergometer

An arm ergometer is a commonly used device for upper-arm exercise. The workrate can be adjusted by altering the resistance against the flywheel. Revolution rates of 60 to 80 per minute for 5- to 10-minute intervals are recommended for upper-extremity endurance training. This exercise is performed with the individual seated and the fulcrum of the handles set at shoulder height.

Many training modalities combine endurance exercise of the upper and lower extremities. Examples include cross-country ski machines, rowing machines, combined arm-leg ergometers, swimming, and aerobic dance. Given the strenuous nature of many of these exercises, they are not recommended for individuals with low functional capacity who are beginning an exercise program or with serious disabilities.

Resistance Exercise

By improving strength and muscle endurance, resistance training can be beneficial to all individuals because routine, daily activities frequently involve a combination of isotonic and isometric effort. Although weight training was believed to be unsafe for cardiac patients, recent data have documented its safety and efficacy in cardiac rehabilitation programs. Resistance exercise performed 2 to 3 days per week is now advised to complement aerobic training in individuals with and without CVD (127).

Equipment for resistance training may include free weights, wall-mounted pulleys, or exercise machines with stackable weights. Exercise should be performed in a manner that isolates specific muscle groups, using movements of slow to moderate speed and encompassing full ranges of motion. Special instruction is recommended to avoid musculoskeletal injury. The exercises should involve the anterior and posterior of each large muscle group, such as the biceps and triceps of the arm, the chest and back of the torso, and the hamstrings and quadriceps of the legs. Resistance intensity can be varied by changing the amount of weight, the number of repetitions, and the number of sets.

Risks of Exercise

The inherent risks of physical activity must be considered to promote the health benefits of exercise while minimizing injury. Because nearly every activity carries some risk, the risk-benefit ratio must be examined for each individual. Major hazards involve the cardiovascular and musculoskeletal systems.

Cardiovascular Risks

The risks of cardiovascular morbidity and mortality depend on whether one studies the general population or individuals with CAD. Although the risk of death during exercise is low, death in individuals over 35 years of age is usually the result of atherosclerotic CAD, whereas younger individuals are more likely to suffer from congenital cardiac malformations (128). The incidence of sudden cardiac death during exercise for the population at large is 1 in 565,000 events per hour (129). The risk of sudden death during exercise is much lower for young individuals than for middle-aged and older adults. Among high school and college athletes, the sudden death rate is estimated to be 1 in 133,333 male athletes and 1 in 769,230 female athletes (130). The exertionally related sudden death rate in previously healthy middle-aged men is approximately 6 to 7 in 100,000 events per year (131,132).

For healthy sedentary men, the risk of cardiac arrest is 56 times higher during exercise compared with times of inactivity. In contrast, the risk for active men during exercise is five times the risk during times of inactivity. Despite this transient increased risk during strenuous exercise, regularly active men have a cumulative cardiac arrest risk that is 40% lower than the risk in inactive men (132). In a prospective study of 21,481 male physicians who were reportedly free of CAD, the relative risk of sudden death after an episode of heavy exertion was 1.9. However, the absolute risk of dying was extremely low (1 in 1.5 million episodes of exertion). Furthermore, habitual vigorous exercise was associated with a significant reduction in the incidence of sudden death (133). This and other studies (132,134) demonstrate that the risk of primary cardiac arrest during exertion is reduced among those who are physically active.

There is also evidence that heavy exertion may trigger acute MI. Two studies have found that the relative risk for MI within 1 hour after strenuous physical exertion was increased by two to six times that of patients who were sedentary or less active during that hour (135,136). However, the risk was inversely related to the amount of leisure-time physical activity performed by the subjects. Thus, the more active the individual, the lower the risk for developing acute MI during strenuous exertion. There is also evidence that sexual activity can trigger acute MI; however, the risk is low (137). The relative risk for MI within 2 hours of sexual activity was 2.5 in healthy subjects, 2.1 in those with a history of angina, and 2.9 in those with a history of MI. The absolute risk for MI in all groups was low and was not increased in individuals with CAD. In addition, the risk was reduced in individuals who exercised regularly.

In individuals with known CAD, exercise training is relatively safe. In a study of 167 cardiac rehabilitation programs involving 51,000 patients, the incidence of cardiac arrest was 1 in 112,000 person-hours, with a successful resuscitation rate of 86% (138). The incidence of MI was 1 in 294,000 person-hours, and the incidence of death was 1 in 784,000 person-hours. More recent data from a single cardiac rehabilitation center report the incidence of major cardiovascular complications to be 1 in 60,000 participant-hours, with no deaths occurring (139). Limited data are available regarding home exercise in patients with cardiac disease. Using heart-rate monitors and transtelephonic electrocardiographic transmission, DeBusk and colleagues (140) found a similar rate of reinfarction and death after 26 weeks in patients randomized to home training versus subjects randomized to group training. Similarly, Ades et al. reported no major cardiac arrest or death during 3,100 hours of home exercise (141).

Musculoskeletal Risks

The risk of musculoskeletal injury depends on the type of exercise performed, as well as the intensity. The incidence of injury to runners is high, with approximately 35% to 65% of individuals sustaining injuries per year (142). Injuries tend to increase as running distance increases; injuries also increase in sedentary individuals who begin a vigorous exercise program (143). In runners, the most common site of injury is the knee (143); however, the foot, ankle, and lower leg are also at risk (144). Upper-extremity exercise (e.g., racquet sports, baseball, and swimming) may lead to difficulties with the hand, wrist, elbow, and shoulder.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Promotion of Physical Activity

The message from America's leading scientists is clear, unequivocal, and unified: physical inactivity is a risk factor for CVD. It is highly prevalent and is a matter of public health. This unprecedented focus on physical activity and exercise is the product of copious research, including epidemiologic observational studies, cohort studies, randomized controlled trials, and basic research. It is clear that the promotion of physical activity has reached the forefront of our national public health agenda, as manifested by the publication of the 1996 Surgeon General's report on physical activity and health (6). Much work remains to promulgate this message and implement strategies to achieve the ambitious goals of the Healthy People 2010 objectives (145). Broad-based efforts that affect every level of our social infrastructure are needed ultimately to impact the health status of the United States. Although educational and media campaigns that directly target youth and adults are essential, these efforts must be supported by policy makers, legislators, educators, health care providers and insurers, employers, community leaders, and researchers.

Federal, state, and local governments must adopt policies that foster the promotion of physical activity. Physical education programs in schools throughout our nation are vital for the development of positive attitudes and the acquisition of appropriate knowledge and skills that foster active and healthy lifestyles throughout adult years. All individuals should develop an understanding and appreciation of the benefits that can be derived from the wide range of physical activity options. The nature of these activities range from everyday house chores to organized sports, from walking the dog to running on a treadmill. Physicians, nurses, and allied health care providers play a pivotal role in counseling their patients on physical activity and influencing subsequent behavior. These initiatives by the health care team must, in turn, be supported by government and private health insurance providers, who must realize that appropriate lifestyle interventions can reduce or eliminate a large number of health risks and, ultimately, reduce health care costs. Communities and employers have remarkable opportunities to provide environments and incentives to promote physical activity. Finally, scientists and researchers should be stimulated to answer the many remaining questions regarding physical activity, exercise, and health. Of course, such work cannot be done without the much-needed support of federal and private funding agencies. Funding opportunities and initiatives for clinical, behavioral, and basic research in this area are essential to transform present-day goals into future reality.

Dose and Intensity of Physical Activity

Despite the large body of literature from more than half a century of research in the area of physical activity, large gaps in the knowledge base remain. A prudent conclusion has been drawn from the studies to date: moderate-intensity activity for 30 minutes a day leads to health and, presumably, mortality benefits. Inherent properties in this recommendation are dose (i.e., total energy expanded per week) and intensity (i.e., the energy requirements per unit of time for a given activity). Prospective, randomized controlled trials are needed to evaluate variations of dose versus intensity of activities on specific health outcomes—including definite cardiac events—in any large representative cohort of the population or among any specific subgroup (e.g., youth, elderly, patients with known CVD). Recent studies indicate that exercise training of low to moderate intensity can increase physical fitness and result in improvements in several health variables (e.g., insulin sensitivity, HDL levels, blood pressure). Epidemiologic data support the relation of moderate-intensity activity to lower mortality; however, intensity of activity in these studies is not directly measured, but it is categorized based on estimated energy requirements per unit of time or subjective perception of activity intensity. Indeed, the lowest threshold for dose or intensity to achieve specific cardiovascular benefit is not known, nor is the ideal dose-intensity prescription for specific biologic outcomes or total cardiovascular health.

Considering the high prevalence of physical inactivity among American youth and adults, the existing broad-based public health recommendations are reasonable and scientifically sound. However, it is hoped that customized activity prescriptions tailored to individual needs, risks, and benefits will someday replace the current generic recommendations.

Medical Screening before Exercise

It is anticipated that the public health efforts to promote physical activity will impact all Americans, including the one in four who have some form of CVD. Although regular exercise leads to health benefits, the incidence of cardiovascular events during exercise is estimated to be 10 times greater than that at rest among otherwise healthy persons (129). The CDC (6) and AHA (129) conclude that most persons do not need to see their physician before starting a moderate-intensity physical activity program. However, it is advised that men older than 45 years and women older than 55 years who plan to start a program of vigorous intensity (>60% $\dot{V}O_2$max) or individuals with risk factors, signs, or symptoms of cardiovascular or chronic disease consult their physician to design an exercise program. These recommendations seem reasonable, yet are they practical? Should asymptomatic men and women, based on their age, undergo a screening exercise test before participation in exercise training programs designed to improve fitness, strength, or both? Indeed, the utility of the exercise test in screening asymptomatic individuals may often result in false-positive tests, which may cause undue concern and lead to further, more expensive and invasive tests. Conversely, are the many individuals with CVD who do not seek regular evaluation by a health care professional placing themselves at significantly increased risk by beginning an unsupervised exercise program at home or at a fitness club? The specific answers to these questions remain unknown, as there are no scientific data that evaluate the benefits, costs, and potential risks of specific medical screening practices—or the lack thereof—for individuals who are about to begin or who are actively participating in moderate- to vigorous-intensity exercise programs. As such, current recommendations must be left to expert consensus opinion until more data are available. General medical screening guidelines (6,127,129) and those directed at cardiovascular screening at fitness facilities (146) must be promulgated to the public and the health care professional in concert with efforts promoting physical activity.

THE FUTURE

Evidence regarding the health benefits of physical activity is overwhelming; however, there are many unanswered questions, and future research is needed. For example, further study of the specific mechanisms responsible for the decrease in cardiovascular events, as well as total mortality, is needed. In addition, whether specific physiologic and biochemical changes differ among the various types of exercise is undetermined. For instance, what are the effects of chronicity, intensity, and duration of activity on these parameters? The effects of physical activity in persons of different age, gender, race, and ethnicity are unknown (9). Moreover, no prospective, randomized controlled trial has compared the effects that the high-dose versus low-dose range of these exercise recommendations has on fitness levels or modifiable cardiovascular risk factors (including weight, body composition, and lipid profile). Importantly, no study has evaluated the cardiovascular benefits of these recommendations on racial minorities.

The economic effects of physical activity on various diseases need additional investigation. Knowledge of the cost-effectiveness of exercise for the treatment or prevention of atherosclerotic diseases is important (9).

The U.S. Department of Health and Human Services has published recommendations for the promotion of health and prevention of disease in Americans (145). A major objective is to enhance the physical activity of inactive individuals in an attempt to reduce chronic diseases and improve quality of life. Certain special populations have been targeted due to their lack of participation in leisure-time physical activity, including ethnic minorities such as blacks, Hispanics, Native Americans, low-income groups, the elderly, the disabled, and obese individuals. Methods that aid in promoting, implementing, and maintaining physical activity are needed.

OVERVIEW

Hypertension is a major cardiovascular risk factor that directly contributes to myocardial infarction (MI), cerebrovascular accidents, congestive heart failure (CHF), peripheral arterial insufficiency, and premature mortality. Optimal and cost-effective management of the condition depends on careful diagnosis, treatment minimization, optimized adherence, parsimonious selection of tests and treatments, and practice efficiency.

Over the natural history of hypertension, early endothelial dysfunction and elevations of cardiac output (CO) usually give way to increased peripheral vascular resistance, reflecting an array of genetic, environmental, and homeostatic factors. Early perturbations may be slight and reversible; subsequent chronic changes tend to be larger, slower, and irreversible.

Successful reduction in blood pressure (BP) and other cardiovascular risk factors can dramatically reduce the incidence of cerebrovascular and coronary morbidity and mortality, especially for individuals with the highest elevations of BP, individuals with multiple risk factors, and the elderly. Nondrug therapy is often sufficient for mild or labile elevations of BP. The large number of antihypertensive drug options necessitates individualization for particular patients and a thoughtful balancing of hypotensive efficacy, impact on key vascular beds, patient cost and convenience, and long-term consequences on metabolic and other baseline functions.

Secondary hypertension with curable potential makes up <2% of unselected hypertensive populations and usually produces characteristic clues or refractoriness to therapy. Suboptimal compliance with prescribed medications and suboptimal drug combinations are more common causes of apparent resistance to standard treatment than is secondary hypertension.

Continued controversy surrounds the optimal threshold of treatment and the optimal choice of antihypertensive medications.

INTRODUCTION

Hypertension is a major cardiovascular risk factor that contributes to MI, cerebrovascular accidents, CHF, peripheral arterial insufficiency, and premature mortality (1). Of all the known cardiovascular risk factors, hypertension is the most prevalent: it occurs in up to 30% of the United States population (approximately 80 million Americans), when using a threshold of 140/90 mm Hg (2). Hypertension is the most common reason cited for office visits to American internists (3) and the most common indication for the use of prescription medication in the United States (4). In 1995, direct costs of American antihypertensive management and treatment of its complications totaled $24 billion (2).

Definitions of hypertension continue to evolve as more epidemiologic data and randomized controlled trials clarify the distributions of BPs and the thresholds for net benefit from treatment. Traditional definitions have used systolic BP (SBP) ³140 mm Hg and/or diastolic BP (DBP) ³90 mm Hg to delimit the upper bounds of normal. More recently, the recommendation has shifted to defining normal BP as mean daytime SBP <135 mm Hg and DBP as <85 mm Hg (5).

Recent reanalysis suggests that hypertensive patients fall in two groups. Approximately one-fourth consists of individuals under the age of 50 who are predominantly male and have diastolic hypertension. The remaining three-fourths are older than the age of 50, are slightly more than half (58%) women, and often display isolated systolic hypertension. From Framingham data, the best predictors of coronary heart disease differ in the three age clusters: <50 years old, 50 to 59 years old, and ³60 years old. Among patients <50 years old, DBP predicted subsequent coronary heart disease better than SBP. Among patients 50 to 59, SBP, DBP, and pulse pressure served equally well as predictors. At age 60 years and older, pulse pressure was the best predictor followed by SBP (6,7).

On the basis of its high prevalence, responsiveness to treatment, and financial impact, hypertension deserves our attention (8). Perhaps most importantly, hypertension represents a success story in which evolving therapies and concerted public and professional educational efforts have combined to reduce its disease burden of morbidity and mortality (9). The overall cost-effectiveness of antihypertensive management depends on five factors: correct diagnosis, treatment minimization, optimized adherence to therapy, parsimonious selection of tests and treatments, and practice efficiency (10).

HISTORICAL PERSPECTIVE

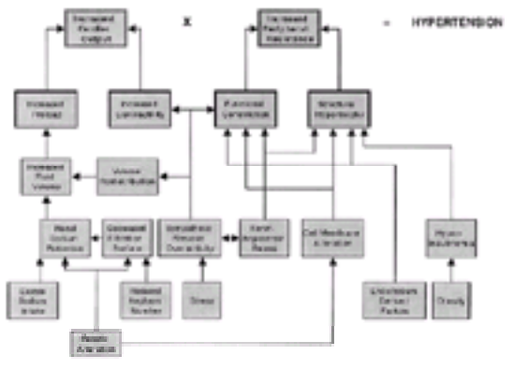
The first report of direct BP measurement dates back to 1726, when Stephen Hales cannulated a horse's crural artery and assessed the height of the blood column before and after hemorrhage. The monaural stethoscope appeared in the early nineteenth century; the binaural stethoscope came to America in 1852, well before Riva-Rocci's introduction of the sphygmomanometer cuff in 1896. Firmly shifting attention away from assessing the pulse wave (11), Korotkoff reported the auscultatory method of measuring arterial pressure in 1905, permitting measurement of diastolic pressure and systolic levels for the first time (12).

As early as 1827, Bright recognized that patients who had high BP also had contracted kidneys and hypertrophied left ventricles. By 1852, Johnson had described medial hypertrophy of the renal afferent arterioles from high BP, and Traube associated left ventricular hypertrophy (LVH) with increased arterial tension in 1856. In 1913, Janeway described 500 of his private practice patients followed for 9 years, concluding, "It does not seem to me that any very definite prognostic conclusions can be drawn from the height of the blood pressure" (13). Fully 26 years later, Keith, Wagener, and Barker published their landmark study of survival curves for four groups of hypertensive patients classified by eyeground patterns (14). With these and many subsequent advances, the medical focus shifted from simple measurement of BP to its clinical consequences.

Early efforts to reduce extreme hypertension by adrenalectomy or sympathectomy frequently led to disastrous results. Some early authorities concluded that such hypertension was not merely primary but "essential," because brusque pressure reductions were deleterious. Serious work on experimental hypertension started with Goldblatt's description of the renal artery clip model in 1934 (15). Thus began a series of discoveries of one intriguing complexity after another: renin, angiotensin, atrial natriuretic factor, cation fluxes, endothelial factors, vascular remodeling, central monoaminergic, and hypothalamic factors, among others.

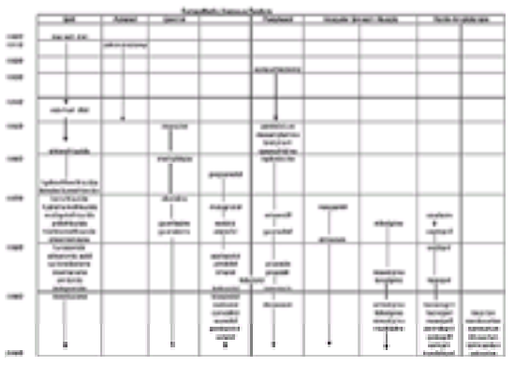
With each decade, new potential culprits were identified, each carrying some plausible basis for a role in causing or maintaining BP elevations. For most hypotheses, the perspective remained the same as that proposed in 1960 by Page in his "mosaic theory" of hypertension: a disease of regulation in which abnormal regulatory systems fail to reduce BP once it is elevated (16). More precisely, the control of arterial pressure was likened to a kaleidoscope of interlocking, dynamic equilibria that determined the net effect while continually shifting from one set of relations to another. Although the regulatory factors were limited, their changing interplay was not (17).

The strength of the model lies in its adaptability to new data. Because there is likely to be no unique cause for most cases of hypertension but many potentially contributing factors, one struggles to integrate all the possible components. The mosaic concept offers a way to combine diverse factors—from genetic and physiologic to emotional and environmental. eFigure 5.0.1 lays out some of the major factors affecting BP.



***e*FIGURE 5.0.1** Interactions among the genetic, environmental, and physiologic factors that affect blood pressure in health and in disease. (Adapted from Kaplan NM. Primary hypertension: pathogenesis. In: Kaplan NM, ed. *Clinical hypertension*. Baltimore: Williams & Wilkins, 1994:47–108.)

Despite no unanimity on the causation of hypertension, the field of antihypertensive therapeutics evolved exponentially from humble beginnings. eFigure 5.0.2 summarizes these developments. Many of the medications were originally developed for other purposes and later applied to hypertension as an afterthought or via serendipity. Most of the reported drug toxicity has been dose related and, therefore, potentially avoidable; perhaps this reflects an early, excessive enthusiasm for high doses not always coupled by close follow-up (18).



***e*FIGURE 5.0.2** Time frame of major developments in antihypertensive therapy by sites or mechanisms of pharmacologic action.

The early array of therapeutic options was severely limited, often poorly tolerated, and inconsistently effective. Progress really began with the arrival of thiazide diuretics, leading to the first therapeutic trials for key clinical outcomes by the late 1960s. Most early trials used diastolic BP criteria (19,20). The decision reflected controversy about how best to approach isolated systolic hypertension that was common among the elderly, who least tolerated the available antihypertensive agents. The results of pioneering clinical trials were wildly encouraging. By starting with patients with greatest diastolic elevations and highest cardiovascular risk, the studies successively demonstrated large benefits for severe elevations (DBP >114 mm Hg) in 6 months (19), moderate elevations (DBP 105 to 114 mm Hg) in 3 years (20), and mild elevations (DBP 95 to 104 mm Hg) in 5 years (21,22).

Each successful trial offered further expectation that extending treatment to other, untested patient groups would yield attractive benefits at acceptable societal and personal cost. In recent years, investigators returned to the elderly—especially those with isolated systolic hypertension—and confirmed net benefit from treatment (23,24,25 and 26). Despite previous worries, the benefits from treating isolated systolic hypertension occurred without demonstrable impact on mood, cognitive function, basic self-care, or leisure activity (27).

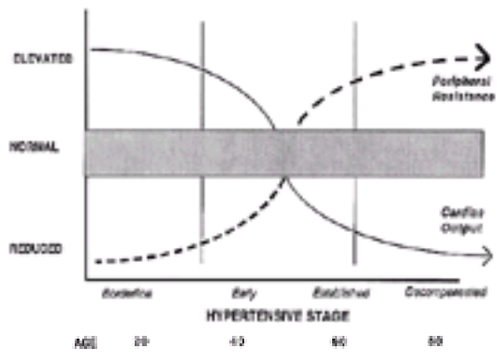
Despite the many advances, hypertension still largely epitomizes the "triple paradox" by which a condition (a) easy to diagnose often remains undetected, (b) simple to treat often remains untreated, and (c) for which, despite available and potent drugs, treatment all too often is ineffective (28).

ANATOMIC CONSIDERATIONS

At its simplest level, the circulatory system consists of a pump, an array of outgoing and returning vessels, and regulatory mechanisms to modify flow and pressure. These components constitute the hemodynamic core: BP as the product of CO (itself made up of stroke volume and heart rate) and peripheral vascular resistance. The vascular smooth muscle of smaller arterioles serves as the principal determinant of peripheral resistance. In large arteries, the structure of the arterial wall determines the pulsatile hemodynamics of pressure and flow. Mechanical wall stiffness, wall thickness, and elastin and collagen content vary along the arterial tree, further contributing to regional differences in pressure and blood flow.

Over the natural lifetime of many hypertensive subjects, the relative proportion of these components undergoes a predictable evolution. The early predominance of

elevated CO gives way to normal or even reduced levels, whereas peripheral resistance rises. This sequence is summarized in *e*Figure 5.0.3 (29).



***e*FIGURE 5.0.3** Evolution of hemodynamic patterns from borderline or early hypertension through its advanced or decompensated states. (Adapted from Messerli FH, Garavaglia GE, Schmieder RE, et al. Disparate cardiovascular findings in men and women with essential hypertension. *Ann Intern Med* 1987;107:158–161.)

This model provides insight into the hypertension of early pregnancy and hyperthyroidism. Both conditions reflect high CO with relatively normal or even reduced peripheral resistance. In contrast, most patients with chronic primary hypertension exhibit reduced CO and elevated peripheral resistance.

The hypertensive patient responds to interventions for lowering BP in predictable ways, often as if to restore BP to its elevated, preintervention level. Most commonly, the body compensates with fluid retention, increased heart rate, or both.

PATHOPHYSIOLOGY

As summarized in *e*Figure 5.0.1, the numerous factors affecting BP control are complex in themselves and their interrelationships. Striking examples of the interdependencies include observations that insulin resistance precedes hypertension in individuals genetically predisposed to it (30) and that hyperinsulinemia, salt sensitivity, obesity, and increased sympathetic drive are covariants (31).

Genetic Factors

BP has been called “a quantitative multifactorial trait” with environmental and genetic determinants (32). Essential hypertension occupies simply one extreme of the BP distribution (33). Variation in BP represents the combined effects of multiple genes rather than single gene disorders with discrete separation (34). A strong family history (³2 first-degree relatives with hypertension before age 55 years) predicts a future occurrence of hypertension with a relative risk (RR) of 3.8 (35). Obesity, hypertension, and the associated metabolic syndrome occur from childhood through to adult life, underscoring the importance of early prevention (36). In the majority of hypertensive patients, the hereditary determinants of BP elevations remain unknown. The search for genetic determinants is handicapped by the absence of a marker to identify prehypertensive individuals before the pressure rises because, thereafter, the initiating factor may be rendered unrecognizable.

To date, four gene mutations have been implicated in human hypertension: (a) syndrome of apparent mineralocorticoid excess, (b) glucocorticoid-remediable aldosteronism (from ectopic expression of aldosterone synthetase enzymatic activity), (c) Liddle’s syndrome (b-subunit mutations of the amiloride-sensitive epithelial sodium channel), and (d) primary hypertension in some whites (variants at the angiotensinogen locus) (37,38). Family pedigrees indicate that greater left ventricular (LV) wall thickness and mass, altered vascular capacity, and pressor responsivity all occur more commonly among normotensive individuals with a positive family history than among normotensive controls (39).

Sodium Intake

Primitive societies have had diets characterized by low salt (10 to 30 mmol per day) and high potassium intakes. In such settings, hypertension is rare. Only a subset of people (20% to 50%) appears to be salt sensitive by showing a pressor response when fed diets of more than 50 mEq sodium per day (~1/2 tsp of salt per day, because 1 tsp of salt = 6 g salt = 2.4 g sodium = 104 mEq sodium = 104 mmol sodium). Most Americans consume substantially more than this level. Proving the unique contribution of excessive salt intake, however, is difficult. Some have argued that the sodium-potassium ratio or the chloride intake may be crucial. Still, most data support a role for dietary sodium excess in producing hypertension in some individuals (40,41).

Despite attractive theories to the contrary, Intersalt—the superbly executed, worldwide study of salt intake and BP (10,079 subjects from 32 countries)—was unable to confirm a consistent relationship between dietary salt intake and BP in diverse settings (42). In other studies, no single marker has predicted salt sensitivity with accuracy. Even the reproducibility of salt loading in such individuals leading to pressor responses has been questioned (40). A recent metaanalysis of 56 published trials could confirm only 3.7/0.9 mm Hg reductions in systolic and diastolic pressures among 1,131 hypertensive subjects who reduced dietary salt intake by 100 mmol per day (41).

Given these small differences, testing for salt sensitivity cannot be justified in routine clinical practice, especially because the standard protocol is difficult to administer: determination of baseline BP after a 4-hour infusion of 2 L of normal saline, and then comparison with BP after 1 day of a 10-mmol sodium diet coupled with three oral doses of furosemide at 10 a.m., 2 p.m., and 6 p.m. in search of ³10 mm Hg decline in mean BP.

Natriuresis and Renal Function

In healthy individuals, homeostasis prevails. When BP rises, sodium and water excretion via the kidneys increases to return BP to baseline. This process is termed *pressure natriuresis*. Among hypertensives and prehypertensives, renal blood flow appears reduced compared to normotensives. The causative sequence may include preferential constriction of efferent arterioles (perhaps via the renin-angiotensin system), reduction in renal blood flow, and increased filtration fraction. The peritubular capillary blood with less sodium and water develops higher oncotic pressure and facilitates sodium reabsorption, leading to higher blood volume and higher BP. Pressure natriuresis occurs but only to sustain BP at a higher level.

In some individuals, renal function may contribute to elevated BP after reductions in filtration surface area from lower numbers of functioning nephrons. Controversy surrounds whether both the number and the function of nephrons are reduced, either globally or in a patchy distribution (43). Intrarenally, prostaglandin function—especially prostaglandin E_2 influencing natriuresis and prostaglandin I_2 modulating renin release—may serve as intermediary derangements (44). Regardless of the precise mechanism, the kidney acts to return the pressure all the way back to a balance of input and output—the “set point” of the system—even if disease has deranged the set point to pathologic levels (45).

Renin-Angiotensin System

Since its discovery in 1898, renin has assumed growing importance as a pressor hormone and a growth factor. A single-chain polypeptide, renin is secreted from the renal juxtaglomerular apparatus in response to macula densa signals of lowered cytosolic calcium, decreased renal arteriolar pressure, or increased renal alpha- or beta-adrenergic nerve activity. Renin likely has no physiologic effect except for stimulating the activation of angiotensin I from angiotensinogen. Angiotensin I, in turn, undergoes conversion to the four–amino acid angiotensin II (AII, sometimes called *angiotensin 1-8*) in multiple tissues, especially the lung. AII becomes inactivated by angiotensinases that are present in many tissues, especially red blood cells. Complete renin-angiotensin systems operate in the brain, reproductive tract, and heart and play physiologic roles in epithelial, fibroblast, and macrophage cell function (46).

The principal effects of AII consist of the following: (a) vasoconstriction that leads to elevated BP by inhibiting adenylate cyclase mediated through G proteins, particularly for the kidney’s efferent arterioles; (b) volume retention via promoting aldosterone secretion by the adrenal and stimulating antidiuretic hormone and thirst; and (c) vascular hypertrophy, especially in the heart, peripheral vessels, and renal vasculature (47,48). Of the two AII receptors, the AT_1 subtype mediates all the known actions of AII on BP control and is widely distributed in the body (49).

From first principles, one would predict that renin levels would be low among most hypertensive patients because the kidney “sees” higher than normal pressures. This is not the case. Renin levels may remain normal despite hypertension from abnormal modulation in response to AII by renal and adrenal tissues, both of which blunt aldosterone secretion in response to sodium restriction and do not increase renal blood flow after sodium loading (50). Compared to normotensive controls, hypertensive patients and offspring of hypertensive parents exhibit lower levels of renin and renal blood flow and a greater responsiveness to subpressor doses of AII (51). Thus, available data support a view of distorted homeostatic mechanisms within the renin-angiotensin system that contribute to establishing and maintaining hypertension.

Over more than two decades, controversy has raged about the utility of renin profiling in predicting cardiovascular prognosis and optimal therapy for hypertensive patients. One study reported differential rates of MI among 1,717 mild to moderate hypertensives followed for more than 8 years; these rates were based on high, normal, or low renin-sodium profiles (52). Pending confirmatory reports from other studies, renin profiling is still not standard practice, although it is useful in some cases of refractory disease (53).

Sympathetic Nervous System

In parallel with the renin-angiotensin systems, the sympathetic nervous system (SNS) may couple with high sodium intake to raise BP. Often, stress activates the SNS, especially in patients genetically or environmentally predisposed to respond with increased levels of epinephrine, norepinephrine, and neuropeptide Y (54). Baroreceptor sensitivity—both sinoaortic and cardiopulmonary—rapidly undergoes resetting and decreased sensitivity among hypertensives, predisposing to heightened BP variability (55). Catecholamine-mediated vasoconstriction may contribute to changes in efferent arterioles. In parallel with diurnal cortisol variation, increases in a-sympathetic activity likely play a role in early morning pressor responses. Higher BP, higher pulse rates, and increased risk for cardiovascular events all ensue (56,57).

Increased sympathetic activity serves as initiator and sustainer of hypertension, promotes the development of LVH, and predisposes to dysrhythmias and sudden death. The link between obesity and hypertension may reflect increased renal sympathetic tone without suppression of cardiac norepinephrine spillover (58).

The precise role of psychological stress remains largely undefined. Most likely, its effects depend on complex interactions among the nature of the stressor, the individual’s perception of the stress, and the individual’s physiologic susceptibility (59). In this way, people may become hypertensive because they respond differently to stress, not merely because of the stress itself. Such hyperreactivity is demonstrable among hypertensives and their normotensive offspring when compared to normal controls (60). The most common pattern is one of greater anger and hostility, along with greater suppression of these emotions. These patterns are more sustained among hypertensives and their offspring than among controls.

As hypertensive patients age, their sympathetic system tone—as measured by neurotransmitter levels—tends to fall, as if less sympathetic drive is needed to maintain neurogenic hypertension once it is established (61).

Vascular Constriction and Vascular Remodeling and Hypertrophy

The simple notion of the circulatory system as a collection of passive pipes attached to a pump is incorrect. *In vivo*, systemic resistance vessels depend on complex interactions among smooth muscle contractility, the vessels’ geometric design, vessel wall distensibility, and distending pressure (62). Structural changes increase the ratio between wall thickness and lumen diameter, in turn producing higher wall stress and intraluminal pressure when resistance vessels are sympathetically stimulated.

The vascular tree acts like a Windkessel system, in which there is a distensible component that absorbs energy during systole and releases it during diastole. The net effect is to sustain perfusion to peripheral vascular beds, despite the rhythmic cardiac contractions. In hypertension, vessel wall compliance (i.e., the change in vessel diameter for a given change in pressure) falls. This reduction occurs throughout the arterial side but predominantly among smaller, distal, resistance vessels, rather than large or medium-sized vessels, and increases dramatically with age (63). These changes result from a multitude of vasoactive trophic factors originating within the vessel wall itself (64).

Regardless of the specific initiating events, hypertension is maintained by vascular hypertrophy, which sustains elevated peripheral resistance. In such a pathophysiologic formulation, hypertension proceeds in two steps: (a) an initiating step by which any one of an array of possible small, largely undetectable perturbations occurs, especially in the context of those genetically or environmentally predisposed to derangement; and (b) an amplification step, which is slow, progressive, ultimately large, and likely nonspecific (65).

Cell Membrane Alteration

Abnormal ionic fluxes across cell membranes potentially affect both vessel tone and hypertrophy. The contractile machine of vascular smooth muscle consists of thick and thin filaments, similar to the model of skeletal muscle. The force of contraction reflects cycling activity of myosin bridges, which is initiated by an increase in intracellular calcium concentration and determined by the degree of phosphorylation of the myosin light chain (66). Most attention, therefore, has focused on fluxes of sodium and calcium ions.

Despite more than a decade of *in vitro* studies, there remains considerable skepticism about the relevance of the findings to human hypertension (67). Five sodium transport systems have potential involvement: (a) Na^+ channel, (b) Na^+-H^+ antiport/Na^+-Li^+ countertransport exchange, (c) Na^+-K^+-Cl^- cotransport, (d) Na^+-Ca^{2+} exchange, and (e) Na^+-K^+ ATPase pump. If dysfunctional Na^{2+}-H^+ transport occurs, increased intracellular Na^+ accompanies intracellular alkalinization (a recognized stimulus for cell growth) and increased intracellular Ca^{2+} (a stimulus for vascular reactivity). In this way, defects in sodium elimination might be unmasked only when sodium intake rises substantially, perhaps above a threshold level.

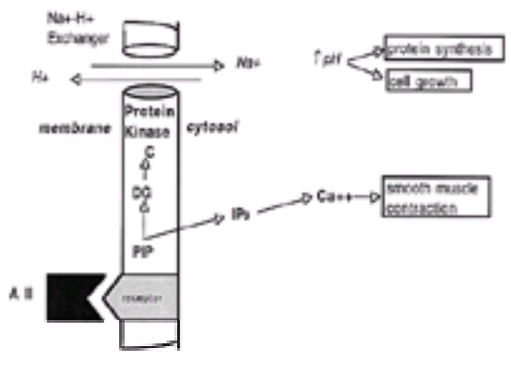
Some authors challenge that intracellular sodium is increased in hypertension. The multitude of other reported abnormalities may be nothing more than markers for the disturbed physicochemical properties of the cell membrane (68). More intriguing are the correlations between ion transport defects and plasma lipid levels that further link dyslipidemia and hypertension (69). Na^+-Li^+ countertransport appears to be increased in subsets of patients with hypertension, dyslipidemia, pregnancy, and diabetes mellitus (70).

Similarly, three reported defects in calcium transport have emerged that involve (a) the Ca^{2+} pump, (b) the Na^+-Ca^{2+} exchange, and (c) the dynamic release and sequestration of free Ca^{2+} between cytosol and mitochondria (71). As little as a 5% increase in intracellular Na^+ by inhibiting the sodium pump could inhibit Na^+-Ca^{2+} exchange enough to increase the resting tone of vascular smooth muscle by 50% (72). The two cation regulatory clusters may be linked through at least two interrelated cellular pathways: the kinase/phosphatase cascade and the Ca^{2+}/calmodulin system (73). While the specifics remain debatable, strong and plausible links among cell membrane alterations, vascular reactivity, and cell growth continue to appear.

Vascular Hypertrophy

Many of the same factors that produce immediate pressor responses also yield trophic influences for protein synthesis and cell growth. *In vitro* studies confirm that AII can increase protein synthesis within aortic cells by 80% within 24 hours of application (74) and induce protooncogene and growth factor genes within 30 minutes (75). At least seven distinct growth factors for vascular smooth muscle have been described, including platelet-derived growth factor, insulin-like growth factor, and transforming growth factor-b (47).

At a cellular level, the sequence generally follows this order: (a) once stimulated, the growth factor (e.g., AII) occupies its membrane receptor; (b) receptor occupancy activates membrane phosphodiesterase, which hydrolyzes phosphatidylinositol biphosphate; (c) the hydrolysis introduces inositol triphosphate into the cytosol and retains 1-2-diacylglycerol in the membrane; (d) inositol triphosphate releases calcium from nonmitochondrial organelles, producing smooth muscle contraction; (e) as a second messenger, diacylglycerol activates protein kinase C, which controls the Na^+-H^+ exchanger; (f) Na^+ enters the cell and H^+ leaves it; and (g) the cell becomes more alkaline, stimulating the nucleus to initiate protein synthesis and division. eFigure 5.0.4 schematically summarizes the process, although the process and components likely are more complex (76).



***e*FIGURE 5.0.4** Schematic of intracellular mechanism by which angiotensin II (AII) produces enhanced Na^+-H^+ exchange, smooth muscle contraction, protein synthesis, and cell growth. See text for details. DG, 1-2-diacylglycerol; IP_3, inositol triphosphate; PIP, phosphatidylinositol biphosphate. (Adapted from Kaplan NM. Primary hypertension: pathogenesis. In: Kaplan NM, ed. *Clinical hypertension*. Baltimore: Williams & Wilkins, 1994:47–108.)

Two components are distinguishable. The contraction stimulus and response are finite and short-term, whereas cellular growth occurs once tissue stimulation is prolonged. Antihypertensive treatment may partially reverse structural changes (77).

Much of the smooth muscle cell growth and remodeling occurs as a consequence of endothelium-derived growth factors in response to shear forces, intravascular pressure, circulating hormones, and platelet factors (78). One of the most critical is endothelium-derived relaxing factor—later determined to be nitric oxide (NO)—released into the lumen to inactivate platelets and into the vessel wall to relax vascular smooth muscle. Hypertensive subjects often display blunted vasodilatory response to various stimulations of endothelially dependent factors (79)—a defect not corrected by antihypertensive therapy (80). As another link to cardiovascular risk, hypercholesterolemia produces NO inactivation by the lysolecithin component of oxidized lipoprotein that is, in turn, reversed by L-arginine stimulating NO production (81).

A growing litany of endothelial mediators has emerged with many postulated interactions and interdependencies. The major factors include prostacyclin, NO, superoxide anion, endothelin, endothelium-derived hyperpolarizing factor, prostaglandin H_2, thromboxane A_2, serotonin, and platelet-derived factors.

Hyperinsulinemia and Insulin Resistance

Hyperinsulinemia and insulin resistance commonly coexist with essential hypertension, augmenting the overall cardiovascular risk profile. In contrast, secondary hypertension does not lead to insulin resistance. Prospective follow-up of individuals with elevated fasting insulin demonstrated a high correlation with subsequent development of hypertension at two- to threefold higher rates than controls (82). The association is not perfect; individuals from ethnic groups with high prevalence of diabetes mellitus (e.g., Mexican Americans and Pima Indians) do not display higher incidences of hypertension. Undoubtedly, complex interactions among genetic, environmental, and other factors determine the clinical outcomes (83), because insulin's ability to mediate glucose disposal can differ by as much as tenfold among subjects with normal glucose tolerance (84).

Obese individuals' degree of insulin resistance does not increase if hypertension is present. This lack of additive effect suggests that hypertension, exogenous obesity, and diabetes mellitus may act independently but along a final, common pathway (85). A review of 25 prospective studies correlating plasma insulin levels with heart disease did not support hyperinsulinemia by itself as a major cardiovascular risk factor (86). In contrast, insulin resistance correlates closely with atherosclerosis, thrombogenesis, hypertension, obesity, and diabetes mellitus (87,88).

The vasodilatory effects of insulin appear blunted among hypertensives, compounded by the increased SNS tone of obesity and the insulin resistance all three conditions share (89). Other proposed mechanisms by which insulin resistance and hyperinsulinemia may lead to hypertension include (a) increased sensitivity to dietary salt intake, (b) heightened renal sodium and water reabsorption, (c) augmented pressor and aldosterone responses to AII, (d) increased Na^+-H^+ pump activity and decreased Na^+-K^+ ATPase activity leading to augmented intracellular Na^+, (e) increased intracellular Ca^{2+}, (f) stimulation of vascular smooth muscle growth factors, (g) stimulation of SNS activity, (h) reduced vasodilatory prostaglandins, (i) increased endothelin secretion, and (j) impaired vasodilation (90). Not surprisingly, given the several overlapping effects, hypertension may be clustered with obesity, dyslipidemia, glucose intolerance, and type II diabetes mellitus; sometimes, these conditions are lumped together as "metabolic syndrome X" or "insulin resistance syndrome." Individually and collectively, these conditions lead to accelerated atherosclerosis and cardiovascular disease (91).

Other Potential Contributors

The list of other potential causes of primary hypertension is long and diverse, although the evidence in support of their role is less convincing.

Atrial natriuretic factor is one of several natriuretic peptides that can increase glomerular filtrate without increasing renal blood flow, relax preconstricted vasculature (especially in the renal bed), reduce systemic BP, and suppress renin levels and its secretion (92). Despite a number of attractive hypotheses linking decreased levels or altered responsiveness of atrial natriuretic factor to the pathogenesis of hypertension (93), strong evidence remains elusive (94).

Prostaglandins undoubtedly play important roles in circulatory control and thrombosis. Their role in primary hypertension is less clear, although it likely contributes to preeclampsia (95). Prostacyclin inhibits platelet aggregation, relaxes vascular smooth muscle, and promotes natriuresis. Prostaglandin E_2 causes vasodilation, whereas prostaglandin F_2a causes vasoconstriction.

Interleukins, such as interleukin-1, may inhibit angiotensinogen synthesis, whereas interleukin-6 may enhance the protein-producing messenger RNA transcription rate (96).

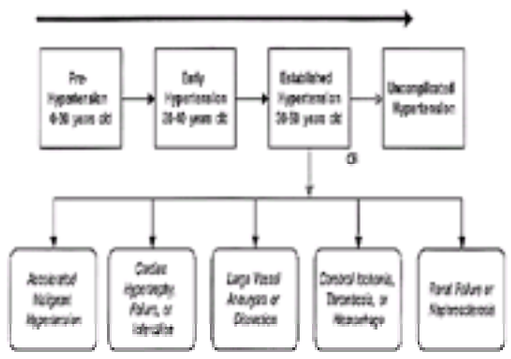
Medullipin serves as a counterbalance to AII. It is secreted from renal medullary cells but requires activation by the hepatic cytochrome P-450 system for its effect, independent of renin-angiotensin or autonomic nervous function (97).

To date, there have been no convincing data on the role of dietary calcium, potassium, magnesium, lead, zinc, or cadmium in causing primary hypertension. Caffeine may cause pressor effects in the uninitiated but rapidly accommodates (90). In contrast, chronic alcohol use, especially in excess of two drinks per day, may elevate BP and increase mortality (98).

CLINICAL PROFILE

Natural History of Hypertension

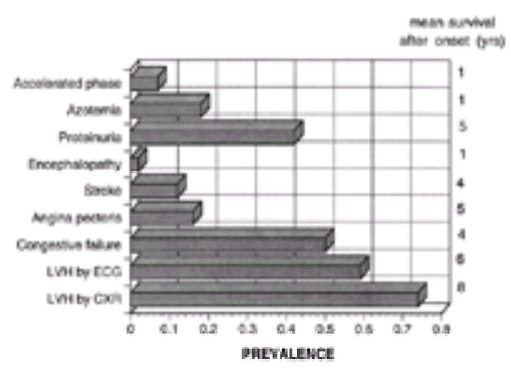
Whether viewed as a distinct disease or as a cardiovascular risk factor, hypertension commonly produces structural changes in arteries and target organs in a variety of patterns. This sequence appears in *e*Figure 5.0.5.



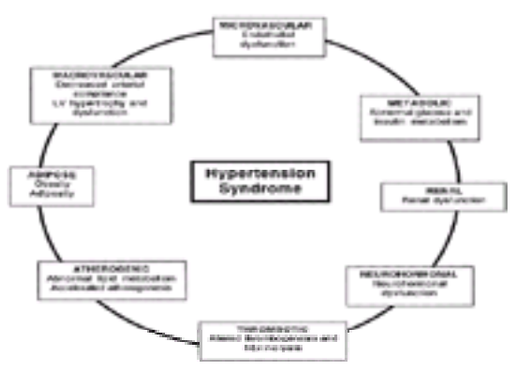
***e*FIGURE 5.0.5** Sequence of stages by which hypertension may evolve and affect one, some, or all key target organs. (Adapted from Kaplan NM. Natural history, special populations, and evaluation. In: Kaplan NM, ed. *Clinical hypertension*. Baltimore: Williams & Wilkins, 1994:109–143.)

During the prehypertension phase, repetitive perturbations of cardiovascular homeostasis occur, reflecting an array of hereditary and environmental factors. In time, these small changes accumulate and yield larger changes that are recognizable as early hypertension. If the BP elevations are caught in time and reversed by lifestyle changes, normalization may occur. In the Australian Therapeutic Trial, 13% of screenees with entry DBP >95 mm Hg had spontaneous BP reduction that continued for at least 1 year. An additional 48% of subjects' BPs remained <95 mm Hg while on placebo treatment for 3 years (21).

Patients with sustained elevations may progress to established hypertension. Subsequent events are somewhat difficult to predict in individual patients, because BP on its own provides only the most crude index of prognosis. Observed log-linear associations between BP and risk of coronary heart disease death display approximately constant risk regardless of the specified definition of hypertension (99). A few individuals (<5%) enter a fulminant course with rapid deterioration in cardiac, renal, and neurologic function. Another distinct subset (»20%) undergoes a more subdued course, commonly producing moderate to severe target organ changes with progression over years, rather than over weeks to months. The most common organ systems involved with these destructive processes include (a) the heart itself (diastolic dysfunction, LVH, endocardial scarring, CHF, and coronary insufficiency), (b) the large and medium-sized arteries (accelerated atherosclerosis, aneurysm formation with or without dissection), (c) the brain and intracranial circulation (ischemia, infarction, whether hemorrhagic or thrombotic), and (d) renal circulation (nephrosclerosis, with or without renal failure). These target organ complications reflect a wide array of contributing factors, often inherited, that extend well beyond elevated BP alone. This cluster has been termed *hypertension syndrome* (100). One patient series antedating effective antihypertensive therapy gives a glimpse of the array and progression of events, as summarized in eFigure 5.0.6. eFigure 5.0.7 displays the cluster of pathophysiologic derangements of the hypertension syndrome.

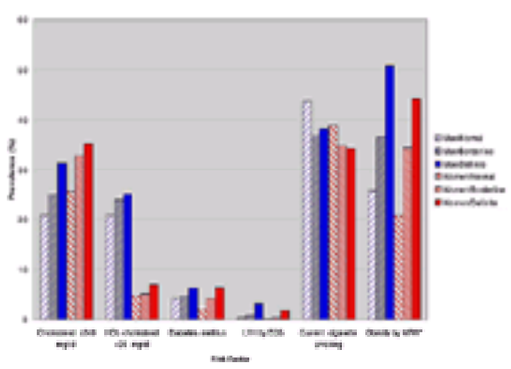


***e*FIGURE 5.0.6** Data from era before effective antihypertensive therapy, highlighting the array of major hypertension-related complications and the mean survival after onset. CXR, chest x-ray; ECG, electrocardiogram; LVH, left ventricular hypertrophy. (Adapted from Perera GA. Hypertensive vascular disease: description and natural history. *J Chron Dis* 1955;1:33–42.)



***e*FIGURE 5.0.7** *Hypertension syndrome* refers to a complex of inherited alterations of physiology that affects multiple tissues and target organs. The alterations emerge, persist, and sometimes even progress, even if the elevated blood pressure is reduced to normal levels. Consequently, such individuals remain at increased risk for cardiovascular morbidity and mortality; their conditions may partially explain the limited success in reducing coronary heart disease despite antihypertensive therapy. LV, left ventricular. (Adapted from Neutel JM, Smith DH. Hypertension control: multifactorial contributions. *Am J Hypertens* 1999;12:164S–169S.)

The majority of individuals displays an indolent course in which changes occur over decades; these changes usually are mediated by diffuse atherosclerosis and predispose to stroke, heart attack, congestive failure, renal dysfunction, and peripheral arterial insufficiency. The specific events and time course for an individual are greatly affected by comorbidities, especially dyslipidemia, cigarette smoking, diabetes mellitus, and exogenous obesity, as well as other factors such as sedentary lifestyle, salt intake, and situational stress. In addition, the occurrence of target organ damage such as LVH or peripheral arterial insufficiency makes subsequent target organ damage more likely (101). eFigure 5.0.8 illustrates the prevalence of many of these factors in the Framingham cohort.



***e*FIGURE 5.0.8** Data from the Framingham Heart Study (1970–1982) summarizing the prevalence of key cardiovascular risk factors by hypertensive status among adults aged 35 to 64 years. ECG, electrocardiogram; HDL, high-density lipoprotein; LVH, left ventricular hypertrophy; MRW, Metropolitan relative weight. (Adapted from Kannel WB. Blood pressure as a cardiovascular risk factor: prevention and treatment. *JAMA* 1996;275:1571–1576.)

Most hypertension first appears before age 50 years. Early stages are commonly labile or borderline in the degree of elevation. Only 20% of new cases present over age 60 years in the context of regular BP checks (102). As the population ages, individuals—hypertensive or not—are more likely to sustain a cardiovascular event. At all ages, women display a better prognosis for hypertension-related complications, providing the basis for higher treatment thresholds (eFig. 5.0.8). Adult blacks in the United States display higher levels of BP and a higher prevalence of hypertension, as well as higher rates of hypertension-related complications (103). A number of hypotheses to explain the higher rates include (a) unique genotypes, (b) differences in sodium sensitivity and sodium transport, (c) stress, (d) increased vascular responsiveness, (e) growth factor responsiveness, (f) diet, and (g) insulin resistance (104). The American Southeast has long displayed especially high prevalence of hypertension and its complications, perhaps in part because of suboptimal access to medical care and close follow-up (103).

Among hypertensives, as with most other Americans, death usually results from ischemic heart disease. Individuals with severe, resistant disease often die of strokes, whereas those with severe retinopathy or renal dysfunction at first presentation tend to die of renal failure. The presence of demonstrable atherosclerosis (e.g., carotid stenosis, lower extremity arterial insufficiency) substantially increases mortality among patients with hypertension. Over a 4-year follow-up, mortality among patients with atherosclerosis was fivefold higher (23% vs. 5%) than those without atherosclerosis (105).

The pathologic changes include (a) hyperplastic or proliferative arteriosclerosis; (b) hyaline arteriosclerosis affecting intima and media and narrowing the lumen; (c) miliary aneurysms especially in small, penetrating, cerebral arterioles; (d) atherosclerotic or nodular arteriosclerosis producing plaques that narrow the lumen and trap thrombi; and (e) other media changes such as cystic medial necrosis predisposing to dissections.

Effective treatment that reduces BP dramatically changes the natural history of hypertension-related end points, especially for cerebrovascular events and, somewhat less so, for coronary events. Hypertension carries a high population-attributable risk for subsequent CHF, accounting for 39% of cases in men and 59% in women. The overall RR of CHF in 12 randomized controlled trials between 1967 and 1991 was reduced to 0.48 [95% confidence interval (CI), 0.38–0.59] among treated versus control subjects (106). As in most situations, preventing the end organ damage is more effective than trying to reverse the changes once they are established. There continues to be controversy about the optimal drug therapy for hypertension, especially to prevent major target organ damage, as occurs in stroke, MI, and renal dysfunction (107). The proportions of American hypertensives who are aware of their condition (50% to 82%) and who are treated for it (37% to 72%) have increased dramatically in the last two decades, but the percentage of patients consistently controlled with their medications remains at <30% (108), illustrated by Figure 5.1. The benefits of treatment accrue to both genders (109).

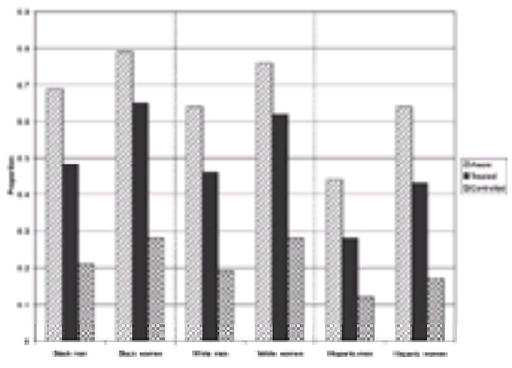


FIGURE 5.1 Data from National Health and Nutrition Examination Survey III (NHANES III) Study classifying American hypertensives by gender, ethnic group, and hypertensive status: Aware of hypertension, under treatment for hypertension, and controlled by treatment. (Adapted from Burt VL, Whelton P, Roccella EJ, et al. Prevalence of hypertension in the U.S. adult population. Results from the Third National Health and Nutrition Examination Survey, 1988–1991. *Hypertension* 1995;25:305–313.)

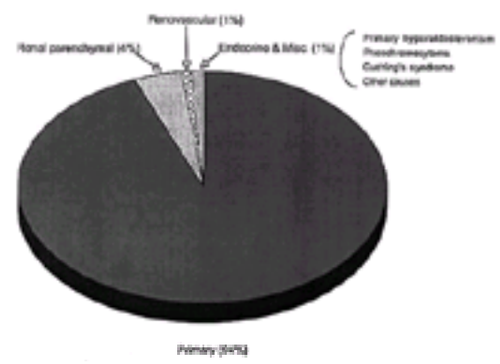
Common Presentations

The vast majority of hypertensive patients (93% to 95%) displays no demonstrable, curable abnormality of anatomy or physiology (110). Termed *primary hypertension*, the condition carries no consistent hallmark symptoms or signs, except for the elevated BP itself. Most cases are detected incidentally as part of routine examinations and generally in the absence of target organ damage at initial presentation. Reports of headache, dizziness, fatigue, palpitations, and chest discomfort occur commonly among hypertensive and nonhypertensive patients. Because the symptoms prompt clinician attention, hypertension is more likely to be detected among patients with symptoms. For the majority of hypertensives, symptoms and symptom levels do not correlate well with BP level (111).

Even among individuals with proven secondary hypertension, clinical presentations are often nonspecific. Together accounting for 5% to 7% of all hypertensives, secondary causes represent a diverse collection of conditions. Renal parenchymal disease is the most common condition and occurs often in the context of known predisposing illnesses such as diabetes mellitus, connective tissue disease, or drug toxicities. The early (<age 30 years) or late (>age 65 years) onset of hypertension moderately raises the likelihood of secondary causes. The section Evaluation for Secondary Forms of Hypertension explores specific constellations of symptoms and signs by secondary cause (eFig. 5.1.1).



***e*FIGURE 5.1.1** Prevalence of primary versus secondary hypertension among unselected adult patients, based on composite data from several studies in diverse international sites. See text for references.

Establishing the Diagnosis and Risk Profile

The Joint National Committee on the Detection, Evaluation, and Treatment of High Blood Pressure has defined hypertension as indirect, sphygmomanometric levels of ³140 mm Hg systolic, ³90 mm Hg diastolic, or both (5). Other groups have urged more stringent thresholds for high-risk populations such as diabetics in special danger of target organ damage, infants, children, and pregnant women. The standard criteria, cardiovascular risk factors, and consequent treatment and risk categories are summarized in Table 5.1, *e*Table 5.1.1, and Table 5.2.

Category	Systolic (mm Hg)	Diastolic (mm Hg)
Optimal	<120	<80
Normal	<130	<85
High normal	130–139	85–89
Hypertension		
Stage 1	140–159	90–99
Stage 2	160–179	100–109
Stage 3	≥180	≥110

[a]When systolic and diastolic pressures fall into different categories, the higher category should guide the classification.

TABLE 5.2 DEFINITIONS AND RISK STRATIFICATION FOR HYPERTENSION

By single BP determinations, nearly one in every four adult Americans have hypertension. Using the somewhat more stringent criteria of intercurrent antihypertensive drug therapy or ³2 occasions with sustained BP elevations, the prevalence falls to 35 to 45 million Americans. Its prevalence rises with advancing age, from <5% among individuals under age 29 to >50% among those over age 60 (113). On average, black women develop hypertension 10 years before white women do. As the population ages and women tend to outlive men, the number of hypertensive women continues to predominate with higher attributable risk than that of men, even though men and women develop hypertension at comparable rates (3). Each year, approximately 2 million new hypertensive patients are added to the pool of Americans who may benefit from antihypertensive intervention (114).

When assessing a hypertensive patient, the clinician seeks to (a) confirm the existence and magnitude of hypertension, (b) assess the extent of end organ damage, (c) evaluate for contributing comorbidities and risk factors, (d) screen for secondary causes of hypertension, (e) understand any special circumstances that may impact treatment over time, and (f) help create professional trust and the patient's commitment for reducing cardiovascular risk over time. The most important components of initial and follow-up visits in the ambulatory setting are enumerated in Table 5.3.

Initial visit
Evidence for secondary hypertension?
Evidence for target organ damage at presentation?
Clues for optimal future management?
Follow-up visits
Interim symptoms/signs from hypertension-related pathology?
Interim symptoms/signs attributable to antihypertensive treatment?
Obstacles to optimal medication/diet/exercise/other compliance?

TABLE 5.3 COMPONENTS OF AMBULATORY ANTIHYPERTENSIVE MANAGEMENT

Not all patients require drug therapy. For individuals with sustained elevations not responding to nondrug treatments over 3 to 6 months, consistent support has emerged for antihypertensive drug therapy as producing net benefit—even among the elderly with isolated systolic hypertension (23,24,25 and 26)—without compromising quality of life (115). The benefit is especially marked in patients with higher pretreatment BPs (116) or multiple risk factors, rather than in patients with hypertension alone (117).

The critical components of history and physical examination are summarized in *e*Table 5.3.1 and *e*Table 5.3.2; recommended baseline tests are summarized in *e*Table 5.3.3. The highest priorities in gathering history surround the presence or absence of major cardiovascular risk factors, duration and extent of past BP determinations, age of onset, and clinical context, including major comorbidities such as pregnancy, renal insufficiency, or need for chronic medications with pressor effects. Other important components include prior antihypertensive treatments and their effectiveness and tolerability, and patients' perceptions, hopes, and fears about hypertension, its prognosis, and its treatment.

***e*TABLE 5.3.1** INITIAL HISTORY FOR HYPERTENSIVE PATIENTS

Sociodemographics	Age, gender, race, occupation, education, psychosocial constraints
Hypertension history	Duration, monitoring intervals, past evaluations, response to past therapy, recent weight changes
Symptoms of hypertensive complications	TIA, CVA, angina, CHF, arterial PVD, claudication

Symptoms of secondary hypertension	Episodic headaches, palpitations, sweating, weight loss (pheochromocytoma); muscular weakness, cramps, paresthesia, and polyuria (first-degree hyperaldosteronism); weight gain, acne, bruising, hirsutism (Cushing's syndrome); and lower-extremity claudication (coarctation of aorta)
CV risk factors	Dyslipidemia, diabetes mellitus, smoking, high salt intake, saturated fat intake, stress, low activity level, alcohol use, gout; family history of hypertension, CAD (especially if <60 yr old), CVA, diabetes mellitus, dyslipidemia
Complicating comorbidity	Renal or hepatic dysfunction, COPD or asthma, obesity, gout
Medications	All, including pressors (e.g., amphetamines, cocaine, appetite suppressants, diet and cold capsules, nasal sprays), fluid retainers (e.g., oral contraceptives, corticosteroids, NSAIDs), and other (e.g., cyclosporine tacrolimus, MAO inhibitors, erythropoietin, licorice, thyroid hormones)

CAD, coronary artery disease; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CV, cardiovascular; CVA, cerebrovascular accident; MAO, monoamine oxidase; NSAIDs, nonsteroidal antiinflammatory drugs; PVD, peripheral vascular disease; TIA, transient ischemic attack.

***e*TABLE 5.3.2** INITIAL PHYSICAL EXAMINATION FOR HYPERTENSIVE PATIENTS

Vital signs, including ³2 BP determinations (averaged) both supine or sitting and standing, separated by ³2 min; notation and selection of "higher" arm if asymmetric BPs; ankle-brachial index or arm and leg BP
Weight and height, calculation of BMI (weight in kg/height in m^2)
Funduscopic examination for retinopathy
Neck examination for carotid artery, jugular venous distention, thyromegaly
Cardiac and chest examination for heart size, murmurs, gallops, arrhythmias, and rales
Abdominal examination for masses, bruits, abnormal aortic pulsations
Extremity examination for peripheral vascular pulses, bruits, edema, and radial-femoral pulse delay
Neurologic examination for baseline assessment and focal findings
Check for stigmata of gout, dyslipidemia, thyroid dysfunction, Cushing's syndrome, neurofibromatosis

BMI, body mass index; BP, blood pressure.

***e*TABLE 5.3.3** INITIAL TESTS FOR HYPERTENSIVE PATIENTS TO ESTABLISH BASELINE LEVELS AND SEARCH FOR CARDIOVASCULAR RISK FACTORS

	Specific tests
Initial	Serum potassium, creatinine
	Blood glucose (preferably fasting) or hemoglobin A1c
	Total, LDL-C, and HDL-C, urinalysis
Desirable but not essential	Complete blood cell count, uric acid, triglycerides, electrocardiogram
Sometimes useful	Plasma renin/urinary sodium ratio, echocardiogram, home or ambulatory blood pressure monitoring

HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

The principal components of the focused physical examination are summarized in *e*Table 5.3.2. The most critical component is attention to optimal techniques of BP determination, including properly sized cuff, preparation of the patient, and multiple determinations (118). During the initial visit, the examiner should obtain BP in the supine and upright positions and compare BPs in the arms, noting discrepancies of ³10 mm Hg and taking future BP determinations in the arm with the higher BP. Although it is a time-consuming extra step, the measurement of BP in supine and standing positions offers two insights: (a) the amount, if any, of orthostatic drop and, therefore, the safety margin to start or increase the antihypertensive dose, especially in the frail or elderly; and (b) the less common compensatory responses of tachycardia or even BP elevation when standing. If the heart rate increases but the BP remains unchanged, or if the BP rises rather than falls when the patient stands, one may consider starting or increasing an antiadrenergic agent to slow the compensatory tachycardia or blunt the exaggerated baroreceptor response. The cuff bladder should encircle at least 80% of the arm circumference, and its width should be ³15 cm in the average adult. Rolled sleeves constricting the arm may distort BP values, but thinly sleeved arms display no significant effect (119).

All manometers, especially aneroid units, may lose accuracy over time. Periodic recalibration offers reassurance against some diagnostic errors. In one study of physicians' office practices, 8% of mercury sphygmomanometers were out of calibration by ³4 mm Hg, and 30% of aneroid sphygmomanometers deviated by ³10 mm Hg. In the same study, only 3% of the physicians used the appropriate cuff size on all patients (120). The examiner's characteristics may play an additional role. Higher BP readings may result when the examiner is male rather than female and wearing a white coat rather than dressed in casual clothing (121). The prevalence of "white-coat hypertension" and the degree of transient BP elevations appears consistently higher among women than men (122).

Many problems arise as artifacts of measurement techniques themselves. Perhaps the most critical factors are selection of optimal cuff size for the patient's arm (123), sufficient initial elevation of cuff pressure with confirmation by palpation to avoid auscultatory gaps (124), and proper preparation of the patient (i.e., avoiding full bladder or bowel conditions; cold or uncomfortable ambient temperature; and caffeine compounds, smoking, or physical exertion within 30 minutes of measurement) (125). Arriving late for an appointment, fighting traffic, or having parking difficulty may also cause transiently higher pressures.

To avoid underestimating SBP within an auscultatory gap, the examiner should palpate the radial or brachial pulse during inflation and begin auscultation only after noting the pressure at which the pulse first appears. The systolic pressure is the point at which the Korotkoff sounds first become audible with each heart beat; diastolic pressure is recorded when heart sounds disappear, except in unusual circumstances in which disappearance (phase V) extends close to zero. In such circumstances, using phase IV (muffling) reasonably approximates DBP. When obtaining ³2 BP determinations, the second reading is almost always lower than the first, sometimes by 5 to 10 mm Hg with little subsequent change (126). *e*Table 5.3.4 lists potential errors in BP measurement.

***e*TABLE 5.3.4** POTENTIAL ERRORS IN BLOOD PRESSURE (BP) MEASUREMENT

Equipment
- Inaccurate or uncalibrated manometer
- Improper sphygmomanometer bladder size

Patient preparation
- Not resting for ³5 min in quiet, comfortable environment

Drinking caffeine-containing beverage or smoking within 30 min
Observer technique
- Not supporting arm or torso to decrease muscle artifact
- Not keeping arm position at heart level
- Not centering cuff bladder on brachial artery
- Not estimating systolic BP by palpating radial pulse before auscultation to detect ausculatory gap
- Not keeping eyes at level of mercury manometer
- Not consistently using phase V sounds for diastolic BP (use Korotkoff phase IV if sounds continue until close to 0 mm Hg)
- Inflating bladder too slowly or deflating it too fast
- Not measuring in both arms at first to establish symmetry of BP is present
- Not completely deflating cuff and waiting 1–2 min before remeasurement

General caveats
- Ignoring distortion from any cardiac dysrhythmias
- Ignoring observer bias and digit preference

Clinicians' office settings, even when protected from distractions, interruptions, and irritations, often yield higher BP levels than when determinations occur in less stressed environments such as home. On one hand, office recordings remain the basis for most epidemiologic correlations with subsequent cardiovascular morbidity and mortality. On the other hand, office BP values correlate less well with target organ damage [e.g., eye (127), heart (128), arteries (129), and kidney (130)] than do BPs obtained from home determinations or ambulatory monitoring.

Home or ambulatory monitoring provide the benefit of additional data, especially over a variety of physiologic conditions, compared to the relatively brief times spent in clinicians' offices (131). Home determinations may reduce the need or frequency of physician visits with improved BP control and reduced costs (132). Important cautions about using home BP determinations include the need for thorough instruction in proper BP-taking technique and validation that the specific BP measuring device is accurate (133,134). Most indirect methods using arms cuffs tend to underestimate SBP and overestimate DBP when compared to direct assessment of BP by intraarterial measurement, which is usually reserved for research settings or rare situations in which validation of BP is essential (135).

Ambulatory BP monitoring by electronic technology is rarely necessary for the diagnosis of hypertension (136), but it may prove valuable in isolated cases for whom

white-coat hypertension (137) needs to be excluded (5). No consensus currently exists about the optimal analysis for ABPM data, although the concept of BP load has gained special prominence. The *load* refers to the percentage of readings during which the SBP or DBP exceeds predefined limits (e.g., 140/90 mm Hg while awake and 120/80 mm Hg during sleep). In one study, when the BP load exceeded 40%, the probability of increased LV mass index or decreased LV filling rate was 61%, compared to only 17% when the load was <40% (138). BPs tend to be highest at work, lower at home, and lowest during sleep in most individuals (139).

The remainder of the physical examination should search for target organ damage and evidence of atherosclerotic disease, concentrating on evidence for cardiomegaly, vascular insufficiency, bruits, and possible stigmata of secondary hypertension or comorbidities such as hepatic or renal dysfunction that can complicate therapy. Recent reports indicating increased risk of dementia among the hypertensive elderly (140) and risk of lacunar infarction underscore the importance of a careful baseline neurologic examination.

Hypertension often keeps close company with other cardiovascular risk factors, including diabetes mellitus, dyslipidemia, hyperinsulinemia, and exogenous obesity (82). In the National Health and Nutrition Examination Survey II, the prevalence of hypertension (BP ³160/95) was 2.9 times higher among patients who were overweight compared to those who were not. Obesity brings a two- to sixfold increase in the probability of developing hypertension (141) and may account for 65% to 78% of its attributable risk (142). Upper-body or android fat patterns (apple-like) are more dangerous cardiovascularly than lower-body or gynoid patterns (pear-like) (143), perhaps more in women than in men (144).

The obese patients were also 2.9 times more likely to have diabetes mellitus and 1.5 times more likely to have hypercholesterolemia, whether mediated through relative insulin resistance (145) or changes in cytosolic calcium (146). Most of the individual factors (e.g., hypercholesterolemia, obesity) exhibit an exponential relation to subsequent rates of adverse outcomes, rising disproportionately as the number of risk factors increases. In combination, these risk factors are multiplicative rather than simply additive (147).

Smoking and alcohol use also contribute to hypertension. Cigarette smoking directly and indirectly leads to endothelial damage and accelerated atherosclerosis. Epidemiologically, smoking is negatively associated with BP, relative body weight, and physical activity during leisure; smoking is positively associated with total cholesterol, psychological stress, and alcohol abuse (148). The use of alcohol itself is associated with higher BP (149). Consuming three or more alcoholic drinks a day (»40 g ethanol per day) increases BP, even when controlling for body mass index, cigarette smoking, and age (150).

PRINCIPLES OF MANAGEMENT

Goal of Antihypertensive Therapy

The overall goal of antihypertensive therapy is to prevent cardiovascular morbidity and mortality. Management generally combines nonpharmacologic and drug therapy to optimize BP control. Table 5.4 summarizes recommendations for nondrug therapy.

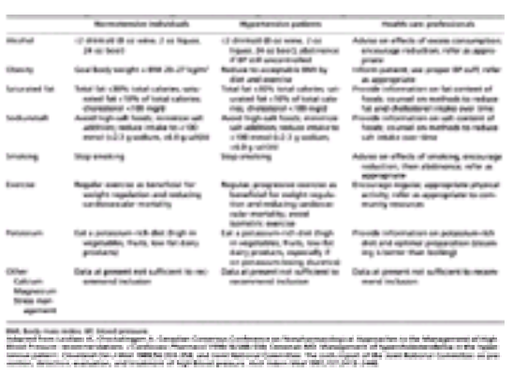

TABLE 5.4 RECOMMENDATIONS FOR NONDRUG THERAPY

Nonpharmacologic Treatment

Most studies confirm that nondrug therapy may be effective for mild or labile hypertension but that combined nondrug and drug therapy is generally more powerful in controlling BP than nondrug treatment alone (151) and more cost-effective for more severe disease (152).

Weight Reduction

Loss of excess weight reduces SBP and DBP. The Trials of Hypertension Prevention (153) produced an average weight loss of 3.8 kg at 18 months, reduction of SBP and DBP by 2.9 mm Hg and 2.3 mm Hg respectively, and a 51% reduction in hypertension incidence among individuals with high normal BP by using caloric restriction and modest physical activity. Similar results have been reported by two other randomized controlled trials of nondrug therapy (154,155) and among patients with morbid obesity (156). None of these trials reported adverse effects from weight loss. Other benefits of weight loss generally include improvement in lipid profile (157) and reduced rates of developing diabetes mellitus, breast cancer, and gout (113).

Most trials confirm that BP reduction is directly related to the weight loss achieved, although less-than-optimal weight loss may still reduce BP to levels below the need for supplemental treatment. If weight gain recurs, hypertension may return, but most trials suggest that the regain is only partial and that long-term benefits of BP reduction persist (153,154 and 155,158).

Exercise

Adding physical activity to a weight-loss program accelerates the weight loss and augments BP reduction (159). An addition of even a 20-minute daily walk can reduce the risk of incident hypertension by 29% (160). The precise mechanism likely involves decreases in CO and peripheral resistance, as well as modifications in serum norepinephrine levels, insulin sensitivity, electrolyte balance, neural and baroreflex mechanisms, and vascular structure (161).

After increased physical activity, BP falls as much as 6 to 7 mm Hg for SBP and DBP, independent of any weight changes (113). Escalating daily activity level may be superior to concentrated workouts three times per week (162), and moderate-intensity endurance exercise proves as effective as higher-intensity exercise for reducing BP (163). To plan exercise programs, summaries of energy expenditures for representative activities and lists of contraindications may be helpful (164).

Dietary Adjustment

Some of the most dramatic evidence supporting nondrug therapy has emerged from the Dietary Approaches to Stop Hypertension trial (165). The study evaluated 459 subjects with mild hypertension (<160/80–95) randomized to usual diet or to a diet with increased fruits and vegetables with or without reduced total and saturated fat intake. Despite lasting only 8 weeks, the combined dietary intervention reduced BP by 11.4/5.5 mm versus 7.2/2.8 mm achieved by increasing fruits and vegetables alone (p <.01). Fully 70% of subjects on combination diet—versus only 45% on increased fruits and vegetables alone and 23% on usual diet—were normotensive at the end of 8 weeks (166). The Dietary Approaches to Stop Hypertension combination diet emphasizes fruits, vegetables, and low-fat dairy products; it includes whole grains, poultry, fish, and nuts and decreases fat, red meat, sweets, and sugar-containing beverages. The precise mechanisms by which such dietary changes can rapidly lower BP remain uncertain.

Sodium Restriction

More than 70 published studies have addressed the impact of reducing sodium intake on BP (40,167). Despite crossover and parallel group comparisons in normotensive and hypertensive trial populations, most trials have been too small to assess definitively the sodium hypothesis of hypertension causation. A metaanalysis of 32 randomized controlled trials of reducing salt intake estimated the net effect of decreasing intake by 100 mmol per day as –6 mm Hg systolic (168). Another review of 56 trials found the BP reduction at –3.7 mm Hg for a mean 95 mmol salt intake reduction (41). A metaanalysis of nine trials of 24-hour urinary sodium

excretion suggested that salt intake was an independent determination of LV mass (169).

Pooled estimates suggest that BP reductions are most impressive among older individuals, those with higher baseline levels of BP, and particularly those who are salt-sensitive (167). Most important, sodium restriction often allows reduction in the need for antihypertensive medications, regardless of combination with weight loss (170). In one trial of sodium reduction with or without weight reduction among elderly hypertensives, 34% to 44% of patients were able to remain off their antihypertensives, compared to only 16% who continued on their usual diet (171). The principal hurdles include maintaining such reductions over the long haul and dealing with the high sodium content of most processed foods (36). Despite these data, the optimal guideline for salt use remains controversial (172).

Alcohol Restriction and Smoking Cessation

Restricting habitual consumption to two or fewer alcohol drinks per day can reduce BP in normotensive and hypertensive individuals and may help prevent hypertension (113). Whereas stopping smoking generally does not reduce BP, its cessation dramatically reduces overall cardiovascular risk. An important caution surrounds the weight gain that commonly accompanies the cessation of smoking and creates a major hurdle to individuals otherwise willing to stop.

The impact of alcohol use occurs in both genders, increases with age, combines with obesity, and may be aggravated by cigarette smoking (36). Among individuals consuming four to six standard drinks a day, the pressor effect lasts throughout the 24-hour period (173). There may also be a withdrawal component to patients exhibiting higher pressures after binge intake (36).

Stress Reduction/Relaxation Training

Some benefit of relaxation, meditation, or biofeedback has been reported from workplace and clinical settings (174,175). One review of 25 published randomized controlled trials enumerated 823 subjects on active treatment, but the studies had many methodologic limitations: small sample sizes (17 of 25 studies had <40 subjects), short duration (average = 3 months), and small effects (176). Only two of five studies with >15 subjects per treatment arm and ³12 months of treatment duration exhibited significant BP reductions. The one randomized controlled trial testing the value of stress management in preventing the development of hypertension could not demonstrate a clear benefit (153). There is insufficient current evidence to support stress reduction as a principal treatment modality for hypertension. Conflicting data exist as to whether high job stress alone is a powerful predictor of subsequent hypertension or whether the methods for coping with stress are more determinant (36).

Other Dietary Changes

Most of the published trials of potassium supplementation have been small, short, and limited to normotensives or subjects with mild BP elevations. Even when the trials were larger, longer, or pooled for data analysis, the net effect of potassium supplementation was modest: 3 to 5 mm Hg net reduction in BP (113,177).

The data in support of calcium's beneficial effect for hypertension are scant. Although 25 randomized controlled trials of calcium supplementation have been reported, most show small or inconsistent results. Even when pooling results from 23 of the trials, the average net reduction in BP was 0.5 to 1.0 mm Hg (113).

Similarly disappointing results have emerged about magnesium supplementation. Of the nine published clinical trials, many are confounded by intercurrent use of antihypertensive medications (113,153). Magnesium supplementation, moreover, frequently caused indigestion, diarrhea, or other gastrointestinal complaints.

No association for BP was demonstrable for total dietary fat (178). Replacing saturated fats with mono- or polyunsaturated fats has produced no significant change in BP, although replacing these fats still is beneficial for reducing overall cardiovascular risk. Similarly, reductions in dietary protein or increases in dietary fiber show no net effect on BP. Fish oil supplements of ³3 g per day (at least two 100-g servings of fish or 6 to 10 fish oil capsules) produced net reductions of 3 to 5 mm Hg among hypertensives that were accompanied by flatulence and a taste and smell found disagreeable to many patients and their families (179).

Selecting Drug Therapy

If 3 to 6 months of nondrug therapy fail to reduce BP to acceptable levels, the clinician should consider antihypertensive medications. *e*Table 5.4.1 summarizes the objectives for antihypertensive drugs (180).

***e*TABLE 5.4.1** OBJECTIVES FOR ANTIHYPERTENSIVE DRUGS

Display efficacy as monotherapy in more than 50% of all patients
Provide 24-h blood pressure control during all activities
Reduce vascular resistance and improve arterial compliance
Preserve cardiac output and maintain perfusion to critical organs
Reverse the pathologic structural changes (e.g., cardiac hypertrophy)
Minimize target organ damage
Avoid tolerance or pseudotolerance
Avoid reflex volume retention or stimulating neurohumoral mechanisms
Reduce ventricular ectopy if present and maintain normal hemodynamic response to exercise
Display favorable biochemical and metabolic effects and favorable profiles in comorbidities
Offer few side effects and good quality of life
Facilitate optimal compliance with drug regimen and offer once-per-day dosing

Adapted from Houston MC. Hypertension strategies for therapeutic intervention and prevention of end-organ damage. *Prim Care* 1991;18:713–753.

No single strategy for selecting antihypertensive drug therapy is relevant and helpful for all patients. Four principal approaches have emerged as useful: stepped care, demographic analysis, renin profiling, and individualization.

Stepped Care

Over the past two decades, the concept of progressive, stepped care has evolved from a narrow set of incremental options to a broader set of guidelines by the Joint National Committee VI (JNC VI) (5):

Step 1—Prescribe lifestyle modifications, including weight reduction, moderated alcohol intake, regular physical exercise, reduced sodium intake, and smoking cessation.

Step 2—If response is inadequate, continue the lifestyle modification and add monotherapy for mild to moderate (stage 1–2) hypertension with thiazide diuretics or beta-blockers, unless there is a contraindication. Other agents [e.g., angiotensin-converting enzyme (ACE) inhibitors, calcium antagonists, $alpha_1$-blockers, and alpha-beta-blockers] are satisfactory substitutes for patients with contraindications, although the long-term net benefit of these drugs is not established.

Step 3—If response to initial treatment is inadequate, increase drug dose, substitute another antihypertensive drug, or add a second agent from a different drug class.

Step 4—If response is still inadequate, add a second or third agent from a different drug class, including an appropriate diuretic (if not already administered).

This approach carries several major advantages: simplicity of understanding and implementation, emphasis on administration of complementary drug classes for synergism, and titration to minimize toxicities. The JNC VI offers limited sensitivity to three issues: hemodynamic diversity among hypertensives, negative metabolic effects of thiazides and beta-blockers, and the need for direct testing of stepped care versus alternative approaches.

Demographic Analysis

Several investigators have propounded useful, if simplistic, heuristics that summarize relative responsiveness of demographic subgroups to different antihypertensive drug classes. Although helpful as generalizations, these guidelines reflect relative, not absolute, effectiveness.

Younger patients may exhibit high or normal CO, which is often associated with a sympathetically activated, hyperkinetic circulation. Such individuals may be responsive to ACE inhibitors or antiadrenergic agents such as beta-blockers. Older patients more commonly display low or normal plasma renin activity (PRA), volume expansion, and increased peripheral resistance. Such patterns often respond to diuretic or calcium antagonist therapy. A majority of black hypertensive patients shows volume-dependent, low-renin patterns, compared to about 10% of white hypertensives. Whereas diuretic therapy may be especially effective, other drug classes (e.g., beta-blockers, calcium antagonists, and ACE inhibitors) may also control BP among black hypertensives (181). Such differences in demographic responsiveness to medications decrease when more than one class of antihypertensive agents are used. The demographic and hemodynamic differences offer modest support for the principles summarized in eTable 5.4.2.

***e*TABLE 5.4.2** DEMOGRAPHIC/HEMODYNAMIC CLUSTERING OF RELATIVE RESPONSIVENESS TO MONOTHERAPY BY ANTIHYPERTENSIVE DRUG CLASS

Factor	Diuretics	Beta-blockers	Alpha$_1$-blockers	ACE inhibitors or AII receptor antagonists	Calcium antagonists
Older age (vs. younger)	+++	+	++	++	+++
Black race (vs. white)	+++	+	++	++	+++
Volume dependency (vs. not)	+++	+	++	+	++
High renin (vs. low)	+	+++	+	+++	+
- Sympathetic activity (vs. -)	+	+++	+++	++	++

AII, angiotensin II; ACE, angiotensin-converting enzyme; +, less effective; ++, effective; +++, more effective than comparison group.
Modified from Dzau VJ. Evolution of the clinical management of hypertension. Emerging role of “specific” vasodilators as initial therapy. *Am J Med* 1987;82:36–43.

Renin Profile Analysis

Classification of hypertensive patients into renin-sodium strata may carry prognostic and therapeutic implications (52,183). The process requires assessment of PRA and 24-hour urinary sodium excretion on a stable diet. By such evaluation, hypertensive populations have been categorized as low-renin (20% to 30% of group), normal-renin (50% to 60%), or high-renin (10% to 15%) subtypes. Pretreatment renin-sodium profiles predict differential rates of subsequent MI among high (14.7/1,000 person-years), normal (5.6), and low (2.8) renin-sodium profile subjects (52). These differences occur despite comparable success in BP control among all three groups. No significant differences were observed over more than 8 years of follow-up for stroke or noncardiovascular events.

Therapeutically, high-renin hypertensives reportedly respond better to ACE inhibitors, central alpha$_2$-agonists, peripheral alpha$_1$-blockers, beta-blockers, and nondihydropyridine calcium antagonists. In contrast, hypertensives with low-renin profiles display higher responsiveness to dihydropyridine calcium antagonists and diuretics. Despite the conceptual attractiveness and prognostic implications, renin profiling has not achieved wide acceptance as a method for selecting drug therapy (184). Practical obstacles to the use of renin profiling include cost, inaccuracies and logistics of 24-hour urinary collections, and suboptimal predictive characteristics. Most clinicians find therapeutic trials of particular medications more feasible and less expensive.

Individualized Approach

Perhaps the most comprehensive strategy for selecting antihypertensive therapy is the individualized approach. It factors in patients’ profiles of hemodynamics and pathophysiology, cardiovascular risk analysis, concurrent medical conditions and therapies, demographics, quality-of-life analysis, and cost. In essence, the customized approach corresponds to a type of “mosaic” model of treatment, incorporating a large number of variables that differ for each individual.

The strategy consists of six components. Responding to the projected *pathophysiology and hemodynamics*, the clinician chooses medications to reverse the underlying circulatory dysregulation, lowering the vascular resistance, if elevated, while preserving CO and maintaining perfusion to critical target organs, both at rest and with exercise and over the entire 24 hours.

Reflecting *cardiovascular risk profile analysis*, the clinician should avoid medications that worsen the known risk profile, such as using high-dose thiazides in a patient with elevated low-density lipoprotein cholesterol. In addition, the clinician should prospectively monitor those regimen- affected factors that impact risk and continuously adjust the regimen to minimize overall risk, whether related to atherosclerosis, major arrhythmias, congestive failure, or sudden death (184).

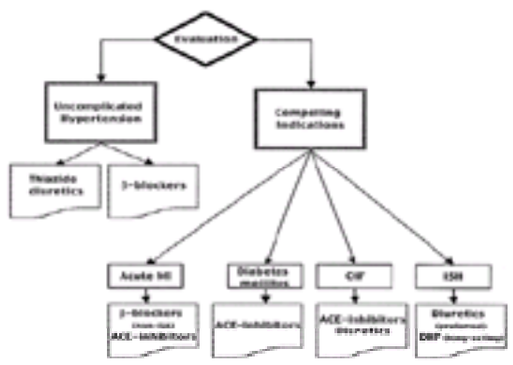
Aware of *concurrent medical conditions and therapies*, the clinician prescribes the fewest antihypertensive drugs to treat the greatest number of concomitant conditions, such as using beta-blockers when angina and hypertension are present in the absence of heart failure, peripheral vascular insufficiency, or bronchospasm. Such therapeutic parsimony facilitates medication adherence by simplifying the overall regimen and minimizes adverse drug reactions and drug-drug interactions. This approach uses the *demographic* patterns previously described but integrates the options related to age and race with the other factors as well (185).

To optimize adherence to the regimen, the clinician seeks to optimize the patient’s *quality of life* by considering physical, mental, social, emotional, and sexual functions (186,187 and 188).

Finally, the strategy considers cost: the sum of drug acquisition cost, required concomitant treatment (e.g., potassium supplementation for thiazide diuretics) and tests (e.g., monitoring serum potassium and renal function), clinician visits, hospitalizations and emergency evaluations, missed work from disease or side effects, and direct and indirect costs of long-term morbidity and mortality, as well as lost wages and productivity (10,189).

The guidelines for initial drug therapy promulgated by the JNC VI reflect these considerations. They incorporate consideration of patient comorbidities and the use of agents proven to reduce mortality in randomized controlled trials.

The JNC VI suggests three pathways for initiating medical treatment in patients requiring drug therapy for hypertension. First, patients with uncomplicated hypertension should be initiated with a beta-blocker or a diuretic. Second, patients with coexisting conditions and “compelling indications” should be started on medications that have been shown to reduce mortality. The choice of these drugs are “compelling” in that they have been shown by randomized controlled trials to reduce mortality in the specific condition (e.g., use of ACE inhibitors in patients with heart failure) and should be used unless strong contraindications to their use exist. Third, patients with comorbidities should be started on medications that are favorable to other medical conditions present (e.g., use of alpha$_1$-blockers in patients with coexisting prostatism) (eFig. 5.1.2).



***e*FIGURE 5.1.2** Flow diagram distinguishing selected “compelling indications” that steer selection of initial antihypertensive monotherapy away from the default choices of thiazide diuretics or beta-blocker treatment. ACE, angiotensin-converting enzyme; CHF, congestive heart failure; DHP, dihydropyridine; ISA, intrinsic sympathomimetic activity; ISH, isolated systolic hypertension. (Adapted from Joint National Committee. The sixth report of the Joint National Committee on prevention, detection, evaluation, and treatment of high blood pressure. *Arch Intern Med* 1997;157:2413–2446.)

One controversial strategy to minimize medication-related cost and toxicity is to attempt cautious “step-down” therapy with progressive reduction and, sometimes, discontinuation of therapy—especially for patients with mild elevations (190) or good control, despite imperfect medication compliance (191,192).

Hemodynamics of Essential Hypertension/Drug Effects

Table 5.5 summarizes the effects of antihypertensive drug therapy on concomitant medical conditions and metabolic disorders, and Table 5.6 lists common drug interactions for antihypertensive therapy. Table 5.7 indicates the dosing guidelines and relative advantages and disadvantages by drug.

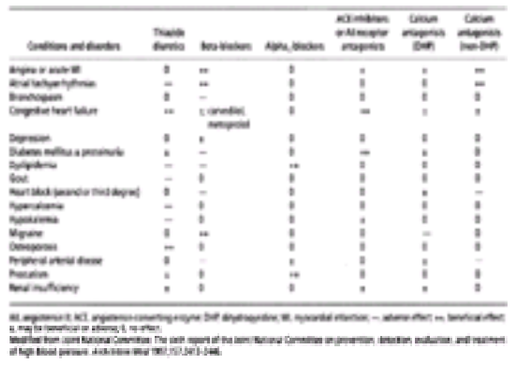


TABLE 5.5 EFFECTS OF ANTIHYPERTENSIVE DRUG THERAPY ON CONCOMITANT MEDICAL CONDITIONS AND METABOLIC DISORDERS

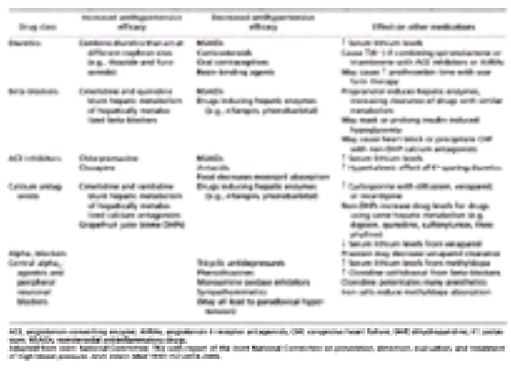

TABLE 5.6 IMPORTANT DRUG INTERACTIONS IN ANTIHYPERTENSIVE THERAPY

TABLE 5.7 ANTIHYPERTENSIVE DRUG THERAPY: A PHARMACOLOGIC SUMMARY

The optimal hemodynamic approach to antihypertensive drug treatment is to reduce systemic vascular resistance (SVR) while preserving CO and perfusion of critical target organs such as brain, heart, and kidney. Available medications for lowering BP conveniently fall into three subgroups by hemodynamic alterations, as summarized in *e*Table 5.7.1.

***e*TABLE 5.7.1** ANTIHYPERTENSIVE DRUGS BY HEMODYNAMIC CLUSTER

Drugs reducing SVR, preserving CO and organ perfusion
- Alpha$_1$-blockers
  - Prazosin, terazosin, doxazosin rimazosin
- Alpha$_2$-central agonists
  - Clonidine, guanabenz, guanfacine, methyldopa
- Diuretics
  - Thiazides, spironolactone
- ACE inhibitors
  - Captopril, enalapril, lisinopril, ramipril, benazepril, quinapril, etc.
- Angiotensin II receptor antagonists
  - Candesartan, eprosartan, irbesartan, losartan, valsartan, etc.
- Dihydropyridines
  - Nifedipine, nicardipine, amlodipine, nitrendipine, nimodipine, isradipine, etc.
- Direct vasodilators
  - Hydralazine, minoxidil, pinacidil

Drugs elevating SVR and reducing CO
- Beta-blockers
  - Without ISA
    - Propranolol, metoprolol, timolol, atenolol, nadolol, betaxolol, penbutolol, etc.
  - With ISA

Pindolol, acebutolol, carteolol, etc.

Drugs reducing SVR and reducing CO
- Combined alpha/beta agents
  - Labetalol, carvedilol, etc.
- Other sympatholytic agents
  - Reserpine, guanethidine, guanadrel
- Nondihydropyridine calcium antagonists
  - Diltiazem, verapamil

ACE, angiotensin-converting enzyme; CO, cardiac output; ISA, intrinsic sympathomimetic activity; SVR, systemic vascular resistance.

The first group of medications *reduces SVR while preserving CO and organ perfusion*. Most of these agents may be administered as initial monotherapy with little compensatory neurohumoral response—except for the direct vasodilators, which induce reflex tachycardia, fluid retention, and increased myocardial work. Diuretics initially produce modest contraction of intravascular volume, but antihypertensive effect may be delayed for weeks or even months as SVR falls and CO returns to near

normal levels. Although calcium antagonists share a common name, the subgroup of dihydropyridines distinctively produces vasodilatation, decreased SVR, and reflex sympathetic stimulation with possible tachycardia, fluid retention, and vasodilatory headache.

The second group of medications *elevates SVR and reduces CO*. Recent studies indicate that all beta-blockers share an unfavorable hemodynamic response to exercise and may compromise perfusion to skeletal muscle, liver, and kidneys. Distinctions between selective and nonselective beta-blockers are dose-dependent and tend to converge on nonselective features as administered dose increases (180).

The third group of medications *reduces SVR and reduces CO*. Whereas unpleasant side effects generally limit the utility of guanethidine and guanadrel, reserpine has received some renewed attention because of low cost, long duration of action to compensate for partial compliance, and demonstrable long-term efficacy, especially in combination with diuretic therapy (193). Combined alpha/beta agents, such as labetalol, offer the convenience of reduced SVR from $alpha_1$-blockade and controlled heart rate from beta-blockade (194), as well as recent reports of better survival in heart failure (195). Finally, the nondihydropyridine calcium antagonists promote vasodilatation and negative inotropic and chronotropic cardiac effects.

There is a growing body of data exploring the duration of drug effect and seeking insights into the optimal dosing pattern. Not all drugs lead to consistent and satisfactory BP control for 24 hours, despite pharmacokinetic patterns justifying once-daily administration (196).

EVALUATION FOR SECONDARY FORMS OF HYPERTENSION

Prevalence

Curable secondary hypertension is relatively rare (197). Among unselected patient series, primary hypertension is the ultimate cause in 93% to 94% of cases, renal parenchymal disease in an additional 5% to 6%, and all other causes of presumably reversible secondary hypertension accounting for only 1% to 2% of the total, as summarized in eFigure 5.1.1 (197,198,199,200 and 201). There is little justification for aggressive evaluation of every hypertensive patient for secondary hypertension in the absence of important clues. The diagnostic process may resume if patients later exhibit new clues or refractoriness to treatment. Several important clues from history, physical examination, or baseline testing may indicate a higher-than-usual likelihood of secondary hypertension. The differential for secondary hypertension appears in eTable 5.7.2, and the clues are summarized in Table 5.8.

***e*TABLE 5.7.2** DIFFERENTIAL DIAGNOSIS OF SECONDARY HYPERTENSION

Renal parenchymal disease
- Anephric
  - Volume dependency
- Chronic dialysis
  - Volume dependency
  - Autonomic dysfunction
- Posttransplantation

- Catecholamine secreting tumors
- Hyperthyroidism
- Hyperparathyroidism

Pharmacologic
- Vasoconstrictors
- Volume expanders
- Other

TABLE 5.8 SECONDARY HYPERTENSION: AN OVERVIEW

Renal Parenchymal Disease

Renal parenchymal disease constitutes a collection of diverse conditions, and it is the single largest cause of secondary hypertension (202). Most of these conditions may not be reversible.

A large array of clinical situations affect renal parenchyma and produce hypertension. Acute renal failure may result from acute glomerulonephritis (especially postinfectious, crescentic, or focal segmental changes), vasculitis (especially systemic lupus erythematosus, scleroderma, or polyarteritis), or acute obstruction. When the renal dysfunction is more insidious, ultimately destroying ³80% of the nephrons, chronic renal failure occurs. The most common causes are vasculitis, glomerular disease (especially diabetic nephropathy and crescentic or focal segmental glomerulitis), and polycystic renal disease (203). Two patient clusters predominate. Most patients have a volume-dependent form of hypertension that is indicative of chronic glomerulonephritis and is usually relatively easy to control. A less common subset of patients has nephrosclerosis that is dependent on renin rather than volume and is often more difficult to control. Most patients requiring chronic dialysis display a volume dependency and variable degrees of autonomic dysfunction, whereas those with no functional kidneys or post bilateral nephrectomy usually are volume-dependent.

Other, less common causes of hypertension associated with chronic renal disease include pyelonephritis, membranous and membranoproliferative glomerulonephritis, immunoglobulin A nephropathy, renin-secreting tumors, or drug-induced renal dysfunction (e.g., phenacetin-associated analgesic nephropathy) (204). Even after renal transplantation, hypertension may result from continuation of prior hypertension, excess renin from the native kidney if not removed, posttransplant renal artery stenosis, immunosuppressive therapy [e.g., corticosteroids, cyclosporine, and tacrolimus (205)], chronic rejection, recurrent intrinsic renal disease, or volume overload.

Screening tests usually reveal azotemia, microalbuminuria, proteinuria, or abnormal urinary sediment. The most important management decisions usually revolve around the desirability and timing of dialysis or transplantation, as well as the optimal management of the volume component of the hypertension. The volume component usually responds to diuretics or to dialysis, whereas the renin component may require beta-blockers, ACE inhibitors, AII receptor antagonists, or minoxidil. Several of the standard antihypertensive agents may need dose adjustments in chronic renal failure (204). Optimizing BP control—usually to a lower target pressure (120–130/70–80 mm Hg) than for other hypertensive patients—may slow progression of the renal disease. Proteinuria itself serves as an independent risk factor for renal dysfunction (206), as well as for overall risk of cardiovascular disease (207). Direct comparison of the calcium antagonist nisoldipine versus the ACE inhibitor enalapril revealed that BP control was more important than the specific agent used for preserving creatinine clearance (208). More importantly, the trial demonstrated

that renal function can be stabilized in type II diabetes over 5 years before frank albuminuria by achieving BPs no higher than 138/86 mm Hg.

Vascular Causes of Hypertension

Hypertension may result from physiologically significant stenosis of the renal arteries, the aorta, and a variety of other vascular structures.

Renovascular Causes of Hypertension

Activation of the renin-angiotensin-aldosterone system can result from compromise of arterial flow to either or both kidneys. Depending on the status and participation of the contralateral kidney, the ischemic stimulus may elevate renin, promote fluid retention, or both.

Two clinical subgroups comprise the majority of patients with renovascular hypertension: fibromuscular dysplasia and atherosclerotic disease. Fibromuscular dysplasia of the renal arteries accounts for less than 10% of all renovascular hypertension and occurs almost exclusively in younger patients, especially females. Although five pathologic subtypes are described, 70% of affected individuals display medial fibroplasia, and an additional 20% show perimedial fibroplasia. Both of these subtypes exhibit classical beaded appearance on angiography (209). Although the precise pathogenesis is uncertain, the natural history usually consists of slow progression of stenosis without frank occlusion (210).

Atherosclerotic disease, making up about 90% of the total causes, usually involves the proximal third of the renal artery with or without encroachment of the ostium itself. Lesions generally arise bilaterally, although one side may predominate. Atherosclerosis disease may extend for years without signaling its presence with hypertension or even elevated serum creatinine. Left untreated, most lesions progress, including complete occlusion and renal failure (210). If stenosis exceeds 75%, the probability of progression to full occlusion approaches 40% over 1 year (211). As many as 5% to 15% of individuals entering dialysis programs have previously undetected renovascular hypertension (210).

Less common causes of renovascular hypertension include Takayasu's arteritis, polyarteritis nodosa, aneurysms, radiation fibrosis, thromboemboli (including cholesterol emboli), and extrinsic compression of the renal arteries by tumor.

Two scenarios are most likely to herald renovascular hypertension: (a) recent onset of hypertension in a young white woman with no family history of hypertension; or (b) late onset or exacerbation of hypertension in an older man with strong evidence of coronary, cerebrovascular, or peripheral vascular insufficiency. Although abdominal bruits modestly increase the odds of significant stenosis, the presence or absence of bruits holds limited predictive value. Other potential clues include marked hypertensive retinopathy, marked or progressive worsening of renal function after ACE-inhibitor therapy, progressive worsening of azotemia despite adequate BP control, history of unilateral small kidney from incidental studies, history of smoking, and history of pulmonary edema in a difficult to control hypertensive (212).

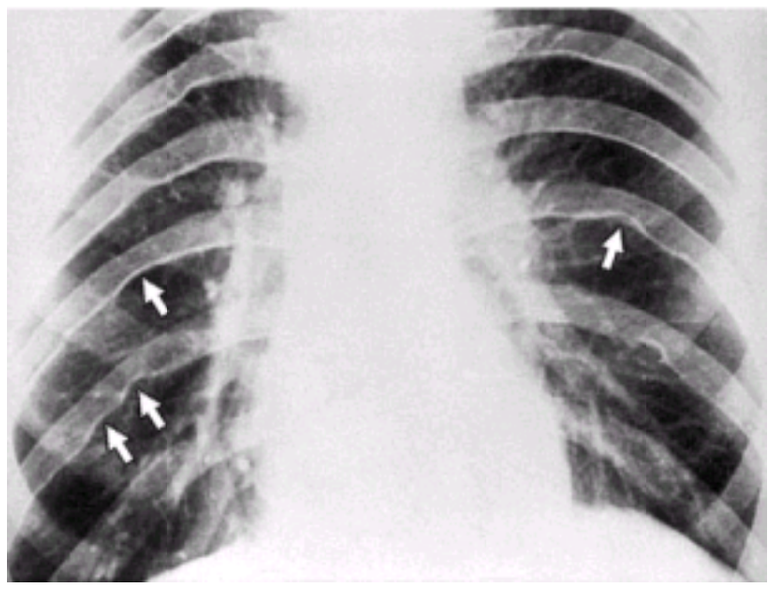
No perfect screening test exists. Baseline testing may demonstrate mild azotemia, proteinuria, or hypokalemia in <20% of individuals with the condition—modestly higher rates than among others with essential hypertension. Proponents exist for elevated peripheral PRA with or without captopril stimulation (213), renal scans, renal digital subtraction angiography (214), intravenous pyelography, and prompt progression to arteriography (215). Although it is an invasive test, arteriography remains the gold standard, searching for critical stenoses of ³80% (216). Given its poor positive and negative predictive value, the marginal utility of obtaining renal vein renins to confirm unilateral versus bilateral disease has been questioned (217). One alternative to direct angiography is the use of captopril scintigraphy, which combines radionuclide scanning of the kidney (especially with mercaptoacetyltriglycine) with captopril stimulation to enhance differences in renal blood flow (218). The ACE inhibitor produces a fall in glomerular filtration rate on the affected side more than a reduction in renal blood flow. A positive scan correlates with successful angioplasty or surgical intervention in ³90% of fibromuscular cases, but it may be less definitive in the elderly or in the presence of renal dysfunction (219). Its sensitivity can approach 100%, with specificity of 68% in selected series (220). Doppler ultrasound and magnetic resonance angiography offer promising results, but some consider them not yet cost-effective alternatives (221).

Preserving renal function preferentially involves endarterectomy, stenting, aortorenal bypass with saphenous vein or hypogastric artery, or partial nephrectomy when multiple distal stenoses occur. Rates of overall improvement and rapidity of improved glomerular filtration are superior among patients with fibromuscular dysplasia compared with those with atherosclerosis (222,223). The latter carry a worse prognosis because of progression of the arteriosclerotic process. Higher rates of successful repairs by angioplasty occur for fibromuscular dysplasia than for atherosclerotic disease. Another advantage of angioplasty is that it may take place at the same time as diagnostic angiography, with or without stenting (224).

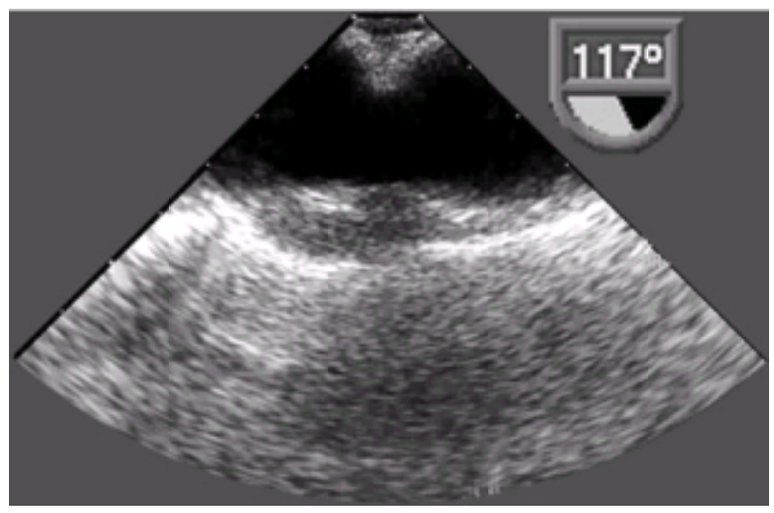
The trade-offs for medical management are especially acute for atherosclerotic disease. Progression of arteriosclerosis with occlusion and renal failure may occur even with adequate BP control. There have been no randomized controlled trials directly comparing the two treatment strategies (210). Useful drug classes have included ACE inhibitors or AII receptor antagonists (with cautions about hypotension, dose adjustment with renal dysfunction, and actual deterioration in renal function), beta-blockers, and dihydropyridine calcium channel blockers.

Aortic Coarctation

A variety of congenital and acquired malformations of the aorta may produce hypertension. Although the majority of patients presents during childhood, an important minority may pass into adulthood before definitive diagnosis (225). The variations include a left, right, or double aortic arch, which produces tracheal, bronchial, and esophageal compression. These conditions can be recognized on chest radiographs or esophagrams and confirmed by ultrasound, angiography, computed tomography (CT), or magnetic resonance imaging (MRI). Other congenital lesions of the aortic arch are characterized by aortic obstruction and include supravalvular aortic stenosis, aortic arch interruption or atresia, and coarctation (226).



Chest x-ray in coarctation of the aorta. There is prominent rib notching (*white arrows*).



A still frame of a transesophageal echo demonstrating a coarctation of the aorta. Note the local narrowing of the aorta located at the junction of the distal arch and descending aorta. There was a 100–mm Hg pressure gradient across the coarctation as determined by continuous wave Doppler.

Color Doppler interrogation of the coarctation demonstrating the high-velocity, turbulent flow across the focal narrowing in the aorta.

Angioplasty and surgery remain the treatments of choice, although complications of these procedures include functional impairment, aortic rupture, aneurysmal formation, and restenosis (227). Useful, noninvasive ways to confirm the diagnosis and monitor for complications include Doppler ultrasound with exercise for arm-leg differences (228), transesophageal echocardiography (229), and MRI (227).

Endocrinologic Causes of Hypertension

Cushing's Syndrome

Spontaneous Cushing's syndrome may be classified into (a) corticotropin-dependent forms (e.g., Cushing's disease, ectopic corticotropin syndrome, and the rare ectopic corticotropin-releasing hormone syndrome); and (b) corticotropin-independent forms (e.g., unilateral cortisol-producing adenomas and carcinomas). Rarely, bilateral adrenal hyperplasia—especially with functioning nodules—may yield the same clinical constellation of hypercortisolism, including hypertension. As the spectrum of conditions causing ectopic adrenocorticotropic hormone (ACTH) hypersecretion has filled in and expanded, even these distinctions have been become blurred (230). Fully 70% to 90% of patients with ACTH-dependent hypercortisolism have a pituitary tumor, but sophisticated special testing and endocrinologic consultation may still be necessary, once the syndrome is confirmed.

In most patients, the physical stigmata are striking: truncal obesity, moon facies, acne, buffalo hump, striae, and ecchymoses are coupled with osteoporosis, hyperglycemia, and hypertension (231). Up to 70% of individuals with the syndrome display hypertension, regardless of the subtype and independent of salt intake. Increased pressor responsiveness has been reported, probably due to local postsynaptic effector mechanisms in the resistance vessels; circadian BP variations have been decreased, absent, or even reversed (232). Initial screening for the diagnosis is best performed by a 1-mg, overnight dexamethasone suppression test or a 24-hour urinary-free cortisol after 2-mg dexamethasone suppression. Further distinctions require repeated plasma ACTH measurements by radioimmune assay, along with the 8-mg dexamethasone suppression test (233) or a corticotropin-releasing hormone stimulation test with inferior petrosal sinus sampling (234). Localization maneuvers include CT, MRI, or scanning using [^{131}I]6b-iodomethyl-19-norcholesterol—a marker of adrenocortical cholesterol uptake that accurately localizes adrenal cortex dysfunction (235).

Cholesterol emboli. Purpura secondary to cholesterol emboli are shown (*yellow arrows*).

The majority of individuals with Cushing's disease undergoes transsphenoidal exploration with remission rates of about 80%, especially for localized, relatively small tumors (236). Postoperative courses, particularly for patients undergoing adrenalectomy, may be stormy, in part because of cardiac complications associated with LVH (237). Recently described medical options include metyrapone, bromocriptine, and ketoconazole (238).

Primary Aldosteronism

Whereas Cushing's syndrome reflects glucocorticoid excess, a variety of other conditions exhibit mineralocorticoid excess. These conditions include primary hyperaldosteronism (adenoma, carcinoma, or bilateral hyperplasia), enzymatic deficiencies (11-OH-hydroxylase deficiency, 17-OH-hydroxylase deficiency, and 11-OH-dehydrogenase deficiency syndromes), or chronic licorice ingestion containing glycyrrhetinic acid (239). Although all of these conditions are relatively rare, the most common (60% to 90% of the total) is benign unilateral adenoma of the adrenal [aldosterone-producing adenoma (APA)], which yields inappropriately large and autonomous secretion of aldosterone with predictable metabolic and pathophysiologic consequences. Less common variants include idiopathic hyperaldosteronism (IHA or bilateral hyperplasia), nodular adrenocortical hyperplasia, aldosterone-producing renin-responsive adenoma, and glucocorticoid-suppressible hyperaldosteronism (240).

The autonomous secretion of plasma aldosterone (PA) occurs in distinction to its usual diurnal variation that is linked to plasma cortisol concentrations. Nonhormonal factors, such as increased serum potassium or decreased serum sodium, can stimulate aldosterone synthesis directly. Once secreted, aldosterone increases distal tubular sodium resorption and potassium secretion, increases intravascular volume, and suppresses renin secretion. When secreted in excess, aldosterone produces a volume-dependent hypertension, although there is physiologic escape from incessant sodium retention before frank edema develops.

Patients with primary hyperaldosteronism have no distinguishing symptoms from individuals with hypertension, although they may display nonspecific weakness, fatigue, polyuria, or cramps, presumably reflecting hypokalemia. APA is more common in women than in men, generally presenting in the third to sixth decade (241). An excessive loss of potassium or refractoriness to treatment may prompt further investigation. Hypokalemia may reach panic values (£2.8 mEq per L), especially after diuretic therapy, but may be in the low normal range (£4.0 mEq per L) without provocation or after salt restriction in up to 38% of patients (242).

The diagnostic process for primary hyperaldosteronism consists of three components: confirmation of inappropriately high aldosterone secretion, distinction between excisable tumor and nonsurgical glandular hyperplasia, and exclusion of rare variants suitable for medical therapy (other than aldosterone antagonists) (243). Because of many other causes of hypokalemia and low-renin hypertension, the single best screening test for the condition is a 24-hour urinary collection for aldosterone (244). The collection should occur after withdrawing all diuretics and ACE inhibitors for ³2 weeks and all aldosterone antagonists for ³6 weeks and repleting fluid status, sodium, and potassium to normal levels, if necessary, with 3 to 5 days of salt loading to ensure 24-hour urinary sodium of ³200 mEq/L (241). These steps are essential to avoid stimulation of aldosterone secretion by hyperkalemia or its inhibition by hypokalemia. Noninterfering antihypertensive drugs, including alpha$_1$-blockers and ganglionic antagonists such as guanadrel, may be used to control BP before the test. Alternatively, a logistically simpler screening test may be the PA to PRA ratio, if patients can be withdrawn safely from antihypertensive medications for ³2 weeks. A PA/PRA ratio >30 and a PA >20 ng/mL may yield a sensitivity of 90%, a specificity of 91%, a positive predictive value of 69%, and a negative predictive value of 98%. Some investigators have reported both consistent differentiation from essential hypertension and separation between APA and IHA—the two most common forms of primary hyperaldosteronism (245).

Once the triad of hypertension, high aldosterone, and low renin has been confirmed, the clinician can shift attention to detecting adenomata for which surgical excision is the treatment of choice and curative in 70% of cases (241). The hypertension, hypokalemia, and hyperaldosteronism are generally higher in APA than in IHA, but the distinctions are usually too small to be clinically useful. Imaging studies such as CT scans can detect adenomata of ³0.7 cm, but £8% of the normal population may have nonfunctioning, incidental adrenal adenomata. MRI scanning offers no clear advantage. Dexamethasone and Lugol's solution pretreatment and [^{131}I]6b-iodomethyl-19-norcholesterol scanning may highlight a functioning mass while suppressing surrounding adrenal tissue and protecting the thyroid. Unfortunately, scanning must proceed over 2 to 5 days and carries only a 72% accuracy that is highly dependent on the tumor's size (241).

Indirect confirmation of the pathophysiologic significance of such masses may come from orthostatic tests or selective venous sampling. Orthostatic tests for APA versus IHA are based on two complementary features: (a) APA usually displays autonomous aldosterone secretion unaffected by physiologic stimuli such as standing but is exquisitely sensitive to the diurnal variation in cortisol secretion; and (b) IHA exhibits no particular diurnal variation but marked responsiveness to renin-based stimuli such as standing. Most critically, the change in PA from 8 a.m. to noon after overnight recumbency must be interpreted in combination with the concomitant changes in PRA and plasma cortisol (239). An increase in plasma cortisol during the procedure invalidates the test because the procedure seeks to compare the relative strength of two stimuli: orthostatic stimulation from standing versus the physiologic fall in cortisol over the morning hours. Some investigators have reported sensitivities of 85% with the criterion of <30% orthostatic increase in PA (246).

Venous sampling of the adrenals may be justified despite the expense and risks if the CT scan is normal, despite unsuppressible PA. Worrisome complications of the procedure include adrenal infarction. Technically difficult, the catheterization may fail to cannulate the right adrenal vein in up to 25% of cases, but if it is successful, it permits direct measurement of aldosterone-cortisol ratios with ratios of >10:1 to lateralize the overproduction to one adrenal. Concomitant infusion of ACTH or cosyntropin minimizes stress-related changes in PA.

For the subset of patients with APA, unilateral total adrenalectomy is the treatment of choice in surgical candidates. High-dose spironolactone (200 to 600 mg per day in divided doses) for 2 to 6 weeks preoperatively corrects hypertension and hypokalemia, thereby predicting the surgical result (247). Despite careful workups and uncomplicated perioperative courses, long-term cure rates average <70%, even though most patients display improved BP control and simplified regimens. The BP may require 3 to 6 months postoperatively to fall to normal values (241).

For the remaining patients, no cure is available, although outcomes are often satisfactory (248). Treatment usually consists of a low-sodium diet (£80 mEq per day), maintenance of near-optimal body weight, and aldosterone antagonist therapy. Spironolactone is the drug of choice in the form of 200 to 600 mg per day in divided doses. Correction of hypokalemia occurs within days, whereas normalization of BP may require 1 to 2 months. Common side effects include painful gynecomastia, impotence, decreased libido, menstrual irregularities, and gastrointestinal discomfort. Alternative therapies include amiloride (10 to 40 mg per day), dihydropyridines (e.g., nifedipine 30 to 180 mg per day), or ACE inhibitors. In patients with the rare syndrome of glucocorticoid-suppressible aldosteronism, spironolactone therapy may be as effective and better tolerated than dexamethasone 2 mg daily (241).

Pheochromocytoma

Pheochromocytomas and other catecholamine-secreting tumors—termed *paragangliomas* when arising outside the adrenal—may prompt some of the most dramatic moments in hypertension. The clinical spectrum is wide, ranging from previously unsuspected tumors, which first gain recognition from hypertensive crisis after a procedure like anesthesia, to incidentally discovered, slow growing, sometimes large, almost metabolically inactive masses. Nearly 80% of the tumors are limited to the adrenal glands, usually unilaterally. The tumors are more likely to be bilateral or multiple in pediatric presentations or in familial forms such as neurofibromatosis, von Hippel-Lindau disease, or multiple endocrine neoplasia type 2a or 2b. An additional 10% to 20% arise in other intraabdominal sites, and <5% appear from intrathoracic sites along the neurosecretory crest or bladder. A small number come from intracranial sites. Up to 20% of tumors are multiple. Less than 10% of all catecholamine-secreting tumors are malignant, although their presentation may be difficult to distinguish from their more benign equivalents. Prompt diagnosis and definitive treatment is essential to avoid cardiomyopathy, CHF, and other potentially lethal outcomes (249).

Disease manifestations reflect the direct and indirect effects of catecholamines, either hypersecreted at random intervals for variable durations or tonically released. The classic triad of episodic headache, palpitations with or without tachycardia, and inappropriate perspiration accompanying the hypertension may suggest pheochromocytoma. The full textbook description, however, occurs less than half of the time. Other findings that may indicate pheochromocytoma include nervousness and anxiety, tremor, nausea, abdominal or chest pain, orthostatic drops in BP, glucose intolerance, weight loss, pallor, and fatigue (249). Usually the most spectacular symptoms accompany the most dramatic BP elevations. Although less likely without one or more of the classical symptoms, the diagnosis of pheochromocytoma should be considered in patients unresponsive to appropriate triple-drug therapy, patients with paroxysmal hypertension associated with clinical procedures, or patients with hypertension developing after phenothiazine, tyramine, or tricyclic medications. Pregnancy may unmask the disease, as the growing uterus applies pressure on the adrenal, or after micturition in the rare presence of bladder wall-based tumors. Tumors that are nearly silent metabolically may grow to large size before detection, whereas metabolically active lesions generate enough early symptoms to be small when first discovered.

Under most circumstances, the diagnosis of catecholamine-secreting tumor receives first confirmation by elevated urinary levels of one or more of the vasoactive hormones. Most tumors secrete norepinephrine and epinephrine, although the former usually predominates. Because any single hormone may or may not be elevated, most published guidelines call for collecting an array, usually consisting of metanephrine, normetanephrine, total catecholamines, vanillylmandelic acid, norepinephrine, and epinephrine. Some have argued that a negative assay for a single catecholamine has a 98% predictive value for ruling out the disease in a primary care population (250). Optimally, the diagnostic procedure consists of a 24-hour collection that includes a catecholamine and creatinine to monitor sufficiency of urine collection. Shorter timed intervals (e.g., 4 to 8 hours) may be useful when full-day collections are impractical or if episodic symptoms are short-lived and potentially diluted by longer collections. Using µg of catecholamine/mg creatinine, the clinician may extrapolate to a full day's collection. Urine collections should occur at times of sustained hypertension. Plasma catecholamines may be equally diagnostic, as long as collection procedures are assiduously followed to minimize false-positives and false-negatives (249). Recent reports suggest that plasma metanephrine is more sensitive (»100%) than serum catecholamines or urinary metanephrines for the diagnosis of pheochromocytoma and retains specificity (»85%) similar to that of serum catecholamine determinations (251). Newer biochemical techniques usually obviate the need for dietary or drug restrictions (252).

The majority of patients with pheochromocytoma has dramatic elevations of catecholamines that are at least twice normal. If the clinical suspicion is high but the urinary concentration is only equivocally elevated, use of an oral clonidine suppression test (plasma catecholamine levels before and after clonidine, 0.3 mg orally) (253) or overnight clonidine suppression test (clonidine, 0.3 mg orally, at 9 p.m. with overnight urine collections) (254) to minimize hypotensive reactions may distinguish clonidine-suppressible versus irrepressible secretion. Clonidine serves to reduce central sympathetic outflow among patients with essential hypertension, but it leaves autonomous secretion unaffected. The provocative tests commonly recommended in prior decades are now relegated only to the small number of individuals with ambiguously mild elevations but strong clinical suspicion.

Definitive diagnosis and full localization usually require biochemical tests for catecholamines and scanning of potential sites by CT or MRI. On occasion, these scans may fail to localize the tumor. Scanning by [^{131}I]-metaiodobenzylguanidine (MIBG) uses a guanethidine analog with affinity for chromaffin tissue to search the entire body, rather than a more focal anatomic study that generally requires a lesion ³1 cm in diameter for detection. A number of antihypertensive drugs—including labetalol, nifedipine, reserpine, diltiazem, verapamil, and tricyclic medications—may interfere with the test (255).

In most situations, patients with catecholamine-secreting tumors undergo curative resection as definitive therapy. Perioperative management usually includes several weeks of alpha$_1$-blocker therapy, especially phenoxybenzamine, and rehydration to avoid abrupt hypotension from withdrawal of the elevated catecholamines once the tumor pedicle is clamped. Often, the degree of alpha-blockade—using phentolamine or nitroprusside—is only partial to assist the surgeon in localizing the tumor by direct palpation during the exploration and to ensure that BP falls with complete excision. Persistent BP elevations may indicate additional catecholamine-secreting tumors. Beta-blockade can control arrhythmias during the perioperative period but should be administered only in conjunction with alpha-blockers to avoid unopposed alpha-agonist influence. Up to 25% of patients with benign, resected tumors remain hypertensive postoperatively; perhaps this percentage is related to primary hypertension or hypertensive nephropathy (252).

Other Endocrinologic Causes of Hypertension

A variety of other conditions may cause hypertension, including hyperthyroidism and hyperparathyroidism. Usually, hypertension is not the most prominent manifestation of the hormonal derangement but responds over 1 to 2 months after correction of the underlying disease. Screening tests for hyperthyroidism consist of a supersensitive thyroid stimulating hormone assay or, more traditionally, a free thyroxine concentration supplemented by a free triiodothyronine assay, only if the hormonal excess is suspected despite normal screening values. An ionized calcium and parathormone assay by immunoradiometric assay constitute the best screening tests for hyperparathyroidism.

Pharmacologic Causes of Hypertension

A wide variety of medications may produce drug-mediated hypertension, which is correctable once the condition is recognized and the offending agent withdrawn. The drugs logically cluster into several groupings.

1. Vasoconstrictors [e.g., phenylephrine, pseudoephedrine (at higher-than-usual doses), phenylpropanolamine, beta-agonist bronchodilators, ephedrine, and other sympathetic amines, as well as cocaine, stimulant abuse, antiadrenergic agent withdrawal, and monoamine oxidase inhibitor cotreatment with tyramine-containing foods or medications]
2. Volume expanders [e.g., glucocorticoids, estrogens (especially at high doses, as in oral contraceptives), nonsteroidal antiinflammatory agents that inhibit prostaglandins and thromboxane A_2 via cyclooxygenase, and, potentially, cyclooxygenase 2 and cyclooxygenase 1 agents] (256,257 and 258)
3. Miscellaneous other agents [e.g., estrogen-containing compounds, psychotropic drugs that interfere with sympatholytic antihypertensive agents, or drugs with poorly specified mechanisms (cyclosporine, tacrolimus, or erythropoietin)] (259)

Although the newer formulations of oral contraceptives generally have lower estrogen concentrations than their predecessors, the incidence of oral contraceptive–related hypertension is estimated at 5% of users, with rapid reduction of risk once they discontinue contraceptive use (260).

Hypertension related to the immunomodulating drugs cyclosporine and tacrolimus has assumed special importance, because of the critical utility of these agents in many posttransplantation settings and because the incidence of hypertension in such a context can exceed 50%. Possible mechanisms of producing elevated BP include (a) direct nephrotoxicity, (b) renal vasoconstriction by imbalanced production of renal vasoconstrictor eicosanoids or by failure of vasodilatory prostaglandin synthesis, (c) altered renin-angiotensin-aldosterone system status, (d) interference with physiologic mediators such as endothelial-derived relaxation factor, or (e) increased renal sympathetic nerve activity with resultant vasoconstriction (261). Perhaps as a consequence of the binding of cyclosporine to cyclophilin, an intracellular calcium binding protein, hypertensive patients treated with cyclosporine may be particularly sensitive to treatment by dihydropyridine therapy (262). In contrast, ACE-inhibitor therapy may worsen renal function, and diuretic therapy may exacerbate hypomagnesemia. In the presence of worsening renal function or hyperkalemia, the clinician should reduce cyclosporine doses (261).

SPECIAL SITUATIONS

Hypertensive Crises

True hypertensive emergencies are unusual. Many reflect mismanagement—sometimes from patient nonadherence, sometimes from medical system failures, sometimes from both factors (263). Rather than a search for secondary causes, the clinical priority should be the safe, prompt, and gradual lowering of BP without major side effects or complications.

Dangers exist from both undertreatment and overtreatment. Diuretic therapy usually is not needed, unless it is applied in the presence of frank fluid overload or with diazoxide or minoxidil therapy to combat fluid retention. Centrally acting antiadrenergic agents (e.g., clonidine) carry the possibility of sedation, confounding the interpretation of altered mental status in hypertensive crisis. Such drugs, therefore, should be avoided in favor of nonsedating alternatives. The principal drug classes useful in hypertensive crisis reduce peripheral resistance. The clinician selects among them by assessing the need for (a) *prompt* (e.g., diazoxide) versus *less prompt* (e.g., minoxidil) treatment, (b) *precisely* controlled (e.g., nitroprusside) versus *less controlled* (e.g., hydralazine) treatment, and (c) *equipment-intensive* (e.g., nitroprusside) versus *uncomplicated* (e.g., fenoldopam) procedures. Most drug-induced complications may be minimized by anticipating which organs will receive pharmacologic effects in the short erm and the long term.

Clinical decompensation rather than BP level alone should define the situation as urgent (i.e., no target organ damage) or emergent (i.e., target organ damage present). Others have emphasized the term *malignant hypertension* in reference to the association with encephalopathy or nephropathy (264). Although systolic pressures often exceed 180 to 200 mm Hg and diastolics are ³110 to 120 mm Hg, the absolute level is less important than the rate of rise and the absolute difference in BP between the patient's usual level and those observed during crisis. The typical patient in hypertensive crisis is a middle-aged male with inconsistent access to medical care. All sociodemographic groups, however, are at risk.

Early pathophysiologic changes reflect arteriolar spasm, whereas later decompensation results from fibrinoid necrosis, release of vasoactive substances, further vasoconstriction, and myointimal proliferation. Target organ damage may affect brain, eye, kidney, heart, and gut, among other tissues. Most patients offer few specific symptoms. Sometimes cardiovascular decompensation produces palpitations, angina, or congestive failure; neurologic manifestations may include headache, nausea, seizures, or obtundation. Clinical examination may demonstrate retinopathy, CHF, arrhythmias, or focal neurologic deficits. Most screening laboratory tests are normal or nonspecific, such as mild azotemia, proteinuria, and hypokalemia.

Several patterns of clinical presentations deserve emphasis. New onset of hypertension in the absence of prior BP elevations is most consistent with acute drug reactions (e.g., cocaine, amphetamines, phencyclidine, monoamine oxidase inhibitor–tyramine reactions) or acute glomerulonephritis. If BP worsening rather than improvement occurs after diuretic therapy, extra stimulation of the renin-angiotensin-aldosterone system from volume depletion may be the cause from prior vasoconstriction.

There is no single recipe for managing hypertensive crises. Each situation should be assessed individually for critical organ involvement, desired time frame for lowering BP (minutes, hours, or days), and available options, including personnel and equipment. A summary of preferred treatments for hypertensive emergencies appears in Table 5.9. Notably, the use of short-acting nifedipine may cause precipitous falls in BP and should be avoided (265).

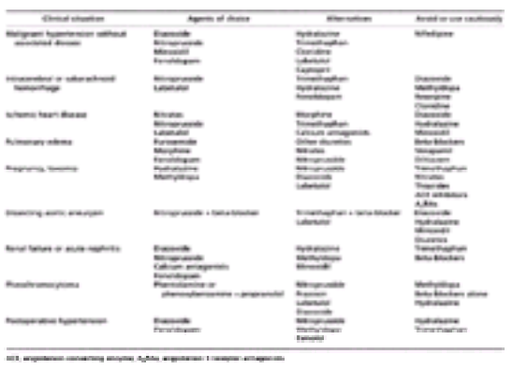


TABLE 5.9 ANTIHYPERTENSIVE THERAPY OF CHOICE FOR HYPERTENSIVE EMERGENCIES

Accelerated hypertension without major target organ damage is the most common situation. It usually occurs in the context of inadequately treated primary hypertension, but it may also reflect renal parenchymal disease, withdrawal from antiadrenergic agents, vasculitis or renovascular disease. In the absence of significant retinopathic, cardiovascular, or neurologic abnormality, the clinician may elect close follow-up rather than automatic hospitalization (266).

More ominous are central nervous system catastrophes. These may result from hypertensive encephalopathy with failure of autoregulation by cerebral blood flow (CBF). There may be focal neurologic findings. Less commonly, transient hypertension can follow any cerebral insult, such as cerebrovascular accident (thrombotic, embolic, or hemorrhagic), trauma, subdural hematoma, neoplasia, encephalitis, vasculitis, or drug withdrawal. Whereas autoregulation generally maintains CBF within narrow limits over a wide range of BPs, chronic BP elevations shift the curve to higher settings, and abrupt changes in BP carry risks of dangerous rises or falls in CBF (267). Therapeutically, the clinician seeks a 10% to 20% reduction in BP over the first hour, then further, stepped reductions over 12 to 24 hours; this therapy is preferred over prompt and full normalization because more aggressive treatment may impair CBF (268).

Hypertension carries extra hazards for *ischemic heart disease*. Angina, like other acute pain, may briefly elevate BP, but MI usually lowers CO and subsequently BP. If persistent, hypertension may increase periinfarction morbidity and mortality. In pulmonary edema or CHF, the priority should be to ameliorate the LV failure. BP

reduction usually follows. Diuretic therapy plays an important role in situations of fluid overload, even though most other hypertensive crises offer little place for diuresis.

Dissecting aortic aneurysms affecting the proximal ascending aorta comprise surgical emergencies and carry poor prognoses. Medical management in that context serves mainly to stabilize the patient as much as possible before transfer to the operating room when surgery is feasible. When localized distal to the left subclavian artery, such aneurysms may be triaged to surgery (good surgical risk) or medical (poor surgical risk) therapy (269). Drug therapy seeks to decrease the rate of pulse wave propagation to limit aneurysmal extension, as well as to lower BP overall.

Less than 5% of pregnant women present with preexisting chronic hypertension (270). During pregnancy, hypertension usually presents among primiparas after the twentieth week. Up to 40% of gestational hypertensives experience sustained hypertension within the subsequent two decades. Preeclampsia, especially when superimposed on chronic hypertension or renal disease, carries substantial risks to mother and fetus, whereas transient hypertension appearing near term is usually mild (271). Pregnancy may unmask previously unrecognized chronic renal disease, renovascular hypertension, and other secondary causes of hypertension. Whereas delivery is the ultimate treatment of choice, interim therapy may include bedrest, methyldopa, or hydralazine. In one study using atenolol, lower birth weights and smaller placentas were observed without demonstrated long-term differences in outcomes (272). ACE inhibitors are specifically contraindicated in pregnancy because of congenital malformations and fetal growth retardation (273).

In the *perioperative period*, hypertension constitutes a relative contraindication to elective surgery. The occurrence of abrupt hypertension during induction may suggest an occult pheochromocytoma. Sudden cessation of beta-blockers, methyldopa, or clonidine in the immediate preoperative period may precipitate hypertensive crises (274).

Refractory Hypertension

Resistant or *refractory hypertension*—defined as failure to lower BP to <140/90 mm Hg despite a regimen of ³3 antihypertensive agents—may occur from factors related to the prescribing clinician, the patient, the disease, or combinations of all three (275). Such a definition assumes that careful and appropriate measurement of BP has occurred on several occasions, including adequate patient preparation, elimination of interfering substances, and use of proper instruments and techniques.

The differential diagnosis of refractory hypertension heavily depends on selective factors of primary care versus referral practice. Whereas partial compliance with prescribed regimens may figure prominently in primary care, the most common cause of resistant hypertension is usually inappropriate or inadequate drug regimens in a referral practice (259). Other causes of refractory hypertension are summarized in *e*Table 5.9.1. Even in the context of refractory hypertension, specific, identifiable secondary causes of hypertension comprise only approximately 10% of the total. Although not common, correctable secondary forms of hypertension may first appear more likely after treatment has started. For example, increased BP after starting ACE-inhibitor therapy may suggest occult, bilateral renovascular hypertension, especially in association with drug-induced renal insufficiency.

***e*TABLE 5.9.1** DIFFERENTIAL DIAGNOSIS OF REFRACTORY HYPERTENSION

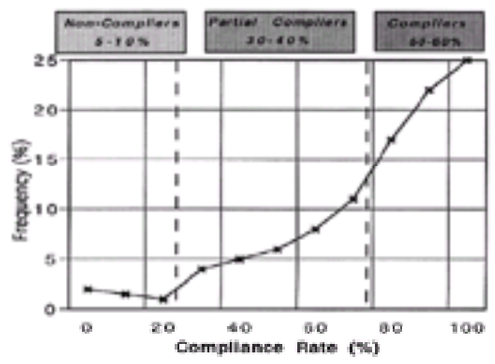
Specific identifiable disorder (second-degree hypertension)	10%
Exogenous substances	15%
Agents that raise blood pressure in susceptible persons	
Agents that interfere with antihypertensive drug action	
Complicating biologic factors	5%
Inappropriate or inadequate drug regimen	45%
Noncompliance or partial compliance with regimen	25%

Adapted from Setaro JF, Black HR. Refractory hypertension. *N Engl J Med* 1992;327:543–547.

Once the diagnosis of resistant disease is confirmed, the clinician should review the regimen to confirm its sufficiency. If the dose or dosing frequency of prescribed medications is submaximal, they may be reasonably increased, as long as adverse drug reactions have not occurred. When prescribed as monotherapy, most antihypertensive medications prompt physiologic compensation. These compensatory reactions usually involve reflex tachycardia, fluid retention, or other stimulation of the renin-angiotensin-aldosterone system. Perhaps the most common difficulty surrounds unrecognized “pseudoresistance” from subclinical fluid retention, especially after the use of vasodilators or antiadrenergic agents. BP control usually follows quickly the (re)institution of adequate diuretic therapy, commensurate with the level of renal function. Most thiazide diuretics lose antihypertensive potency as creatinine clearance falls below 40 mL per minute. Inappropriate antihypertensive combinations may also occur. Using more than one drug of the same drug class or creating adverse drug-drug interactions, as summarized in Table 5.6, may blunt BP control.

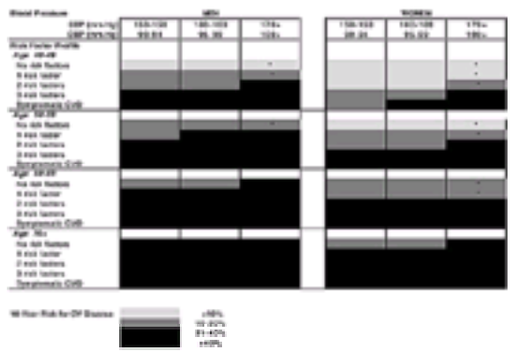
A patient’s failure to adhere to prescribed regimens—sometimes termed *partial compliance* or *adherence*—frequently reflects suboptimal knowledge of the regimen or of the importance of consistent medication taking. When queried nonconfrontationally, many patients acknowledge that a variety of “hassle” factors interfere, such as complex regimens, disruption of daily schedules, side effects, and cost (276). Other concerns for some patients may include health beliefs discordant from those of the treating clinician, especially about the significance of the “hypertension” diagnosis or the effectiveness of the prescribed treatment (277).

Electronic monitoring of medication-taking behavior has demonstrated several important epidemiologic patterns, as summarized in *e*Figure 5.1.3. Whereas 50% to 60% of individuals appear to take their regimens consistently and accurately, an additional 5% to 10% of the total demonstrate poor adherence with negligible compliance and early dropout from treatment. An intermediate group of partially compliant patients, comprising 30% to 40% of the total, exhibits highly variable medication-taking behavior—from perfect patterns to “drug holidays” (278). These patients appeared to accept the principle of antihypertensive therapy but had difficulty with consistent adherence. Their important gaps in medication taking—sometimes lasting for days—predispose to withdrawal, rebound, or other side effects, as well as to submaximal benefit (279). Recognition of the problem is often confounded by physicians’ disinterest in noncompliance, as well as by the insensitivity of patient self-report, clinician opinion, and prescription refill rates (280).



***e*FIGURE 5.1.3** Remarkably similar distributions of compliance rates have been reported with electronic monitoring of patients with hypertension, seizure disorders, glaucoma, and congestive failure. (Reviewed in Rudd P. Clinicians and patients with hypertension: unsettled issues about compliance. *Am Heart J* 1995;130:572–579.)

Compliance-enhancing strategies for the clinician include (a) watching for nonattenders and nonresponders, (b) inquiring nonconfrontationally about compliance barriers, (c) encouraging the development and use of the patient’s own medication-taking system, (d) providing simple and clear instructions, (e) simplifying the regimen as much as possible, (f) guiding behavioral changes in “small packets,” (g) monitoring progress to goal, both in BP and in compliance, (h) reinforcing desirable behaviors and outcomes whenever possible, (i) making explicit the value of the regimen and adherence to it, (j) applying help from all possible sources, (k) emphasizing the importance of dose-timing when appropriate, and (l) customizing the regimen to the patient’s needs and preferences (281) (*e*Fig. 5.1.4).



***e*FIGURE 5.1.4** Guidelines for selecting patients for antihypertensive therapy, based on cumulative risk of major cardiovascular morbidity and mortality. CVD, cardiovascular disease; DBP, diastolic blood pressure; SBP, systolic blood pressure; *, treatment advised if blood pressure sustained above these levels despite low absolute risk. (Adapted from Alderman MH, Cushman WC, Hill MN, et al. International roundtable discussion of national guidelines for the detection, evaluation, and treatment of hypertension. *Am J Hypertens* 1993;6:974–981.)

Confronted with a patient demonstrating refractory hypertension, the clinician should review the regimen, goal BP, and past patterns of BP control. Subsequent steps include ruling out confounding conditions such as drug-related side effects, excess salt intake, drug-drug interactions, and secondary hypertension. Inquiring about toxicities should be nonconfrontational and assess potentially embarrassing symptoms such as altered libido, impotence, or incontinence (282). When relevant, the clinician should consider a change in regimen—especially the inclusion of an appropriate diuretic—commensurate with the level of renal function. Adjusting the regimen should permit simplification, tailoring the regimen details to the patient's daily lifestyle, and minimizing side effects. On occasion, powerful additional hypertension agents such as minoxidil may be necessary. Table 5.10 summarizes guidelines for management of refractory hypertension.

Principle 1	Increase the dose of drug A to the maximal tolerated dose before adding drug B (selected for complementary mechanism of drug action).
Principle 2	Review the fluid/volume/diuretic status for "pseudoresistance." Thiazide diuretics are superior antihypertensive agents than loop diuretics when glomerular filtration rate (GFR = C_{cr}) >50 mL/min. Longer-acting metolazone or indapamide may be useful when GFR <50.
Principle 3	Simplify the regimen (number of drugs, frequency of dosing).
Principle 4	Decrease out-of-pocket costs (consider using free medication samples as test).
Principle 5	Inquire about side effects (especially awkward symptoms, like decreased libido, impotence, or incontinence) and adjust regimen to reduce them.
Principle 6	Use nonconfrontational phrasing to help detect partial compliance and to explore useful options to reduce it.
Principle 7	Consider formal monitoring of compliance (diary vs. pill count vs. biologic assay vs. electronic dispenser).

C_{cr}, creatinine clearance; GFR, glomerular filtration rate.

CONTROVERSIES AND PERSONAL PERSPECTIVES

In a field as vast and rapidly changing as hypertension, controversies thrive, and new ones emerge just as the old ones appear less compelling. Two of these controversies deserve special attention.

Significance of White-Coat Hypertension

The phenomenon of labile hypertension is familiar, as when patients exhibit a degree of hour-to-hour variability in excess of the usual 15% to 20% variation. Such variation includes physiologic dipping of the BP to lower levels during sleep. In 1983, Mancia et al. (283) proposed the term *white-coat syndrome* to reflect the systolic and diastolic BP increases of 27 mm Hg and 15 mm Hg, respectively, when a physician entered the patient's room during intraarterial BP monitoring. Over time, *white-coat hypertension* has come to mean elevated BP occurring in a medical setting despite normal ambulatory BP monitoring (284). The prevalence of such discrepant BP levels may affect up to 20% of men and 54% of women in reported series (122).

The difficult question then arises: what is the significance of such discrepancies? Unfortunately, the data are murky (284). The original prospective series of Verdecchia et al. (285,286) restricted white-coat hypertension to patients with elevated BP during clinic visits but normal ambulatory BPs (daytime pressures <130/80). Such patients had the same cardiovascular morbidity as patients with normal office BP (<140/90) on at least three visits on different days. Liberalizing the criteria even slightly (£136/87 for men or £131/86 for women) raised CV risks close to those of sustained hypertensive patients. Several additional investigators (287,288 and 289) have reported intermediate risk for patients with white-coat hypertension, as reflected in abnormal levels of carotid stiffness and LV relaxation.

Accordingly, some have challenged the assumption that office hypertension among patients with normal ambulatory BP need not be treated. This argument starts with the reminder that office BPs are the basis for most published clinical trials in which treating hypertension appears beneficial (284). Several additional studies suggest that home BPs of £ 135/85 (290) or 137/82 (291) represent the upper limit of normality. Finally, to confound the matter, other investigators report that "white-coat normotension" (i.e., elevated ambulatory pressures despite normal office BP) correlates with augmented LV mass index and relative wall thickness compared to patients with sustained normotension (292). For the moment, there is no simple resolution. Given a curvilinear relation between BP and cardiovascular risk, no simple or universal threshold is likely to emerge.

Best Options for Initial Monotherapy

The JNC VI unambiguously recommended diuretics and beta-blockers as drugs of choice for initial monotherapy in the absence of specific contraindications (5). With the exception of diabetics, for whom the use of ACE inhibitors or AII receptor antagonists are particularly advantageous (147,293), a large number of other primary prevention trials found strong and consistent support for endorsing diuretics and beta-blockers over the alternatives. Diuretics and beta-blockers have been evaluated in 18 long-term randomized trials (294). Compared with placebo, beta-blocker therapy was effective in preventing stroke (RR, 0.71; 95% CI, 0.59–0.86) and CHF (RR, 0.58; 95% CI, 0.40–0.84). The findings were similar for high-dose diuretic therapy (for stroke, RR, 0.49; 95% CI, 0.39–0.62; and for CHF, RR, 0.17; 95% CI, 0.07–0.41). Low-dose diuretic therapy prevented not only stroke (RR, 0.66; 95% CI, 0.55–0.78) and CHF (RR, 0.58; 95% CI, 0.44–0.76), but it also reduced coronary disease (RR, 0.72; 95% CI, 0.61–0.85) and total mortality (RR, 0.90; 95% CI, 0.81–0.99).

Several other randomized controlled trials highlight reduction in stroke risk with the use of the calcium antagonist nitrendipine (295) and reduced rates of stroke, coronary disease, and heart failure among patients receiving the ACE inhibitor ramipril (296), but not in those receiving captopril (297). Concomitantly, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) investigators reported the elimination of the $alpha_1$-blocker doxazosin treatment arm because of unexpectedly higher rates of congestive failure compared to the diuretic chlorthalidone (298). Together, these reports create ambiguities as to whether alternative drug classes offer net benefit versus risk as initial monotherapy for hypertension. At least 2 more years will pass before the final ALLHAT results are published, allowing head-to-head comparisons of the remaining treatment arms among more than 24,000 patients at 625 centers: the calcium antagonist amlodipine, the ACE inhibitor lisinopril, and chlorthalidone. The controversy continues.

Finally, the contention about calcium antagonists and their linkage to higher mortality has greatly softened in recent years. Early reports of higher rates of MI, gastrointestinal hemorrhage, and breast cancer (299) have not been confirmed in larger trials of nitrendipine (300), nifedipine gastrointestinal therapeutic system, amlodipine (301), or verapamil (302). The risks of shorter-acting dihydropyridines remain debated.

THE FUTURE

As one tries to predict the future of hypertension management, there will continue to be exciting developments in three major areas. First, basic scientific advances in molecular and genetic medicine will likely shed light on the initial and initiating events that cause the deranged physiology of hypertension. Second, evolving insights from epidemiology will refine definitions of high-risk groups and clusterings to focus efforts that produce the greatest positive yield for a population, despite resource constraints. Finally, the development of more effective and better tolerated antihypertensive medications will almost certainly combine with more sophisticated behavioral approaches to enhance adherence. In so doing, patients may enjoy the full benefits of risk reduction while maintaining an excellent quality of life.

OVERVIEW

Worldwide, there are approximately 1 billion individuals who smoke cigarettes. The overall prevalence of smoking in the United States in 1994 was 25.5%. Cigarette smoking remains the most important preventable contributor to premature death, disability, and unnecessary health expense in this country, and it is a major risk factor for all manifestations of coronary artery disease (CAD), stroke, and peripheral artery disease. Smoking also has been estimated to cause between 17% and 30% of all deaths due to cardiovascular disease. Although the risk of CAD after smoking cessation drops by approximately 50% 1 year after cessation, it approaches that of a person who has never smoked within 3 to 4 years. Smoking contributes to the pathogenesis of CAD and sudden death through a variety of mechanisms, including the promotion of atherosclerosis, the triggering of coronary thrombosis, coronary artery spasm, and cardiac arrhythmias, and through reduced capacity of the blood to deliver oxygen.

Nicotine is a powerful pharmacologic agent with a wide variety of stimulant and depressant effects involving the central and peripheral nervous, cardiovascular, endocrine, and other systems. These effects contribute to nicotine's addictive properties. The characteristics and patterns of chronic nicotine use have much in common with the use of other psychotropic drugs, and nicotine dependence is a recognized psychiatric disorder. Chronic nicotine use associated with smoking produces tolerance and a characteristic withdrawal syndrome that contributes to difficulty in achieving abstinence.

Cardiologists have an especially important role to play in smoking cessation. Because cardiologists frequently encounter patients in the setting of an acute cardiovascular event, they have the opportunity to take advantage of these "teachable moments" when patients may be most receptive to smoking cessation advice or intervention. In 1996, a *Clinical Practice Guideline on Smoking Cessation* was released by the Agency for Health Care Policy and Research based on an extensive review of the scientific literature. The guideline was recently updated and released by the U.S. Department of Health and Human Services, Public Health Service (*Treating Tobacco Use and Dependence: Clinical Practice Guideline*). The guideline recommends that clinicians determine and document the tobacco-use status of every patient treated in a health care setting; provide a minimal intervention to every patient who uses tobacco; offer several first-line pharmacotherapies—including bupropion and nicotine replacement therapy (NRT)—to all patients willing to make a quit attempt; provide a brief intervention designed to increase motivation to quit to all patients unwilling to commit to quitting; and use problem-solving and skills-training strategies, clinician-provided support, and help in securing social support outside of treatment to aid the smoker's quitting efforts. Because most patients seen for routine care are not motivated to make a quit attempt, clinicians should match their counseling interventions to patient's level of readiness for change. Motivational interventions that include personalized feedback and use an empathic style are most likely to be effective for patients not committed to quitting smoking.

NRT (e.g., gum, transdermal nicotine, inhaler, and nasal spray) and bupropion are efficacious smoking cessation treatments. Clonidine and the antidepressant nortriptyline are also efficacious but are considered second-line treatments. Other pharmacotherapies, such as buspirone and the combination of nicotine and mecamylamine, have shown some promise. Among behavioral or psychosocial treatments, problem solving and skills training, clinician-delivered social support, and aversive therapies have the most evidence of efficacy. Multicomponent groups are highly effective, especially when combined with nicotine replacement treatment. Intensive case management for myocardial infarction (MI) patients has produced excellent smoking cessation outcomes. Finally, organizational systems to support office-based smoking interventions are useful for insuring optimal delivery of these interventions in medical care settings.

GLOSSARY

Aversive therapy: A behavioral treatment for smoking cessation that uses aversive experiences to make smoking unpleasant and less reinforcing. Techniques used to produce the aversive experience include rapid smoking, smoke holding, and rapid puffing.

Fagerstrom Tolerance Questionnaire: A scale for measuring the level of nicotine dependence; helpful in determining risk of relapse after attempted cessation and likelihood of benefit from high-dose nicotine gum or nicotine nasal spray.

Nicotine dependence: A well-defined psychiatric disorder characterized by physical dependence on nicotine (i.e., tolerance and withdrawal), as well as a maladaptive pattern of nicotine use.

Nicotine replacement therapy (NRT): Pharmacotherapy that delivers doses of nicotine to help manage nicotine withdrawal and promotes smoking cessation in tobacco users who are attempting to quit. Currently approved forms of NRT are nicotine gum, transdermal nicotine, and nicotine nasal spray.

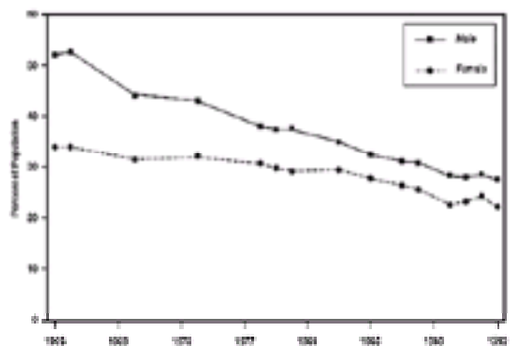
Nicotine withdrawal: A syndrome of disturbing symptoms that occur in the setting of abstinence from nicotine.

Stimulus control: A behavioral smoking cessation strategy that involves identification of cues associated with smoking and removal or avoidance of these cues during attempts at smoking cessation.

EPIDEMIOLOGY OF SMOKING

Smoking Prevalence and Incidence

There are approximately 1 billion individuals who smoke cigarettes worldwide, with approximately one-third living in China (1). An estimated 48 million adults (25 million men and 23 million women) were current smokers in the United States in 1994 (2); another 46 million adults were former smokers, indicating that almost one-half of all individuals who had ever regularly smoked cigarettes had successfully quit. After a steady decline in the prevalence of cigarette smoking from the late 1960s to the early 1990s, there has been little to no change in these rates from 1990 to 1997 (2) (*e*Fig. 6.0.1). The overall prevalence of current smoking among adults in 1994 was 25.5% (28% of men, 23% of women) (2). In 1997, the prevalence was 24.7% (27.6% for men, 22.1% for women) (3). Because the proportion of “ever-smokers” who are now former smokers is increasing at a yearly rate of less than 1%, smoking prevalence is likely to remain high well beyond the year 2000 (4). In developing countries, prevalence rates of cigarette smoking is actually increasing at an alarming rate; for example, in China, cigarette consumption increased from 700 cigarettes per adult in 1970 to approximately 2,000 per year in 1992 (1).



***e*FIGURE 6.0.1** Smoking prevalence among adults in the United States, 1965–1993.

Several factors contribute to the relatively slow decline in smoking prevalence in the United States. Although approximately 70% of current smokers say they want to quit smoking (2), only approximately 20% are actively attempting to do so (5). Relapse rates for those who do attempt to quit approach 80%, even when smokers use pharmacologic agents or seek assistance from formal treatment programs (6). Moreover, among the 90% of smokers who attempt to quit smoking on their own, only 3% to 5% achieve successful abstinence after 1 year (7). Other factors contributing to the slow decline in smoking prevalence in the United States include tobacco corporations’ aggressive marketing and high rates of smoking initiation among youth. In the 1980s, approximately 1 million young persons per year were recruited to regular smoking—the equivalent of about 3,000 new smokers each day (4). Also, as the prevalence of smoking has declined, a greater proportion of smokers are likely to have conditions that make quitting more difficult, such as high levels of physical dependence on nicotine, dependence on other psychoactive substances, depression, and other psychiatric comorbid conditions (8,9).

The decrease in smoking prevalence in the United States since the 1960s has not been equal among demographic groups. Smoking prevalence has declined more rapidly among men than women, and the decline has been highest among persons with 16 or more years of education. Currently, smoking prevalence is almost 40% among individuals with 9 to 11 years of education (2). Smoking prevalence is also much higher among those living below the poverty level (35%) than among those at or above the poverty level (24%) (2).

Several factors may explain the slower decline in smoking prevalence among women than men: Over the last decade, young girls initiated smoking at a greater rate than young boys (10,11); women quit smoking at the same rate as men but were less likely to maintain long-term abstinence (10,11); smoking prevention and cessation programs may not have adequately addressed weight concerns and tension reduction—the issues of greatest concern to women (10,11); and women were the targets in tobacco industry marketing campaigns (12). The increased rate of smoking among disadvantaged groups (e.g., low income, low education) may be related to decreased access to information about the negative health effects of smoking and decreased access to smoking cessation resources, increased use of smoking as a strategy to manage stressful life situations, and targeting of these groups by tobacco company marketing efforts (12).

Morbidity and Mortality Associated with Smoking

Cigarette smoking remains the most important preventable contributor to premature death, disability, and unnecessary medical expense in this country (13). In developed countries as a whole, tobacco was responsible for more than 1.8 million deaths in 1990, representing 24% of all male deaths and 7% of all female deaths (14). Although studies in the 1960s and 1970s reported that overall mortality rates in women were not as high as men at the same age and level of daily consumption, more recent epidemiologic studies show that overall mortality ratios in female smokers are similar to those seen in men (15). In the United States, cigarette smoking accounts for more than 400,000 deaths each year; in 1990, tobacco use accounted for 19% of all deaths (16). Smoking has also been estimated to cause between 17% and 30% of all deaths due to cardiovascular disease (16). The average loss of life for all cigarette smokers is approximately 8 years, whereas loss of life approaches 16 years for those whose deaths are attributed to tobacco (14). Approximately half of all smokers in developed countries die from a smoking-related illness (14). Based on current worldwide smoking patterns, epidemiologists have estimated that approximately half a billion of the world’s current population will eventually be killed by tobacco, and approximately half of them will be 35 to 69 years of age when they die (14).

Cigar smoking, which has become popular again in recent years, is also associated with increased mortality. Cigar smokers who smoke five to eight and nine or more cigars daily have mortality rates that are 22% and 40% greater, respectively, than nonsmokers (15). Former cigarette smokers who switch to cigars or pipes continue to have an increased risk for subsequent stroke (17), perhaps because they are more likely to inhale (18). A problem in estimating the risk of disease in individual cigar smokers is the wide variation in cigar size, nicotine content, nicotine concentration, and patterns of smoking (19). Because of variation in nicotine concentration, cigar size is not an accurate predictor of nicotine content (19). However, some fat cigars contain as much tobacco as a pack of cigarettes and may be smoked over the course of an hour, leading to significant exposure to toxic smoke (19,20).

Health Effects of Environmental Tobacco Smoke

Exposure to environmental tobacco smoke (ETS)—also known as *passive smoking*—is associated with an increased risk of death from heart disease, increased risk of lung cancer, and an increased frequency of respiratory infections in children (21).

In ten epidemiologic studies on the risk of death from CAD among nonsmokers living with smokers, the group exposed to tobacco smoke experienced a 20% to 30% increase in risk (21). Individuals with CAD who are exposed to ETS have increases in heart rate, blood pressure, and carboxyhemoglobin; angina patients exposed to ETS experience an approximately 20% to 40% reduction in exercise capacity (22). Moreover, physiologic and biochemical studies have documented deleterious effects of ETS on platelets, the endothelium, and cellular respiration (23).

The risk of lung cancer is increased approximately 30% for nonsmoking spouses of smokers relative to nonsmoking spouses of nonsmokers (21). In 1992, the Environmental Protection Agency reviewed 30 studies of passive smoking and lung cancer and concluded that ETS is a “known human carcinogen” that is responsible for 3,000 lung cancer deaths per year in never-smokers and ex-smokers (24). Among children of parents who smoke, ETS is estimated to produce approximately 300,000 additional cases of bronchitis and pneumonia, as well as up to 1 million exacerbated cases of asthma per year (21).

Smoking and Cardiovascular Disease

Cigarette smoking is a major risk factor for all manifestations of CAD, stroke, and peripheral artery disease (25,26). In ten major cohort studies in several countries, each found a higher incidence of MI and death from coronary heart disease among smokers, averaging 70% higher in cigarette smokers versus nonsmokers (27). The 1990 Surgeon General’s report on the health benefits of smoking cessation lists 25 prospective studies that documented the effects of smoking on CAD risk (eTable 6.0.1). Pooled data from five large studies demonstrated that middle-aged men (40 to 59 years of age) who smoked 20 or more cigarettes per day have two to three times the risk of experiencing a major coronary event, as compared with nonsmokers (28). An analysis of the 30-year Framingham data found that the relative risk for CAD was almost three times as great in male smokers aged 35 to 44 as nonsmokers, although the relative CAD risk for smokers declined for each succeeding age

group (29). The higher relative risk for CAD among younger smokers likely is due to the rather low risk for CAD among nonsmokers in this age group.

Rockville, MD: U.S. Department of Health and Human Services, Public Health Service, Centers for Disease Control and Prevention, 1990, with permission.

The risk for CAD among smokers is dose-related (26) (Fig. 6.1), and smoking as little as one to four cigarettes per day significantly increases risk (30). Women whose smoking patterns are similar to patterns of men have a similar increased risk of CAD morbidity and mortality (15,26). Women in the Nurses' Health Study who smoked more than 25 cigarettes per day had 5.5 times the risk of fatal CAD and 5.8 times the risk of nonfatal CAD than nonsmoking women (30). Women who smoke and use an oral contraceptive have a 13-fold increase in risk of fatal CAD than oral contraceptive users who do not smoke (31). Smoking in the presence of other coronary risk factors (e.g., hypertension, hypercholesterolemia) appears to have a synergistic effect on cardiovascular disease (CVD) morbidity and mortality (15,26) (Fig. 6.2).

It has been estimated that 15% of the 150,000 stroke deaths that occur annually in the United States are directly related to smoking (15). Male and female cigarette smokers younger than 65 years experience stroke mortality rates that are 3.7 and 4.8 times greater, respectively, than those of nonsmokers (15). There is a clear dose-response relationship between smoking and mortality from stroke (26) (Fig. 6.3). Cigarette smoking is also associated with an increased risk of advanced atherosclerotic vascular disease in peripheral arteries (32). The likelihood of claudication, amputation, abdominal aortic aneurysm, and failure of vascular reconstruction is significantly higher in smokers than nonsmokers (32).

Smoking Cessation and Reduction of Cardiovascular Disease Risk

Smoking cessation after the development of symptomatic CAD reduces the risk of mortality. Subjects in the Framingham Study who stopped smoking by the age of 65 years reduced their risk of initial or recurrent serious coronary events by 50%, compared to those who continued to smoke (29). Results from the Coronary Artery Surgery Study documented a 40% reduction in 5-year mortality in quitters compared to persistent smokers (33) (*e*Fig. 6.3.1). Although the risk of CAD after smoking cessation drops by approximately 50% 1 year after cessation, it approaches that of a person who has never smoked within 3 to 4 years (26) (Fig. 6.2 and *e*Fig. 6.3.2). The benefits of quitting on CAD risk are not limited to younger smokers. Even individuals older than 60 years experience significantly reduced CAD risks after smoking cessation (26). Smoking cessation also decreased the risk of recurrent cardiac arrest by approximately 30% in 310 survivors of out-of-hospital cardiac arrest who were followed for 3 years (34). Smoking cessation may also decrease the rate of restenosis after percutaneous transluminal coronary angioplasty (PTCA) (35) and recurrence of disease in saphenous vein bypass grafts after coronary artery bypass surgery (36). In the Nurses Health Study, more than one-third of the 31% decline in the incidence of coronary disease was explained by a reduction in smoking (37).

***e*FIGURE 6.3.2** Estimated relative risk of myocardial infarction after quitting smoking among men younger than 55 years, adjusted for age. Ninety-five percent confidence intervals are indicated by vertical lines; relative risk for men who never smoked is 1.0. [From U.S. Department of Health and Human Services. *The health*

benefits of smoking cessation: a report of the Surgeon General, DHHS Publication no. (CDC) 90–8416. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service, Centers for Disease Control and Prevention, 1990.]

Cessation rates after the diagnosis of clinical CAD range from 35% to 75% and appear to be related to the severity of disease at the time of hospitalization or coronary arteriography (38). Smoking cessation rates for patients with CAD are also related to the intensity of the smoking cessation interventions that are provided to patients. Ockene and colleagues (39) reported that an in-hospital smoking cessation intervention provided to patients who had just undergone coronary arteriography produced 12-month quit rates of 35%, compared with 28% for patients receiving usual care. In a study of patients hospitalized for an acute MI, DeBusk and colleagues (40) produced a 1-year smoking cessation rate of 70% using an intensive case-management system, compared to a rate of 53% for usual care. It must be noted, however, that both the usual care condition and the intensive case-management system in the DeBusk study included brief physician-smoking cessation counseling during hospitalization. In contrast to the high smoking cessation rates obtained post-MI or after angiography, 1-year smoking cessation rates produced by behavioral interventions delivered to ambulatory patients at risk for CAD range from 15% to 35% (41,42). Strategies for enhancing smoking cessation among cardiac patients is discussed in the section Intensive Case Management for Myocardial Infarction Patients.

HEALTH EFFECTS OF SMOKING

Cigarette Smoking and Nicotine: Effects on the Cardiovascular System

Smoking contributes to the pathogenesis of CAD and sudden death through a variety of mechanisms, including the promotion of atherosclerosis, the triggering of coronary thrombosis, coronary artery spasm, and cardiac arrhythmias, and reduced capacity of the blood to deliver oxygen (26). Smoking's effects on each of these mechanisms is described in the following sections.

Atherosclerosis

Acceleration or promotion of atherosclerosis due to smoking is attributed to a number of mechanisms: direct endothelial damage, increased proliferation of smooth muscle in atherosclerotic lesions, decreased endothelium-dependent coronary vasodilation, and reduced levels of high-density lipoprotein cholesterol (HDL-C) (26) (*e*Table 6.0.2). In animal models, endothelial damage was induced by blood nicotine levels, which are similar to those produced by human smokers (43,44), whereas studies in humans have demonstrated that smoking two cigarettes almost doubled the number of damaged endothelial cells found in circulating blood (45,46). A study that examined the effect of smoking on mothers' umbilical arteries and endothelium found pronounced degenerative changes among mothers who smoked that were not found in the arteries of nonsmoking mothers (47). Smoking-induced endothelial injury may result from oxidative damage caused by lipid peroxidation and the production of free radicals (48).

***e*TABLE 6.0.2** EFFECTS OF NICOTINE ON THE CARDIOVASCULAR SYSTEM
Atherosclerosis
Direct endothelial damage
Increased proliferation of smooth muscle in atherosclerotic lesions
Increased platelet adhesion to endothelium
Increased platelet aggregation
Decreased endothelium-dependent coronary vasodilation
Reduced levels of high-density lipoprotein cholesterol
Thrombosis
Increased platelet adherence to endothelium
Inhibits endothelial cell prostacyclin production
Increases thromboxane
Impairs platelet-derived nitric oxide release
Increased fibrinogen levels
Increased plasma viscosity
Decreased red cell deformity
Increased arterial wall stiffness, leading to increased risk for plaque rupture
Impairment of endothelium-dependent coronary vasodilation
Coronary artery spasm
Vasoconstrictor effect on coronary vasculature
Increased alpha-adrenergic tone
Increased platelet and plasma vasopressin, vasopressin carrier protein, and oxytocin
Arrhythmias
Release of catecholamines may decrease threshold for ventricular arrhythmias
Increased oxygen demand
Reduced oxygen carrying capacity

Smooth muscle proliferation—a primary feature of atherosclerotic lesions—appears to be stimulated by smoking-induced increases in the adherence of platelets to arterial endothelium (26). Blood drawn from persons after smoking two cigarettes results in a more than 100-fold increase in the adhesion of platelets to rabbit endothelium than does blood drawn from persons before smoking or from never-smokers (49). Platelets from smokers have a greater tendency to aggregate on an artificial surface than those from nonsmokers (50); in pigs, cigarette smoke increases the adhesion of platelets to arterial endothelium (51).

Smoking contributes to lipid infiltration of the arterial intima by reducing levels of HDL-C (26). An inverse relationship between smoking and HDL-C has been demonstrated in multiple cross-sectional and prospective studies (26). Prospective studies have also demonstrated an increase in HDL-C after smoking cessation in men and women (26). Although smoking and low-density lipoprotein cholesterol are not clearly related, smokers have twice the level of serum malondialdehyde as nonsmokers, which may promote the incorporation of low-density lipoprotein cholesterol into arterial wall macrophages (26,52,53). Smokers also have a decreased net transport of cholesterol from cell membranes into plasma, which could contribute to the accumulation of cholesterol in arterial walls (54).

Thrombosis

In addition to smoking's effects on atherosclerosis, smoking promotes coronary artery thrombosis by increasing platelet adherence to endothelium and platelet aggregation (26,46). Tobacco smoke appears to increase platelet aggregation by inhibiting endothelial cell prostacyclin production and increasing thromboxane (26). Recent research has demonstrated that platelet-derived nitric oxide release, which inhibits platelet aggregation, is significantly impaired in long-term smokers (55). Smoking also appears to decrease platelet monoamine oxidase, which may promote platelet aggregation by increasing catecholamine levels (55). Smoking also may promote thrombosis by increasing fibrinogen levels, increasing plasma viscosity, and decreasing red cell deformity (26). Short-term increases in arterial wall stiffness induced by cigarette smoking may increase the risk for plaque rupture, thereby triggering an acute ischemic event (56). Impairment of endothelium-dependent coronary vasodilation has also been shown in long-term smokers, which may also promote the development of atherosclerosis and thrombosis (57). This finding is likely due to reduced endothelial nitric oxide release (55). Although smoking promotes thrombosis, transdermal delivery of nicotine does not appear to do so (58).

The strong positive relationship between smoking and coronary artery thrombosis may paradoxically convey a "benefit" to smokers undergoing fibrinolytic therapy after acute MIs. Several studies have found that smokers who have an acute MI have a better prognosis than nonsmokers (59,60) and appear to be more responsive to fibrinolytic therapy than nonsmokers (61,62 and 63). Quantitative arteriographic analysis suggests that the mechanism of infarction in smokers is more often thrombosis of a less critical atherosclerotic lesion, as compared with nonsmokers (64). Smokers receiving thrombolysis for acute MI also appear to present significantly younger and have less comorbidity or severe CAD than nonsmokers (61). Two recent analyses of large thrombolytic trials found that smoking status was not associated with better outcome when results were adjusted for other baseline characteristics (61,64).

Coronary Artery Spasm

Both chronic and acute cigarette smoking have a vasoconstrictor effect on coronary vasculature (26). Current smokers have 20 times the risk of vasospastic angina compared to never-smokers (65). Smoking even a single cigarette has been demonstrated to produce coronary artery spasm during angiography (66). Smoking-associated vasoconstriction is mediated by an alpha-adrenergic increase in arterial tone and by smoking-associated increases in platelet and plasma vasopressin, vasopressin carrier protein, and oxytocin (26). In some cases of variant or Prinzmetal's angina, smoking induced a profound vasospastic effect; unless

cessation is assured, this may be refractory to medical management (67,68).

Arrhythmias and Reduced Oxygen-Carrying Capacity

Nicotine-induced release of catecholamines increases blood pressure and heart rate and may produce a lowered threshold for ventricular arrhythmias (26). In animal studies, cigarette smoke lowers the threshold for ventricular fibrillation (69). In a study of more than 10,000 men, smoking was associated with a 21% increase in ventricular premature beats on electrocardiographic rhythm strips (70). Moreover, nicotine's sympathetic effects increase myocardial oxygen demand, which is also accompanied by a reduction in oxygen carrying capacity due to the presence of 3% to 6% carbon monoxide in cigarette smoke (26). Carbon monoxide's high affinity for hemoglobin elevates levels of carboxyhemoglobin, interfering with oxygen exchange. The combination of increased myocardial oxygen demand and impaired oxygen exchange can produce or exacerbate myocardial ischemia. These effects on oxygen delivery may also lower the threshold for ventricular arrhythmias (26).

Smoking, Other Health Effects, and the Health Benefits of Smoking Cessation

In addition to cardiovascular diseases, smoking is also a direct cause of cancer of the lung, larynx, oral cavity, esophagus, and bladder; smoking also contributes to the development of cancers of the kidney, pancreas, stomach, and cervix (15,26). However, 10 years after smoking cessation, the risk of lung cancer is approximately 50% of the risk in continuing smokers; with further abstinence, the risk continues to drop (26). The risk of other cancers associated with smoking also declines substantially within several years after cessation (26).

Smoking is the major cause of chronic obstructive pulmonary disease and is responsible for approximately 90% of all deaths from these diseases (15,26). Smoking cessation reduces rates of respiratory symptoms and infections compared to continued smoking (26). With continued abstinence, the rate of decline in pulmonary function among ex-smokers returns to that of never-smokers (26).

Cigarette smoking during pregnancy increases the risks of low birth weight, spontaneous abortion, prematurity, and perinatal mortality, whereas cessation during pregnancy decreases the likelihood of these negative pregnancy outcomes (26,71). Smoking also causes women to have natural menopause 1 to 2 years earlier, which may be related to an antiestrogen effect (26,72). Smoking's antiestrogen effect, which appears to be due to an alteration in the metabolism of estradiol, leading to enhanced formation of the inactive catechol estrogens (72), may contribute to the increased cardiovascular disease risks associated with smoking in women.

Smoking also increases the risk of duodenal and gastric ulcers, osteoporotic fractures, infertility, cataracts, and macular degeneration (26,73). Among these conditions, improvement in clinical outcome after smoking cessation has been demonstrated for ulcer disease (26).

Nicotine as a Psychoactive Drug

Nicotine rapidly accumulates in the brain after cigarette smoking. Maximum brain concentrations are reached within 1 minute (13). This rapid accumulation of nicotine in combination with nicotine's effects on brain activity and function provide optimal conditions for the development of drug dependence (13). Acute and chronic tolerance to many effects of nicotine contribute to an increase in cigarette consumption, as individuals smoke more to obtain desired effects of nicotine (13,74).

Actions of Nicotine

Nicotine is a powerful pharmacologic agent with a wide variety of stimulant and depressant effects involving the central and peripheral nervous, cardiovascular, and endocrine systems, as well as other systems (13,74). These effects contribute to nicotine self-administration. Central effects include electrocortical activation (as noted on an electroencephalogram) and increases in brain serotonin, endogenous opioid peptides, pituitary hormones, catecholamines, and vasopressin (13,74). The rewarding properties of nicotine may be related to nicotine's stimulatory effects on dopaminergic pathways in the mesolimbic system (75). Nicotine has been shown to increase attention, memory, and learning in smokers—especially in the setting of low environmental demand, when stimulation is most desirable (26). Nicotine also has anxiolytic and antinociceptive effects, and there is evidence that smokers are more apt to use cigarettes during stressful situations or in situations involving negative mood (26). Recently, research has demonstrated an association between a history of clinical depression, depressive symptoms, and difficulty in quitting smoking (76,77 and 78). Nicotine's effects on negative mood states in some smokers may help to explain the relationship between smoking, depression, and other psychiatric disorders (77). There is considerable variability in nicotine's effects between and within individuals over time. This variability results from a number of factors including dose, biphasic pharmacologic effects of stimulation and blockade, the influence of setting, the current state of the individual, and individual differences in dependence, genetics, and learning history (79).

Nicotine as an Addicting Drug

The characteristics and patterns of chronic nicotine use have much in common with the use of other psychotropic drugs: Humans self-administer nicotine in the laboratory to reproduce desired effects, patterns of relapse to smoking after smoking cessation are quite similar to the patterns noted after treatment for other forms of drug abuse and dependence, chronic nicotine use produces tolerance, and a withdrawal state is noted with abstinence (13,74).

Nicotine recently has been included among the drugs that may produce psychoactive substance dependence in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, 4th edition* (*DSM-IV*) (80). The diagnosis of nicotine dependence by these criteria require evidence for any three of nine criteria. The criteria are listed in *e*Table 6.0.3. Among older adult smokers, 87% are estimated to meet *DSM-IV* criteria for nicotine dependence (81).

***e*TABLE 6.0.3** DIAGNOSTIC CRITERIA FOR NICOTINE DEPENDENCE

A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-mo period:

1. Tolerance, as defined by either
a. A need for markedly increased amounts of the substance to achieve desired effect.
b. Markedly diminished effect with continued use of the same amount of substance.
2. Withdrawal, as manifested by either
a. The characteristic withdrawal syndrome for the substance.
b. The substance is taken to relieve or avoid withdrawal symptoms.
3. The substance is often taken in larger amounts or over a longer period than was intended.
4. There is persistent desire or unsuccessful effort to cut down substance use.
5. A great deal of time is spent in activities necessary to obtain the substance or use the substance.
6. Important social, occupational, or recreational activities are given up or reduced because of substance abuse.

Adapted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, 4th edition* (*DSM-IV*). Washington, DC: American Psychiatric Press, 1994:489.

The nicotine withdrawal syndrome is well characterized (Table 6.1 lists the *DSM-IV* criteria for nicotine withdrawal) and experienced by approximately 50% of the smokers who make a serious attempt to quit smoking (80,82). In addition, a craving for sweets and impaired performance on vigilance tasks can occur (82,83). The signs and symptoms of the nicotine withdrawal syndrome can appear within 2 hours after the last use of tobacco, usually peak between 24 and 48 hours after cessation, and usually last from a few days to 4 weeks, although craving and hunger can persist for months (82). The mean decrease in heart rate is eight beats per minute, and the mean weight gain is 2 to 3 kg (82).

1. Daily use of nicotine for at least several weeks
2. Abrupt cessation of nicotine use, or reduction in the amount of nicotine used, followed within 24 h by four (or more) of the following signs:
   a. Dysphoric or depressed mood
   b. Insomnia
   c. Irritability, frustration, or anger
   d. Anxiety
   e. Difficulty concentrating
   f. Restlessness
   g. Decreased heart rate
   h. Increased appetite or weight gain
3. The symptoms in criterion 2 cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
4. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Reprinted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, 4th edition* (*DSM-IV*). Washington, DC: American Psychiatric Press, 1994:489.

TABLE 6.1 DIAGNOSTIC CRITERIA FOR NICOTINE WITHDRAWAL

Women tend to gain more weight than men when they quit smoking (3.8 kg vs. 2.8 kg) (84). Subsets of both men and women (9.8% and 13.4%) are likely to gain a major amount of weight when they quit smoking (e.g., in excess of 13 kg). However, amount of weight gain is influenced by several factors, including race (blacks > whites), age (younger > older), and smoking rate (heavier > lighter) (84,85,86 and 88).

Fear of weight gain is an important deterrent to smoking cessation among women (88). Women report that they are less willing than men to tolerate weight gain if they quit smoking (89). Moreover, concerns about postcessation weight gain are particularly salient in younger and overweight women (90,91).

Some evidence suggests that weight gain during smoking cessation predicts an early relapse to smoking (92,93). Paradoxically, however, other studies suggest that longer-term abstinence is associated with greater weight gain (85). Behavioral weight-control interventions coupled with smoking cessation treatment appear to impede smoking cessation (94,95). However, vigorous exercise programs and pharmacologic adjunctive treatments (e.g., nicotine gum or serotonergic agents) may hold some promise in preventing postcessation weight gain (96,97 and 98).

There is a great deal of individual variation in the pattern and course of withdrawal symptoms. Moreover, future experiences with withdrawal cannot always be predicted from past quitting experiences (83). For many patients, the development of nicotine withdrawal is an important barrier to quitting smoking. Fortunately, the availability of effective pharmacotherapy for managing nicotine withdrawal has improved our capacity to assist patients in quitting smoking.

Nicotine dependence can be measured using the Fagerstrom Tolerance Questionnaire (99) (*e*Table 6.1.1). A high score on this scale predicts smoking cessation after attempted abstinence; it also predicts which smokers may benefit most from some forms of nicotine replacement (e.g., nicotine gum, 4-mg dose).

***e*TABLE 6.1.1** FAGERSTROM TOLERANCE QUESTIONNAIRE

Questions	Answers	Points
How soon after you wake up do you smoke your first cigarette?	Within 5 min	3
	6–30 min	2
	31–60 min	1
	After 60 min	0
Do you find it difficult to refrain from smoking in places where it is forbidden?	Yes	1
	No	0
Which cigarette would you hate most to give up?	The first one in the morning	1
	All others	0
How many cigarettes per day do you smoke?	10 or fewer	0
	11–20	1
	21–30	2
	31 or more	3
Do you smoke more frequently during the first hours of waking than during the rest of the day?	Yes	1
	No	0
Do you smoke if you are so ill that you are in bed most of the day?	Yes	1
	No	0

Effects of Cigarette Smoking and Nicotine on Drug Metabolism

Smoking is known to accelerate the metabolism of many drugs (100,101), including several drugs used regularly in treating cardiovascular disease (e.g., propranolol, lidocaine, and theophylline). The blood levels of these medications may increase significantly when individuals stop smoking. Because hospitals are largely smoke-free, drug toxicity can develop if doses of these medications are not adjusted after hospitalization, whereas if an individual's dose of medication is stabilized in the hospital, drug levels may decrease after discharge if the patient resumes smoking. This effect was noted with propranolol in the Beta-Blocker Heart Attack Trial (102). The effects of smoking on metabolic pathways are likely due to nicotine and other constituents of cigarettes, including polyaromatic hydrocarbons (100). Because cigarette smoking's effects on metabolism are complex, it is difficult to generalize about the effects of cigarette smoking or nicotine use on entire classes of drugs. For example, although propranolol metabolism is affected by smoking, pindolol metabolism is not (100).

Smoking also appears to have an important independent effect on anticoagulation in response to intravenously administered heparin (103). Granger and colleagues (103) monitored the activated partial thromboplastin time in response to intravenous heparin in more than 29,000 patients participating in the Global Utilization of Streptokinase and t-PA for Occluded Coronary Arteries (GUSTO-I) trial. Current smokers had significantly lower activated partial thromboplastin times than nonsmokers, even after adjustment for weight, age, and gender (103). This finding is consistent with previous studies of the pharmacokinetics of heparin, which have demonstrated that heparin is eliminated more rapidly among smokers (104). Therefore, when smokers are treated with heparin, anticoagulation parameters should be followed closely to ensure an adequate response.

SMOKING CESSATION

Role of the Cardiologist and Other Health Care Providers in Smoking Cessation

All physicians can play a central role in reducing the morbidity and mortality associated with cigarette smoking. Cardiologists have an especially important role in smoking cessation, for several reasons. Many cardiologists serve as primary care physicians for many of their patients. Because primary care providers have multiple opportunities over several years to intervene with their patients who smoke, they are in a unique position to provide smoking cessation advice and treatment. Moreover, because cardiologists frequently encounter patients in the setting of an acute cardiovascular event, they have the opportunity to take advantage of these "teachable moments," when patients may be most receptive to smoking cessation advice or intervention (39). *The Clinical Practice Guideline on Cardiac Rehabilitation*, published by the Agency for Health Care Policy and Research and the National Heart, Lung, and lood Institute, recommends the inclusion of smoking cessation interventions as an essential component of cardiac rehabilitation programs (105). Even if the patient is asymptomatic, health care providers can link the patient's smoking to increased risk for disease in the future (e.g., heart disease, if the patient has a family history of early CAD). Finally, the widespread adoption of smoke-free policies in hospitals and other health care institutions provides additional new opportunities for health care provider intervention.

Although physicians recognize the importance of smoking cessation as a disease-preventive measure, few physicians are confident in their ability to help patients stop smoking (106,107). Moreover, less than half of smokers report that they have ever been advised to quit smoking by their physician (108,109 and 110).

Smoking Cessation: Effectiveness of Brief Interventions

Perhaps the most compelling reason to focus on physician-delivered smoking cessation interventions is that they are effective (111,112 and 113). In April 1996, after a comprehensive and exhaustive review and analysis of the existing scientific literature, the Agency for Health Care Policy and Research Smoking Cessation Guideline Panel released the *Clinical Practice Guideline on Smoking Cessation* (113,114). The Panel was reconvened recently, and the Guideline was updated and reissued by the Department of Health and Human Services, Public Health Service (114). Table 6.2 outlines the principal recommendations of the Guideline.

Tobacco dependence is a chronic condition that often requires repeated intervention. However, effective treatments exist that can produce long-term or even permanent abstinence.

Because effective tobacco dependence treatments are available, every patient who uses tobacco should be offered at least one of these treatments. Patients willing to try to quit tobacco use should be provided with treatments identified as effective in the Guideline; patients unwilling to try to quit tobacco use should be provided with a brief intervention designed to increase their motivation to quit.

It is essential that clinicians and health care delivery systems institutionalize the consistent identification, documentation, and treatment of every tobacco user seen in a health care setting.

Brief tobacco dependence treatment is effective, and every patient who uses tobacco should be offered at least brief treatment.

There is a strong dose-response relation between the intensity of tobacco dependence counseling and its effectiveness. Treatments involving person-to-person contact are consistently effective, and their effectiveness increases with treatment intensity.

Three types of counseling and behavioral therapies were found to be especially effective and should be used with all patients attempting tobacco cessation: provision of practical counseling (problem solving or skills training), provision of social support as part of treatment, and help in securing social support outside of treatment.

Numerous effective pharmacotherapies for smoking cessation now exist. Except in the presence of contraindications, these should be used with all patients attempting to quit smoking. Five first-line pharmacotherapies were identified that reliably increase long-term smoking abstinence rates: bupropion SR, nicotine gum, nicotine inhaler, nicotine nasal spray, nicotine patch. Two second-line pharmacotherapies were identified as efficacious and may be considered by clinicians if first-line pharmacotherapies are not effective: clonidine and nortriptyline.

Over-the-counter nicotine patches are effective relative to placebo, and their use should be encouraged. Tobacco dependence treatments are both clinically effective and cost-effective relative to other medical and disease prevention interventions.

Adapted from Fiore M, Bailey W, Cohen S, et al. *Treating tobacco use and dependence: clinical practice guideline*. Rockville, MD: U.S. Department of Health and Human Services, Public Health Services, 2000.

TABLE 6.2 RECOMMENDATIONS OF THE AGENCY FOR HEALTHCARE AND RESEARCH QUALITY TREATING TOBACCO USE AND DEPENDENCE CLINICAL PRACTICE GUIDELINE

The Panel's recommendations were based on evidence that was derived primarily from metaanalyses of published randomized controlled trials (113,114). Highlights of the evidence is summarized in the following paragraphs. First, several studies have demonstrated that systems that identify and document smoking status result in significantly higher rates of smoking cessation interventions by clinicians (113,114). Further, the presence of these screening systems appears to result in higher quit rates among patients who smoke (113,114).

Second, even brief advice (e.g., less than 3 minutes) by a clinician significantly increases quit rates compared to the absence of such advice (113,114). The magnitude of the increase in quit rates with brief clinician advice is approximately 25% (113,114).

Third, smoking cessation interventions delivered by any type of health care provider increase cessation rates with no clear advantage to any single provider type (e.g., physician, nurse, psychologist, health counselor) (113,114). Moreover, interventions delivered by multiple types of providers more than double the likelihood of smoking cessation, suggesting that smoking cessation interventions should be delivered by as many clinicians and types of clinicians as feasible (113,114). This finding has implications for specialized inpatient cardiac units and cardiac rehabilitation programs, which provide unique opportunities to deliver interventions from multiple providers.

Fourth, there is a strong dose-response relationship between the intensity of person-to-person contact and a successful smoking cessation outcome (113,114). In Table 6.3, the results of a metaanalysis are presented that examine the relationship between smoking cessation outcome and level of intensity of contact across 43 randomized controlled trials. As noted above, even brief counseling significantly increases quit rates. However, more counseling is clearly even better, with rates exceeding 20.0% (compared with 10.9% for the no-contact reference group) for more than 10 minutes of counseling during a single clinical contact. Moreover, a separate metaanalysis that compared quit rates for varying amounts of the total time spent counseling across multiple visits found that 4 to 30 minutes of total contact time significantly increased quit rates over 1 to 3 minutes of total contact time (114). The estimated abstinence rates increased from 14.4% for 1 to 3 minutes to 18.8% for 4 to 30 minutes of total contact time (114). Although time, especially a physician's, is at a premium during office-based visits, the delivery of 10 or more minutes of counseling by other professional staff may be feasible, especially in cardiac rehabilitation or inpatient settings. Brief motivational messages from a physician followed by interventions delivered by an allied health professional can reduce physician burden, make counseling more likely, and produce significantly increased cessation rates compared with brief physician advice alone (115). Indeed, the addition of nurse-delivered interventions to brief physician advice in a primary care setting produced quit rates of 7.1% at 1 year compared to 3.9% for brief physician advice alone (115).

Level of contact	Estimated odds ratio (95% CI)	Estimated abstinence rate (95% CI)
No contact (reference group)	1.0	10.9
Minimal contact (<3 min)	1.3 (1.1–1.6)	13.4 (10.9–16.1)
Brief counseling (>3 min to <10 min)	1.6 (1.2–2.0)	16.0 (12.8–19.2)
Counseling (>10 min)	2.3 (2.0–2.7)	22.1 (19.4–24.7)

CI, confidence interval.

TABLE 6.3 SMOKING CESSATION RATES FOR VARIOUS INTENSITY LEVELS OF PERSON-TO-PERSON CONTACT

Based on their review and analysis of the scientific literature, the Guideline Panel also found evidence that four specific types of behavioral and psychosocial interventions were efficacious: problem solving or skills training, social support provided within the treatment setting, assisting the patient to access social support outside of treatment, and aversive smoking procedures (113,114). Components of the first three of these strategies can be delivered in medical care settings within the context of brief counseling. The Guideline has summarized the essential elements of these strategies, which are reproduced in *e*Table 6.3.1 and *e*Table 6.3.2. Behavioral and psychosocial strategies are discussed in more detail in the section Smoking Cessation: Behavioral and Psychosocial Treatments.

***e*TABLE 6.3.1** COMMON ELEMENTS OF PROBLEM-SOLVING AND SKILLS-TRAINING SMOKING CESSATION TREATMENTS

Problem-solving treatment component	Examples
Recognize danger situations—Identify events, internal states, or activities that are thought to increase the risk of smoking or relapse.	Being around other smokers Being under time pressure Negative affect Experiencing urges Drinking alcohol
Develop coping skills—Identify and practice coping or problem-solving skills. Typically, these skills are intended to cope with danger situations.	Learning to anticipate and avoid temptation Learning cognitive strategies that will reduce negative moods Accomplishing lifestyle changes that reduce stress, improve quality of life, or produce pleasure Learning cognitive and behavioral activities that distract attention from smoking urges
Provide basic information—Provide basic information about smoking and successful likelihood quitting.	The fact that any smoking (even a single puff) increases the likelihood of a full relapse The addictive nature of smoking Withdrawal typically peaks within 1–3 wk after quitting Withdrawal symptoms include negative mood, urges to smoke, and difficulty concentrating

From Fiore M, Bailey W, Cohen S, et al. *Treating tobacco use and dependence: clinical practice guideline*. Rockville, MD: U.S. Department of Health and Human Services, Public Health Services, 2000.

***e*TABLE 6.3.2** COMMON ELEMENTS OF SUPPORTIVE COUNSELING FOR SMOKING CESSATION

Supportive treatment component	Examples
Encourage the patient in the quit attempt	Note that effective tobacco dependence treatments are now available Note that half of all people who have ever smoked have now quit

	Communicate belief in patient's ability to quit
Communicate caring and concern	Ask about how the patient feels about quitting
	Directly express concern and willingness to help
	Be open to the patient's expression of fears of quitting, difficulties experienced, and ambivalent feelings
Encourage the patient to talk about the quitting process	Ask about:
	Reasons the patient wants to quit
	Difficulties encountered while quitting
	Success the patient has achieved
	Concerns or worries about quitting

From Fiore M, Bailey W, Cohen S, et al. *Treating tobacco use and dependence: clinical practice guideline*. Rockville, MD: U.S. Department of Health and Human Services, Public Health Services, 2000.

Finally, the Guideline Panel also found that bupropion hydrochloride and various forms of NRT (e.g., transdermal nicotine) were as efficacious as smoking cessation interventions, regardless of the intensity of adjuvant psychosocial interventions, and recommended their use with all smokers (113,114). Pharmacologic treatments for smoking cessation are discussed in more detail in the section Smoking Cessation: Pharmacotherapy.

Physician-delivered smoking interventions are not only effective, they are also highly cost-effective, especially when compared to such accepted medical practices as the treatment of mild to moderate hypertension or hypercholesterolemia (116,117). Using a very conservative estimate of the effectiveness of brief advice (2.7% increase in 1-year smoking abstinence rates), Cummings and colleagues estimated that the cost per year of life saved was $748 (116). This cost compares with costs of more than $11,000 per year of life saved for treating moderate hypertension and more than $65,000 per year of life saved for treating moderate hypercholesterolemia (116).

Smoking Cessation: Matching Interventions to the Patient's Readiness for Change

Although health care provider–mediated smoking cessation interventions are effective, only a small minority of patients who receive interventions from physicians are successful in achieving long-term abstinence. Frustration and feelings of ineffectiveness that result from these low rates of success are important barriers to provider intervention with smokers. The Transtheoretical Model of Change—developed by psychologists James Prochaska and Carlo DiClemente at the University of Rhode Island (118)—can help physicians and other health care providers to intervene more effectively with their smoking patients by offering strategies for the majority of smokers who are not ready to quit smoking when they visit a physician's office.

The Transtheoretical Model of Change identifies five discrete stages of smoking cessation: precontemplation, contemplation, preparation, action, and maintenance (118,119) (Fig. 6.4). Individuals at the precontemplation stage—representing as many as 40% of current smokers seen in a typical medical practice (5)—are not considering stopping smoking in the immediate future. These patients may be uninformed or underinformed, demoralized about their ability to change, or defensive and resistant to change (118). *Contemplation* is a stage of ambivalence that characterizes another 40% of smokers (5). Although individuals at this stage have given serious thought to giving up smoking, they are not yet ready to commit to quitting (118). Only approximately 20% of smokers who seek medical care are in the preparation stage and are intending to quit smoking in the next month. Many of these patients have attempted to quit in the past year or have taken small steps toward quitting, such as delaying their first cigarette in the morning or cutting down on the number of cigarettes that they smoke (118).

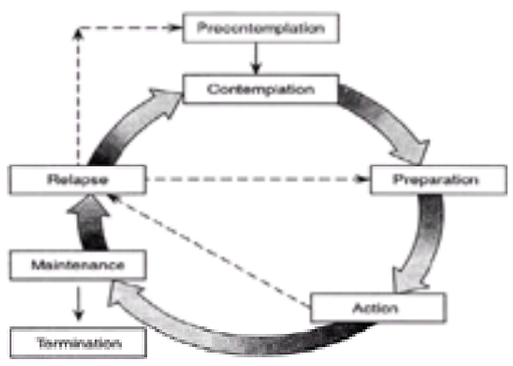

FIGURE 6.4 The Stages of Change (Prochaska and DiClemente). (From Prochaska JO, DiClemente CC. Towards a comprehensive model of change. In: Miller WR, Heather N, eds. *Treating addictive disorders: processes of change*. New York: Plenum Press, 1986.)

When individuals finally reach the action stage, they have overtly tried to quit smoking. Relapse is the rule during this stage, rather than the exception, especially during the first few days and weeks after quitting. *Maintenance*, defined as the stage reached 6 months after quitting, is characterized by continued use of processes to help individuals to change or modify their experience to prevent slips or relapse. The average smoker takes three or four cycles through the stages of change over several years before finally reaching a stable period of maintenance (119). By recognizing that the majority of smokers who visit a physician's office are not ready to take action, physicians can modify their expectations, back off on trying to get all of their patients to quit smoking, and develop strategies to attain intermediate outcomes, such as moving a precontemplator to the contemplation stage (118). Physicians using this approach are less likely to become frustrated and lose hope when the majority of their patients are unable to give up smoking in the short term. Additionally, matching intervention strategies to the stage of change may actually enhance movement through the stages that, in the long term, may shorten the time it takes to reach stable maintenance (118).

Patients in the precontemplation stage respond best to motivational interventions that help them to begin thinking about quitting smoking (120). Personalized information and feedback may help raise the smoker's awareness of the ways smoking affects his or her health and are more likely to be effective than minilectures about the health effects of smoking. Feedback can take several forms, including evidence of the effects of smoking on the patient's laboratory findings (e.g., carbon monoxide levels, pulmonary function tests, high-density lipoprotein), the impact of smoking on disease states (e.g., presence of angina, angiographic findings, transient ischemic attacks), and the relationship between smoking and risk (e.g., risk of sudden death, recurrent MI). Showing a smoker his or her coronary angiogram to demonstrate graphically the presence of diffuse atherosclerosis, as well as plaques in specific coronary arteries, may have a powerful motivating effect. Providing feedback about the deleterious effects of continued smoking should be paired with feedback about smoking cessation's beneficial effects on cardiovascular and other health outcomes. Asking the patient to reflect on his or her feelings about smoking and quitting is another useful intervention for the precontemplator (118). If feelings of demoralization are uncovered, they can be addressed by informing the patient that it may make several quit attempts before he or she is finally successful. It is also useful to offer empathic statements (e.g., "I recognize that it is difficult for many patients to quit") to provide praise for previous efforts to quit or cut down and statements of support (e.g., "When you are ready to quit, I'm willing to help"). An empathic style has been shown to be an important ingredient of effective motivational interventions (120).

Clarification and legitimization of feelings may also help patients in the contemplation stage to feel heard and understood (118). Statements such as "I'm glad that you're thinking about quitting" are especially useful because they reinforce the patient's interest in quitting. It is also useful to explore contemplators' reasons for smoking, as well as other barriers to quitting, so that potential solutions for overcoming barriers can be discussed (118). For example, if a patient reports that she depends on smoking to help manage her weight, the offer and provision of alternative weight-management strategies may precipitate a decision to quit smoking. Contemplators who become chronically stuck in this stage may benefit from encouragement to take small steps toward action, such as cutting down the number of cigarettes they smoke, delaying their first cigarette of the day, or trying to quit for just 24 hours (118).

When the patient is finally in the preparation stage or ready for action, appropriate action-oriented strategies can be advised or prescribed. Useful interventions for patients in the action stage include setting a specific quit date with the patient, writing a contract, providing self-help materials, prescribing or recommending nicotine replacement, teaching behavioral skills (*e*Table 6.3.1), referral to formal treatment programs, and enhancing social support. Individuals are most successful when multiple cognitive and behavioral strategies are used (8,121). As noted above, the *Treating Tobacco Use and Dependence Guideline* supports the use of problem solving, skills training, and supportive counseling (*e*Table 6.3.1 and *e*Table 6.3.2) as effective smoking cessation treatment components (113,114).

Five A's: A Strategy for Brief Provider Intervention

The Guideline (114) provides clinicians with a brief five-step strategy for smoking cessation intervention in medical care settings that includes the important step of assessing patients' readiness for making a quit attempt. This approach builds upon the "Four A's" of smoking cessation counseling that were developed for the National

Cancer Institute's Physician-Delivered Smoking Cessation Program (122). The five steps are as follows:

1. **Ask:** Systematically identify all tobacco users at every visit.
2. **Advise:** Strongly advise all smokers to quit and identify smokers willing to make a quit attempt (provide a motivational intervention if they are not willing to quit).
3. **Assess** willingness to make a quit attempt.
4. **Assist:** Aid the patient in quitting (set a quit date, encourage nicotine replacement, provide advice on successful quitting, refer to formal treatment if desired, and provide supplementary materials).
5. **Arrange:** Schedule follow-up contact.

The *Treating Tobacco Use and Dependence: Clinical Practice Guideline* is available in full text, along with references for the metaanalyses, on the Internet and can be found at http://www.surgeongeneral.gov/tobacco/default.htm. The *Clinical Practice Guideline*, the *Quick Reference Guide for Clinicians*, and the consumer version are also available from the Publications Clearinghouse, which can be reached at 1-800-358-9295 or P.O. Box 8547, Silver Springs, MD, 20907.

Smoking Cessation: Pharmacotherapy

Nicotine Replacement Therapy

NRT has been approved by the U.S. Food and Drug Administration (FDA) for use as an aid to smoking cessation. The four approved forms are nicotine gum, transdermal nicotine, nicotine inhaler, and nicotine nasal spray. As noted above, the Panel's review of the scientific literature found that nicotine gum and transdermal nicotine were efficacious as smoking cessation interventions across a variety of diverse settings and populations and regardless of the intensity of adjuvant behavioral and psychosocial interventions (113,114). This conclusion was based on the results of several published metaanalyses on the efficacy of transdermal nicotine (123,124,125,126 and 127) and nicotine gum (126,127,128 and 129). The American Psychiatric Association's *Practice Guideline for the Treatment of Patients with Nicotine Dependence* also endorsed the use of nicotine gum and patches as effective therapies (121). Moreover, the efficacy of the patch, gum, nasal spray, and inhaler were found to be statistically indistinguishable in the Guideline Panel metaanalyses and in a recent head-to-head clinical trial comparison (130).

Overall, compared with a placebo, transdermal nicotine doubles 6-month to 1-year quit rates, whereas nicotine gum increases long-term quit rates by approximately 50% (113,121). Although nicotine replacement with transdermal nicotine or nicotine gum is efficacious when provided with minimal adjuvant therapy, absolute smoking rates are enhanced when additional behavioral treatment is provided (113,121). A randomized placebo-controlled trial of transdermal patches and minimal supportive treatment (three 10-minute counseling sessions over 6 weeks) in 584 outpatients with cardiac disease found a significant treatment effect at 14 weeks (21% abstinence in the nicotine group vs. 9% in the placebo group), but abstinence rates were not significantly different at 24 weeks (14% vs. 11%) (131). Although they are disappointing, these results should not deter cardiologists from offering NRT to patients with cardiac disease due to the wealth of data regarding the efficacy of transdermal nicotine and nicotine gum. The increased relapse rate in the nicotine group between 14 and 24 weeks suggests that these patients, who were predominantly male veterans, may have required additional behavioral or other supportive treatment to maintain long-term abstinence. A more recent study (132) confirmed the safety and short-term efficacy of the nicotine patch among patients with CAD. One hundred and six patients with CAD were randomly assigned to received nicotine or placebo patches. The cardiovascular effects of nicotine patches were assessed by repeated ambulatory electrocardiographic monitoring and exercise testing. There were no changes in the resting heart rate and systolic or diastolic blood pressure between the active and placebo groups for the duration of the study. Repeated 48-hour ambulatory electrocardiographic monitoring revealed that there were no significant changes in the number and duration of ischemic episodes in both groups. There was no change in the frequency of atrial or ventricular arrhythmias in either group. More patients in the active patch group were abstinent at 2 weeks compared with the placebo group (27% vs. 13%).

Although patients with high levels of nicotine dependence (as measured by the Fagerstrom Tolerance Questionnaire) are less likely to be successful in quitting smoking, both high- and low-dependent smokers benefit from the use of transdermal nicotine (113,121). However, highly dependent smokers are more likely to benefit from the use of 4 mg of nicotine gum than a 2-mg dose (113,121). Most patients prefer the patch to the gum because of ease of use and decreased incidence of side effects (113,114). Side effects of nicotine gum include nausea, jaw soreness, mouth sores, gingivitis, and throat and gastrointestinal distress, whereas transdermal nicotine frequently produces skin reactions and vivid dreams (121). Because of anecdotal reports of MIs occurring in association with simultaneous smoking and nicotine patch use, the safety of NRT in patients with cardiovascular disease has been questioned. Nicotine has sympathomimetic effects that may lead to increases in heart rate and blood pressure and cause coronary vasoconstriction and arrhythmias (26,100,131). However, treatment with transdermal nicotine produces considerably lower peak plasma nicotine levels than cigarette smoking, even if the patient continues to smoke during treatment (131,133). Moreover, a careful study of transdermal nicotine in 156 patients with stable CAD found that transdermal nicotine did not affect angina frequency, overall cardiac symptom status, nocturnal events, arrhythmias, or episodes of ischemic ST-segment depression (134). Also, a recent randomized, double-blind, placebo-controlled trial of transdermal nicotine in 584 outpatients with at least one diagnosis of cardiovascular disease revealed that transdermal nicotine did *not* produce increased rates of death, MI, and cardiac arrest, increased admissions to the hospital due to increased severity of angina, arrhythmia, or congestive heart failure, increased admissions to the hospital for other reasons, or increased outpatient visits due to increased severity of cardiovascular disease (131). Moreover, nicotine gum use was not associated with any cardiovascular illness or events in more than 3,000 participants in the Lung Health Study (135).

Transdermal nicotine and nicotine gum are now available over the counter (OTC). Although pharmaceutical companies that produce nicotine gum and patches have provided the FDA with evidence of the effectiveness of OTC use of these products (121,136), health care provider monitoring and support is recommended and will likely lead to higher long-term quit rates (113,121). OTC preparations are virtually identical to the nicotine gum and transdermal products that were previously available only by prescription, although the Nicotrol 16-hour patch is only available OTC in the 15-mg (highest dose) preparation. Recommendations for use of transdermal nicotine are provided in *e*Table 6.3.3.

***e*TABLE 6.3.3** SUGGESTIONS FOR USE OF NICOTINE TRANSDERMAL PATCHES
Selection of patients: Avoid during pregnancy and breast feeding, in the presence of unstable angina or other unstable vascular disease. Patients with an allergy to adhesive or generalized skin diseases may be unable to use patches.
Dosage and duration: Initially, use highest dose patch *unless* smoking less than 10 cigarettes per day or if the patient weighs less than 100 lb. After 4 weeks at initial dose, taper to intermediate dose for 2 weeks and lowest dose for 2 weeks. Consider supplementing with nicotine gum if breakthrough craving or withdrawal occur. Use of more than one patch at a time can be considered for patients with significant withdrawal symptoms on single patch.
16- versus 24-hour patches: Base on patient preference. 24-hour patch is more likely to cause sleep disturbance or vivid dreams, whereas 16-hour patch may be associated with early morning withdrawal symptoms.
Instruct patient not to smoke while on patch and to discontinue patch if the patient smokes more than 5 cigarettes per day for several days.

Adapted from American Psychiatric Association. Practice guideline for the treatment of patients with nicotine dependence. *Am J Psychiatry* 1996;153[Suppl]:1–31.

Nicotine nasal spray was approved by the FDA in 1996 as a smoking cessation treatment. Nasal spray provides a more rapid rise in nicotine levels than transdermal or gum products, with peak levels of nicotine occurring within 10 minutes (121). Three published studies of nicotine nasal spray that meet the requirements for the Guideline metaanalyses have documented its efficacy when combined with adjunctive psychosocial treatment (121,114), and one study documented the efficacy of nicotine nasal spray in a minimal contact setting (137). Nicotine nasal spray has considerably more side effects than other forms of NRT and appears to have greater dependence liability (121). Side effects include nasal and throat irritation, rhinitis, sneezing, coughing, and watering eyes (121). However, tolerance to these side effects often develops within several days. At present, nicotine nasal spray seems best suited for individuals who have failed other forms of NRT. In a metaanalysis of four studies, nicotine inhalers—which produce a nicotine vapor when air is drawn through a tube into the mouth and throat—were found to be efficacious when combined with adjunctive behavioral therapy (114). In addition to its pharmacologic benefits in terms of nicotine replacement, the inhaler provides the user with an oral-handling substitute for cigarettes, which may confer additional therapeutic benefit. The inhaler is FDA-approved for use in the United States as a prescription product (121).

Bupropion and Other Pharmacotherapy

Bupropion recently received FDA approval for smoking cessation. Bupropion is a unique antidepressant with noradrenergic and dopaminergic activity. Clinical trials have demonstrated the efficacy of bupropion SR (a delayed release preparation) for smoking cessation with or without concomitant transdermal nicotine (121,138,139 and 140). The recommended dose of bupropion SR for smoking cessation is 150 mg twice daily. In clinical trials, medication was started 1 to 2 weeks before patients' quit days and was continued for 7 to 12 weeks. Because bupropion may lower the seizure threshold, it is contraindicated in patients with a seizure disorder and should be avoided when a patient has a condition predisposed to seizures (e.g., head injury, alcohol abuse or dependence) (Table 6.4). Common side effects include headache, insomnia, nausea, and restlessness. If sleep difficulty occurs, move the p.m. dose to the late afternoon or early evening. Bupropion has little or no adverse effects on the cardiovascular system (i.e., no significant alpha-adrenergic blockade, anticholinergic activity, or effects on cardiac conduction) (141,142 and 143), although elevations in blood pressure have been noted on occasion.

Selection of patients: Avoid during pregnancy and breast feeding unless increased likelihood of smoking abstinence, with its potential benefits, outweighs the risk of bupropion SR treatment and potential concomitant smoking. There is a small risk of hypertension. Contraindicated in patients with a history of seizure disorder, eating disorder, use of another form of bupropion (e.g., Wellbutrin), or use of a monoamine oxidase inhibitor in the past 14 days.

Dosage and duration: Begin with a dose of 150 mg q.a.m. for 3 days, increasing to 150 mg b.i.d. and continuing for 7–12 weeks after quit date. Patients should begin treatment 1–2 weeks before quitting. Use alcohol in moderation.

TABLE 6.4 SUGGESTIONS FOR USE OF BUPROPION SR

Clonidine is an alpha$_2$-agonist that dampens sympathetic activity and attenuates withdrawal symptoms associated with alcohol, opiate, and nicotine abstinence (121,144). Recent metaanalytic reviews (114,145) concluded that clonidine was more effective than placebo in promoting abstinence from smoking (144). Doses used for smoking cessation are 0.1 to 0.4 mg per day for 2 to 6 weeks in oral or transdermal formulations (121). The most common side effects are sedation, dry mouth, constipation, lightheadedness, and postural hypotension (144). Although it is uncommon, rebound hypertension after discontinuation is also a concern, especially in patients with cardiac disease. Clonidine is recommended as a second-line treatment for smokers who have failed NRT or bupropion (114,121) or as an alternative for smokers who prefer not to receive nicotine.

In addition to bupropion, other antidepressants have been evaluated as potential treatments for smoking cessation (121). Doxepin and fluoxetine have produced promising results in early clinical trials (121,138). However, further evidence of their efficacy is needed before they can be recommended as first-time treatments for smoking cessation. Two randomized double-blind clinical trials have demonstrated long-term (1-year) efficacy of nortriptyline versus placebo for smoking cessation (146,147). However, nortriptyline is recommended as a second-line treatment, largely because of its anticholinergic side effect profile. Nortriptyline's quinidine-like effects on cardiac conduction and its propensity to cause postural hypotension limit its safety and value as a smoking cessation treatment in patients with cardiac disease. Antidepressants may be useful for treating nicotine dependence for several reasons: a history of depression is associated with an increased difficulty with smoking cessation; depressive symptoms commonly occur during nicotine withdrawal, especially when there is a history of depression; nicotine appears to be a powerful regulator of negative effect; and antidepressants have been useful in ameliorating the withdrawal state associated with other drug withdrawal states (8,77,121).

Buspirone—a serotonergic agonist with anxiolytic properties—has also shown promise as a smoking cessation treatment, especially in high-anxiety smokers (121,138). Mecamylamine, a noncompetitive blocker of central and peripheral nicotine receptors, has produced promising results when combined with NRT (121,148,149).

Smoking Cessation: Behavioral and Psychosocial Treatments

As noted in the section Smoking Cessation: Effectiveness of Brief Interventions, the *Treating tobacco use and dependence guideline* panel found evidence that four specific types of behavioral and psychosocial interventions were efficacious: problem solving or skills training, social support provided within the treatment setting, assisting patients to access social support outside of treatment, and aversive smoking procedures (113,114). The essential elements of problem solving or skills training and supportive counseling are listed in *e*Table 6.3.1 and *e*Table 6.3.2. This section reviews the efficacy of aversive therapy and other behavioral and psychosocial treatments, including stimulus control, relaxation, hypnosis, acupuncture, and multicomponent groups.

Aversive Therapy

Aversive therapy is based on the premise that pairing smoking with aversive experiences makes smoking less reinforcing and unpleasant. Techniques used to produce the aversive experience include rapid smoking, smoke holding, and rapid puffing (150). Although these techniques have been shown to increase smoking cessation outcomes when compared to control conditions, compliance and safety issues have limited their acceptability and widespread use (113,121,150).

Stimulus Control

Stimulus control therapy includes identification of cues associated with smoking and removal or avoidance of these cues during attempts at smoking cessation to reduce urges to smoke (113,121,150). For example, patients who are preparing to quit are advised to discard all cigarettes, lighters, matches, and ashtrays and to avoid other smokers or settings where smoking is prevalent. Stimulus control strategies are often included in multicomponent behavioral treatment programs and can also be used as a component of brief problem-solving or skills-training treatments.

Relaxation

Strategies such as progressive relaxation and deep breathing often have been taught within the setting of multicomponent behavioral treatment programs. Although there is little evidence for their efficacy when used alone (113,121,150), some patients may find these strategies useful when dealing with trigger situations or craving.

Hypnosis

In isolation, hypnosis has not been demonstrated to be an efficacious smoking cessation treatment (113,121,150,151), although it may be of value when combined with behavioral skills training or in-treatment support. In a metaanalysis, acupuncture was also unproven as a smoking cessation treatment (114).

Multicomponent Treatments

Success rates are generally greater in multicomponent treatments than in programs using only one or two behavioral and psychosocial strategies (6,113,121,150). Six-month quit rates with multimodal group treatment are typically increased twofold over control groups, producing 6-month quit rates of approximately 20% to 25% (6,121). The combination of multimodal behavioral and pharmacologic interventions is likely more efficacious than either treatment strategy alone (114,121).

Group treatment settings have frequently been used to deliver multicomponent treatment. This approach takes advantage of the social support component of group treatment, is less costly than individual treatment, and facilitates the involvement of multiple therapists who may have overlapping, but distinct, therapeutic skills (e.g., a physician or nurse skilled in pharmacologic intervention and a psychologist skilled in behavioral interventions).

The *Treating Tobacco Use and Dependence Guideline* has developed recommendations for intensive multicomponent smoking cessation programs that include careful assessment of smokers' barriers to quitting, use of multiple types of clinicians, at least four sessions of at least 10 minutes each for a total contact time of at least 30 minutes, use of individual or group format or proactive telephone counseling (supplemented with self-help materials), use of multiple behavioral strategies (e.g., problem solving, skills training, and in-treatment and extratreatment social support), and use of pharmacotherapies endorsed in the guidelines (113,114) (*e*Table 6.4.1). These recommendations are especially relevant for the development of specialized intensive smoking cessation services for patients enrolled in cardiac rehabilitation programs.

***e*TABLE 6.4.1** RECOMMENDATIONS REGARDING INTENSIVE SMOKING CESSATION PROGRAMS

Assessment

Determine whether smokers are motivated to quit via an intensive smoking cessation program. Other assessments that may be used to guide treatment include level of nicotine dependence, presence of psychiatric comorbidity and emotional distress, presence of smoking-related medical conditions or risks, self-monitoring of smoking to identify important cues and triggers, reasons for smoking and quitting, level of social support for quitting, stressful life circumstances or events, and self-efficacy.

Program clinicians

Multiple types of clinicians are effective and should be used. One counseling strategy would be to have a medical or health care clinician deliver messages about health risks and benefits and deliver pharmacotherapy and to have nonmedical clinicians deliver additional psychosocial or behavioral treatments.

Program intensity
Because of evidence of a strong dose-response relation, the intensity of the program should be the following: session length longer than 10 minutes; 4 or more sessions; total contact time longer than 30 minutes.
Program format
Group or individual counseling may be used. Proactive telephone counseling is also effective. Use of adjuvant self-help material is optional.
Type of counseling and behavioral therapies
Counseling and behavioral therapies should involve practical counseling (problem solving or skills training) and social support.
Pharmacotherapy
Every smoker should be encouraged to use pharmacotherapies endorsed in the Guideline, except in the presence of special circumstances (e.g., pregnant adolescents). The clinician should explain how these medications increase smoking cessation success and reduce withdrawal symptoms. The first-line agents include bupropion SR, nicotine gum, nicotine inhaler, nicotine nasal spray, and nicotine patch.

Adapted from Fiore M, Bailey W, Cohen S, et al. *Treating tobacco use and dependence: clinical practice guideline*. Rockville, MD: U.S. Department of Health and Human Services, Public Health Services, 2000.

Intensive Case Management for Myocardial Infarction Patients

As noted in the section Smoking Cessation and Reduction of Cardiovascular Disease Risk, cessation rates after the diagnosis of clinical CAD range from 35% to 75%. Using an intensive case-management system, DeBusk and colleagues (40) produced a 1-year smoking cessation rate of 70% compared to a rate of 53% for usual care for patients hospitalized with acute MI (p = .03). The case-management system included the following components: in-hospital counseling (by a physician) lasting approximately 2 minutes, an in-hospital comprehensive assessment and counseling session conducted by a nurse trained in behavioral problem-solving skills, provision of a self-help manual focusing on relapse prevention and a relaxation audiotape, and telephone calls by the nurse 48 hours and 1 week after hospital discharge and monthly for 6 months. Patients who relapsed after discharge also were offered one additional visit with the nurse for further counseling, as well as nicotine gum or transdermal nicotine. The usual-care condition included physician counseling on smoking cessation, nutritionist counseling on dietary change during hospitalization, and physician-managed, lipid-lowering drug therapy after hospital discharge. Patients in the usual-care group also had access to a group smoking cessation program and group exercise rehabilitation at a number of community facilities.

Organizational Systems to Support Office-Based Smoking Interventions

Barriers to the provision of smoking counseling in medical settings include lack of organizational support and limited availability of materials to aid physicians and patients in smoking cessation efforts. Kottke, Solberg, and Brekke have described the organizational components and systems that are essential to the delivery of effective and consistent counseling in primary care office settings (152,153). An amended list of these components is presented in *e*Table 6.4.2.

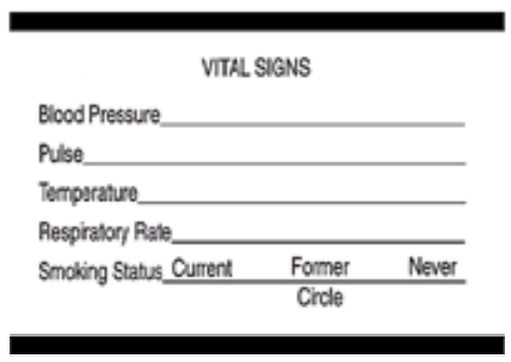
As noted in the section Smoking Cessation: Effectiveness of Brief Interventions, research has demonstrated that the use of systems that identify and document smoking status result in significantly higher rates of smoking cessation interventions by clinicians and that the presence of these screening systems results in higher smoking cessation rates (113,114). The Guideline suggests the use of a vital-sign stamp that includes smoking status, along with blood pressure, pulse, and temperature, as a device to remind staff to assess and intervene with smokers (113,114) (*e*Fig. 6.4.1).



***e*FIGURE 6.4.1** Vital sign stamp. (From Fiore M, Bailey W, Cohen S, et al. *Smoking cessation: clinical practice guideline no. 18*. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services, 1996.)

Resources for patients, physicians, and office staff are important tools that enhance the capacity of the health care provider to provide information and advice. Self-help manuals are available through voluntary agencies, the National Cancer Institute, and the Surgeon General (Table 6.5). Although most of these materials have been developed for smokers in preparation or action stages, materials such as the National Cancer Institute's *Why Do You Smoke?* pamphlet are geared toward precontemplators or contemplators. The pharmaceutical companies that produce nicotine transdermal patches and bupropion also have developed useful self-help materials that are available from their field representatives. As part of the purchase price, these products also support quitters' assessment and provide telephone counseling services tailored to the needs of the smoker.

Once an office has decided to implement a system for supporting smoking cessation interventions, the establishment of a specific policy that is endorsed by all staff is a useful device for generating staff commitment and delineating specific roles among staff. For example, a policy might identify who is responsible for tasks such as ensuring that patients complete smoking questionnaires, ordering patient materials, or providing follow-up calls or letters. Identifying a single office staff person to be responsible for coordinating all smoking intervention activities is useful in larger offices or clinics. A policy to establish a smoke-free office is another useful step that clearly demonstrates a commitment to reducing the health risks for all patients, visitors, and staff. The presence of posters and prominent displays of patient-education materials also makes a "statement" that smoking cessation is a priority of the office's physicians and staff.

Finally, Kottke and colleagues have stressed the importance of developing a maintenance program once an office has implemented several systems for supporting smoking intervention efforts (152,153). A maintenance program may include regular audits of charts to provide feedback to staff, spirit-building activities (e.g., parties for achieving modest goals), and repeat training sessions to retain and enhance skills.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Harm Reduction

Proponents of a harm-reduction approach maintain that any decrease in smoking rate, even short of complete abstinence, is desirable. On the surface, this makes sense, given the clear dose-dependent relationship between the amount of tobacco smoked or consumed and the risk of cardiovascular diseases. However, this approach has several drawbacks. It is unlikely that most smokers can maintain a decrease in the amount that they smoke. Somewhere between 5% to 10% of all smokers smoke five or fewer cigarettes per day, but these "chippers" are more likely to have maintained this level of smoking for most of their smoking careers than to have decreased the amount that they smoked (154). Very few intervention studies have adopted decreases in smoking as a goal, largely because it is ineffective and because this strikes most smokers as unacceptable. Moreover, even though disease risk is reduced when smoking rate decreases, it is not eliminated. Smoking even one to four cigarettes a day increases risk of cardiovascular disease (30). Therefore, unlike with problem drinking—in which there is some evidence that a harm-reduction approach is feasible and that drinking moderate quantities of alcohol may be salubrious—complete abstinence from smoking should remain the desired outcome.

Another approach to harm reduction, ironically championed by the tobacco industry, is the low-tar and low-nicotine cigarette. However, considerable evidence now suggests that smokers compensate for decreased nicotine yield by smoking more effectively (e.g., more frequent and deeper puffing) and by blocking cigarette ventilation holes. Often, such compensation occurs outside of conscious awareness. In some cases, smokers even overcompensate by increasing their overall nicotine intake (i.e., smoking more cigarettes) after switching to a low-tar, low-nicotine brand. A study of women who smoked "low-yield" cigarettes produced a similar increase in the risk of having a first MI to those who smoked a higher-yield cigarette (155). Thus, there does not appear to be such a thing as a safe or even a safer cigarette, and this approach to harm reduction cannot be condoned because it is false.

Still another variation on harm reduction is the position that all nicotine replacement products should be sold as OTC medications. This includes not only slow-release formulations such as the nicotine patch and gum, but also the faster-release formulations such as nicotine nasal spray and inhaler, although abuse liability appears to be increased with the faster-release formulations. The argument in favor of this approach is simply that it is better to ingest pure nicotine rather than to be exposed simultaneously to carcinogens, carbon monoxide, and the other toxic components of tobacco during the combustion process, thereby increasing the risk of disease. However, because nicotine alone appears to increase the risk for cardiovascular disease by increasing adrenergic tone and by its effect on lipids, one has to question the wisdom of this suggestion. Moreover, an unknown number of non- and former smokers might use OTC nicotine delivery devices to boost memory and cognitive performance, to control weight, or for other "benefits," thereby risking addiction. Our perspective is that, although harm reduction appears laudable, it seems impossible to implement. Therefore, complete abstinence from smoking and nicotine should remain the treatment goal.

Policy, Regulation, and Advocacy

Should the sale of tobacco products be illegal? Can the sale of tobacco products be made illegal? The answer to the former question is a tentative yes; the answer to the latter is very probably no. A ban on tobacco products is extremely unlikely because (a) historically, they have been manufactured and sold legally, (b) a substantial number of Americans smoke, and (c) tobacco is very big business. Can tobacco products be regulated? Possibly. By calling nicotine an addictive drug, the FDA may be able to regulate aspects of tobacco manufacture and sales. However, governmental regulatory efforts face the challenge of the tobacco industry, its lobbyists, and politicians who are friendly toward the tobacco industry. The future of increased government regulation remains uncertain, given the vicissitudes of the political process. In our opinion, only "grass roots" reform will permit more effective regulation; unfortunately, there is as yet no evidence of an antitobacco groundswell.

Economic regulation (e.g., increasing taxes on tobacco products) is probably effective, to some degree, in motivating smokers to quit. However, this type of regulation has its limits. For example, recently the Canadian government substantially increased taxes on cigarettes, which increased the price of a pack of cigarettes two-to threefold. This resulted in a small decrease in smoking prevalence and a substantial increase in the cigarette black market, which is reminiscent of the effects of prohibition on alcohol use in the United States. The Canadian government repealed the high taxes on cigarettes when it was realized that tax revenues were decreasing. As a result, black market activity decreased. This scenario illustrates another reason why banning tobacco would be nearly impossible.

Another approach to regulation that has been debated is the application of a special tax on cigarette sales, which would then be used to offset the cost of smokers' disproportionately high use of health care resources as they become ill as a result of their smoking. In fact, variations on this theme are already in place (e.g., higher life insurance premiums for smokers). It is unclear to what degree such a tax would serve as a disincentive to smoke. There probably would be some effect, but we are not likely to see this form of regulation adopted anytime soon.

Should physicians advocate the control of tobacco? The answer is a resounding "yes!" Indeed, several physician organizations, including the American Medical Association (AMA) and the American Psychiatric Association, have drafted policy papers on this topic. Effective advocacy starts with education. Physicians are urged to learn about tobacco control by reading about the work of the AMA and established advocacy groups such as Doctors Oughta Care and the Action on Smoking and Health. The American Academy of Family Physicians has developed a model tobacco control program called Tar Wars. The principal goal of Tar Wars is to educate youth regarding tobacco-free lifestyles by developing partnerships between physicians, schools, and community agencies supporting tobacco control. The program supports physicians and other health care clinicians to deliver lessons to fifth- and sixth-graders on the effects of tobacco use on health and strategies for countering the advertising images that tobacco companies use to market their products. Physician-teachers also judge "counter-advertising" posters developed by the children as a follow-up activity. As enthusiastic participants in the Tar Wars program in our own communities, we strongly encourage cardiologists and other clinicians treating patients with cardiac disease to get involved in similar community-based tobacco control programs. It is a wonderful way to promote tobacco control, teach children about prevention, and have fun!

We also encourage physicians who are members of clinical and scientific societies to develop position papers similar to the AMA documents and to disseminate these papers to their membership. The AMA has also recommended divestiture of tobacco and tobacco-related stock. Does the American College of Cardiology or other similar societies own stock in tobacco and related industries? Do your employer-related retirement plans invest in tobacco-related stock? Recently, the Teacher's Insurance Annuity Association–College Retirement Equities Fund—the largest retirement fund for employees of educational institutions—was prompted by its membership to hold a vote on whether to divest all of its tobacco-related holdings. The motion was voted down.

An important but neglected topic is reimbursement for smoking cessation treatment provided by health care providers. The *Treating Tobacco Use and Dependence Guideline* recommends that those smoking cessation treatments found to be effective be included as paid services for all subscribers of health insurance programs (113,114). Lack of reimbursement is an important barrier, preventing the busy physician from spending more time motivating and assisting their patients to quit smoking. Physicians and other health care providers should push hard for third-party reimbursement. Voluntary agencies can provide more information on this issue (Table 6.5).

Finally, health care providers should not turn a blind eye to tobacco consumption on a worldwide scale. The United States enjoys one of the lowest smoking prevalence rates in the world, due in large part to increasing public awareness about the health risks of smoking and to considerable research on developing and disseminating effective smoking cessation treatments. Other countries, especially underdeveloped or newly developing ones, fare much worse in terms of smoking prevalence and efforts to educate and treat smokers. The American tobacco industry is one of the world's largest suppliers of tobacco. We should question American export practices, which actively promote the sale and distribution of tobacco products to developing countries, thereby directly contributing to a worldwide pandemic in tobacco-related diseases.

THE FUTURE

This is a time for considerable optimism. New behavioral and pharmacologic treatments for nicotine dependence are currently being developed to add to the many known effective treatments (58,156,157 and 158). Research is helping us to understand the biobehavioral mechanisms responsible for nicotine dependence and how to target these mechanisms for treatment. A few areas, however, stand out as especially important in terms of furthering our ability to help smokers to quit; one has to do with increased understanding of the biologic and psychological substrates of nicotine dependence. For example, symptoms of depression are associated with nicotine dependence and difficulty quitting, and promising new treatments for smoking cessation include antidepressant medications and psychosocial treatments that target depressive symptoms. Research on nicotine receptors in the mesolimbic areas associated with addiction suggest that more specific antagonists can be developed to block the reinforcing effects of nicotine, thereby helping smokers quit.

Another area of importance that dovetails with the study of biobehavioral mechanisms is patient–treatment matching. No single treatment proves effective for every smoker; there are many reasons why people smoke and become addicted. However, smokers with certain characteristics may respond more favorably to certain treatments. For example, smokers with symptoms of depression achieve better outcomes when treated with an antidepressant than smokers with no symptoms of depression. Better matching of treatment to patient will increase the chances of successful treatment.

Finally, if we are to truly have a significant impact on smoking, subpopulations in whom smoking prevalence has stabilized—or is even increasing—must be targeted for treatment (9). In particular, there is an epidemic of adolescent smoking in the United States. The adolescent smokers of today are the addicted smokers of tomorrow who will suffer from smoking-related cardiovascular and other diseases. Efforts to prevent the initiation of smoking are of paramount importance (the Tar Wars program described above is one such effort), but so is treatment of the adolescent smoker. Many of the same treatments that have proven effective among adult smokers, (e.g., nicotine replacement and bupropion) should be evaluated for efficacy among adolescent smokers. In addition, new innovative strategies for adolescent smokers need to be evaluated and tested.

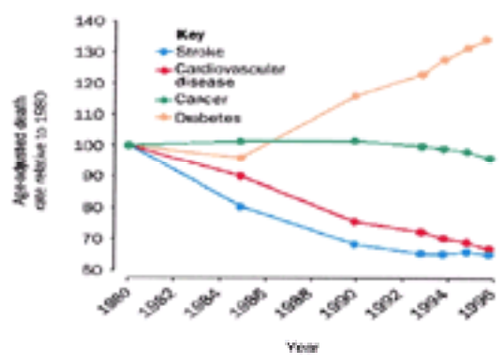
OVERVIEW

Both type 1 and type 2 diabetes are powerful and independent risk factors for coronary artery disease (CAD), stroke, and peripheral arterial disease (1,2). Atherosclerosis accounts for virtually 80% of all deaths among North American diabetic patients, compared with one-third of all deaths in the general North American population (3). More than 75% of all hospitalizations for diabetic complications are attributable to cardiovascular disease (3). Sixteen million people in the United States are estimated to have diabetes, and more than 90% of these patients have type 2 diabetes (4). In addition, it is estimated that up to one-half of type 2 diabetic patients have not been diagnosed. The World Health Organization estimates that the number of diabetic adults will more than double globally, from 143 million in 1997 to 300 million in 2025, largely because of dietary and other lifestyle factors.

Whereas other major multifactorial diseases (e.g., heart disease, stroke, and many cancers) have declined or remained stable, the age-adjusted death rate for diabetes in the United States has increased 30% since 1980 (5) (*e*Fig. 7.0.1). The decline in heart disease mortality in the general U.S. population has been attributed to the reduction in cardiovascular risk factors and improvement in treatment of heart disease. However, patients with diabetes have not experienced the reduction in age-adjusted heart disease mortality that has been observed in nondiabetic people, and an increase in age-adjusted heart disease mortality has been reported in diabetic women (6).



***e*FIGURE 7.0.1** Increasing number of deaths from diabetes, 1980 to 1996. (From National Center for Health Statistics, 1998. From McKinlay J, Marceau L. U.S. public health and the 21st century: diabetes mellitus. *Lancet* 2000;356:757–761, with permission.)

Several autopsy studies have shown that diabetic subjects have more extensive atherosclerosis of both coronary and cerebral vessels than age- and sex-matched nondiabetic controls. In the International Atherosclerosis Project, 23,000 subjects from 14 countries were examined. The severity of coronary atherosclerosis in diabetics varied in parallel with the severity of disease in subjects from the same country. However, the effect of diabetes was superimposed on any level of average severity of atherosclerosis (7).

Autopsy studies have shown that diabetics have a greater number of coronary vessels involved and more diffuse distribution of atherosclerotic lesions (8). Large angiographic studies comparing diabetics with matched controls have corroborated the autopsy studies. Thus, diabetic patients with established CAD undergoing cardiac catheterization for acute myocardial infarction (9), angioplasty (10), or coronary bypass (11) have significantly more severe proximal and distal CAD. Furthermore, postmortem (12) and angioscopic (13) evidence indicates a significant increase in plaque ulceration and thrombosis in diabetic patients.

CORONARY ARTERY DISEASE IN TYPE 1 DIABETES

In contrast to type 2 diabetes, cardiovascular risk in type 1 diabetes can be examined in relation to hyperglycemia *per se*. Long-term follow-up of patients with type 1 diabetes from the Joslin Diabetes Center has shown that an excess of cardiovascular mortality can only be observed after the age of 30 (14). The first cases of clinically manifest CAD occur late in the third decade or in the fourth decade of life, regardless of whether diabetes developed early in childhood or in late adolescence, suggesting that diabetes mainly accelerates the progression of early atherosclerotic lesions that occur at a young age in the general population (14). CAD risk increases rapidly after the age of 40; by the age of 55 years, 35% of men and women with type 1 diabetes die of CAD. This rate of CAD mortality far exceeded that observed in an age-matched nondiabetic cohort from the Framingham Heart Study (8% for nondiabetic men and 4% for nondiabetic women) (14). Similar to women with type 2 diabetes, the protection from CAD observed in nondiabetic women is lost in women with type 1 diabetes (14,15).

Diabetic nephropathy occurs only in a subset of 30% to 40% of type 1 diabetic patients and increases dramatically the prevalence of CAD. Data from the Steno Memorial Hospital showed that in patients with persistent proteinuria the relative mortality from cardiovascular disease was 37 times that in the general population, whereas in patients without proteinuria cardiovascular mortality was only 4.2 times higher (16). In a case-control study of type 1 diabetes patients who were followed from the onset of microalbuminuria (a urinary albumin excretion rate of greater than 20 µg per min but less than 200 µg per min or 30 to 300 mg per 24 hours), coronary heart disease (CHD) developed eight times more frequently than in a diabetic population of similar age, sex, and diabetes duration (17). In the Joslin clinic cohort, the risk of developing CAD in patients with persistent proteinuria was 15 times higher than in those without this renal complication (14). Microalbuminuria in type 1 diabetes is, therefore, not only a marker for renal disease, but it is also a potent risk marker of CAD.

Prospective studies demonstrated that in type 2 diabetes patients, microalbuminuria is also an independent predictor of increased cardiovascular mortality (18). Proteinuria in a patient with type 2 diabetes increases the risk of fatal CAD by a factor of only two to four.

When nephropathy is superimposed on diabetes, some of the atherogenic mechanisms present in diabetes are accentuated. An aggregation of cardiovascular risk factors for cardiovascular disease, including hypertension, lipid abnormalities, and a hypercoagulable state, are detectable in the early stages of diabetic nephropathy, when renal function is still normal (19). Hypertension is frequently present in diabetic nephropathy even when the creatinine concentrations remain normal and can intensify CAD in type 1 diabetes patients. In the World Health Organization Multinational Study on Vascular Disease in Diabetes, patients with both hypertension and proteinuria experienced 11-fold and 18-fold increased mortality for men and women, respectively (20). Microalbuminuria is associated with an atherogenic lipoprotein profile that includes elevated low-density lipoprotein (LDL) and chylomicron remnants levels, decreased high-density lipoprotein (HDL) levels, and elevated lipoprotein(a) levels (21,22). In addition, plasminogen activator inhibitor-1 (PAI-1) activity, factor VII, and plasma fibrinogen are significantly higher in microalbuminuric type 1 diabetes patients (23). Finally, nephropathy results in accelerated accumulation of advanced glycosylation end products (AGEs) in the circulation and tissue that parallels the severity of renal functional impairment (24). The accumulation of AGEs improves markedly with successful renal transplantation (25).

Contrary to other microvascular complications of diabetes (e.g., retinopathy), the risk for the development of diabetic nephropathy is only partially determined by glycemic control or disease duration and is highly influenced by genetic susceptibility (26,27). Familial clustering of cardiovascular disease occurs in diabetic patients with nephropathy. Parents of insulin-dependent diabetic patients with proteinuria have a significant excess of cardiovascular disease compared with parents of insulin-dependent diabetic patients who do not develop kidney disease. Among diabetics with nephropathy, those who had a cardiovascular event are six times more likely to have a familial history of cardiovascular disease than those who had no such event. A history of cardiovascular disease in both parents or in the father of type 1 diabetes patients increases the risk of nephropathy in the offspring ten- and threefold, respectively (28). Parents of diabetic offspring with nephropathy also have higher levels of arterial blood pressure than do parents whose diabetic offspring do not have diabetic nephropathy (29). Thus, a subgroup of type 1 diabetes subjects has a genetically determined predisposition to renal disease and hypertension, and this predisposition is linked to enhanced risk of CAD. The genetic link between diabetic nephropathy and CAD may be related, in part, to the ACE I/D polymorphism (see Genetic Factors). This inherited susceptibility to CAD might be more likely to be expressed in patients with poor glycemic control.

Patients with End-Stage Renal Disease and Postrenal Transplantation

In diabetic patients reaching end-stage renal disease, the overall mortality has been reported to be greater than in nondiabetic patients with end-stage renal disease. For example, in the age group of 35 to 44 years old, the 3-year survival rate of diabetic patients is 44% in men and 66% in women compared with 75% and 87% for nondiabetic patients with end-stage renal disease (30), and the majority of these deaths are secondary to CAD (31). The relative risk for age-specific death rate from myocardial infarction among all diabetic patients during the first year of dialysis is 89-fold higher than that of the general population (30).

The most common cause of death in diabetic patients who have undergone renal transplantation is also CAD, which accounts for 40% of deaths in these patients. In one study, a death rate of 30% was reported over a mean follow-up period of 4 years, and the majority of these deaths were from cardiovascular causes (32). Consequently, long-term survival of diabetic patients with renal allograft is substantially inferior to that of nondiabetic patients. In most centers, coronary angiography is performed in all diabetic transplant candidates (33), and coronary revascularization has been shown to be superior to medical therapy in this setting (34).

CORONARY ARTERY DISEASE IN TYPE 2 DIABETES

CHD is the leading cause of death among patients with type 2 diabetes, regardless of duration of diabetes. Several population-based studies have consistently shown that the relative risk ratio of cardiovascular disease in type 2 diabetes compared with the general population is increased twofold to fourfold (2,15,35). Patients with type 2 diabetes without previous myocardial infarction have CAD mortality as high as nondiabetic patients with a previous infarction (36).

The increased cardiovascular risk is particularly striking in women. A number of studies reported a disproportionate effect of CAD on diabetic women compared with diabetic men (37). Indeed, the usual protection that premenopausal women have against atherosclerosis is almost completely lost when diabetes is present (38).

Although the degree and duration of hyperglycemia are the principal risk factors for microvascular complications (39), in type 2 diabetes, there is no obvious association between the extent or severity of macrovascular complications and the duration or severity of the diabetes. An increased prevalence of CAD is apparent in newly diagnosed type 2 diabetes subjects (40). In fact, even impaired glucose tolerance carries an increased cardiovascular risk despite minimal hyperglycemia (41).

In individuals who are genetically prone to develop type 2 diabetes, insulin resistance is the earliest detectable metabolic defect and can occur 15 to 25 years or more before the clinical onset of overt diabetes (42). Although there is some uncertainty regarding the primary lesion and the relative importance of the different tissues, metabolic defects in the liver and peripheral tissues such as fat, muscle, and pancreatic beta cells all contribute to the syndrome.

The term *insulin resistance* usually connotes resistance to the effects of insulin on glucose uptake and metabolism in adipocytes and skeletal muscle and impaired suppression of hepatic glucose output (43). Insulin resistance is a common condition, associated with genetic predisposition, sedentary lifestyle, and aging. It is exacerbated and produced by obesity. Even in the absence of diabetes, insulin resistance is a major risk factor for CAD (44) because impaired insulin action coupled with compensatory hyperinsulinemia leads to a number of proatherogenic abnormalities referred to as the *insulin resistance syndrome* (Table 7.1). The association of insulin resistance with several established atherogenic risk factors (45,46 and 47) (Table 7.1) promotes atherosclerosis many years before overt hyperglycemia ensues (48) (Fig. 7.1).

Hypertension (45,46)
Abdominal obesity (47)
Dyslipidemia
Increased very-low-density lipoprotein triglyceride (52,71,72)
Decreased high-density lipoprotein (52,71,72)
Small dense atherogenic low-density lipoprotein particles (91,92)
Postprandial lipemia (82,87)
Prothrombotic state
Elevated plasminogen activator inhibitor-1 activity (158)
Fibrinogen (155)
von Willebrand factor (154)
Endothelial dysfunction (136)
Chronic subclinical inflammation (?) (51)

TABLE 7.1 CARDIOVASCULAR RISK FACTORS ASSOCIATED WITH INSULIN RESISTANCE

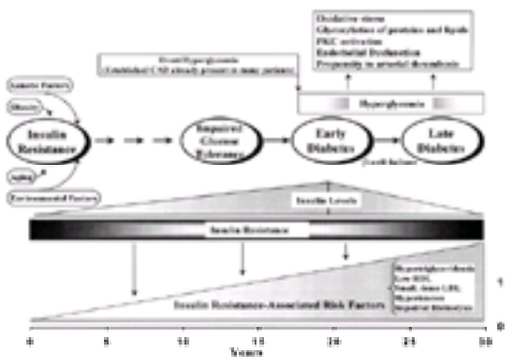


FIGURE 7.1 Schema of cardiovascular risk factors in patients with type 2 diabetes. Patients are exposed to the proatherogenic effects of the insulin resistance many years before the development of frank hyperglycemia. Therefore, macrovascular complications are commonly found when diabetes is diagnosed. When overt hyperglycemia ensues, it promotes atherosclerosis through several other mechanisms. CAD, coronary artery disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PKC, protein kinase C.

The dyslipidemia associated with insulin resistance entails elevated very-low-density lipoprotein (VLDL)–triglyceride levels, low HDL levels, delayed postprandial clearance of triglyceride-rich lipoprotein remnants, and the presence of the very atherogenic, small, dense LDL particles (49) (Table 7.1). This atherogenic lipoprotein phenotype is the most common lipoprotein abnormality seen in patients with CAD and imparts a risk for CAD at least equal to that of isolated moderate to severe hypercholesterolemia (50) (see Lipoprotein Disorders in Diabetes).

Insulin-resistant subjects also exhibit endothelial dysfunction (see Vascular Endothelial Dysfunction in Diabetes) and a hypercoagulable state (see Diabetes as a Prothrombotic State). Chronic subclinical inflammation has emerged as part of the insulin-resistance syndrome. C-reactive protein, a sensitive marker of inflammation associated with cardiovascular events, is independently related to insulin sensitivity (51).

The proatherogenic metabolic risk factors in insulin-resistance subjects worsen continuously across the spectrum of glucose tolerance (52). In the Framingham Offspring Study, the deterioration of insulin resistance (and glucose tolerance) over time was associated with a continuous increasing gradient of metabolic atherogenic risk factors (Fig. 7.2).

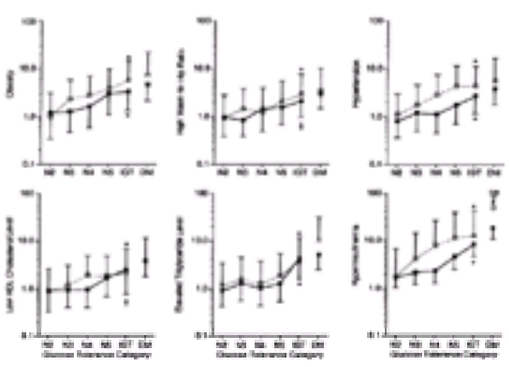

FIGURE 7.2 Multivariable odds ratios for metabolic risk factors by glucose tolerance category: odd ratios and 95% confidence intervals (*error bars*) of obesity (body mass index ³27.3 kg/m^2 in women or ³27.8 kg/m^2 in men, elevated waist-to-hip ratio (>0.9 for women and >1.0 for men), hypertension (two measurements of diastolic blood pressure >90 mm Hg, systolic blood pressure >140 mm Hg, or use of hypertensive medications), low high-density lipoprotein (HDL) cholesterol level (<45 mg per dL for women and <35 mg per dL for men), elevated triglyceride level (>200 mg per dL), and hyperinsulinemia (fasting insulin level greater than ninetieth percentile of its distribution among Framingham Offspring Study participants with normal glucose tolerance among women (*white squares* and *dotted lines*) and men (*black squares* and *solid lines*) are shown for each glucose tolerance category from lowest quintile (N1) to highest quintile (N5) of fasting plasma glucose level among participants with normal glucose tolerance, impaired glucose tolerance (IGT), and previously undiagnosed diabetes mellitus (DM). *p <.001; †p = .002; ‡p = .008 for trend from the lowest quintile of normal fasting glucose level to impaired glucose tolerance. (From Meigs JB, Nathan DM, Wilson PW, et al. Metabolic risk factors worsen continuously across the spectrum of nondiabetic glucose tolerance. The Framingham Offspring Study. *Ann Intern Med* 1998;128:524–533, with permission.)

Whether compensatory hyperinsulinemia promotes atherosclerosis in insulin-resistant subjects is still unclear. Several prospective studies reported the association between fasting or postprandial hyperinsulinemia and future CAD (53,54). Other studies reported inverse correlations between insulin sensitivity and atherosclerosis (55,56). In addition, it has been suggested that chronic hyperinsulinemia exerts a deleterious effect on the arterial wall (57) based on the ability of insulin at high concentrations to stimulate the insulin growth factor-1 receptor. However, the association between hyperinsulinemia and atherosclerosis has been demonstrated only in healthy male middle-aged white cohorts (53,54) but not in women (44,58), or in other ethnic groups such as Pima Indians (59) or Hispanic Americans (60).

The inconsistent association between plasma insulin levels and CAD may stem from the fact that hyperinsulinemia is only a compensatory response of pancreatic beta cells to the peripheral insulin resistance. Prospective studies have shown that type 2 diabetes progresses over a continuum of worsening insulin action, beginning with

peripheral insulin resistance and ending with a loss of insulin secretion. Thus, plasma insulin levels reflect not only the degree of insulin resistance but also the ability of beta cells to compensate. In fact, the natural course of type 2 diabetes is characterized by gradual loss of insulin secretion. Whereas hyperinsulinemia is characteristic in patients with impaired glucose tolerance and mild type 2 diabetes, increased glucose levels seen in patients with moderate-to-severe type 2 diabetes are associated with a progressive decline in both fasting and postprandial insulin concentrations as a result of pancreatic beta cell failure (43). Cross-sectional (52) and prospective (61) studies have shown that fasting and glucose-stimulated insulin concentrations have an inverted U-shaped curve when plotted against plasma glucose concentrations. This pattern has been termed the *Starling curve of the pancreas* (43). Thus, the insulin-resistance state itself—not the accompanying compensatory hyperinsulinemia—is more important than hyperinsulinemia as a risk factor for atherosclerosis (55).

Insulin-resistant individuals who go on to develop type 2 diabetes become exposed also to the atherogenic effects of hyperglycemia (Fig. 7.1). Indeed, the atherogenic risk factor profile observed in insulin-resistance patients accounts for only a portion of the excess risk for CAD in patients with type 2 diabetes (15,62), indicating that hyperglycemia itself plays a central role in accelerating atherosclerosis in these patients. Because many years of asymptomatic hyperglycemia may precede the clinical diagnosis of type 2 diabetes, the duration of diabetes is frequently underestimated. Furthermore, the threshold above which hyperglycemia becomes atherogenic is unknown but may be in the range defined as impaired glucose tolerance (63). Despite these confounding factors, many population-based studies in patients with type 2 diabetes have shown a positive association between the degree of glycemic control and CAD morbidity and mortality in middle-aged and elderly type 2 diabetic subjects (64,65 and 66).

LIPOPROTEIN DISORDERS IN DIABETES

The metabolic abnormalities associated with types 1 and 2 diabetes result in profound changes in the transport, composition, and metabolism of lipoproteins. Lipoprotein metabolism is influenced by several factors including type of diabetes, glycemic control, obesity, insulin resistance, the presence of diabetic nephropathy, and genetic background (67). Abnormalities in plasma lipoprotein concentrations are commonly observed in diabetic individuals and contribute to the atherosclerotic process.

Lipoprotein Profile in Type 1 Diabetes

The level of glycemic control is the major determinant of lipoprotein levels in type 1 diabetic patients (68). In well- to moderately controlled diabetes, lipoprotein levels are usually within the normal range (69). In poorly controlled type 1 diabetic patients, triglycerides are markedly elevated, LDL is modesty increased (usually when HbA_{1c} is greater than 11%), and HDL levels are decreased (69) (Table 7.2).

	Type 1 diabetes		Type 2 diabetes		
Lipoprotein	Conventional therapy	Intensive therapy	Poor control	Good control	Atherogenic modifications
VLDL	Normal or increased	Decreased	Increased	Normal or increased	Cholesteryl ester–rich VLDL
LDL	Normal or increased	Normal or decreased	Normal	Normal	Glycosylation of LDL, apolipoprotein B; LDL susceptible to oxidative modification; high proportion of small, dense LDL
HDL	Normal	Increased	Decreased	Normal or decreased	Decreased HDL, increased cholesteryl ester transfer protein activity; low paraoxonase activity (?)

HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

TABLE 7.2 LIPOPROTEIN ABNORMALITIES IN DIABETES

Intensive insulin therapy normalizes all lipoprotein abnormalities. Hypertriglyceridemia and hypercholesterolemia are readily reversible with insulin therapy (69), and HDL levels may be higher than in normal controls (21). When high LDL levels exist in well-controlled type 1 diabetes, the existence of diabetic nephropathy or a separately inherited lipid disorder should be suspected (68).

Lipoprotein Profile in Type 2 Diabetes

In contrast to type 1 diabetes, the pathophysiology of dyslipidemia in type 2 diabetes results from a complex relationship between hyperglycemia and the insulin-resistance state (67). An atherogenic pattern of lipoprotein changes (Table 7.1) is often present for years before the development of fasting hyperglycemia and the diagnosis of type 2 diabetes (70).

The typical lipoprotein profile associated with type 2 diabetes includes high triglycerides, low HDL levels, and normal LDL levels (Table 7.2). The most consistent change is an increase in VLDL-triglyceride levels (71,72). Population studies, including studies of the Pima Indians who have virtually no forms of genetic hyperlipidemia, indicate that type 2 diabetes generally produces only a 50% to 100% elevation of VLDL or total triglycerides (73). Thus, type 2 diabetic subjects with total triglycerides greater than 350 to 400 mg per dL probably have other genetic disorders in lipoprotein metabolism that may be exacerbated by diabetes. HDL levels are typically approximately 25% to 30% lower than in nondiabetic subjects and are commonly associated with other lipid and lipoprotein abnormalities, particularly high triglyceride levels.

Very-Low-Density Lipoprotein Metabolism in Diabetes

Hypertriglyceridemia in type 2 diabetes results from high fasting and postprandial triglyceride-rich lipoproteins, especially VLDL (71). Type 2 diabetic subjects with hypertriglyceridemia have both overproduction and impaired catabolism of VLDL (67,72). Increased VLDL production is almost uniformly present in patients with type 2 diabetes and hypertriglyceridemia (72). Increased VLDL production in diabetes is a consequence of an increase in free fatty acid mobilization (because maintenance of stored fat in adipose tissue depends on the suppression of hormone-sensitive lipase by insulin) and high glucose levels (74) (Fig. 7.3). Because free fatty acid availability is a major determinant of VLDL production by the liver, VLDL overproduction and hypertriglyceridemia occur (72).

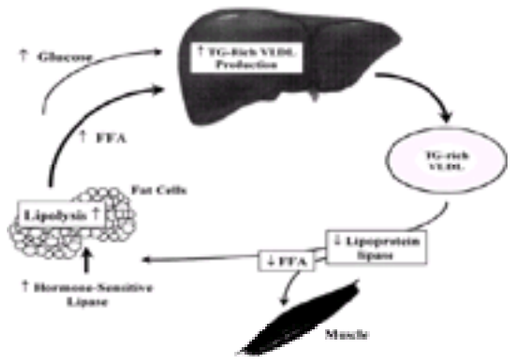

FIGURE 7.3 Mechanism of increased very-low-density lipoprotein (VLDL) triglyceride (TG) in diabetes. In the setting of insulin deficiency or insulin resistance, higher rates of glucose and free fatty acids (FFAs) flux to the liver lead to enhanced VLDL production and secretion. Decreased lipoprotein lipase activity contributes to the accumulation of these particles in the plasma.

The rest of the dyslipidemic phenotype that characterizes insulin resistance and type 2 diabetes (low HDL and small, dense LDL)—which has been termed *atherogenic lipoprotein phenotype* (50)—follows once VLDL secretion increases, mainly through the action of cholesteryl ester transfer protein and lipoprotein compositional

changes that occur in plasma (75).

Increased fatty acid flux to the liver also results in the production of large triglyceride-rich VLDL particles because the size of VLDL is also mainly determined by the amount of triglyceride available. VLDL size is an important determinant of its metabolic fate. Large triglyceride-rich VLDL particles may be less efficiently converted to LDL (76), thereby increasing direct removal from the circulation by non-LDL pathways. In addition, overproduction of large triglyceride-rich VLDL is associated with the atherogenic small, dense LDL subclass (50).

In type 2 diabetic subjects with more severe hypertriglyceridemia, VLDL clearance by lipoprotein lipase (LPL)—the rate-limiting enzyme responsible for the removal of plasma triglyceride-rich lipoproteins—is also impaired (71). LPL requires insulin for maintenance of normal tissue levels (77), and its activity is low in patients with poorly controlled type 2 diabetes (71). The result is enzymatic activity insufficient to match the overproduction rate, with further accumulation of VLDL triglyceride.

Although triglyceride concentrations are associated with premature CAD, the relation weakens when the strong inverse relation between HDL cholesterol and risk is taken into account (78). In addition, an important confounder of triglyceride and CAD risk is the heterogeneity of the triglyceride-rich lipoproteins. However, studies have shown that triglyceride-rich lipoproteins play an important role in the progression of atherosclerosis (79). Furthermore, in contrast to the controversy regarding hypertriglyceridemia as a risk factor for CHD in the nondiabetic population, several studies indicate that elevated triglyceride levels are independently associated with increased CHD risk in diabetic patients (71,80,81). Hypertriglyceridemia in diabetic patients often correlates with LDL density and subclass (i.e., small, dense LDL) and decreased levels of HDL_2 (50,78), which appear to increase overall risk synergistically (78).

Postprandial Lipemia

Exaggerated postprandial lipemia resulting from impaired remnant clearance is a factor in atherogenesis, involving endothelial dysfunction and enhanced oxidative stress (82,83,84 and 85). Several studies have shown that postprandial triglycerides may be a better predictor of CAD than fasting triglycerides (83,84). In support of this hypothesis is the observation that remnant lipoproteins are associated with impaired endothelial function (85).

Postprandial lipemia consists of a heterogeneous group of triglyceride-rich particles of different composition and origin. By definition, a remnant is an apolipoprotein B (apoB)–containing lipoprotein that has delivered some of its original triglyceride content to tissues by means of LPL-mediated lipolysis (82). After fat intake, the intestine secretes chylomicrons whose triglycerides are lipolyzed by LPL. The liver secretes triglyceride-rich VLDL particles that are also lipolyzed by LPL, forming VLDL remnant particles. This VLDL delipidation is reduced postprandially because of competition with chylomicrons for LPL-mediated lipolysis, and VLDL plasma residence is, therefore, prolonged. Consequently, although 80% of the increase in postprandial triglyceride levels is accounted for by chylomicrons (which carry a large number of triglyceride molecules), the number of endogenous (liver-derived) VLDL constitutes over 90% of the triglyceride-rich particles in the postprandial state (82). Delayed VLDL clearance results in the accumulation of partially catabolized VLDL remnants that are reduced in size and enriched in cholesteryl ester. A considerable body of evidence indicates that these small, cholesteryl ester–enriched VLDL particles are atherogenic.

Because type 2 diabetes is characterized by increased VLDL production and impaired removal, it is not surprising that patients with type 2 diabetes exhibit excessive postprandial lipemia and impaired remnant clearance (82,86). The increase in postprandial triglyceride concentrations strongly correlates with insulin resistance (87).

An inverse relation exists between lipoprotein particle size and their capacity of lipoproteins to enter the arterial wall. Accordingly, small VLDL (S_f 20–60) and intermediate-density lipoprotein (S_f 12–20) seem to share a similar mechanism and potential for penetrating the arterial intima. It is probable that the relative cholesteryl ester enrichment also contributes to their atherogenic potential. In the apoE knockout mouse the accumulation of triglyceride-rich lipoproteins that contain mainly cholesteryl ester and little triglyceride fatty streaks and complicated arterial lesions appear rapidly (88).

High-Density Lipoprotein Metabolism in Diabetes

As in nondiabetic subjects, low HDL levels are powerful indicators of CHD in diabetic patients (50,78). Decreased HDL levels in diabetes result from decreased production and increased catabolism of HDL and are closely related to the abnormal metabolism of triglyceride-rich lipoproteins (71,72) (Fig. 7.4).

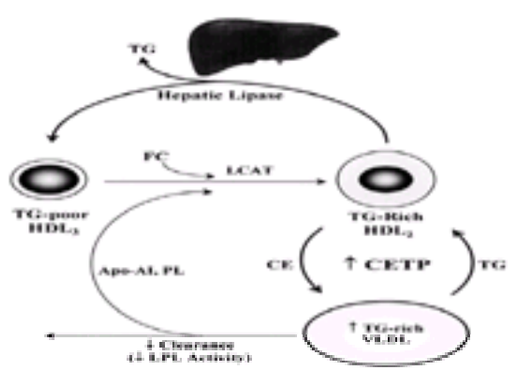

FIGURE 7.4 Mechanism of decreased high-density lipoprotein (HDL) in diabetes. The rate of HDL_2 formation is dependent on the rate of flux of surface components from lipolysis of triglyceride (TG)-rich lipoproteins. Inefficient low-density lipoprotein–mediated TG-rich lipoprotein catabolism reduces the rate of HDL_2 formation. Excess of TG-rich lipoproteins enhances cholesteryl ester transfer protein (CETP), resulting in the formation of HDL_2, which is a TG-rich particle that efficiently interacts with hepatic lipase. The result is the predominance of the small and dense HDL_3 in diabetic patients. A similar mechanism governs the predominance of small, dense species of low-density lipoprotein. Apo-AI, apolipoprotein AI; CE, cholesteryl ester; FC, free cholesterol; LCAT, lecithin-cholesterol acyltransferase; LPL, lipoprotein lipase.

During lipolysis of chylomicrons and VLDL, surface components (free cholesterol, redundant phospholipids, and apolipoproteins) are transferred into the HDL fraction. These components may enter nascent discoid HDL particles secreted by the liver. The free cholesterol is esterified by lecithin-cholesterol acyltransferase to generate mature spherical HDL. Alternatively, these surface components may be incorporated into preexisting HDL particles (see Chapter 3). The latter process results in an increase in size and decrease in density of HDL particles, leading to the conversion of preexisting HDL_3 (triglyceride depleted) to HDL_2.

Decreased HDL synthesis is related to the decreased LPL activity. Both genetic and acquired LPL (89) deficiencies are associated with low HDL because the rate of HDL_2 formation is dependent on the rate of flux of surface components from lipolysis of triglyceride-rich lipoprotein (Fig. 7.4). When LPL-mediated VLDL catabolism is inefficient, less surface material is transferred to HDL, impairing HDL formation.

Increased catabolism of HDL in diabetes can occur because increased secretion of VLDL into plasma promotes the transfer of triglycerides from these lipoproteins to HDL in exchange for cholesteryl ester. This exchange occurs in plasma and is facilitated by cholesteryl ester transfer protein, generating a triglyceride-enriched (and cholesteryl ester–depleted) HDL_2. This particle is highly susceptible to catabolism by hepatic triglyceride lipase (HTGL), an enzyme found primarily on endothelial cells of hepatic sinusoids (72,90). Hepatic triglyceride lipase has both triglyceride hydrolase and phospholipase activity and generates smaller HDL_3 particles that are depleted in triglycerides and phospholipids (Fig. 7.4).

Low-Density Lipoprotein Metabolism in Diabetes

As discussed, patients with types 1 and 2 diabetes in reasonable metabolic control have normal LDL cholesterol levels. However, although the absolute number of LDL particles is normal, alterations in LDL clearance and susceptibility to oxidative modification result in an increase in LDL atherogenic potential.

Low-Density Lipoprotein Composition and Insulin Resistance

In insulin-resistant patients with or without overt type 2 diabetes, the composition of LDL particles is altered, resulting in a preponderance of small, triglyceride-enriched and cholesterol-depleted particles (phenotype B). A preponderance of small, dense LDL particles is related to many characteristics of the insulin-resistance syndrome.

In nondiabetic subjects, LDL subclass phenotype B is associated with other components of the insulin-resistance syndrome, including central obesity, hypertension, glucose intolerance, and hyperinsulinemia (91,92 and 93).

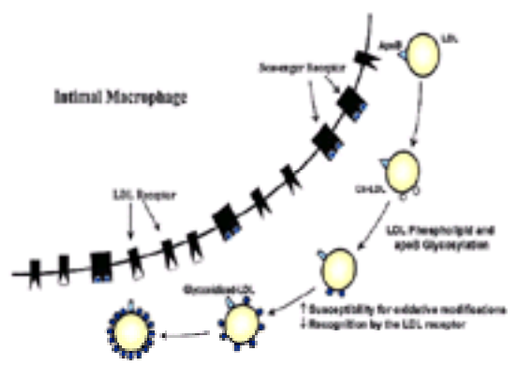
The formation of small, dense LDL in diabetes occurs in a similar fashion to the increased formation of small and dense HDL_3, as described previously. Cholesteryl ester transfer protein mediates the exchange of triglyceride from VLDL for cholesteryl ester in LDL. If sufficient LDL cholesteryl ester is replaced by triglyceride from VLDL, then when the particle comes into contact with hepatic lipase hydrolysis of newly acquired triglyceride in LDL and HDL by HTGL in turn decreases the size of LDL particles (94). The symmetry of the mechanisms for the formation of small, dense species of LDL and HDL (Fig. 7.4) helps to explain why low HDL levels and a preponderance of small dense LDL are both components of the insulin-resistance syndrome and why HDL cholesterol level is strongly correlated with LDL size (94).

Small, dense LDL has been associated with CAD risk independently of the absolute concentrations of LDL cholesterol or other CAD risk factors (50). Small, dense LDL particles are more susceptible to oxidative modification (95) and are particularly prone to induce endothelial dysfunction (96). In addition, there is enhanced arterial wall penetration by the small LDL particles (97).

Low-Density Lipoprotein Glycosylation

The glycosylation process (see Role of Advanced Glycosylation End Products in Diabetic Atherosclerosis) occurs both on the apoB (98) and phospholipid (99) components of LDL, resulting in profound functional alternations in LDL clearance and susceptibility to oxidative modification.

Clinical studies have shown an increased level of AGEs on LDL obtained from diabetics compared with healthy individuals (99,100). Glycosylation of LDL apoB occurs mainly on a positively charged lysine residue within the putative LDL receptor binding domain, which is essential for the recognition of LDL by the LDL receptor (100). LDL glycosylation increases with glucose levels and impairs LDL receptor–mediated LDL clearance (eFig. 7.4.1).



***e*FIGURE 7.4.1** Potential mechanisms by which low-density lipoprotein (LDL) glycosylation increases its atherogenicity. Advanced glycosylation of the phospholipid component of LDL is accompanied by the progressive oxidative modification of unsaturated fatty acid residues. Glycosylation of LDL apolipoprotein B (apoB) reduces its recognition by the LDL receptor.

Another atherogenic effect of glycation is to increase LDL susceptibility to oxidative modification. Advanced glycosylation of an amine-containing phospholipid component of LDL is accompanied by progressive oxidative modification of unsaturated fatty acid residues (99). Thus, glycation confers increased susceptibility of LDL to oxidative modification (101,102), which is considered a critical step in its atherogenicity.

Clinical Trials of Lipid Lowering in Diabetic Patients

In general, these trials suggest that aggressive lipid reduction has greater incremental benefit in diabetic than nondiabetic patients (eTable 7.2.1). However, with the exception of the Scandinavian Simvastatin Survival Study (4S), the number of diabetic subjects in these trials was too small to demonstrate statistical significance for this observation, and higher event rates were evident in diabetic patients even with lipid-lowering therapy.

***e*TABLE 7.2.1** SECONDARY PREVENTION TRIALS OF LIPID LOWERING IN DIABETIC PATIENTS

			Patients (n)		Risk reduction (%)	
Study	**End points**	**Follow-up (years)**	**No diabetes**	**Diabetes**	**No diabetes**	**Diabetes**
Scandinavian Simvastatin Survival Study (103,403)	Nonfatal MI/CAD death/total mortality/revascularization	5.4	4,242	202	29	43
Cholesterol and Recurrent Events trial (104)	Nonfatal MI/CAD death	5.0	3,573	586	23	25
Post–coronary artery bypass graft (353)	Composite cardiovascular events	4.3	1,235	116	13	43
Long-Term Intervention with Pravastatin in Ischaemic Disease Study Group (404)	CAD death	6.1	4,116	386	19	25
AFCAPS/TexCAPS (410)	Nonfatal MI/unstable angina/CAD death	5.2	6,440	155	26	43
Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial Study Group (112)	Nonfatal MI/CAD death, stroke	5.1	1,904	627	24	24
Helsinki Heart Study (111)	Nonfatal MI/CAD death	5.0	3,946	135	30	68

CAD, coronary artery disease; MI, myocardial infarction.

The 4S was the first to demonstrate the effectiveness of cholesterol-lowering therapy for secondary prevention of death and morbidity in diabetic patients. The risk reduction for CHD and overall mortality in diabetic subjects was 55% and 43%, respectively, compared with diabetic patients in the placebo group (103). Subjects in 4S had relatively high LDL cholesterol levels at baseline (approximately 185 mg per dL). However, the majority of patients with coronary disease (including diabetics) has lower LDL cholesterol levels. The Cholesterol and Current Events study examined the effect of cholesterol-lowering therapy in patients with coronary disease with average cholesterol levels (mean, 139 mg per dL). In 586 diabetic subjects with CAD, the mean baseline lipid concentrations (136 mg per dL LDL cholesterol, 38 mg per dL HDL cholesterol, and 164 mg per dL triglycerides) were similar to those in the nondiabetic group. The magnitude of LDL cholesterol reduction by pravastatin was also similar (27% and 28%) in the diabetic and nondiabetic groups. Pravastatin treatment reduced the absolute risk of coronary events for the diabetic and nondiabetic patients by 8.1% and 5.2% and the relative risk by 25% (p = .05) and 23% (p <.001), respectively (104).

These results demonstrate that cholesterol lowering improves the prognosis of diabetic patients with CAD. The absolute clinical benefit achieved by cholesterol lowering may be greater in diabetic than in nondiabetic patients with CAD, because diabetic patients have a higher absolute risk of recurrent CAD and higher case fatality rates (105) or because LDL cholesterol in diabetic patients is more atherogenic (91,92,99,101).

Management of Dyslipidemia in Diabetic Patients

The American Diabetes Association recommendations for the management of hyperlipidemia in patients with diabetes generally follow the guidelines of the National Cholesterol Education Program (see Chapter 3) with several differences (106).

Nonpharmacologic strategies to treat dyslipidemia in diabetics include dietary modification (similar to those recommended by the National Cholesterol Education Program), weight loss, physical exercise, and improved glycemic control (106). In patients with type 1 diabetes, optimal glycemic control should result in normal or below normal lipoprotein levels (68) and prevent the atherogenic state associated with lipoprotein glycosylation. Improved diabetic control in type 2 diabetes is beneficial but not always associated with reversal of lipoprotein abnormalities (Table 7.3). Improved glycemic control using sulfonylurea, insulin (21), metformin (107), or thiazolidinediones (e.g., pioglitazone, rosiglitazone) (108) therapy often causes a substantial reduction (20% to 50%) in VLDL triglyceride levels. The magnitude of improvement in triglycerides generally correlates with the change in glucose levels rather than the mode of therapy. However, agents that improve insulin sensitivity such as metformin (107) and thiazolidinediones (108) lead to greater lowering of triglyceride compared with sulfonylurea. The effect of improved glycemic control on HDL is more variable and often results in only a small increase (3 to 4 mg per dL) in HDL levels (21).

Drug	Therapeutic effect: Triglyceride level	Chl level	Chl size	HDL level	Main indication	Special considerations
Nicotinic acid	[illegible]	[illegible]	↑	[illegible]	Generally not indicated	Adverse effect on glycemic control May be used in refractory dyslipidemias No adverse effect on glucose metabolism Increased risk for cholesterol gallstones
Fibric acid derivatives*	[illegible]	↓ or ↑	↑	[illegible]	Probably the drugs of choice for the treatment of hypertriglyceridemia	
3-Hydroxy-3-methyl-glutaryl-coenzyme A reductase inhibitors	[illegible]	[illegible]	↑ or ↓	[illegible]	Drugs of choice for the treatment of hypercholesterolemia	
Bile acid resins	↑–↑↑	[illegible]	↓	↓	Mixed dyslipidemia, in combination with fibric acid derivatives	Extreme elevations in triglyceride level occur mainly in patients who already had marked hypertriglyceridemia The only drug therapy recommended for children and adolescents Impaired absorption of several drugs, including glycosides

↑, increased ↑↑, markedly increased ↓, decreased →, no change.
*Fibrates using 500 mg twice (see dosing regimen).
†Greatest reductions in patients with higher baseline levels.
‡Depending on initial triglyceride concentration (see text).
§Generally in relation to the magnitude of reduction in plasma triglyceride and very low-density lipoprotein levels.

TABLE 7.3 ANTIHYPERLIPIDEMIC DRUG THERAPY IN DIABETIC PATIENTS

Despite less than optimal response in lipids, optimal control of plasma glucose levels should be attempted before lipid-lowering agents are added to the therapeutic regimen. However, the physician should not wait too long to initiate concomitant drug therapy, because the significantly increased risk of macrovascular disease in type 2 diabetes has probably been present for many years before overt diabetes (70). In addition, “perfect” glycemic control is not attained in many type 2 diabetic patients. If 3 to 6 months of nonpharmacologic therapy fails to improve lipid level, drug therapy is warranted.

Relatively recent publications have argued against the relevance of the traditional classification to primary and secondary CHD prevention in the setting of diabetes (21,36). The rationale for this approach stems from both the high event rates in diabetic patients without clinical evidence of CAD (presumably because of the high rates of subclinical atherosclerosis) (21), as well as the worse prognosis in diabetic patients who have had a clinical event compared with nondiabetic subjects (105). These considerations led to the suggestion that LDL cholesterol should be lowered to less than 100 mg per dL in diabetic subjects without prior CAD (21,36).

Drug Therapy

Antihyperlipidemic drug therapy in diabetic patients is similar to that in nondiabetic subjects (see Chapter 3) with several specific considerations (Table 7.3). 3-Hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase inhibitors are highly effective in lowering cholesterol levels in type 2 diabetic patients in whom the principal finding is elevated LDL cholesterol level. They do not adversely affect glycemic control (21,109).

The fibric acid derivatives are effective in the treatment of hypertriglyceridemia in diabetic patients (110) (Table 7.3). These agents decrease VLDL levels, increase HDL, and can increase LDL particle size in hypertriglyceridemic patients with small, dense LDL particles (110). In the Helsinki Heart Study, gemfibrozil reduced the incidence of cardiovascular events in patients with type 2 diabetes (111). The Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial randomized 2,531 patients with CHD (25% of whom had diabetes) with low HDL cholesterol to gemfibrozil or placebo (112). Treatment with gemfibrozil over 5 years increased HDL 6% and reduced 22% of major coronary artery events, without lowering LDL cholesterol.

Fibric acid derivatives do not adversely affect glucose metabolism. In patients with normal triglyceride levels, these drugs lower LDL cholesterol by 5% to 15%. However, in hypertriglyceridemic patients, the decrease in triglyceride levels is frequently accompanied by an increase in LDL cholesterol levels (110). This increase probably reflects the elimination of small, dense LDL particles characteristic of the hypertriglyceridemic patients, resulting in less atherogenic LDL cholesterol (113).

Cholestyramine is efficacious in decreasing LDL cholesterol levels in diabetic patients (114). However, bile acid resins can increase VLDL triglycerides significantly, particularly if they are already elevated above 250 to 300 mg per dL or in patients with poorly controlled diabetes.

Nicotinic acid is the most effective drug in raising HDL levels in patients with hypertriglyceridemia and can increase particle size in patients with small, dense LDL particles (115). The use of nicotinic acid has been discouraged in patients with diabetes because of possible deterioration in glycemic control (21,116) secondary to the induction of insulin resistance. In one study of patients with type 2 diabetes, a niacin dose of 4.5 g per day reduced plasma cholesterol levels by 24% and triglyceride levels by 45% and raised HDL cholesterol by 34%. However, the glycosylated hemoglobin level increased by 21% (116). In another study, niacin at a lower dose (3 g per day) produced a 8% reduction in LDL, a 23% reduction in triglycerides, and a 29% increase in HDL level, whereas HbA_{1c} increased by only 0.3% (117).

Niacin therapy may be considered as an alternative to statin drugs or fibrates in patients with diabetes in whom these agents are not tolerated, or in whom they fail to sufficiently correct hypertriglyceridemia or low HDL (117). Glycemic status should be carefully monitored during niacin therapy and the dose modified or discontinued if glycemic control deteriorates.

VASCULAR ENDOTHELIAL DYSFUNCTION IN DIABETES

Endothelial cells situated at the vessel wall–blood interface participate in a number of important homeostatic and cellular functions that protect from atherosclerosis and intraluminal thrombosis (eTable 7.3.1). Endothelial dysfunction can promote both the formation of atherosclerotic plaques and the occurrence of acute events. Endothelial *injury*, which results in endothelial *dysfunction*, has a critical role in the pathogenesis of atherosclerosis.

***e*TABLE 7.3.1** DIABETES-INDUCED ALTERATIONS IN ENDOTHELIAL CELL FUNCTIONAL PROPERTIES

Endothelial function	Effectors	Diabetes-induced perturbations	Atherosclerosis/events promoting effects
Selective permeability barrier	Continuous endothelium with tight junctions in the lateral borders	Increased permeability; delayed regeneration (118,119,121,122)	Allow low-density lipoprotein or bloodborne mitogens to reach the subendothelial space
Provides a nonthrombogenic surface	EDRF, PGI_2 tissue-type plasminogen activator, heparan sulfate, thrombomodulin	Reduced antithrombotic and fibrinolytic phenotype (decreased EDRF, decreased PGI_2, increased plasminogen activator inhibitor-1, increased tissue factor) (409)	Promote thrombosis and inhibit fibrinolysis
Provides a nonadherent surface for circulating leukocytes	EDRF	Induction of adhesion molecules (e.g., vascular cell adhesion molecule-1, E-selectin) (122,123,124 and 125)	Recruit macrophages into the vascular wall
Regulation of vascular tone	EDRF, PGI_2, endothelin-1	Reduced vasodilator function (decreased EDRF, decreased PGI_2, increased endothelin-1) (128,131); increased advanced glycosylation end products quench nitric oxide (406)	Failure of vasodilation
Secrete growth inhibitors	EDRF, heparan sulfate	Inactivation of EDRF (406); reduced EDRF production (138)	Reduced antiproliferative activity of EDRF on vascular smooth muscle cells

EDRF, endothelium-derived relaxing factor; PGI_2, prostacyclin.

Endothelial dysfunction in diabetes entails profound perturbations in several critical functions of the endothelium (eTable 7.3.1, Fig. 7.5) that contribute to the initiation and progression of the atherosclerotic process, as well as to the occurrence of clinical events.

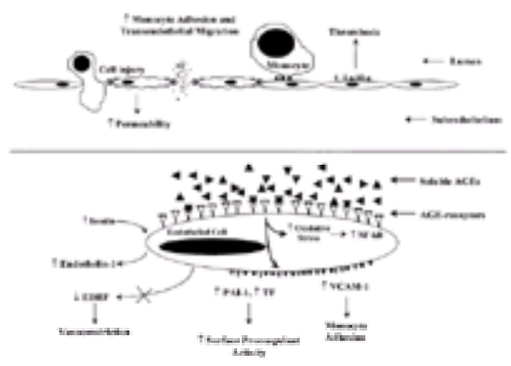


FIGURE 7.5 Generation of a dysfunctional endothelium in diabetes. See text for details. AGE, advanced glycosylation end product; EDRF, endothelium-derived relaxing factor; PAI-1, plasminogen activator inhibitor-1; TF, tissue factor; VCAM-1, vascular cell adhesion molecule-1.

Endothelial Permeability

The endothelial lining of the large arteries is of the continuous type characterized by tight junctions in the lateral borders, which restrict the movement of macromolecules from reaching the subendothelial space. Human vascular endothelial cells cultured in glucose concentrations comparable with those of uncontrolled diabetes exhibit delay in reaching confluence and in the rate of replication (118). Endothelial cell regeneration following deendothelialization (e.g., after balloon angioplasty) is slower (119). Endothelial cells in diabetic animals also exhibit morphologic abnormalities that include the presence of craters resulting from weakened intercellular junctions (120). Furthermore, AGEs, with their specific receptor, diminish endothelial barrier function (121,122). These abnormalities may explain the increased vascular permeability and transendothelial macromolecular transport (118).

Leukocyte Adhesion to the Vascular Endothelium

Among the earliest events in atherogenesis is the binding of mononuclear leukocytes to the endothelium with subsequent entry into the vessel wall. This is mediated through the expression of inducible adhesion molecules on the endothelial cell surface. Hyperglycemia stimulates the expression of vascular cell adhesion molecule-1 and E selectin (123). In addition, AGE interaction with the AGE receptor (see Advanced Glycosylation End Products) results in the induction of oxidative stress and, consequently, of the transcription factor NF-kB (124,125) and vascular cell adhesion molecule-1 (122). Thus, early events in the atherosclerosis process in diabetes may be mediated through enhanced adhesive interactions of monocytes with the endothelial surface. Indeed, monocyte binding to human aortic endothelial cells is increased by chronic incubation in high glucose (126). In addition, diabetic normolipidemic rabbits exhibit progressive adherence of mononuclear leukocytes to aortic endothelium and recruitment to the subendothelial space (127).

Impaired Endothelium-Dependent Vasodilation

Impairment of endothelium-dependent vasodilation in human coronary arteries has been demonstrated both in atherosclerotic segments of coronary arteries and in patients with risk factors for atherosclerosis and angiographically normal coronary arteries.

Impaired endothelium-dependent relaxation, which is mediated through the release of endothelium-derived relaxing factor (EDRF), is a consistent finding in animal models and in human diabetes (128,129) and occurs in a variety of vascular beds, including the coronary arteries (129). Impaired endothelium-dependent relaxation has been demonstrated in both type 1 and type 2 diabetes in the absence of clinical complications (129), while endothelium-independent vasodilation is preserved (128,129). Furthermore, impaired endothelium-dependent relaxation can be demonstrated in the insulin-resistant subject with normal glucose tolerance.

An attenuated effect of EDRF can render blood vessels vulnerable to spasm. However, the loss of EDRF has a much more profound effect on the arterial wall. EDRF is protective against the development of vascular disease because it inhibits platelet aggregation and adhesion, circulating monocyte adhesion to endothelial cells, and vascular smooth muscle proliferation (*e*Table 7.3.1).

Hyperglycemia Induces Endothelial Dysfunction

Hyperglycemia is recognized as the primary mediator of diabetic endothelial dysfunction. Impaired endothelium-dependent relaxation can be induced by short exposure (several hours) to high glucose concentrations, implying a hyperglycemia-dependent metabolic defect rather than irreversible damage to endothelial cells (130).

Similar to the mechanism of endothelial dysfunction observed in hypercholesterolemia, hyperglycemia-induced endothelial dysfunction is thought to result primarily from increased generation of oxygen free radicals that inactivate EDRF (131). Experimental and clinical data suggest that scavengers of oxygen radicals (132) and antioxidants such as vitamin E and vitamin C (131) improve endothelium-dependent relaxation in diabetic arteries. Angiotensin-converting enzyme (ACE) inhibition has also been reported to improve endothelium-dependent vasodilation in diabetic patients (133), probably through the reduction of oxidative stress.

Insulin-Resistant Subjects Exhibit Impaired Endothelium-Dependent Vasodilation

Insulin is a physiologic vasodilator of skeletal muscle vasculature in humans, and its vasodilatory effect is blunted in insulin-resistant subjects. The vasodilating effect of insulin is EDRF-mediated (134,135), and several studies have shown that in insulin-resistant *normoglycemic* subjects, vasodilatory responses to the endothelium-dependent vasodilator methacholine are also impaired (136,137) and the ability of insulin to enhance endothelium-dependent vasodilation is reduced (136). Thus, insulin resistance also contributes to endothelial dysfunction in diabetic patients.

The mechanism by which insulin resistance impairs endothelium-dependent vasodilation is not well understood. A positive correlation has been reported between endothelial nitric oxide production and insulin sensitivity in healthy subjects (138). Elevated circulating free fatty acids (139) and oxidized small, dense LDL (92) may mediate, in part, endothelial dysfunction in insulin-resistant subjects.

Endothelin

By maintaining a critical balance between relaxing and contracting factors, the endothelium regulates both vascular tone and growth. Endothelin-1, a potent cardiovascular peptide, mediates vasoconstriction, sodium retention, and mitogenesis. Key metabolic variables that are changed in diabetes, such as insulin and glucose, directly regulate the release of endothelin-1 from endothelial cells (140).

Insulin increases endothelin-1 gene expression in endothelial cells (141) and physiologic concentrations of insulin enhance the secretion of endothelin-1 from endothelial cells. Plasma endothelin concentrations are significantly increased in hyperinsulinemic patients with type 2 diabetes (142). Hyperglycemia has also been reported to enhance the production of endothelin-1 in endothelial cells (143) through a protein kinase C (PKC)–dependent mechanism.

DIABETES AS A PROTHROMBOTIC STATE

The coagulation and fibrinolytic systems are especially important in atherosclerosis because of the substantial contribution that mural thrombosis may make to the later stages of plaque progression, and because thrombotic occlusion plays a vital role in the development of clinical events. In the vast majority of cases, the fundamental mechanism in the development of potentially life-threatening events such as unstable angina or myocardial infarction is thrombosis arising at sites of plaque disruption. Not all disruptions of atherosclerotic plaques result in clinically apparent or symptomatic events. Thus, both local and systemic thrombogenic risk factors at the time of plaque disruption may determine the degree of thrombus formation; hence, the clinical outcome. Indeed, several hemostatic variables are powerful predictors of acute events in patients with established CAD (144,145 and 146).

Diabetes is characterized by a variety of individual alterations in the coagulation and fibrinolytic systems that combine to produce a prothrombotic state. These

alterations include increased platelet functional behavior, increased levels of several coagulation components, and impaired fibrinolysis (eTable 7.3.2).

***e*TABLE 7.3.2** COAGULATION AND FIBRINOLYTIC ABNORMALITIES OF PROGNOSTIC SIGNIFICANCE IN DIABETES

Factor	Prognostic significance	Diabetes effect
Platelet hyperactivity	Spontaneous platelet aggregation *in vitro* predicts coronary events and mortality in patients surviving myocardial infarction (146)	Platelet hyperaggregability in response to agonists (147) and increased fractions of circulating activated platelets (151)
von Willebrand factor	Increased concentrations of endothelium-derived von Willebrand factor reflect endothelial perturbation (23,144) and are associated with subsequent myocardial infarction (144)	Elevated von Willebrand factor levels, especially in the presence of vascular complications and endothelial dysfunction (23) or insulin resistance. Confers a high risk for cardiovascular events
Fibrinogen	High fibrinogen levels associated with increased risk for reinfarction and death (144,145)	Increased in diabetic patients (155)
Factor VII	High levels of factor VII coagulant activity are associated with increased risk for coronary events	Elevated and correlates with glycemic control and microalbuminuria
PAI-1	Reduced fibrinolytic capacity because of increased plasma PAI-1 levels predisposes to myocardial infarction in postinfarction patients or patients with angina (144,157)	Elevated PAI-1 levels occur mainly in the presence of insulin resistance (158,159,161)
Tissue factor	Expressed in coronary atherosclerotic plaques and may account for the magnitude of the thrombotic response to rupture of coronary atherosclerotic plaques	Advanced glycosylation end products and receptor for advanced glycosylation end products interaction induces cell surface expression of tissue factor (409)

PAI-1, plasminogen activator inhibitor-1.

Platelet Aggregation

Platelet hyperaggregability, including the presence of spontaneous platelet aggregation (144) and increased platelet aggregability induced by conventional stimuli (145), increases the risk for cardiovascular events.

Platelets from diabetic subjects exhibit enhanced adhesiveness and hyperaggregability in response to both strong [e.g., thrombin, thromboxane A_2 (TxA_2)] and weak (e.g., adenosine diphosphate, epinephrine, collagen) agonists (147,148). Shear-induced platelet adhesion and aggregation are increased in diabetic patients (149). Platelet hypersensitivity is more evident in diabetic patients with vascular complications. However, it is also observed in newly diagnosed diabetic patients, suggesting that altered platelet function may be a consequence of metabolic changes secondary to the diabetic state (147,150). Elevated fractions of $CD62^+/CD63^+$ (activated) platelets circulate in diabetic patients in the absence of clinically detectable vascular lesions (148,151). Enhanced activity of the arachidonic acid pathway with increased TxA_2 formation occurs in diabetic individuals (152). There is a significant correlation between TxA_2 production and fasting plasma glucose or HbA_{1c}, and TxA_2 production can be restored by strict glycemic control with continuous subcutaneous insulin infusion.

Alterations in Coagulation Factors

von Willebrand Factor

von Willebrand factor (vWF) is probably the most important among adhesive molecules mediating hemostatic interactions between platelets and vessel wall components. vWF is involved in the initial adhesion of platelets to the subendothelium of injured vessel wall and supports the progression of platelet-fibrin microthrombi to an occlusive thrombosis (153). High vWF levels are associated with subsequent myocardial infarction in patients with overt CAD (144,153).

vWF is synthesized and secreted by endothelial cells, and high circulating levels of vWF are considered markers of endothelial dysfunction. In diabetic patients plasma concentrations of vWF are elevated and are closely associated with the presence of vascular complications and endothelial dysfunction (23). Epidemiologic data have demonstrated a relation between plasma vWF and the insulin-resistance syndrome (154).

Fibrinogen

A large body of evidence indicates strong independent direct correlation between high fibrinogen plasma levels and an increased risk of CAD. Fibrinogen levels are often increased in diabetes, and this elevation is associated with poor glycemic control (155). Fibrinogen levels may decrease with intensive insulin therapy (156).

Altered Fibrinolysis in Diabetes

The intensity of endogenous fibrinolysis depends on a dynamic equilibrium involving plasminogen activators, primarily tissue-type plasminogen activator, and inhibitors. The principal physiologic inhibitor of tissue-type plasminogen activator is plasminogen activator inhibitor-1 (PAI-1). Attenuated fibrinolysis caused by an increase of PAI-1 activity has been associated with increased risk for myocardial infarction in patients with established CAD (144,157).

Reduced plasma fibrinolytic activity caused by increased PAI-1 levels is a characteristic feature of insulin resistance and hyperinsulinemia. Elevated concentrations of PAI-1 have been recognized consistently in the plasma of hyperinsulinemic type 2 diabetics (158) but occur also in normoglycemic insulin-resistant subjects (157,158). Increased plasma PAI-1 strongly correlates with parameters that define the insulin-resistance syndrome—in particular, body mass index and visceral accumulation of body fat, rather than with diabetes *per se* (158,159). Furthermore, interventions that lower insulin resistance, such as weight loss, are invariably accompanied by a reduction in plasma PAI-1 concentrations (160).

The mechanisms for the increased expression of PAI-1 in type 2 diabetes are complex. Insulin and especially proinsulin, a precursor of insulin, augment PAI-1 gene expression in hepatocytes resulting in an increased PAI-1 synthesis by the liver, which is the primary source of PAI-1 in plasma (161). Proinsulin levels are elevated in insulin-resistant subjects because of stimulation of pancreatic beta cells and in part because of the impaired processing of proinsulin to insulin that is typical of the condition. Exogenous insulin administration is accompanied by a decline in plasma PAI-1 levels, as stimulation of the pancreatic beta cells by hyperglycemia decreases. The production of PAI-1 by adipose tissue has been demonstrated and could be an important contributor to the elevated plasma PAI-1 levels observed in insulin-resistant patients (159). Hyperglycemia can also increase PAI-1 levels because it stimulates transcription of the PAI-1 gene through an effect on its promoter region (162).

Clinical Correlates of Hypercoagulability in Diabetic Patients

Although it remains possible that some of the hemostatic abnormalities in diabetes are partly markers of underlying vascular disease rather than the primary abnormalities, the clotting and fibrinolytic profile of diabetic patients bears a striking similarity to that of patients at high risk for future cardiovascular events (eTable 7.3.2).

The prothrombotic state in diabetes explains the observation that intracoronary thrombus formation is more frequently found by angioscopic examination in diabetic patients with unstable angina (13), and its clinical correlate, the higher risk of adverse outcome, namely death, nonfatal infarction (105), or recurrent unstable angina (163,164). In addition, high PAI-1 levels have been implicated in causing resistance to thrombolytic therapy (165).

HYPERGLYCEMIA AS AN ATHEROGENIC FACTOR

Hyperglycemia induces a large number of alterations in vascular tissue that potentially promote accelerated atherosclerosis. Currently, three major mechanisms have emerged that encompass most of the pathologic alterations observed in the vasculature of diabetic animals and humans: (a) nonenzymatic glycosylation of proteins and lipids; (b) oxidative stress; and (c) PKC activation. Importantly, these mechanisms are not independent. For example, hyperglycemia-induced oxidative stress promotes the formation of AGEs and PKC activation (166).

Role of Advanced Glycosylation End Products in Diabetic Atherosclerosis

One of the important mechanisms responsible for the accelerated atherosclerosis in diabetes is the nonenzymatic reaction between glucose and proteins or lipoproteins in arterial walls, collectively known as *Maillard's* or *browning reaction* (167). Glucose forms chemically reversible early glycosylation products with reactive amino groups of circulating or vessel wall proteins (Schiff's bases), which subsequently rearrange to form the more stable Amadori-type early glycosylation products.

Equilibrium levels of Schiff-base and Amadori products (the best known of which is hemoglobin A_{1c}) are reached in hours and weeks, respectively (168) (Fig. 7.6). Some of the early glycosylation products on long-lived proteins (e.g., vessel wall collagen) continue to undergo complex series of chemical rearrangements to form AGEs (168). Once formed, AGE-protein adducts are stable and virtually irreversible. Although AGEs comprise a large number of chemical structures, carboxymethyl-lysine-protein adducts are the predominant AGEs present *in vivo* (169).

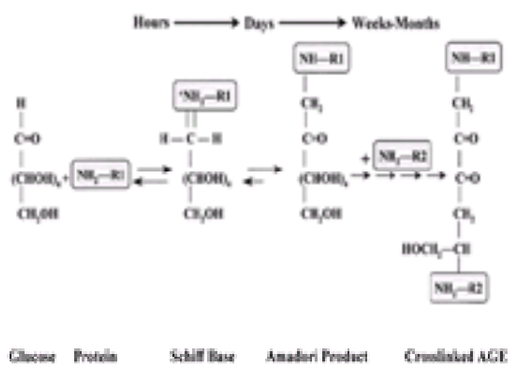

FIGURE 7.6 The formation of advanced glycosylation end product (AGE).

AGEs accumulate continuously on long-lived vessel wall proteins with aging and at an accelerated rate in diabetes (168). The degree of nonenzymatic glycation is determined mainly by the glucose concentration and time of exposure (168). However, another critical factor to the formation of AGEs is the tissue microenvironment redox potential. Thus, AGEs formation increases substantially in situations in which the local redox potential has been shifted to favor oxidant stress (166,170,171,172,173 and 174).

AGEs can accelerate the atherosclerotic process by diverse mechanisms that can be classified as non–receptor dependent (Table 7.4) and receptor mediated (Table 7.5).

Extracellular matrix
Collagen cross-linking (176)
Enhanced synthesis of extracellular matrix components (168)
Trapping of LDL in the subendothelium (405)
Glycosylated subendothelial matrix quenches nitric oxide (406)
Functional alterations of regulatory proteins
Basic fibroblast growth factor glycosylation reduces its heparin binding capacity and its mitogenic activity on endothelial cells (407)
Inactivation of the complement regulatory protein CD59 (175)
Lipoprotein modifications
Glycosylated LDL (99,100)
Reduced LDL recognition by cellular LDL receptors (98)
Increased susceptibility of LDL to oxidative modification (99)

LDL, low-density lipoprotein.

TABLE 7.4 ATHEROSCLEROSIS PROMOTING EFFECTS OF ADVANCED GLYCOSYLATION END PRODUCTS: NON–RECEPTOR-MEDIATED MECHANISMS

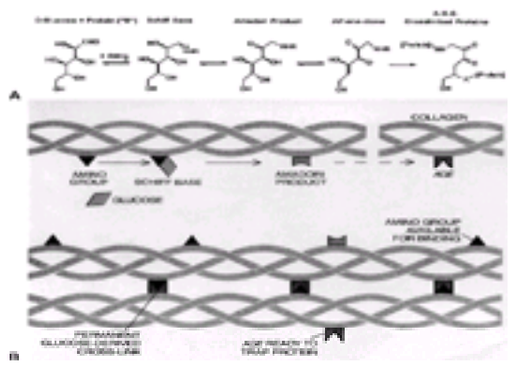
Promoting inflammation
Secretion of cytokines such as tumor necrosis factor-α, interleukin-1 (176)
Chemotactic stimulus for monocyte-macrophages (178,408)
Induction of cellular proliferation
Stimulation of platelet-derived growth factor (408) and insulin-like growth factor I secretion from monocytes and possibly smooth muscle cells
Endothelial dysfunction
Increased permeability of endothelial cell monolayers (121,409)
Increased procoagulant activity (409)
Increased expression of adhesion molecules (122)
Increased intracellular oxidative stress (121,124)

TABLE 7.5 ATHEROSCLEROSIS PROMOTING EFFECTS OF ADVANCED GLYCOSYLATION END PRODUCTS: RECEPTOR-MEDIATED MECHANISMS

Non–Receptor-Mediated Mechanisms

Glycosylation-modified proteins and lipoproteins can interfere with their normal function (Table 7.4). Examples are the proatherogenic effect LDL glycosylation described previously (see Low-Density Lipoprotein Metabolism in Diabetes) and glycation of the complement regulatory protein. Deposition of the membrane attack complex of complement (MAC) in blood vessels stimulates proliferation of fibroblasts and smooth muscle cells, in part by releasing growth factors such as fibroblast growth factor and platelet-derived growth factor from MAC-targeted endothelium. MAC deposition is normally restricted because cells express the regulatory membrane protein CD59, which limits complement activation and MAC formation. Glycation of the complement regulatory protein CD59 results in its inactivation (175) and may increase the sensitivity of the diabetic endothelium to MAC-induced release of growth factors and cytokines.

Another important consequence of AGEs formation is the ability to cross-link adjacent proteins. For example, collagen can become cross-linked because AGEs form covalent heat-stable intermolecular bonds (176) (*e*Fig. 7.6.1). The amount of cross-linked collagen peptides formed increases as a function of both time and glucose concentration (176). In contrast to normal cross-links within normal collagen, which occur only at two discrete sites at the N-terminal and C-terminal ends of the molecule, AGEs form cross-links throughout the collagen molecule (168). Collagen cross-linking plays an important role in changing the mechanical properties of tissues, leading to the increased vascular rigidity and the reduced left ventricular compliance in diabetic patients (see Diabetic Cardiomyopathy).



***e*FIGURE 7.6.1** Schematic description of the formation of collagen cross-links **(B)**. Glucose attaches to an amino group (NH_2) of a protein (*top*), such as collagen, to form Schiff's base, which subsequently transforms itself into an Amadori product [see **(A)** for chemical structure]. The latter can pass through several incompletely understood steps (*broken arrows*) to become an advanced glycosylation end product (AGE). AGEs can react with free amino groups on adjacent protein to form

cross-links (*bottom*). Cross-linking can lead to decreased compliance of large vessels and of the myocardium (see text). (From Cerami A, Vlassara H, Brownlee M. Glucose and aging. *Sci Am* 1987;256:90–96, with permission.)

Glycosylation of matrix components such as collagen VI, laminin, and vitronectin decreased binding of anionic heparan sulfate, leading to greater turnover of heparan sulfate (168). The absence of heparan sulfate is thought to stimulate a compensatory overproduction of other matrix components through altered partitioning of growth regulatory factors between matrix-bound proteoglycans and cells (168). AGEs on matrix also alter the normal interactions of transmembrane integrin receptors with three specific matrix ligands. For example, modification of the cell-binding domains of type IV collagen causes decreased endothelial cell adhesion (168).

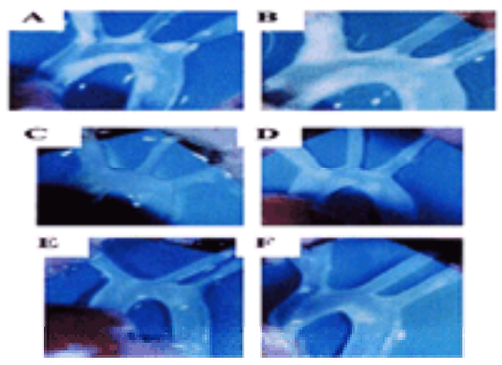
Receptor-Mediated Mechanisms

The cellular interactions of AGEs are mediated through a specific receptor for AGE determinants on cell surfaces (173). The presence of the AGE receptor (RAGE), a member of the immunoglobulin superfamily of receptors, has been demonstrated in all cells relevant to the atherosclerotic process including monocyte-derived macrophages, endothelial cells, and smooth muscle cells (173) (Table 7.5). In mature animals, RAGE expression on these cells is low (174). However, under certain pathologic circumstances, sustained upregulation of RAGE occurs. In pathologic lesions, abundance of RAGE-expressing cells is usually associated with sites of accumulated RAGE ligands. In diabetic vasculature, cells expressing high levels of RAGE are often proximal to areas in which AGEs are abundant (174).

The consequence of AGEs interaction with RAGE on endothelial cells has been previously discussed. Binding of soluble AGEs to RAGE induces monocyte chemotaxis (177), followed by mononuclear infiltration through an intact endothelial monolayer (178). Pathologic studies of human atherosclerotic plaques showed infiltration of RAGE-expressing cells in the expanded intima. Monocyte-macrophage interaction with AGEs results also in the production of mediators such as interleukin-1, tumor necrosis factor-a, platelet-derived growth factor, and insulin-like growth factor I (179,180).

In smooth muscle cells, binding of AGE-modified proteins to RAGE is associated with increased cellular proliferation. Although the precise mechanism of this response is unknown, the growth-promoting effects mediated by the RAGE are likely to be cytokine or growth-factor mediated. Thus, under conditions of enhanced tissue AGE deposition, receptor-mediated interaction of AGE proteins with vascular wall cells facilitates the migration of inflammatory cells into the lesion with the subsequent release of growth-promoting cytokines.

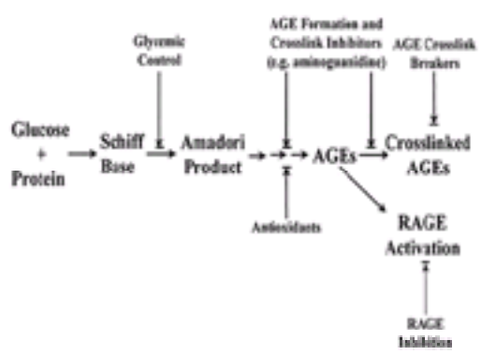
The potential role of RAGE in the atherogenic process in diabetes has been demonstrated by Park and associates (181). In the model of atherosclerosis-prone mice caused by homozygous deletion of apoE gene, the induction of diabetes using streptozotocin resulted in atherosclerosis of increased severity compared with euglycemic apoE controls. The development of vascular disease was more rapid with the formation of more complex lesions (fibrous caps, extensive monocyte infiltration, and so forth) and atherosclerosis extending distally in the aorta and major arteries (eFig. 7.6.2). Increased expression of RAGE and the presence of AGEs in the vessel wall, especially at sites of vascular lesions, were also evident. Blockade of AGE-RAGE interaction using a truncated soluble extracellular domain of RAGE resulted in a striking suppression of lesions in diabetic mice, with lesions largely arrested at the fatty streak stage and a large reduction in complex lesions (181).



***e*FIGURE 7.6.2** Effect of blockade of advanced glycosylation end product and advanced glycosylation end product receptor (RAGE) interaction using a truncated soluble extracellular domain of RAGE (sRAGE) on the development of atherosclerotic lesions in diabetic apolipoprotein E (apoE)-null mice. Diabetic mice without treatment **(A,B)**; diabetic mice treated with sRAGE at 20 µg per day **(C)** or 40 µg per day **(D)**; control euglycemic apoE-null mice without treatment **(E)** or sRAGE at 20 µg per day **(F)**. Also, note that diabetic apoE-null mice **(A,B)** develop atherosclerosis of increased severity compared with euglycemic controls **(E,F)**. (Modified from Park L, Raman KG, Lee KJ, et al. Suppression of accelerated diabetic atherosclerosis by the soluble receptor for advanced glycation endproducts. *Nat Med* 1998;4:1025–1031, with permission.)

Therapeutic Options

Normalization of blood glucose may decrease AGE formation and tissue accumulation. Aminoguanidine, an analog of the side chain of arginine and a small nucleophilic compound, is a potent inhibitor of AGEs formation and protein-to-protein and protein-to-lipid cross-linking (176,182). The terminal amino group of the compound reacts with glucose-derived reactive intermediates at the post-Amadori stage (Fig. 7.6 and eFig. 7.6.3). Aminoguanidine and other compounds such as pyridoxamine (183) have proved effective in animal models and clinical studies as inhibitors of AGE formation and the development of diabetic complications.



***e*FIGURE 7.6.3** Treatment strategies for blocking the formation of advanced glycosylation end products (AGEs), AGE cross-links, and the interaction of AGEs with AGE receptor (RAGE).

When tissue damage has already occurred, aminoguanidine-like compounds are not effective. In this setting, the development of cross-link “breakers” such as N-phenacylthiazolium bromide, which can cleave diketone bridges (184), may be a valuable therapeutic tool (eFig. 7.6.3). In diabetic animals, AGE breakers have been shown to reverse large artery stiffness (185) and increase left ventricular compliance (186). These results provide the conceptual basis for the design of drugs to reverse tissue damage that has already occurred (see Role of Advanced Glycosylation End Products in Pathogenesis of Diabetic Cardiomyopathy).

Antioxidant therapy may retard the formation of glycoxidation products formed by the combined processes of glycation and oxidation (187), and mitigate the oxidative stress generated by the interaction between AGEs and the cell surface AGE receptor.

The interaction between AGEs and RAGE may underlie chronic smoldering inflammatory responses that accelerate diabetic vascular disease (174). Blockade of AGE-RAGE interaction has been accomplished by administration of soluble, extracellular domain of RAGE and has been shown to block vascular permeability and

suppress the development of accelerated diabetic atherosclerosis in murine models (121,181).

PROTEIN KINASE C

The metabolic consequences of hyperglycemia can be expressed in cells in which glucose transport is largely independent of insulin. The resulting intracellular hyperglycemia has been implicated in the pathogenesis of diabetic complications through the activation of the PKC system (188,189).

High ambient glucose concentrations activate PKC by increasing the formation of diacylglycerol (DAG), the major endogenous cellular cofactor for PKC activation, from glycolytic intermediates such as dihydroxy-acetone phosphate and glyceraldehyde-3-phosphate. The elevation of DAG and subsequent activation of PKC in the vasculature can be maintained chronically (190).

PKC is a family of at least 12 isoforms of serine and threonine kinases. Although several PKC isoforms are expressed in vascular tissue, in the rat model of diabetes there is a preferential activation of PKC b2 in the aorta, heart, and retina, and PKC b1 in the glomeruli (191,192).

The PKC system is ubiquitously distributed in cells and is involved in the transcription of several growth factors and in signal transduction in response to growth factors (143,191,193). In vascular smooth muscle cells, PKC activation has been shown to modulate growth rate, DNA synthesis, and growth factor receptor turnover (189,191).

PKC activation increases the expression of transforming growth factor-b (TGF-b), which is one of the most important growth factors, regulating extracellular matrix production by activating gene expression of proteoglycans and collagen and decreasing the synthesis of proteolytic enzymes that degrade matrix proteins. Increased expression of TGF-b is thought to lead to thickening of capillary basement membrane, one of the early structural abnormalities observed in almost all tissues in diabetes. PKC b selective inhibitor (LY333531) attenuates glomerular expression of TGF-b and extracellular matrix proteins such as fibronectin and type IV collagen (192,193).

Hyperglycemia-induced PKC activation also results in increased platelet-derived growth factor-b receptor expression on smooth muscle cells and other vascular wall cells (e.g., endothelial cells, monocyte-macrophages) (194).

OXIDATIVE STRESS

Oxidative stress is widely invoked as a pathogenic mechanism for atherosclerosis. Among the sequelae of hyperglycemia, oxidative stress has been suggested as a potential mechanism for accelerated atherosclerosis (166,187,195). Importantly, there appears to be a strong pathogenic link between hyperglycemia-induced oxidant stress and other hyperglycemia-dependent mechanisms of vascular damage, namely AGEs formation and PKC activation (Fig. 7.7).

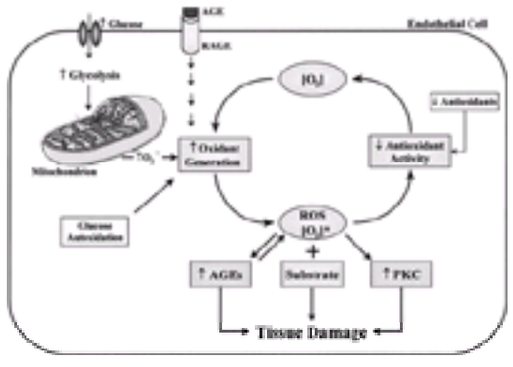


FIGURE 7.7 Relationship between rates of oxidant generation, antioxidant activity, oxidative stress, and oxidative damage in diabetes. *$[O_2]$** represents various forms of reactive oxygen species (ROS). The overall rate of formation of oxidative products leading to oxidative tissue damage is dependent on ambient levels of both $[O_2]$* and substrate. Increased generation of $[O_2]$* depends on several sources, including glucose autoxidation, increased mitochondrial superoxide production, and as a result of the receptor for advanced glycosylation end products activation. $[O_2]$* deactivation is reduced because antioxidant defenses are compromised in diabetes. Note that oxidative stress also promotes other hyperglycemia-induced mechanisms of tissue damage. Oxidative stress activates protein kinase C (PKC) and accelerates the formation of advanced glycosylation end products (AGEs).

Hyperglycemia can increase oxidative stress through several pathways. A major mechanism appears to be the hyperglycemia-induced intracellular reactive oxygen species, produced by the proton electromechanical gradient generated by the mitochondrial electron transport chain and resulting in increased production of superoxide (166).

Two other mechanisms have been proposed that may explain how hyperglycemia causes increased reactive oxygen species formation. One mechanism involves the transition metal-catalyzed autoxidation of free glucose, as described in cell-free systems. Through this mechanism, glucose itself initiates an autoxidative reaction and free radical production yielding superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2) (196). The other mechanism involves the transition metal-catalyzed autoxidation of protein-bound Amadori products, which yields superoxide and hydroxyl radicals and highly reactive dicarbonyl compounds (195) (see Glycoxidation).

There is also evidence that hyperglycemia may compromise natural antioxidant defenses. Under normal circumstances, free radicals are rapidly eliminated by antioxidants such as reduced glutathione, vitamin C, and vitamin E. Reduced glutathione content (197), as well as reduced vitamin E (198), have been reported in diabetic patients. Plasma and tissue levels of vitamin C are 40% to 50% lower in diabetic patients compared with nondiabetic subjects (199).

Glycoxidation

Some of the individual advanced glycosylation products such as Ne-(carboxymethyl)lysine and pentosidine are formed in reactions of protein with glucose only under oxidative conditions (172,200,201). Thus, some AGEs are produced by combined processes of glycation and oxidation and have been termed *glycoxidation products* (187). Each AGE structure has its own formation mechanism and thus its own dependence on oxidative stress. However, because glycoxidation products on proteins are irreversible, it has been suggested that they may be an integrative biomarker for the accumulated oxidative stress to which the respective tissue has been exposed (171,195).

As previously discussed, the interaction between AGE epitopes and the cell surface AGE receptor upregulate oxidative stress response genes (124) and release oxygen radicals (202). Thus, hyperglycemia simultaneously enhances both AGEs formation and oxidative stress, and the mutual facilitatory interactions between glycation and oxidation chemistry can contribute synergistically to the formation of AGEs, oxidative stress, and diabetic complications (Fig. 7.7). Indeed, there are strong correlations between levels of glycoxidation products in skin collagen and the severity of diabetic retinal, renal, and vascular disease (203).

Oxidative Stress and Protein Kinase C Activation

Oxidative stress may also be involved in the activation of DAG-PKC in vascular tissue (166). Oxidants produced in the setting of hyperglycemia can activate PKC (204). Furthermore, several studies have shown that antioxidants such as vitamin E can inhibit PKC activation probably by decreasing DAG levels (166,205).

EFFECT OF OTHER CARDIOVASCULAR RISK FACTORS ON CORONARY ARTERY DISEASE RISK IN DIABETIC PATIENTS

Prospective studies indicate that all of the major cardiovascular risk factors continue to act as independent contributors to CAD in diabetic patients (2,206,207). Standard cardiovascular risk factors account for at least two-thirds of the excess risk from cardiovascular disease in diabetic subjects. In general, for any given degree of abnormality, individuals with diabetes have two to four times greater risk of developing CAD than individuals without diabetes (2).

Hypercholesterolemia

The U.K. Prospective Diabetes Study (UKPDS), including 2,693 patients with newly diagnosed type 2 diabetes, evaluated the significance of all major cardiovascular risk factors for CAD by stepwise multivariate Cox analysis (64). The most important risk factor for CAD—fatal and nonfatal myocardial infarction, angina pectoris—was high LDL cholesterol, followed by low HDL cholesterol, and HbA_{1c}. These results emphasize the contribution of concomitant classic risk factors for CAD in diabetic patients.

Hypertension

Hypertension occurs approximately twice as frequently in patients with diabetes as in the general population (208,209). Isolated systolic hypertension is considerably more common in diabetics. Type 1 diabetes mellitus is associated with hypertension only when albuminuria and early nephropathy develop, but type 2 diabetes mellitus may be associated with hypertension at or even preceding diagnosis (208,209).

The combined presence of hypertension and diabetes considerably accelerates the development of both macrovascular and microvascular diabetic complications. However, the most significant manifestation of this combination of diseases is that they confer a greater risk of ischemic heart disease, stroke, and peripheral vascular disease in affected individuals (208,209,210 and 211). The high cardiovascular risk associated with the coexistence of hypertension and diabetes led the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure to include hypertensive patients with diabetes in the same risk group as hypertensive patients who have clinically manifest cardiovascular disease (212). These patients should be considered for prompt pharmacologic therapy, even if they have high-normal blood pressure (212).

Pharmacologic Therapy of Hypertension in Diabetic Patients

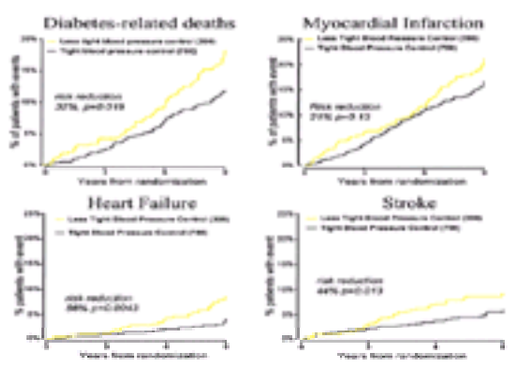
Current evidence suggests that for the prevention of cardiovascular events, ACE inhibitors (213,214), low-dose diuretics (215), or beta-adrenergic blockers (216) are the preferred first-line agents for hypertensive patients with diabetes, whereas a controversy exists with regard to the efficacy of calcium antagonists in preventing cardiovascular complications (217). In the Appropriate Blood Pressure Control in Diabetes trial, patients in the nisoldipine group had a fivefold higher risk of fatal and nonfatal acute myocardial infarction than did the enalapril group (213). The Swedish Trial in Old Patients with Hypertension 2 reported that ACE inhibitors were superior to calcium channel blockers in preventing myocardial infarction and congestive heart failure (CHF) in the subgroup of elderly patients with diabetes (218).

In the Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial patients receiving fosinopril had half the risk of the combined outcome of acute myocardial infarction, stroke, or hospitalized angina than those receiving amlodipine (214). However, the combined therapy resulted in a lower incidence of cardiovascular events than either treatment alone and could be interpreted as evidence that combination therapy is a safe strategy (219). These results are important because hypertension control is not achieved by monotherapy in many diabetic patients, as demonstrated in Appropriate Blood Pressure Control in Diabetes trial (213) and UKPDS (216).

The Systolic Hypertension in Europe study compared outcomes of treatments with nitrendipine versus placebo in patients with isolated systolic hypertension. Endpoint reduction achieved by active treatment was significantly larger in the diabetic subgroup (–69% vs. –26% cardiovascular events), indicating a remarkable benefit from first-line treatment with a calcium antagonist (220). Similarly, the results of the Hypertension Optimal Treatment trial showed a reduction of myocardial infarction event rates in diabetic patients (n = 1,501, representing the largest calcium antagonist trial in diabetic patients) using the long-acting dihydropyridine calcium antagonist felodipine (221).

In the UKPDS, no difference was found between atenolol and captopril (216). In the Captopril Prevention Project study, no difference in outcomes was noted between subjects receiving a combination of diuretic and beta-blockers and those receiving captopril. By contrast, in the subgroup of patients with diabetes, captopril was associated with an approximately 40% decrease in the primary end point, fatal and nonfatal myocardial infarction, stroke, and cardiovascular deaths (222).

The evidence for aggressive antihypertensive treatment in patients with diabetes, hypertension, and nephropathy is now overwhelming (223,224). ACE inhibitors are particularly useful in this population, with clear evidence that these agents reduced the progression of kidney dysfunction and the number of patients who will develop end-stage renal failure (225,226 and 227). Furthermore, the UKPDS indicated that among patients with hypertension and type 2 diabetes, aggressive lowering of blood pressure (mean, 144/82 mm Hg vs. 154/87 mm Hg), either with ACE inhibitors or a beta-blocker, provides greater protection against death from cardiovascular causes and major nonfatal events than did less aggressive therapy (228) (*e*Fig. 7.7.1). A similar benefit was observed in the Hypertension Optimal Treatment study among hypertensive patients with diabetes, who were randomly assigned to intensive therapy with calcium channel blockers (221). In summary, ACE inhibitors appear to be the preferred antihypertensive therapy in diabetic patients, but other antihypertensive agents are also effective in reducing cardiovascular mortality and morbidity. In addition, aggressive blood pressure reduction may be more important than the specific agent being used.



***e*FIGURE 7.7.1** Effect of blood pressure control on morbidity and mortality of type 2 diabetic patients in the United Kingdom Prospective Diabetes Study. The mean blood pressure in the tight control group was 144/82 versus 154/87 in the less tight control group. (Modified from Tight blood pressure control and risk of macrovascular and microvascular complications in type 2 diabetes: UKPDS 38. *BMJ* 1998;317:703–713, with permission.)

The sixth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure has incorporated these principles for the treatment of hypertension in the presence of diabetes and has included a more aggressive program of blood pressure reduction, aiming for a target of less than 130/85 mm Hg in both type 1 and type 2 diabetic patients (212,229). In addition, the guidelines included a target of 125/75 mm Hg in patients with greater than 1 g per day proteinuria (212,223,224).

Smoking

Cigarette smoking has a strong influence on the development of CAD in diabetic individuals (2,230,231 and 232). Furthermore, smoking increases the risk of microvascular complications (232). Several prospective cohort studies suggest that smoking is associated with the development of impaired glucose tolerance (233) and diabetes (232,234). This may be related to the ability of chronic cigarette use to induce insulin resistance (235), which also contributes to the excess CAD risk. In addition, smoking is known to stimulate release of counterregulatory hormones and consequently temporary elevation in plasma glucose levels (236).

Interestingly, both aqueous extracts of tobacco and cigarette smoke contain highly reactive glycation products (called *glycotoxins*) that can rapidly induce AGE formation on proteins *in vivo* and are readily absorbed through the lungs from cigarette smoke. In contrast to glucose, which induces AGE formation over a period of weeks, glycotoxins can induce AGE formation in hours (237). Thus, smoking can accelerate AGE-induced macrovascular and microvascular damage.

Hyperhomocysteinemia

Cross-sectional and prospective studies have shown that hyperhomocysteinemia appears to be a greater risk factor for CAD in diabetic patients compared with nondiabetic subjects (238,239). In a prospective population-based study with a 5-year follow-up, hyperhomocysteinemia was a stronger (approximately twofold) risk factor for death in diabetic than in nondiabetic subjects. For each 5 µmol per L (1 standard deviation) increment in serum homocysteine, the risk of 5-year mortality rose

by 17% in the nondiabetic and 60% in the diabetic subjects (238). High homocysteine concentrations may enhance prothrombotic state, oxidative stress, and endothelial dysfunction in diabetic subjects (240).

Genetic Factors

Complications of diabetes involve multiple organ systems, and their clinical presentation occurs after a period of time following onset (diagnosis) of diabetes. This delay may be short (a few years) or long (a few decades) in duration. Not all diabetic subjects develop a complication, although a portion have several complications. The distribution of complications in diabetic subjects—both in type of complications and in timing of their appearance—suggests that susceptibility to complications is partially controlled by complex unknown genetic factors.

For example, a subgroup of type 1 diabetes subjects have a genetically determined predisposition to renal disease and hypertension, and this predisposition is linked to a high risk of early CAD (see Coronary Artery Disease in Type 1 Diabetes). Studies have shown that an association between ACE I/D polymorphism, potentially affecting the level of angiotensins and kinins in the kidney, can affect the development of renal disease in type 1 diabetic patients (27). The same polymorphism has been linked to myocardial infarction in nondiabetic subjects, as well as in type 1 diabetic (241,242) and type 2 diabetic (243) patients.

Another example is the polymorphism in the paraoxonase gene. During a search for susceptibility genes for vascular disease in diabetes, a polymorphism in the paraoxonase gene was identified as a genetic risk factor for ischemic heart disease in type 2 diabetes (244). Paraoxonase, a serum enzyme entirely bound to HDL, retards the oxidation of LDL by preventing the generation of lipid peroxides (245). Decreased serum paraoxonase activity, caused by polymorphism in the promoter region of the paraoxonase gene, increases the risk of LDL oxidation, and consequently the risk of CAD. The reduced antioxidant capacity may be of particular relevance in diabetic patients because of the inherent propensity for increased oxidative stress (see Oxidative Stress).

DIABETIC CARDIOMYOPATHY

The risk for CHF and idiopathic cardiomyopathy is strongly increased in diabetes (246,247), particularly in women (246,248). In the Framingham Heart Study, although both young women and young men with diabetes had a greater incidence of heart failure than those without, the effect was greater in women (an eightfold versus a fourfold increase) (248).

Although data on the effect of diabetes on the prognosis of patients with CHF are limited, several studies suggest that diabetes is an independent predictor of poor prognosis in this setting. In the Studies of Left Ventricular Dysfunction study, diabetes was an independent predictor of morbidity and mortality in patients with symptomatic heart failure, asymptomatic patients with an ejection fraction less than or equal to 35%, and in the registry population (247). In the Framingham Heart Study, survival after the diagnosis of CHF was significantly worse only in diabetic women, with a 70% increase in mortality (249). Furthermore, one reason for the poor prognosis in patients with both diabetes and ischemic heart disease seems to be an enhanced myocardial dysfunction leading to accelerated heart failure (207).

The cardiomyopathic process associated with diabetes mellitus manifests initially as diminished left ventricular compliance in the presence of normal left ventricular systolic function (250,251 and 252). Diastolic abnormalities occur in 27% to 69% of asymptomatic diabetic patients (250,251). A lower ejection fraction in response to dynamic exercise in the presence of a normal resting ejection fraction has been demonstrated in several studies (252,253 and 254), suggesting that contractile reserve is decreased in many asymptomatic patients with diabetes. Systolic dysfunction may appear, usually in patients with long-standing disease who suffer from advanced microvascular complications (253,255). However, even subclinical cardiomyopathy with reduced myocardial reserve may become clinically important in the presence of myocardial ischemia (256) or with coexistent uncontrolled hypertension.

Pathogenesis of Diabetic Cardiomyopathy

Role of Hypertension and Insulin Resistance

The coexistence of hypertension and diabetes exerts a particularly deleterious effect on the heart. The coexistence of hypertension has been considered a major factor in the expression of diastolic dysfunction in diabetic patients (257). In hypertensive subjects, diabetes is an important precursor of CHF, with a greater relative risk in women than in men (258). The mechanisms responsible for the increased risk for the development of CHF are not fully understood, but may be related in part to an exaggerated increase in left ventricular mass (259).

Conventional clinical measurements of blood pressure have been only weakly related to echocardiographic left ventricular mass. Several observations suggest that insulin resistance and compensatory hyperinsulinemia may promote an increase in left ventricular mass. The association of increased left ventricular mass and hyperinsulinemia has been described in several rare genetic disorders such as leprechaunism (260) and total lipodystrophy (261). It also has been demonstrated in infants of diabetic mothers and in infants with nesidioblastosis and hyperinsulinemia (262). Obesity, which is characterized by insulin resistance and hyperinsulinemia (42,43), is strongly correlated with increased left ventricular mass independent of age and blood pressure (263). Furthermore, left ventricular mass in normotensive obese subjects is related more to the severity of insulin resistance than to the obesity itself as expressed by the body mass index (264). The reduction in left ventricular mass with weight loss (265,266) may be secondary to the improvement in insulin sensitivity.

In hypertensive patients with normal glucose tolerance, who commonly exhibit insulin resistance and hyperinsulinemia (45,48), left ventricular mass has been shown to correlate with the degree of insulin resistance (267,268). A similar association is also observed in nonhypertensive insulin-resistant subjects (267,269).

Hypertension, insulin resistance, hyperinsulinemia, and type 2 diabetes are commonly associated (45,48,270) and result in a high risk for cardiovascular complications (53,54,55 and 56,58,271). Left ventricular mass is a strong predictor of cardiac and cerebrovascular morbidity independent of blood pressure or other risk factors (272) and is a powerful risk factor for the development of symptomatic CHF (248). Thus, the association between insulin resistance and left ventricular hypertrophy may contribute to the increase risk of symptomatic CAD in insulin-resistant subjects.

Metabolic Abnormalities

Several investigators emphasize metabolic abnormalities including abnormal intracellular Ca^{2+} handling, defects in myocardial glucose use, and activation of PKC (273) as possible explanations for the pathogenesis of diabetic cardiomyopathy.

For example, hyperglycemia-induced activation of PKC-b isoforms (see) may contribute to the development of left ventricular dysfunction in diabetes. Transgenic mice overexpressing PKC-b isoform in the heart develop cardiac hypertrophy and accumulation of an excessive amount of extracellular matrix resulting in multifocal fibrosis (273) and decreased cardiomyocyte calcium responsiveness and contractility (274).

Role of Advanced Glycosylation End Products in Pathogenesis of Diabetic Cardiomyopathy

Part of the normal aging process of humans and other long-lived species is the gradual decrease in the elasticity of the cardiovascular system, which leads to increased arterial as well as to left ventricular stiffness and, consequently, diastolic dysfunction. Diabetic patients have increased arterial stiffness compared with nondiabetic individuals (275,276) and manifest diminished left ventricular compliance at a young age (250,251 and 252).

Several investigators have demonstrated that diabetes has several features of accelerated aging at the tissue level and at the level of collagen itself (277,278). Aging and diabetes mellitus are associated with cross-linking and nonenzymatic glycosylation of collagen. This led to the concept that glycosylation could explain the progressive cross-linking of collagen during normal aging and at an accelerated rate in diabetes, leading to changes in vascular tissue mechanical properties.

Thus, disturbances of vascular and cardiac mechanical properties in diabetes may be caused by a common mechanism. Among the structural alterations associated with AGEs formation is collagen-to-collagen cross-linking (168,176) (eFig. 7.6.1), which alters the structure and function of this protein, leading to tissue rigidity (176). Increased arterial stiffness in patients with diabetes strongly correlates with increased aorta and myocardial collagen advanced glycation (276).

Further evidence supporting the AGE hypothesis is the observation that agents that specifically inhibit AGE formation effectively prevent the pathologic stiffening process of diabetes and aging (279,280). For example, treatment of diabetic rats with aminoguanidine, an inhibitor of AGE formation, significantly increases carotid artery compliance, decreases aortic impedance (280), and prevents the decreased myocardial compliance (279).

To further substantiate this concept, studies have used the relatively newly developed AGE “breaker” compound (184). Treatment of rats with streptozotocin-induced

diabetes with the AGE breaker ALT-711 for 1 to 3 weeks reversed the diabetes-induced increase of large artery stiffness (185). Similarly, ALT-711 therapy resulted in a significant reduction in age-related left ventricular stiffness in dogs (186).

DIABETIC PATIENT WITH AN ACUTE ISCHEMIC EVENT

Acute ischemic events represent a major cause of death in the diabetic population (281). Diabetics who suffer myocardial infarction have a higher mortality than nondiabetic subjects both in the acute phase and on long-term follow-up (105).

Acute Myocardial Infarction

Numerous studies have shown that in-hospital mortality from myocardial infarction in diabetic patients is 1.5- to 2.0-fold higher than in nondiabetic patients (9,256,282,283). Diabetic women have a particularly poor prognosis, with an almost twofold increase in mortality compared with diabetic men (9,256,282,283).

Diabetes mellitus remains an independent predictor for a poor prognosis in the thrombolytic era. In the Thrombolysis and Angioplasty in Myocardial Infarction trials, the in-hospital mortality was nearly twice as high in patients with diabetes, with more CHF and twice the rate of clinically recognized reinfarction (9). In the GUSTO-I trial, mortality at 30 days was highest among diabetic patients treated with insulin (12.5%) compared with non–insulin-treated diabetic (9.7%) and nondiabetic (6.2%) patients (284). Similar results have been reported from the other large studies (285,286). Diabetes is also a risk factor for cardiogenic shock in the setting of acute ischemic syndromes (287). Despite the overall improvement in survival from an acute myocardial infarction with thrombolysis, the in-hospital mortality in diabetics remains 1.5 to 2.0 times higher than in nondiabetic subjects (9,284,286). Primary angioplasty appears to be an effective alternative to thrombolysis in diabetic patients (288,289).

The excess in-hospital mortality in diabetics correlates primarily with an increased incidence of CHF (105,256,282,283), although increased reinfarction, infarct extension, and recurrent ischemia also contribute (256,290,291).

CHF and cardiogenic shock are more common and more severe in diabetic subjects than would be predicted from the size of the index infarction (282,283,286). Indeed, studies using serial determinations of total creatine kinase activity, radionuclide ventriculography, or echocardiography have shown no evidence that diabetic patients sustain more extensive infarctions than their nondiabetic counterparts (105). However, a reduction in both left ventricular ejection fraction (256) and the regional ejection fraction of the noninfarcted myocardium occurs in diabetic patients following myocardial infarction compared with nondiabetic subjects. For example, early angiography in the Thrombolysis and Angioplasty in Myocardial Infarction trials has demonstrated worse noninfarct zone ventricular function in diabetics (9). These findings can be ascribed to several additional pathogenic processes that reduce the ability of the noninfarcted myocardium to compensate (Fig. 7.8). The observation that clinical manifestations of heart failure occur in diabetic patients despite a modest decrease in left ventricular ejection fraction led to the suggestion that preexisting diastolic dysfunction is a major culprit of the congestive symptoms (256). Subclinical diabetic cardiomyopathy, in which the salient finding is diastolic dysfunction (see Diabetic Cardiomyopathy) is likely to be an important factor in this setting.

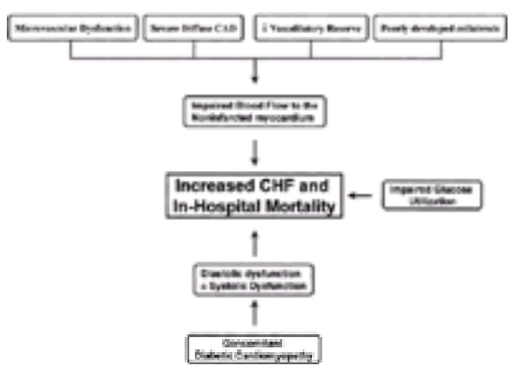


FIGURE 7.8 Factors promoting in-hospital and long-term mortality of diabetic patients following myocardial infarction. CAD, coronary artery disease; CHF, congestive heart failure.

The performance of the left ventricle following myocardial infarction is largely determined by the extent of coronary disease and the quality of collateral circulation. Thus, the diffuse nature of coronary atherosclerosis in diabetes may contribute to systolic dysfunction of the noninfarcted myocardium. Moreover, diabetic patients have a reduced ability to develop collateral blood vessels in the presence of CAD (292), a finding that may also explain the more frequent occurrence of postinfarction angina and infarct extension (105,256,291). Finally, an altered pattern of exogenous substrate use during ischemia and in the postreperfusion period may result in increased oxygen consumption by the myocardium and reduced contractility and may prevent myocardial preservation (see Abnormal Myocardial Substrate Metabolism).

Long-Term Outcome of Diabetic Patients after Myocardial Infarction

Diabetic patients surviving myocardial infarction suffer from higher late mortality than do their nondiabetic counterparts (256,291,293). Late mortality is mainly related to recurrent myocardial infarction and the development of new CHF (104,286).

Survival and recurrent cardiovascular events in diabetic patients after myocardial infarction are closely related to the following categories of risk: (a) extent of global pump dysfunction following the infarct; (b) multivessel CAD; (c) the diabetic hematologic milieu (see Diabetes as a Prothrombotic State); and (d) diabetic autonomic neuropathy, which may predispose to sudden death, especially in postinfarct patients (see Diabetic Autonomic Neuropathy and the Heart).

Medical Therapy in Diabetic Patients with Myocardial Infarction

Diabetic patients treated with fibrinolytic agents benefit by the same mortality reduction as nondiabetic patients (9,105,294). In an overview of fibrinolytic trials in patients with myocardial infarction, the proportion reduction in 35-day mortality was slightly, but not significantly, greater in diabetic patients than in nondiabetic patients (21.7% vs. 14.3%) (294). Importantly, no increase in serious bleeding complications or stroke has been observed in diabetics (9,285,294). Retinal bleeding is an extremely uncommon complication of thrombolytic therapy in diabetic patients. In the GUSTO-I study, 300 of 6,011 diabetic patients had proliferative retinopathy, but none developed intraocular hemorrhage (295). It is unlikely that thrombolytic therapy would increase vitreous hemorrhage, which is caused by vitreous detachment in patients with diabetic retinopathy. Thus, the concern that many clinicians have with regard to thrombolytic therapy in patients with diabetic retinopathy is not supported by the results of large clinical trials. It is probably unjustified to deny these patients the proven life-saving benefit of thrombolysis.

Beta-blockers are effective in reducing reinfarction and sudden death in diabetic patients, perhaps to a greater extent than in nondiabetic subjects (296,297 and 298). Early treatment of myocardial infarction with beta-blockers resulted in a 37% mortality reduction in diabetics compared with a 13% mortality reduction in all patients, whereas long-term mortality reduction was 48% and 33% in diabetics and all patients, respectively (296). Deterioration in glycemic control or blunted counterregulatory response to hypoglycemia are seldom a serious clinical problem, especially when cardioselective $beta_1$-blockers are used (296).

ACE inhibition is unequivocally associated with a substantial mortality reduction in patients surviving myocardial infarction with left ventricular dysfunction (ejection fraction less than 40%) (299). The GISSI-3 investigators compared the effect of early administration (within 24 hours of admission) of lisinopril in patients with and without diabetes presenting with myocardial infarction (300). Compared with placebo, lisinopril dramatically reduced both 6-week (30% vs. 5%) and 6-month (20% vs. 0%) mortality in diabetics versus nondiabetic subjects. These findings are corroborated by a retrospective analysis using data from the Trandolapril Cardiac Evaluation study, a randomized, double-blind, placebo-controlled trial evaluating trandolapril in patients after acute myocardial infarction with an ejection fraction less than or equal to 35%; it showed a 36% reduction of death from any cause and a 62% reduction in the risk of progression to severe heart failure (301). ACE inhibitors do not adversely affect glycemic control and lipid profile (3,208). In fact, ACE inhibitors may actually enhance insulin sensitivity in type 2 diabetic patients (302).

The Antiplatelet Trialists' Collaboration metaanalysis quantified the benefit of aspirin in diabetic patients who have had a previous cardiovascular event (303). The relative benefit on vascular events was 17% in the diabetic patients and 22% in those without diabetes. Although the number was lower for diabetic patients than for nondiabetic patients in terms of percentage benefit, the absolute number of events prevented was similar in the two groups (38 ± 12 per thousand compared with 36 ±

3 per thousand, respectively), probably because of the higher event rates in diabetic patients.

Unstable Angina in Diabetic Patients

Of all patients presenting with unstable angina, 20% to 25% have diabetes (163,304). Diabetes is an important risk factor for an adverse outcome (e.g., death, infarction, or readmission with unstable angina at 1 year; relative risk, 4.9) (164). Hospitalization for unstable angina or non–Q-wave myocardial infarction predicts a high 2-year morbidity and mortality in patients with diabetes. Diabetic patients with no previous cardiovascular disease have the same long-term morbidity and mortality as nondiabetic patients with established cardiovascular disease after hospitalization for unstable CAD (163).

These observations may be related to the higher proportion of ulcerated plaque (94% vs. 60%) and intracoronary thrombi (94% vs. 55%) observed by angioscopy in diabetic patients presenting with unstable angina (13). Coronary tissue obtained from culprit lesions of diabetic patients with unstable angina or myocardial infarction exhibit a larger content of lipid-rich atheroma, macrophage infiltration, and a higher incidence of coronary thrombus, which occupies a larger area (305).

ABNORMAL MYOCARDIAL SUBSTRATE METABOLISM

Tight coupling between cardiac work, coronary flow, and substrate oxidation is a central feature of cardiac physiology. Fatty acids are normally the predominant fuel for cardiac energy production, whereas glucose becomes the main substrate for oxidative metabolism of the heart when fatty acid levels are low and when the concentrations of glucose and insulin are high, as in the postprandial state, but also under ischemic conditions.

Transport of glucose across cell membranes is catalyzed by members of the facilitative glucose transporter family. The most important glucose transporters in cardiac myocytes are GLUT1 and GLUT4. GLUT1 is expressed ubiquitously and is mainly responsible for basal glucose transport. GLUT4, the insulin responsive glucose transporter, resides in intracellular membrane compartments, where it is prevented from contributing to cellular glucose transport. Insulin stimulates GLUT4 translocation from the intracellular pool to the plasma membrane, resulting in increased glucose uptake by myocardial cells. GLUT4 also translocates to the plasma membrane in response to increased metabolic demand such as increased workload, hypoxia, and myocardial ischemia (306,307 and 308). Mice with genetic ablation of the GLUT4 gene exhibit cardiac hypertrophy and heart failure, suggesting that GLUT4 is essential for normal cardiac function (309).

The ischemic myocardium relies largely on the anaerobic metabolism of glucose. The relative contribution of glucose to energy production in the ischemic heart is highly dependent on the severity of ischemia. In moderate ischemia glucose extraction increases and glucose metabolism is directed from oxidation to lactate production (306,307). Although ischemia results in a flow-dependent decrease in glucose delivery and a decrease in interstitial glucose levels, glucose uptake can still be accelerated, reflecting a greater capacity of glucose transport across the sarcolemmal membrane (306,307).

Under such ischemic conditions, myocardial glucose extraction is inversely related to coronary flow, until the degree of ischemia becomes so severe that glycolysis is inhibited by the accumulation of its products and glucose uptake progressively decreases. This “metabolic exhaustion” occurs before irreversible ischemic injury is observed and results from inhibition of glycolytic activity caused by accumulation of protons, Na^+, and Ca^{2+} and the inability to extrude the products of glycolysis (307). The decrease of glucose uptake during prolonged severe ischemia can be attenuated by an increase in extracellular glucose concentrations or the addition of insulin (310). Furthermore, the effect of physiologic hyperinsulinemia and ischemia on GLUT4 translocation and glucose uptake is additive (308).

Free fatty acids are commonly increased in most clinically relevant conditions of myocardial ischemia secondary to increased plasma catecholamine levels. Furthermore, heparin activates LPL and markedly increases circulating free fatty acid levels (311). The inhibition of glucose oxidation by fatty acids is a well-known phenomenon of mammalian metabolism (the glucose–fatty acid cycle). Indeed, increased free fatty acid levels have been shown to be toxic to ischemic myocardium and are associated with increased membrane damage, arrhythmias, and accelerated functional deterioration (312,313).

Increased glucose uptake and metabolism during acute myocardial ischemia are associated with preserved myocardial function (310,314). Hence, decreased GLUT4 translocation caused by insulin deficiency could limit glucose availability, thereby promoting myocardial damage, and possibly reducing the capacity of the noninfarcted myocardium to compensate. In addition, insulin deficiency reduces myocardial glucose use with a shift toward fatty acid metabolism. This altered pattern of exogenous substrate use may result in increased oxygen consumption by the myocardium, reduced contractility, and increased production of free radicals (313).

If specific metabolic abnormalities induced by diabetes can adversely affect mechanical performance or increase the myocardial vulnerability to ischemic insults, insulin administration and improved metabolic control may reduce myocardial damage, improve contractility, and decrease mortality. Noninvasive quantification of myocardial glucose uptake using positron emission tomography with the glucose analog ^{18}F-fluorodeoxyglucose has shown that myocardial glucose uptake can be significantly improved or normalized if adequate insulin substitution is provided (315).

These potential benefits—increased glucose uptake and decreased circulating fatty acid levels—have been exploited clinically with the use of glucose-insulin-potassium infusions in the setting of myocardial infarction.

In experimental studies, the protective effects of high glucose and insulin levels are much more apparent after reperfusion than during the preceding ischemic period (310). During reperfusion, fatty acid oxidation quickly recovers and again dominates as the source of energy. Therefore, glucose oxidation rates are markedly inhibited. The use of fatty acids instead of glucose strongly impairs the efficiency of the reperfused heart. Stimulation of glucose oxidation at the onset of reperfusion improves and accelerates functional recovery, whereas inhibition of glucose use induces a strong impairment of postischemic contractility (316). Thus, glucose-insulin-potassium may slow the rate of development of ischemic necrosis and prolong the time during which reperfusion therapy can salvage ischemic myocardium, as well as the amount of salvage that is achieved (312).

In the DIGAMI trial of diabetic patients with acute myocardial infarction (half receiving thrombolysis) in-hospital mortality was unchanged with insulin and glucose infusion. However, there was a trend to a decreased mortality at 3 months, which became significant at 1 year (29% relative mortality reduction, $p = .27$) (317). It is unclear, however, whether this mortality benefit is related to myocardial salvage or to other beneficial effects of improved glycemic control.

CORONARY REVASCULARIZATION IN DIABETIC PATIENTS

Because CAD is a major health problem in patients with diabetes, the need for revascularization procedures arises frequently. An increasing proportion of patients undergoing angioplasty are diabetics. In the 1977 to 1981 National Heart, Lung, and Blood Institute registry, 9% of patients undergoing angioplasty were diabetics (318). More recent large trials indicate that the prevalence of diabetes in patients undergoing angioplasty has increased to 17% to 26% (319).

Studies performed in the last decade have evaluated the relative efficacy of revascularization methods in diabetic patients. These studies reveal unique problems in diabetic patients, including higher periprocedural complication rates, a greater incidence of restenosis following successful angioplasty, and adverse long-term outcome after percutaneous and surgical revascularization, especially in the presence of multivessel disease, and suggest that the determination of optimal revascularization in these patients requires special attention.

Coronary Angioplasty

Procedural Outcomes and Complication Rates

In general, procedural success rates and completeness of revascularization do not significantly differ between diabetics and nondiabetic subjects (10,320,321,322 and 323). In-hospital complication (of death, infarction, and need for emergency surgery) rates have been reported to be higher in diabetic patients undergoing balloon angioplasty (10,320) and stenting (323). With stenting, a trend toward higher rates of subacute stent thrombosis was reported (323,324).

These differences are small and have not been confirmed in all studies. Based on data from the EPILOG study, Kleiman et al. concluded that with current angioplasty techniques, the in-hospital event rates for diabetic patients are comparable with those for nondiabetic patients (325). However, when acute ischemic complications occur during angioplasty, they may be poorly tolerated by diabetic patients, leading to a higher rate of periprocedural death (326).

Long-Term Results: Restenosis

Long-term outcomes have been disappointing because of the greater incidence of restenosis following successful angioplasty and adverse long-term outcome, especially in the presence of multivessel disease. The importance of diabetes as a consistent clinical predictor for restenosis after percutaneous transluminal coronary angioplasty (PTCA) has been demonstrated in multiple studies. The initial report from the National Heart, Lung, and Blood Institute Angioplasty Registry (327) that the

angiographic restenosis rate in diabetic patients was 47%, as compared with 32% in nondiabetic patients, was subsequently confirmed by many other studies that reported restenosis rates of 49% to 68% among diabetic patients undergoing balloon angioplasty (328,329 and 330). Diabetes is also a clinical predictor for restenosis with other percutaneous revascularization techniques, such as excimer laser angioplasty (331) and coronary atherectomy (321).

Intracoronary stents decrease restenosis compared with balloon angioplasty. However, even with stent use, the majority of studies has shown higher restenosis rates, compared with nondiabetic patients (324,332,333,334 and 335).

The full impact of the higher postangioplasty restenosis rates on the cardiovascular morbidity of diabetic patients is significant. Numerous studies have shown that diabetic patients experience a greater need than their nondiabetic counterparts for repeat revascularization [angioplasty or coronary artery bypass graft (CABG)], a high cardiac event rate, and lower overall survival rates after either balloon angioplasty (10,320,321,336) or stenting (333,334 and 335).

Whereas restenosis may explain the higher repeat angioplasty and CABG rates among diabetics, the exact relationship between restenosis and recurrent events or increased mortality is more complex. The majority of ischemic events outside the time frame of restenosis appears to be disease progression at other coronary sites rather than late restenosis at the original treatment site. Notwithstanding, percutaneous interventions may affect long-term prognosis through other mechanisms, including increased incidence of heart failure (330) and distal embolization (337). In a study of 485 consecutive patients with diabetes undergoing balloon angioplasty without stenting, at least one vessel with restenosis was found in 68% of patients (330). Many of these occlusions were clinically silent, with no angina in 36% and stable angina in 33% of patients. Occlusions were associated with a significant decrease in left ventricular function.

Because of the diffuse atherosclerotic process, poor collateralization, and preexisting microvascular dysfunction, diabetic patients may have reduced adaptive capacity for embolization during percutaneous interventions (337). Studies suggest that the combination of abciximab and stent placement reduces periprocedural myocardial infarction and short-term mortality (338,339). The beneficial effect of abciximab may be related to the reduction of distal embolization at the time of stenting (338,339). Target vessel revascularization rates were not different, suggesting that the risk for restenosis is not affected (338).

Mechanisms of Restenosis in Diabetes

Although vessel recoil may also contribute to loss of lumen, the markedly increased restenosis rate seen in diabetics following stent placement underscores the role of enhanced neointimal proliferation as the major mechanism for restenosis in these patients (334). In a study using intravascular ultrasound, exaggerated intimal proliferation was found in diabetic patients at the site of angioplasty-induced arterial injury, and this proliferative response was particularly striking in restenotic lesions (340).

Multiple potential mechanisms can contribute to intimal hyperplasia following arterial injury in hyperglycemic diabetic patients (reviewed in reference 341). The role of insulin resistance in the pathogenesis of restenosis is of major clinical importance not only for patients with type 2 diabetes or impaired glucose tolerance, but also for a large group of insulin-resistant subjects with normal glucose tolerance (48). Current data are limited and controversial, with studies both supporting (342) and refuting (119,331) the role of insulin resistance in the restenosis process.

When considering restenosis in diabetic patients, an important clinical issue is whether the effect of diabetes on accelerating the development of restenosis occurs in only a subset of patients. If this is the case, can this subgroup of diabetic patients who are at a particularly high risk for restenosis be identified? Restenosis may be predicted, at least to some extent, in diabetic patients based on clinical data, markers of metabolic control, and the presence of other diabetic complications (343) that may share similar pathophysiologic mechanisms (341).

Coronary Artery Bypass Graft

Perioperative Period

In an analysis performed on over 6,000 patients undergoing surgical revascularization, overall operative mortality was 2.3%, and diabetic status was not a predictive factor (344). Smaller studies reported higher operative mortality among diabetics, although only to a relatively small degree (345,346). In the largest series reported to date of 12,198 consecutive patients undergoing CABG at the Emory University Hospitals, the 2,278 diabetic patients had higher rates of postoperative death and stroke (347).

The most often cited complication associated with bypass surgery in diabetics is wound infection involving sternotomy (a complication associated with prolonged hospitalization, reoperation, and increased mortality) and graft harvest sites (348). The results of a large prospective study suggest that the incidence of deep wound infection in diabetic patients can be reduced with perioperative strict glycemic control (349). Renal failure, postoperative arrhythmia, respiratory failure, and intraaortic balloon pump use are mentioned only variably as complications seen more frequently in diabetics. The occurrence of both stroke and perioperative infarction is similar.

Vein Grafts

There are no prospective data on the influence of diabetes on disease progression in vein grafts. Animal studies suggest diabetes may be associated with accelerated intimal hyperplasia in vein grafts (350). Lytle et al. performed angiographic follow-up on 501 patients undergoing bypass surgery. Diabetes was found to be predictive of interval vein graft occlusion by multivariate analysis, although actual graft patency rates among diabetics were not specified (351). Other investigations have not found diabetes to be a significant predictor of progressive vein graft narrowing (352). These studies, however, are limited by total number of patients examined and even smaller numbers of diabetics. The post-CABG trial studied the effects of aggressive cholesterol lowering and low-dose anticoagulation on angiographic end points in patients 1 to 11 years after CABG. Angiographic changes in saphenous vein graft (SVG) conduits 4.3 years after entry were compared in 116 diabetic and 1,235 nondiabetic patients. There was no discernible difference between SVG disease in diabetic and nondiabetic patients for all three angiographic outcomes (substantial progression, occlusion, and change in minimum lumen diameter of SVGs) (353).

Internal Mammary Artery Grafts

Overall, long-term survival and freedom from subsequent cardiac events are better in patients receiving internal mammary artery (IMA) grafts compared with SVGs only. Even in patients with multivessel disease, the use of a single IMA graft conveys a significant survival benefit. Furthermore, the IMA appears to be virtually immune to the development of intimal hyperplasia, which almost universally occurs in aortocoronary vein grafts (354).

Although IMA graft patency rates have not been well documented in the diabetic population, the influence of IMA grafting on survival in diabetic patients was determined in a study of 5,654 consecutive patients of whom 1,132 (20%) were diabetic (355). Use of an IMA graft conveyed an independent long-term survival benefit to both nondiabetic and diabetic patients, and the magnitude of the survival benefit attributable to IMA grafting in the two groups did not differ (355). The importance of IMA grafting is also supported by the results from the Bypass Angioplasty Revascularization Investigation (BARI) trial, suggesting that a large mortality benefit is derived from IMA grafting in diabetic patients (see following discussion) (356).

Long-Term Outcome of Coronary Artery Bypass Graft in Diabetic Patients

The relative survival benefit of CABG surgery versus medical therapy is comparable in diabetic and nondiabetic patients (11,355). However, long-term survival rates after bypass surgery remain lower in diabetic than in nondiabetic patients (11,347,355,357). The BARI study demonstrated that surgically treated diabetic patients have a worse 5-year survival probability than nondiabetic patients (80.6% vs. 91.4%) (320).

Multivessel Angioplasty versus Coronary Artery Bypass Graft

In the last decade, angioplasty has been proposed and evaluated as an alternative to CABG in patients with multivessel disease. The influence of diabetes on outcome after PTCA for patients with multivessel disease received attention following the results of BARI study (358).

The BARI study enrolled 1,829 patients, including 353 diabetics with angiographically documented multivessel CAD and either clinically severe angina or objective evidence of marked myocardial ischemia requiring revascularization. A review of 5-year all-cause mortality showed a near doubling of mortality among diabetics on insulin or oral therapy assigned to multivessel angioplasty compared with those assigned to surgery (35% versus 19%, $p = .003$). In contrast, the 5-year mortality in nondiabetics and diabetics not on drug treatment was 9% with both revascularization strategies (358). Cause-specific 5.4-year cardiac mortality was 3.5 times higher in the PTCA group (20.6% vs. 5.8%) (322). These results raised concern about selection of angioplasty as a revascularization method in diabetic patients with multivessel

CAD.

Subsequent reports from the BARI investigators indicated that the survival benefit of CABG was limited to the 81% of diabetics receiving internal mammary grafts. Cardiac mortality after 5.4 years was 2.9% when internal mammary grafts were used and 18.2% when only SVG conduits were used. The latter rate was similar to patients receiving PTCA (20.6%) (322). The mortality benefit afforded by internal mammary grafting was most apparent in those experiencing myocardial infarction during follow-up, an effect seen also in nondiabetic patients.

The results of two other randomized trials comparing multivessel angioplasty to CABG are consistent with the BARI findings. Long-term follow-up of patients participating in the Emory Angioplasty versus Surgery Trial demonstrated an improved outcome in diabetic patients randomized to CABG (75.5% vs. 60.1% with PTCA at 8 years) (359). In the Coronary Angioplasty versus Bypass Revascularization Investigation, a trend toward a higher mortality was observed among diabetic patients randomized to PTCA (360).

In summary, an accumulating body of evidence points toward CABG as the preferred revascularization strategy in diabetic patients with multivessel disease. It should be emphasized, however, that it is still unknown whether the choice of the initial revascularization strategy in these patients should be based exclusively on a history of diabetes. Some of the questions regarding revascularization in diabetic patients with multivessel disease will be addressed in the BARI II study. This study is designed to examine the effects of revascularization plus aggressive medical therapy versus medical therapy alone, as well as the effect of insulin-providing (sulfonylurea and insulin) versus insulin-sensitizing (metformin and thiazolidinediones) strategies for tight glycemic control.

Mechanism of Coronary Artery Bypass Graft Protection

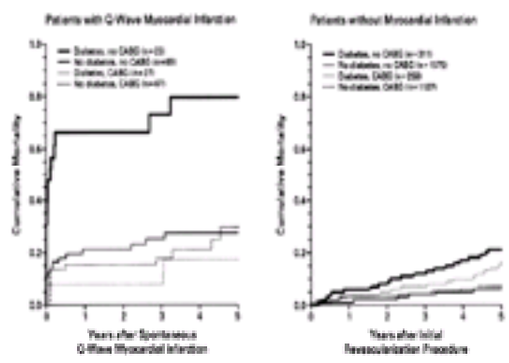
Two major mechanisms have been suggested to explain the apparent superiority of CABG over multivessel balloon angioplasty in diabetic patients: (a) high restenosis rates after angioplasty with incomplete revascularization of ischemic territories (336,361); and (b) accelerated progression of atherosclerosis of native arteries or SVGs (362).

Restenosis with Incomplete Revascularization

Previous CABG studies have shown that complete revascularization, which is accomplished almost exclusively through CABG surgery, is essential for obtaining survival benefit in patients with multivessel disease (363). The superiority of CABG over angioplasty in providing complete revascularization is exemplified in the BARI study itself. In the BARI population, 3.1 grafts were placed per patient undergoing CABG (364), whereas the mean number of successfully treated lesions in the PTCA group was 2.0 (322). Similar numbers are reported by other studies comparing multivessel angioplasty and CABG (336,357,365). In the Emory cohort, revascularization was achieved in 16% of patients undergoing PTCA, and 80% in the CABG group (365). In the study by Gum et al., complete revascularization was accomplished in 79% of patients undergoing CABG and in 42% of the angioplasty group (p <.001) (336).

Given the suboptimal revascularization with multivessel angioplasty compared with CABG, successful application of multivessel angioplasty—which entails a selective high-priority lesion-targeting strategy—requires that a comparable proportion of myocardium supplied through high-priority lesions be revascularized by each of the two strategies. Given the high restenosis rates in diabetic patients, and because when multivessel angiography is preformed, multiple treatment sites can become restenosed independently, it is likely that this goal is frequently not achieved in diabetic patients. Thus, the worse outcome of diabetic patients undergoing PTCA may be mediated in part by the frequent occurrence of incomplete revascularization (336,361). The effect of incomplete revascularization may be even more severe in view of the more diffuse and distal CAD (9,10 and 11,320,322), poor collateral development (292), and microcirculatory dysfunction in diabetic patients (see Vascular Endothelial Dysfunction in Diabetes).

The BARI investigators have analyzed the outcome of BARI-eligible patients, a larger group that included randomized patients and 2,010 additional eligible patients who declined randomization (361). This report identified two mechanisms for the protective effect of CABG in diabetes: (a) a strong protective effect with respect to survival in a small group of patients who sustained a Q-wave myocardial infarction, accounting for approximately 50% of the overall reduction in mortality attributable to the procedure; and (b) a moderate constant reduction in mortality throughout follow-up that occurred in the majority of diabetic patients who remained free of myocardial infarction during follow-up (eFig. 7.8.1). A steadily increasing advantage of CABG compared with PTCA was also apparent at 7-year follow-up (366). These protective effects were not present in nondiabetic patients (361).



***e*FIGURE 7.8.1** Mortality after the initial revascularization procedure in Bypass Angioplasty Revascularization Investigation (BARI) trial. The left panel shows Kaplan-Meier estimates of the cumulative mortality in patients with spontaneous Q-wave myocardial infarction according to diabetes status and coronary artery bypass grafting (CABG) status (the numbers in parentheses refer to the 186 spontaneous Q-wave myocardial infarctions that occurred in 176 patients). Patients who did not undergo CABG were treated only with percutaneous transluminal coronary angioplasty. The right panel shows the cumulative mortality in patients without Q-wave myocardial infarction, both according to diabetes status and with respect to CABG at the time of death. (From Detre KM, Lombardero MS, Brooks MM, et al. The effect of previous coronary-artery bypass surgery on the prognosis of patients with diabetes who have acute myocardial infarction. Bypass Angioplasty Revascularization Investigation Investigators. *N Engl J Med* 2000;342:989–997, with permission.)

Accelerated Atherosclerosis Progression

It has been suggested that accelerated progression of atherosclerosis leading to new plaque ruptures located within the native coronary arteries or vein grafts of diabetic patients accounts for the poor long-term prognosis after multivessel angioplasty (362). Bypass surgery offers some protection from atherosclerosis progression in native arteries by providing a bypass conduit beyond the epicardial coronary segment most vulnerable to future plaque development (usually within the proximal 6 cm of epicardial coronary arteries) (362). However, progression of native CAD in postbypass patients is mainly related to dyslipidemia (352). Currently, there is no evidence that in the group of patients who already have an advanced atherosclerotic process (multivessel disease) continued progression is more rapid in the presence of diabetes. Likewise, progression of vein graft atherosclerosis is mainly related to hypercholesterolemia, and aggressive lipid-lowering therapy reduces the progression of atherosclerosis in vein grafts (367), whereas the effect of diabetes on the accelerated atherosclerotic process that characterizes vein grafts is still unclear (see Vein Grafts). Indeed, in the BARI trial, the type of revascularization had no influence on the incidence of Q-wave myocardial infarction during follow-up (361). In a large study comparing the outcomes of 9,920 patients without diabetes and 2,278 diabetic patients after CABG surgery, there was no difference in myocardial infarction rates at 5 and 10 years (347). Of note is the fact that in post-CABG patients with evolving infarction, approximately two-thirds of culprit lesions are located within vein grafts (368).

Although the incidence of plaque disruption leading to a clinical acute coronary event is probably not affected, a greater proportion of the myocardium may become ischemic because of incomplete revascularization with PTCA. This is particularly important given the high long-term incidence of both fatal and nonfatal events among diabetic patients (10,320,322,361,365). For example, in the BARI study, although CABG offered no protection from myocardial infarction, patients with diabetes were 1.9 times as likely as those without diabetes to have a spontaneous (non–procedure-related) Q-wave myocardial infarction at 5 years (361).

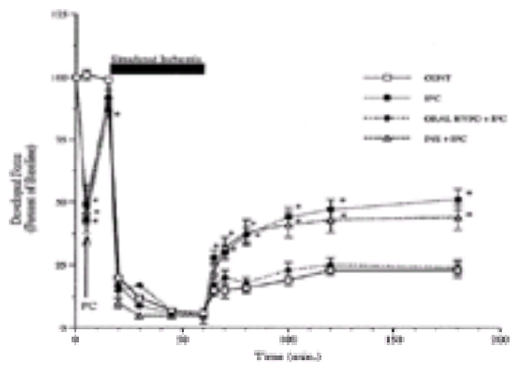
ISCHEMIC PRECONDITIONING

An essential mechanism for ischemic preconditioning is thought to involve the release of adenosine formed from net adenosine triphosphate (ATP) use during the preconditioning period of ischemia. Adenosine A_1 receptors are coupled through G proteins to K_{ATP} channels present on ventricular myocytes and smooth muscle cells (369). These channels are activated during ischemia by decreasing ATP levels in ventricular myocytes and adenosine receptor stimulation. Opening cardiac K_{ATP} channel ventricular myocytes initiates ischemic preconditioning of the myocardium for a subsequent ischemic event and in vascular smooth muscle contributes to

vasodilation (369,370).

In the pancreas, a surge in blood glucose leads to increased production of high-energy phosphate ATP and inhibits K_{ATP} channel opening. With channel closure, an excess of K^+ remains on the inner side of the plasma membrane, leading to depolarization of the beta cell plasma membrane. In turn, membrane depolarization results in opening of voltage-dependent Ca^{2+} channels followed by Ca^{2+}-dependent release of insulin through exocytosis. Sulfonylurea drugs as a class bind with high affinity to a subunit of the K_{ATP} channel known as the *sulfonylurea receptor* (371) and inhibit K^+ flux through the channel pore, leading to membrane depolarization and insulin release. In a similar fashion, sulfonylurea-induced inhibition of potassium efflux through K_{ATP} membrane channel may inhibit preconditioning of myocytes and vasodilation in response to hypoxia or ischemia (369).

Experimentally, sulfonylureas have been shown to increase infarct size and accelerate death of hypoxic cardiomyocytes (370). In humans, ischemic preconditioning during coronary angioplasty (decreased severity of ST-segment depression during second balloon inflation relative to the first) can be prevented by sulfonylureas. Long-term oral hypoglycemic agents abrogate preconditioning in isolated human myocardium (372) (eFig. 7.8.2).



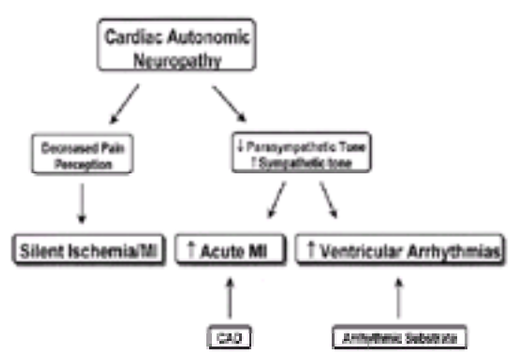
***e*FIGURE 7.8.2** Effects of ischemic preconditioning in trabeculae with and without long-term exposure to oral hypoglycemic agent (ORAL HYPO). Preconditioned trabeculae from patients without oral hypoglycemic exposure (IPC) show increased recovery of developed force relative to trabeculae not given preconditioning stimulus (CONT) after simulated ischemic injury. Conversely, trabeculae from patients with long-term ORAL HYPO + IPC are not functionally protected by ischemic preconditioning stimulus. Insulin (INS) + IPC does not inhibit protection by preconditioning. *p <.05 versus control. (Adapted from Cleveland JC Jr, Meldrum DR, Cain BS, et al. Oral sulfonylurea hypoglycemic agents prevent ischemic preconditioning in human myocardium. Two paradoxes revisited. *Circulation* 1997;96:29–32, with permission.)

In the early 1970s, the results of the University Group Diabetes Program study suggested that patients on sulfonylureas sustain an unexplained increase in cardiovascular mortality compared with diet treatment alone (373). No evidence of deleterious effect of sulfonylurea therapy on myocardial infarction, sudden death, or diabetes-related deaths has been found in the UKPDS (206). Notwithstanding, in the post–myocardial infarction setting, a paradoxical increase in mortality among diabetic patients on sulfonylureas has been observed in some (374), but not all, studies (375). At present, there are insufficient data regarding the effect of sulfonylureas on clinical outcome.

DIABETIC AUTONOMIC NEUROPATHY AND THE HEART

Although clinically apparent autonomic neuropathy (e.g., orthostatic hypotension and gastroparesis) generally occurs only in patients with diabetes of long duration, it has become evident that subclinical diabetic autonomic neuropathy, mainly in the form of cardiac autonomic neuropathy (CAN), evolves early in the course of diabetes (376) and in the absence of other microvascular complications (377). CAN is extremely common in both type 1 and type 2 diabetes, affecting up to 60% of unselected populations (376,378).

CAN involves parasympathetic dysfunction (379) as well as derangements of adrenergic cardiac innervation as assessed by myocardial meta-[^{123}I]iodobenzylguanidine scintigraphy (380). The presence of CAN in diabetic patients has been linked to increased risk of arrhythmias, cardiovascular events, and a high prevalence of silent ischemia and infarction (eFig. 7.8.3).



***e*FIGURE 7.8.3** Cardiac consequences of autonomic neuropathy. CAD, coronary artery disease; MI, myocardial infarction.

Propensity to Arrhythmias

Extensive experimental and clinical evidence suggests that changes in autonomic neural activity are important in the genesis of cardiac arrhythmias (381). In nondiabetic patients, clinical investigations have consistently shown that reduced heart rate variability is a marker of autonomic imbalance that favors the development of cardiac arrhythmias and sudden death, mainly in conjunction with left ventricular dysfunction and in patients surviving myocardial infarction (381,382). Reduced heart rate variability is a hallmark and the earliest indicator of CAN in diabetic patients (376,378,379) and may confer a higher risk for arrhythmic events. QT prolongation (383) and increased QT dispersion (384) have also been described in diabetic patients with autonomic dysfunction and may contribute to increased risk of arrhythmias.

Relation of Autonomic Neuropathy to Abnormal Circadian Rhythms in Diabetic Patients

Abnormalities in the circadian pattern of autonomic nervous system caused by the presence of CAN are associated with alterations in the temporal pattern of thrombotic events and in blood pressure regulation.

In the general population, the circadian pattern of acute myocardial infarction and other thrombotic events parallels the temporal pattern of the autonomic nervous system (385). Sympathetic tone predominates during the daytime, when the onset of cardiac events is maximal (385).

The circadian distribution of onset of symptoms of acute myocardial infarction is altered in the diabetic population with a shift from morning hours to the evening and night hours (386,387). Bernardi and colleagues (388) demonstrated that diabetic autonomic neuropathy is associated with a marked diminution of parasympathetic activation during sleep, which may result in a relative nocturnal sympathetic dominance. This finding led to the hypothesis that the relative nocturnal predominance of sympathetic activity might predispose diabetic patients to cardiovascular events at that time (388).

A nocturnal decline in blood pressure during sleep is characteristic of the 24-hour pattern of blood pressure. In hypertensive patients, this pattern is generally preserved, with an upward shift of the 24-hour mean around which the temporal changes are manifested. In a small proportion of patients with essential hypertension

the pattern of blood pressure is altered because of a blunted decline in nocturnal blood pressure (389). In these so-called nondipper patients, lack of nocturnal decline in arterial blood pressure is associated with left ventricular hypertrophy and increased cardiovascular complications (390). The decrease in plasma catecholamine levels and sympathetic nervous activity during sleep are thought to play a pivotal role in 24-hour changes of blood pressure. Indeed, subjects with autonomic failure lack the nocturnal blood pressure decline (391).

The physiologic nocturnal decrease in blood pressure is blunted or absent in many normotensive and hypertensive diabetic patients and has been linked to the presence of concomitant autonomic neuropathy (392). A high prevalence of nondippers has been documented in both type 1 (392) and type 2 (393) diabetic patients and has been associated with increased risk for the occurrence of various vascular events (393).

Silent Ischemia

The propensity of diabetic patients to present with silent or unrecognized myocardial infarction is well established (394). In the Framingham Study, a higher proportion of myocardial infarctions in diabetic patients was silent and unrecognized (395). Atypical symptoms such as confusion, dyspnea, fatigue, or nausea and vomiting were the presenting complaint in 32% to 42% of diabetic patients with myocardial infarction compared with 6% to 15% of nondiabetic patients. More recently, failure to use reperfusion therapy was observed in diabetic patients (396), which may be attributable, in part, to an atypical presentation.

Although silent ischemia frequently can be demonstrated in nondiabetic patients, several studies have shown that, whether assessed by treadmill exercise testing (377), ambulatory Holter monitoring, or exercise thallium scintigraphy (397,398), silent ischemia is more common in diabetic than in nondiabetic subjects. This finding, however, is not supported by all studies (399). For example, in the Asymptomatic Cardiac Ischemia Pilot study, there was a similar prevalence of asymptomatic ischemia during exercise treadmill testing and 48-hour ambulatory electrocardiographic monitoring (399).

Autonomic neuropathy with involvement of the sensory supply to the heart is a plausible explanation for painless infarction and ischemia episodes in diabetic subjects. In autopsies of diabetic patients who died of silent myocardial infarction, typical diabetic neuropathic changes were found in the intracardiac sympathetic and parasympathetic fibers (400), and several studies correlated abnormalities in autonomic function in patients with silent ischemia (377,401). The anginal perceptual threshold—the time from the onset of myocardial ischemia (assessed by ST-segment depression) to the onset of chest pain during exercise testing—is prolonged in diabetic patients compared with nondiabetic subjects. This delay in the perception of pain is related to the impairment of autonomic nervous function (401).

CONTROVERSIES AND PERSONAL PERSPECTIVES

In the last two decades, the advent of effective therapies of hypertension and hypercholesterolemia resulted in a substantial reduction in mortality and morbidity associated with these risk factors for CAD. Diabetes remains a major risk factor for which the optimal therapy has not been established and is increasingly becoming a research focus in the field of preventive and clinical cardiology.

A central issue in the treatment of diabetic patients is whether tight glycemic control will reduce CAD morbidity and mortality. Whereas randomized primary prevention trials have clearly shown that glycemic control reduces the incidence of microvascular complications in both type 1 and type 2 diabetes, the effect on macrovascular complications was small. Indeed, lipid lowering and aggressive blood pressure reduction appear to be more efficacious as primary prevention in diabetic patients.

There are two key questions with regard to the expected benefit of intensive glycemic control as part of the primary prevention of macrovascular disease. First, the threshold above which hyperglycemia becomes atherogenic is unknown and may be below the range defined as diabetes. It is also unknown whether a continuous relative risk reduction relationship over the range of hemoglobin A_{1c} exists for diabetic macrovascular complications. Second, the time necessary for the reversal of established hyperglycemia-induced vascular damage is not known. For example, in diabetic patients with functioning pancreatic transplants, renal pathology continues to progress for at least 5 years after diabetes has been cured (402). The mechanism for these observations is unclear but may be related to a slow replacement of glycosylated molecules or because phenotypic alterations in vascular cells may persist despite the return of normoglycemia (the so-called memory effect). Notwithstanding, intensive glycemic control as secondary prevention seems to be effective in reducing short-term mortality (317), suggesting that glycemic control may be valuable even in diabetics with established CAD.

The diffuse nature of the atherosclerotic process in diabetic patients is often emphasized. It is commonly accepted that angiographically severe CAD increases the propensity to develop acute coronary syndromes because the presence of the severe stenoses serves as a marker for the presence of angiographically modest or even inapparent noncritically stenotic plaques that are more prone to disruption. However, the striking excess of coronary events in diabetic patients with or without established CAD appears to be out of proportion to the severity of atherosclerosis. These observations raise the possibility that unique pathogenic mechanisms in diabetes operate to weaken plaque stability.

THE FUTURE

Basic and clinical research should be directed to elucidate the unique mechanisms causing accelerated atherosclerosis in insulin-resistant and diabetic individuals. Diabetes promotes initiation of atherosclerosis, progression of lesions, and thrombotic complications by multiple mechanisms. Current lines of investigation focus on the following interactions of diabetes and mechanisms of atherosclerosis: (a) the role of endothelial dysfunction in the pathogenesis of atherosclerosis and propensity to thrombosis; (b) the mechanisms involved in the abnormal hemostatic and fibrinolytic function observed in the diabetic setting; and (c) the role of AGEs and the receptor for AGEs in the pathogenesis of vascular disease in diabetes and the use of specific inhibitors of various steps in the glycosylation process (e.g., aminoguanidine or “AGE breakers”) as a potential therapy; (d) diabetes-induced augmentation of oxidative stress; (e) understanding the relationship between the components of the insulin-resistance syndrome and its importance as a cardiovascular risk factor for both diabetic and nondiabetic subjects; and (f) understanding the relation between inflammation and diabetes. Defining the molecular mechanisms responsible for insulin resistance may lead to the development of new “insulin-sensitizing” agents that can improve insulin action, resulting in a wide spectrum of beneficial metabolic effects and a reduced cardiovascular risk.

The pathogenesis, natural history, and clinical significance of diabetic cardiomyopathy remain to be determined. Likewise, the role of autonomic neuropathy in the cardiovascular complications of diabetes should be explored. More research is also needed with regard to the specific mechanisms involved in the pathogenesis of restenosis in diabetic patients and potential therapeutic approaches that will improve the results of angioplasty in diabetic patients.

Finally, the prevention of type 1 and type 2 diabetes is a major focus of basic and clinical investigations. Screening of the human genome can identify regions of genetic susceptibility, after which the final localization of disease genes can be carried out, followed by sequencing of candidate genes to identify the specific mutations. Multiple molecular defects can lead to type 2 diabetes, and the molecular details of several rare forms of type 1 diabetes have already been identified (e.g., pancreatic glucose “sensor” mechanism).

Diabetes prevention trials based on immunologic toleration to prevent type 1 diabetes, lifestyle changes, and pharmacologic interventions to prevent or delay type 2 diabetes are now being carried out.

OVERVIEW

Cardiovascular disease (CVD) across the entire lifetime is slightly more common as a cause of mortality in women than in men. In addition, CVD in women is a formidable problem because of difficulties in diagnosis and increased morbidity and mortality associated with CVD events at all ages. In the middle years, CVD is associated with multiple risk factors, generally more in women than in men of the same age. Diabetes appears to be a particularly more severe risk factor in women than in men, but smoking is still probably the worst CVD risk factor in any gender. Specific lipid management guidelines are available for the treatment of elevated low-density lipoprotein cholesterol (LDL-C) in women, but the management of combined hyperlipidemia is a more common condition and more important. Postmenopausal hormone replacement therapy, unfortunately, has not been beneficial in preventing progression of established coronary disease in prospective double-blind randomized studies. The evidence of benefit from experimental models may relate to the early rather than the late use of estrogen in the atherogenic process; this is analogous to the lower rates of heart disease in premenopausal women. There are many examples of interaction of sex steroids with lipid disorders that require care and thought and have long-term implications for the cardiovascular health of both men and women.

GLOSSARY

Combined hyperlipidemia: The concomitant elevation of total triglyceride level above 200 mg per dL and LDL-C level above 100, 130, or 160 mg per dL, depending on National Cholesterol Education Program risk factors.

Lipid transfer protein: Also known as *cholesterol ester transport protein*, lipid transfer protein facilitates the transfer of triglyceride from very-low-density lipoprotein (VLDL) to high-density lipoprotein (HDL) and cholesterol from HDL to VLDL and LDL, thereby maintaining a cycle of transport of cholesterol in the body.

Lipoprotein(a) [Lp(a)]: A nonfibrinolytic plasminogen analog that is attached to low-density lipoprotein (LDL) apoprotein B and plasminogen binding sites, inhibiting fibrinolysis and enhancing LDL trapping in the arterial wall.

Polycystic ovary syndrome (PCOS): Syndrome associated with the metabolic syndrome, obesity, and hyperandrogenemia in young women.

Remnant lipoprotein: A lipoprotein particle that is intermediate between VLDL and LDL (also known as *intermediate-density lipoprotein*) and has powerful atherogenic potential.

Syndrome X: The metabolic syndrome that is caused by insulin resistance. Syndrome X is associated with combined hyperlipidemia, obesity, hypertension, diabetes, and PCOS.

INTRODUCTION

The main points of this chapter are raised in the following true case. A 25-year-old woman who used oral contraceptives (OCs) and smoked one pack of cigarettes per day was having vague chest pains for a year, which were variously diagnosed as anxiety and acid reflux. On July 4, 2000, she was seen at an emergency room and sent away. Twelve hours later at the same emergency room, the possibility of a myocardial infarction (MI) was entertained as she went into shock. An emergency two-vessel angioplasty procedure was performed, saving the patient's life. Several other angioplasties and three-vessel bypass surgery have been done since, complicated by bilateral iliac vessel stenosis. She is now somewhat intellectually impaired. On presentation to clinic, the cholesterol was 182 mg per dL, triglyceride was 175 mg per dL, and high-density lipoprotein cholesterol (HDL-C) was 24 mg per dL on 40 mg atorvastatin. The Lp(a) was 19.2 (seventy-fifth percentile). Why did this patient have an MI? Why was it so severe? Why was the MI not recognized during the first emergency room visit? Is this case as rare as it might seem? Is the constellation of symptoms unique to this case or to women in general? What is the approach to managing this patient's lipid disorder? This chapter addresses these and other questions.

INCIDENCE OF CAD: WOMEN VS MEN

The perception persists that coronary artery disease is a rare occurrence in women, especially in young women, leading to the view that arteriosclerotic disease of the vascular tree is less important in women overall. Both perceptions are incorrect. CVD is an equal-opportunity killer in men and women over their lifetimes. In

Washington State in 1991, the incidence of CVD death was 42% in women and 39% in men (1). Nationwide, these numbers approach 50%. The slightly higher percentage of female cardiovascular deaths can be attributed to the greater longevity of women, which is an extremely powerful risk factor in its own right and allows female CVD mortality rates to “catch up” in old age.

A lower rate of CVD mortality in women is certainly observed in young women, especially premenopausally; still, the rates of CVD in women are not negligible and have defined relationships to cardiovascular risk factors. In fact, as shown in Figure 8.1, the increase in CVD with age in the Framingham study (2) lags behind the male age-associated increase by only 10 to 15 years. A similar pattern is seen even in high-risk conditions such as heterozygous familial hypercholesterolemia, again with a delay of 10 years in women compared to men. The delay in onset in women versus men is attributed to the premenopausal exposure to endogenous ovarian estrogen, but, even premenopausally, this effect diminishes with advancing age (Fig. 8.1). The most important point is that the rise in female CVD is highly parallel to the rise of CVD in men. A major inflection in the female risk curve around the time of menopause is not seen (Fig. 8.1). Possibly, some women develop menopause earlier (especially smokers), plasma estrogen levels decline in the 40s (a number of years before menopause), and any restraint of atherogenesis may take a few years to dissipate.

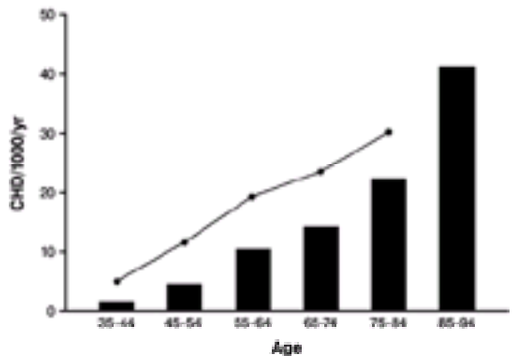

FIGURE 8.1 Annual rate of coronary heart disease (CHD) in men (*line*) and women (*bars*), from the Framingham Heart Study. (From Castelli WP. Cardiovascular disease in women. *Am J Obstet Gynecol* 1988;158:1553–1560, with permission.)

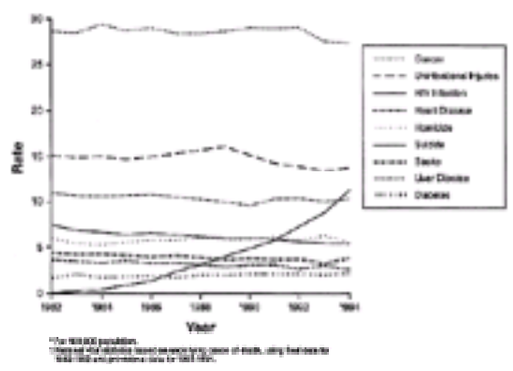
The importance of CVD in young women can be appreciated by comparing CVD death rates in women to other causes of mortality. These rates are shown in *e*Figure 8.1.1. Since 1982, heart disease mortality has occurred at a rate of approximately 11 per 100,000 in women ages 25 to 45 years with little decline, reflecting the level rates for CVD in women overall in the last decade (3). Among young women, approximately one-third of heart disease deaths are coronary in etiology. In men ages 25 to 44 years, the CVD rate is approximately 30 per 100,000—almost ten times more common than in women. As for other causes of mortality in women, cancer accounts for 29 per 100,000 and injuries for 14 per 100,000 (4). In a study of emergency room admissions among young persons (ages 18 to 45 years) for sudden death, 1 of 20 cases of coronary disease was in a young woman (5). In another study, one-fourth of all MI survivors younger than 40 years at a major hospital were women (6). The main point is that CVD incidence in younger women is not negligible, ranging from one-fourth to one-twentieth the rate in men.



***e*FIGURE 8.1.1** Death rates* from leading causes of death among women aged 25 to 44 by year—United States, 1982 to 1994. HIV, human immunodeficiency virus. [From Centers for Disease Control and Prevention. Update: mortality attributable to HIV infection among persons aged 25–44 years: United States, 1994. *MMWR Morb Mortal Wkly Rep* 1996;45(6):121–125, with permission.]

The early lesions of arteriosclerosis—the fatty streak and the fibrous arteriosclerotic plaque—are seen in young women and men. In teenagers and young adults who died traumatic deaths in Bogalusa (7), half of the men and one-fourth of the women were so affected. In blacks, half of men and women were affected and were equal in extent. In both genders, the fatty streak lesions were proportional in extent to the plasma LDL-C. However, the plasma level of VLDL-C (7), which is closely related to the plasma triglyceride level, was associated with lesions only in women (see the discussion of triglyceride as a CVD risk factor in women in the section Plasma Triglyceride Elevations). When coronary lesions are examined, female lesions are more lipid filled, rich in macrophages, and less densely fibrous (8). Thus, lesions in women could be more unstable under certain circumstances, as well as more readily reversed (9). Likewise, coronary calcification is half that of men on ultrafast computed tomography until age 60 years, when the difference between the genders narrows (10).

An excess in female acute MI susceptibility among young blacks is seen in the Bogalusa data (7). This trend is borne out by national mortality data, in which black women have consistently had a 50% to 75% greater risk of death from diseases of the heart since 1950 (11) and into the 1990s (3). The approximate rates (adjusted for age) for white and black women were 110 per 100,000 and 190 per 100,000, respectively, in 1988 (11). The reasons for this greater risk are unclear but could relate to higher blood pressure and Lp(a) levels in blacks.

DIFFERENCES IN DISEASE PRESENTATION

The tendency to overlook CVD in women because of its lesser frequency in youth and middle age is compounded by less classical presentation, which is more frequently angina in women and MI in men (*e*Table 8.0.1). In the Framingham study, the annual incidence of angina pectoris in women exceeded that of MI by a ratio of more than 2:1 in the age ranges of 45 to 54 years and 55 to 64 years. In men, frank MI exceeded angina for all four age groups examined, ranging from 1.5:1.0 between ages 45 and 64 years, 2.4:1.0 between ages 65 and 74 years, and 6.5:1.0 between ages 75 and 84 years (12,13). In a recent study, women presenting for stenting had fewer MIs than men (14). These data are consistent with the clinical impression that angina pectoris is an earlier and more common presentation of the arteriosclerotic process in women.

***e*TABLE 8.0.1** ANNUAL INCIDENCE OF ANGINA, MYOCARDIAL INFARCTION, AND SUDDEN DEATH IN MEN AND WOMEN PER 10,000 POPULATION

	Angina		**Myocardial infarction**		**Sudden death**	
Age (yr)	**Men**	**Women**	**Men**	**Women**	**Men**	**Women**
45–54	30	21	54	9	11	3
55–64	74	54	91	25	21	6
65–74	52	51	119	51	31	13
75–84	25	94	168	90	43	32

Adapted from Lerner DJ, Kannel WB. Patterns of coronary heart disease morbidity and mortality in the sexes: a 26-year follow-up of the Framingham population. *Am Heart J* 1996;111:383–390.

Recognition of cardiovascular chest pain is difficult in women because (a) it is not expected, (b) it is often atypical, and (c) noncardiac chest pain seems to be more common in women than in men. As a result of atypical symptoms, misdiagnosis as chronic fatigue or a psychiatric disorder is not uncommon. The reason for the lack of classical anginal symptoms in many women—despite having validated myocardial ischemia—is unknown. The greater incidence of silent MI in women (13) may also be related to the atypicality of chest pain presentation. One of our patients had fatigue with exercise without ischemic electrocardiogram changes on treadmill testing that

did not resolve until she developed overt angina and had bypass surgery. A tip-off to performing anatomic studies earlier might have been recognition of her severe combined hyperlipidemia (see the section Lipid Screening Guidelines for Hyperlipidemic Women).

As this case suggests, the exercise tolerance test is not as useful in clarifying atypical chest pain in women as in men because it is too susceptible to false-positive and false-negative results. In general, radionuclide or echocardiographic imaging are recommended if an exercise test is to be done (15,16). On the other hand, a female patient with chest pain with a positive exercise test and a negative angiogram might have arteriosclerotic vasospasm with a normal lumen. In this instance, estrogen may be beneficial and even diagnostic if it eliminates the vasospasticity and the chest pain syndrome. In such cases, the long-term prognosis is favorable, and angina in women is collectively associated with approximately one-half the rate of subsequent MI as that in men (16).

Frank MI in women has more unfavorable consequences than in men. Sudden death is more frequent, and early post-MI mortality is greater in women than in men. In the Thrombolysis in Myocardial Infarction (TIMI)-II trial, the 6-week mortality rate was 9% in women versus 4% in men, and post-MI mortality was 1.54 times more likely in women compared to men when adjusting for age and other baseline inequalities (17). The Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO)-I trial demonstrated a similar twofold excess that decreased to a relative risk of 1.4 when adjusted for age and 1.06 when adjusting predictors of 30-day mortality (18). In keeping with this observation, recent Scandinavian data (19) and experience from a Cleveland clinic (18) indicate that nearly all of the excess mortality in women is concentrated within the first 4 weeks post-MI (Fig. 8.2); these data influence all subsequent statistics. After 1 year, a mortality rate of 32% in women versus 16% in men has been observed in the Framingham study (20,21). Thus, postevent nonadjusted mortality is approximately 50% greater in women than in men for various intervals. These trends have been confirmed recently and extended (22) with a higher risk for death relative to younger men (23).

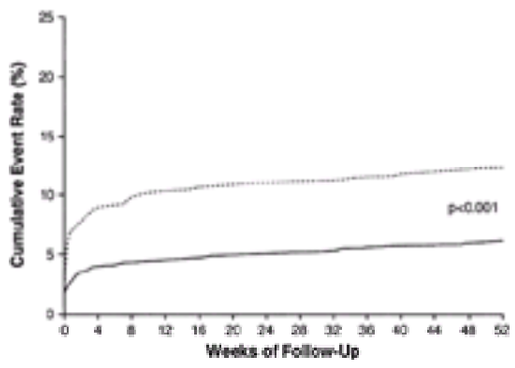


FIGURE 8.2 One-year Kaplan-Meier mortality curves for women and men. The solid line represents men; the dashed line represents women. (From Becker RC, Terrin M, Ross R, et al. Comparison of clinical outcomes for women and men after acute myocardial infarction. *Ann Intern Med* 1994;120:635–645, with permission.)

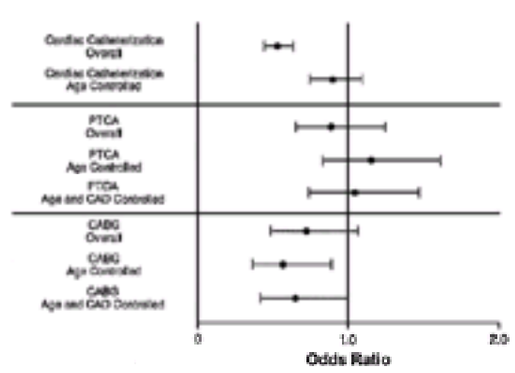
Regarding the cause for the greater female mortality, age and various risk factors interact, but the studies are not entirely consistent, as suggested above (17,18). In elderly Scandinavians with acute MI, a 28% versus 20% excess mortality in women and men, respectively, was eliminated by age adjustment alone (19). In a Spanish study of elderly post-MI outcome, a higher rate of congestive heart failure (CHF) in women explained the greater mortality (40% versus 23% in women and men, respectively), not gender itself (24). A metaanalysis of 27 reports between 1966 and 1994 seemed to rule out the effect of gender when age and other risk factors were taken into consideration (24). In summary, crude mortality post-MI is increased consistently in women versus men. The excess mortality is largely explained by age and other risk predictors, whether metabolic or relating to the severity of the incident MI, including CHF (24,25).

A variable literature has developed regarding the use of diagnostic testing and operative procedures in women versus men. Earlier studies from the 1970s and 1980s indicated that women were less likely to have Holter monitoring, exercise treadmill testing, cardiac catheterization, and angioplasty (26,27). In one study, the frequency of angioplasty in women was not reduced after age adjustment (26). In the Worcester, Massachusetts, area, angioplasty was less frequently performed in women, whereas coronary artery bypass grafting was performed as frequently in men as in women (27). On the other hand, in one Boston hospital, angiography was not performed less frequently in women than in men after age adjustment, angioplasty was performed as frequently in both genders, and bypass surgery was performed less frequently in women (*e*Fig. 8.2.1) (26). In a Seattle study, angiography and angioplasty were performed less frequently in women than in men, but among patients who had angiograms, equal proportions of men and women received bypass surgery (28). Thus, local conditions seem to influence some of the differences in treatment between the genders.



***e*FIGURE 8.2.1** Female-male odds ratios for cardiac procedures. Overall and age-controlled odds ratios are shown for cardiac catheterization. For percutaneous transluminal coronary angioplasty (PTCA) and coronary artery bypass graft (CABG), overall odds ratios are shown, along with odds ratios adjusted for age and severity of coronary artery disease (CAD). Bars represent 95% confidence intervals. (From Krumholz HM, Douglas PS, Lauer MS, et al. Selection of patients for coronary angiography and coronary revascularization early after myocardial infarction: is there evidence for a gender bias? *Ann Intern Med* 1992;116:785–790, with permission.)

As to whether a frank bias exists in physician management of coronary disease and cardiac catheterization of the genders, two investigators indicate that less-aggressive decision making is appropriate in women at low risk for cardiac death, with little probability of benefit (29,30), or with angina pectoris (31). A recent study found more do not attempt resuscitation orders, less aspirin prescription, and less thrombolytic therapy in women compared to men with acute MI (32). However, the issue is still little studied, and what happens in a woman's care depends greatly on the interaction between patient and physician (33).

Several recent studies have examined events surrounding MI treatment with thrombolysis in women and in men. In Kansas City, allocation of men and women to thrombolysis and angioplasty was equivalent (34). In the MITI study in Seattle, intravenous thrombolysis was performed within 6 hours of hospitalization in 57% of men and 54% of women (nonsignificant difference), whereas a total of all acute interventions was somewhat more common in men (72%) versus women (62%) (35).

Regarding outcome after thrombolysis, the recent GUSTO-I and Thrombolysis and Angioplasty in Acute Myocardial Infarction (TAMI) studies revealed a number of features detrimental to women when unadjusted for age and risk factors, as shown in *e*Table 8.0.2. The two studies do not agree in all respects, but both indicate excess stroke, reinfarction, and unadjusted mortality in women (36,37). In addition, CHF, serious bleeding, and shock were more common in women than in men in the GUSTO-I trial. After adjustment for various factors in the TAMI trial, death was insignificantly more common (relative risk = 1.30), reinfarction significantly more common, and stroke approximately twofold more common. Thus, even after age and risk factor adjustment, there appears to be greater residual morbidity and marginally more mortality among acute-MI women treated with thrombolysis compared to men similarly treated (*e*Fig. 8.2.2) (37).

(From Lincoff AM, Califf RM, Ellis SG, et al. Thrombolytic therapy for women with myocardial infarction: is there a gender gap? *J Am Coll Cardiol* 1993;22:1780–1787, with permission.)

Operative procedures also show greater short- and long-term morbidity and mortality in women than in men, though the probability of benefit remains high in both genders. At the Mayo Clinic, percutaneous transluminal coronary angioplasty was successful in 85% of women and 86% of men, but age-adjusted in-hospital mortality was 4.2% in women and 2.7% in men—a significant difference that persisted with multivariate analysis (38). In the case of bypass surgery, in-hospital mortality at Cedars-Sinai Medical Center was 4.6% and 2.6% in women and men, respectively, despite a difference in age of only 4 years (68.2 vs. 64.0) (39). However, more of the women had unstable angina and CHF, whereas more men were referred for abnormal exercise-test results. In this instance, the later stage of disease at the time of operation or the greater inherent severity accounted for the greater mortality in women (39). A recent analysis of stent experience from Germany found rates of death and MI greater in women at 30 days, (3.1% vs. 1.8% in men) but equal after 1 year (6.0 vs. 5.8%) (14) (*e*Fig. 8.2.3). Male-female differences in clinical presentation and prognosis are summarized in Table 8.1.

TABLE 8.1 DIFFERENCES IN CARDIOVASCULAR DISEASE PRESENTATION AND OUTCOME IN WOMEN (W) VERSUS MEN (M)

The most important message from the greater morbidity and mortality associated with coronary disease in women is that high priority should be given to early recognition and treatment of risk factors and early ischemic symptoms in women, as well as in men. The other point is that obscure symptoms of fatigue or atypical chest pain should be worked up aggressively for potential coronary ischemia with exercise and performance imaging, particularly when risk factors for coronary artery disease are present and especially when present in combination.

CARDIOVASCULAR DISEASE RISK FACTORS IN WOMEN COMPARED TO MEN

Similarities in risk factor relationships to arteriosclerotic vascular disease in women and men include hypertension and smoking (12). In the Framingham study, smoking was the worst of any single risk factor among male subjects (40) but had less impact among females. However, in a study of 119,404 female nurses, the cardiovascular risk of smoking is clear (41) and may be increasing in severity in recent birth cohorts (42). The interaction of smoking with OC use is also strong (see the section Oral Contraceptive Use and Cardiovascular Disease Risk). Lp(a), fibrinogen, and homocystine all function as risk factors in women, as well as in men (43,44 and 45). Abdominal obesity, weight gain since age 18, and increments in body weight—even at body mass indexes less than 27—are all associated with increased CVD incidence in women (46). Recently, highly sensitive C-reactive protein (CRP) was found to be a stronger single risk factor than any other, including lipids and apoproteins (47). Marital stress (48) and being early in the menstrual cycle (49) are two other risk factors.

Differences between men and women have been identified for the impact of diabetes, plasma triglyceride, and HDL-C on female vascular health. Diabetes confers a greater increment of susceptibility to atherosclerosis in women than men, resulting in diabetic women having an absolute coronary disease rate equalling or

approaching that of men (50,51). The exaggerated diabetic effect on CVD in women is most marked in middle-aged women and attenuates with age (*e*Table 8.1.1), as does the cholesterol effect due to the increased incidence of coronary disease from other causes, especially age (25).

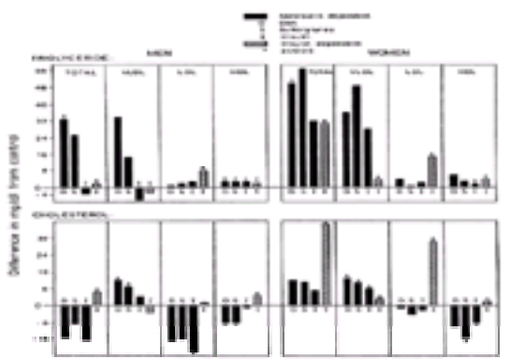
The greater impact of diabetes on CVD in women compared to men is not well understood but may be due to more greatly disturbed lipoprotein levels in the female diabetic than in the male diabetic (50). Specifically, the change experienced by diabetic versus nondiabetic women exceeds that for diabetic versus nondiabetic men for increases in total plasma triglyceride, cholesterol, and LDL-C and reductions in HDL-C (50,52), although insulin deficiency may affect lipoprotein metabolism equally in men and women (*e*Fig. 8.2.4). Whether other effects of gender bear on the atherogenic effects of lipoprotein oxidation and glycoxidation in diabetes requires further study



***e*FIGURE 8.2.4** Lipoprotein lipid changes in diabetic women and men. HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein. (From Walden CE, Knopp RH, Wahl PW, et al. Sex differences in the effect of diabetes mellitus on lipoprotein triglyceride and cholesterol concentrations. *N Engl J Med* 1984;311:953–959, with permission.)

Total plasma cholesterol relates to heart disease risk differently in women than in men. As shown in *e*Table 8.1.2, the increment in CVD in men from a low- to a high-cholesterol level is nearly tenfold in men aged 35 years but attenuates with increasing age to only 1.2-fold by age 65 years. In women aged 65 years, the increase in CVD risk associated with high cholesterol is twofold, but at an absolute increment similar to men: 2.4% versus 1.9%. This trend persists to old age, where LDL has stronger relative risk in women than men (53). Again, the decline in relative risk of cholesterol is due to the dilution of this effect by the increased rate of CVD with age, more so in men than in women.

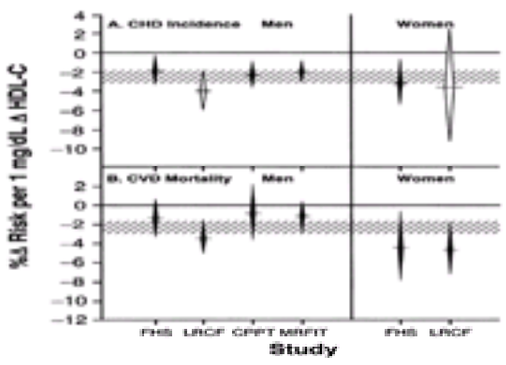
The cluster of risk factors associated with CVD in middle age also differs between men and women. Because women tend to be protected compared to men and have a 10- to 15-year delay in the curve describing the rise in CVD (Fig. 8.1), it follows that for a woman to have coronary disease in middle age, she must have more risk factors or a greater risk burden than a man to experience coronary artery disease, as seen in many studies (14,54). The leading condition embodying multiple risk factors is the metabolic syndrome, also known as the *insulin resistance syndrome* or *syndrome X* (55,56,57 and 58). Along with insulin resistance, abdominal obesity, a propensity to hypertension, overt diabetes, and combined hyperlipidemia characterize this syndrome. Combined hyperlipidemia consists of elevated plasma triglyceride, VLDL-C, intermediate-density lipoprotein cholesterol, LDL-C, small dense LDL, and low HDL-C (56,57). Clotting factor abnormalities are also associated, including elevated factor VII and plasminogen activator inhibitor-1 levels. Thus, in a single entity, four to eight risk factors can be present, affecting approximately 25% of the population.

It is not known if the metabolic syndrome has a greater association with women versus men, but the presence of coronary disease in middle-aged women is highly associated with the metabolic syndrome. For instance, diabetes and hypertension are overrepresented three- and fivefold, respectively, in women with coronary disease compared to women without. In addition, diabetes, hypertension, and hyperlipidemia are present in more women than men with acute MI in virtually every study (14,17,18 and 19,28,29,33,36,37,59,60). In other words, for women to have “premature” coronary disease, they must have a greater number of risk factors; therefore, it is not surprising that the metabolic syndrome is so overrepresented.

The predilection of the metabolic syndrome for coronary disease in women contributes to plasma triglyceride being a stronger risk factor in women than in men—1.8-fold versus 1.2-fold, or even higher (61). Conversely, a reduction in HDL-C is more strongly associated with CVD risk in women than in men, such that a 1-mg-per-dL drop in HDL-C in women is associated with a 3% to 4% increase in coronary artery disease, whereas a 1-mg-per-dL decrease in HDL-C in men is associated with a 2% increment in coronary disease (62) (*e*Fig. 8.2.5). When coronary arteriosclerosis in men and women is graded according to angiographic severity, lipoprotein abnormalities correlating with disease severity in men are total cholesterol, LDL-C, and apoprotein B; in women, the abnormalities are VLDL-C, intermediate-density lipoprotein cholesterol, LDL triglyceride, and low HDL apoprotein (also termed *apoprotein A-I*) (63). Again, it is the combined hyperlipidemia phenotype that seems to predominate as the lipoprotein risk factor in women. The case presented in the introduction to this chapter is a striking and unfortunate example of this association.



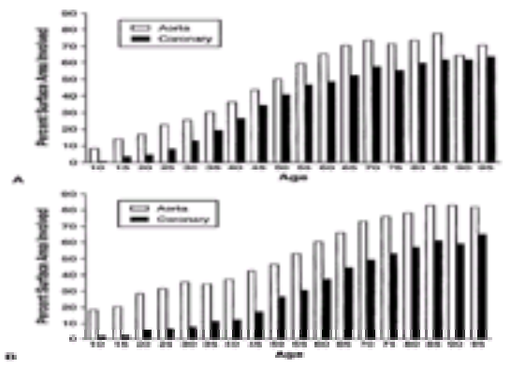
***e*FIGURE 8.2.5** Plots of 95% confidence intervals for the adjusted proportional hazards regression coefficients relating high-density lipoprotein cholesterol (HDL-C) levels to coronary heart disease (CHD) incidence rates **(A)** and cardiovascular disease (CVD) mortality rates **(B)** in Framingham Heart Study (FHS), Lipid Research Clinics Prevalence Mortality Follow-Up Study (LRCF), Lipid Research Clinics Coronary Primary Prevention Trial (CPPT), and Multiple Risk Factor Intervention Trial (MRFIT) participants. The shaded region (~1.9% to ~2.9%) is contained in all 12 confidence intervals. Note that the regression coefficients for LRCF in **(A)** are based on CHD mortality only because nonfatal events were not identified. (From Gordon DJ, Probstfeld JL, Garrison RJ, et al. High-density lipoprotein cholesterol and cardiovascular disease. Four prospective American studies. *Circulation* 1989;79:8–15, with permission.)

Triglyceride should not be rejected as a CVD risk factor because it is overtaken by HDL-C in some multivariate analyses (61). At the very least, triglyceride is a major and easily measured marker for CVD risk in the metabolic syndrome. Second, triglyceride-rich lipoproteins can be found as intact particles in the arterial wall (64). A third point is that regardless of which lipoprotein abnormality one may believe to be important, triglyceride and HDL are highly inversely associated, and treatment of one with lipid-lowering agents helps correct both abnormalities.

PCOS is the earliest manifestation of the metabolic syndrome in the young woman. Such individuals have the plasma lipid profile of combined hyperlipidemia, as described above. Conversely, women with coronary artery disease more frequently have PCOS (65). CVD risk is further aggravated by the excessive secretion of androgen, which attenuates the effect of endogenous estrogen, as discussed in the section Postmenopausal Sex Steroid Hormone Effects on Lipoproteins, Carbohydrate Metabolism, and Clotting.

Two treatments of the insulin resistance syndrome are at hand. Metformin (500 mg b.i.d. for the first week and 1 g b.i.d. thereafter) and the thiazolidinediones rosiglitazone (2 to 8 mg q.d.) and pioglitazone (15 to 45 mg q.d.) are associated with improved insulin sensitivity (even in normoglycemic individuals), a fall in plasma insulin, and a reduction in plasma free testosterone levels in PCOS (66,67). Weight loss is also important in obese individuals with serious CVD risk. The diet and lipid-lowering approach to the management of combined hyperlipidemia in women is discussed in the section Cholesterol-Lowering Interventions and Reductions in Coronary Artery Disease in Women.

A final argument that combined hyperlipidemia in association with insulin resistance syndrome is a major cause of premature coronary disease in middle-aged women is made from the distribution of arteriosclerosis in the vascular tree in women versus men (1,68). As shown in *e*Figure 8.2.6, the increase in arterial surface area affected by arteriosclerosis occurs later in women than in men by approximately 10 years, as does the clinical onset of coronary disease (2), but the distribution of arteriosclerosis in women is greater in the aorta and less in the coronary circulation than in men. The more peripheral distribution of arteriosclerotic vascular disease is typical of patients with diabetes and hypertriglyceridemia—both features of the insulin resistance syndrome.



***e*FIGURE 8.2.6** World Health Organization autopsy data comparing mean percent surface area involved with total atherosclerosis in the abdominal aorta and coronary disease in men **(A)** and women **(B)**. The surface area involved with atherosclerosis in the three coronary arteries has been averaged for comparison with the abdominal aorta. Ages represent a range of 5 years. For example, age 10 represents the age range 10 to 14 years, age 15 represents the age range 15 to 19 years, and so forth. (From Blankenhorn DH, Hodis HN. George Lyman Duff Memorial Lecture. Arterial imaging and atherosclerosis reversal. *Arterioscler Thromb* 1994;14:177–192, with permission.)

In summary, the metabolic syndrome and combined hyperlipidemia are more prevalent in women than in men with arteriosclerosis in middle age. The clinical management point is that treatment should be directed holistically toward the entire metabolic disorder (e.g., insulin resistance, obesity, hypertension, hyperglycemia, dyslipidemia) and not toward a single factor such as elevated LDL, as important as it is (69). Important risk factors in women are listed in Table 8.2.

The metabolic syndrome (syndrome X)
Insulin resistance
Obesity
Hypertension*
Diabetes*
Combined hyperlipidemias

TABLE 8.2 RISK FACTORS FOR CARDIOVASCULAR DISEASE IN WOMEN

DIETARY RESPONSE AND CARDIOVASCULAR DISEASE

Some small-scale diet studies suggest that women are less responsive to diet than men. However, a large study from our own clinic indicates that the National Cholesterol Education Program (NCEP) Step II Diet lowers LDL-C equally in men and women, with LDL-C levels above approximately 160 mg per dL (70). On the other hand, HDL-C declined with Step II Diet to a greater extent in women—5% to 6% as compared to 1% to 3% in men after 6 and 12 months of diet—with the greatest reduction in HDL (2), the estrogen-exercise–sensitive portion of HDL (71).

This study indicates that chronic differences exist in the HDL-C response to diet between men and women. The mechanism and significance of the greater HDL-C decrease in women for CVD risk are not known. At this point, the recommendation for dietary intervention in men and women is not different. Nonetheless, in a woman with coronary disease needing dietary and drug management of hyperlipidemia, the greater propensity to HDL-C lowering with diet further reinforces the point that triglyceride and HDL—as well as LDL—be aggressively managed in the at-risk woman. The NCEP Adult Treatment Panel III (ATP-III) guidelines advocate a diet containing 35% of fat as calories rather than <30%, which is less likely to decrease HDL-C (71a).

EFFECTS OF GONADAL STEROIDS ON LIPOPROTEIN METABOLISM AND THEIR CLINICAL SIGNIFICANCE

The effects of estrogens and progestins on lipoprotein metabolism are shown in Figure 8.3. The main point from the illustration is that estrogen enhances the metabolic traffic of cholesterol transport in virtually every pathway except one, raising triglyceride, lowering LDL, and raising HDL, whereas progestins and androgens have the opposite effect (1,72,73). Details of the pathway effects are presented in the online version of this textbook and in the accompanying CD-ROM.

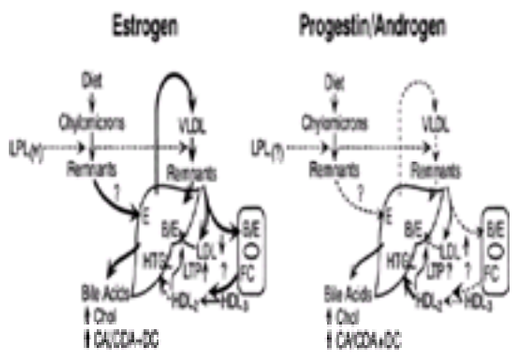

FIGURE 8.3 Effects of sex steroids on lipoprotein metabolism. Width of the lines indicates the rate of cholesterol traffic under the influence of estrogen or progestin/androgen. Question marks indicate effects for which documentation is uncertain or unclear. B/E, low-density lipoprotein receptor; CA, cholic acid; CDA, chenodeoxycholic acid; Chol, cholesterol; DC, deoxycholate; FC, free cholesterol; HDL, high-density lipoprotein; HTGL, hepatic triglyceride lipase; LDL, low-density lipoprotein; LPL, lipoprotein lipase; LTP, leukocyte thromboplastin; VLDL, very-low-density lipoprotein.

Plasma Triglyceride Elevations

Probably the best-recognized effect of estrogen treatment is an increase in plasma triglycerides, one example of which is shown in *e*Table 8.2.1 (74). This effect is great when estrogen is given orally and less when given systemically by injection, patch, or natural ovarian secretion (1,72,73). The increase in plasma triglyceride concentrations is due to an increased hepatic triglyceride secretion in the form of increased entry of VLDL into the circulation. The most extreme, natural, estrogen-dominant condition is pregnancy (75,76).

Estrogen treatment can interact with diabetes or genetic lipoprotein lipase deficiency to cause a marked exaggeration of hypertriglyceridemia that can result in pancreatitis if levels exceed 2,000 mg per dL. The clinical significance is that women given estrogen, especially postmenopausal estrogen, should be checked first for triglyceride elevations. If plasma triglyceride levels are >300 mg per dL, oral estrogen should be withheld. Patch estrogen can be given postmenopausally in this situation because it has little triglyceride-raising effect in the absence of the hepatic first-pass effect (77). The selective estrogen receptor modulator raloxifene can raise triglyceride in such patients, although not in most postmenopausal women (77).

In contrast to estrogen, androgens and androgenic progestins antagonize the effect of estrogen and tend to lower plasma triglyceride levels. For example, an anabolic steroid such as stanozolol or oxandrolone can be used as a last resort in the management of severe hypertriglyceridemia (>2,000 mg per dL) and recurrent pancreatitis, although undesirable effects on LDL and HDL may result. An example of an anabolic steroid effect is shown in *e*Table 8.2.2 (78).

Remnant Lipoprotein Metabolism

Remnant lipoproteins are the product of the removal of triglyceride from chylomicrons and VLDL, as pictured in Figure 8.3. Hepatic LDL receptors recognize remnants by the presence of apoprotein E3 or E4 on the surface of the particle. Without this recognition, remnant removal disease, or type III hyperlipidemia, ensues. Because estrogen upregulates the LDL receptor, estrogen may correct remnant removal disease (1,74). Unfortunately, clinical experience indicates that estrogen-using hypertriglyceridemic women may present with remnant removal disease. This apparent discrepancy reflects the dual etiology of type III hyperlipidemia, which involves excessive entry of VLDL into the circulation and impaired remnant removal. Clinicians need to be alert to the possibility that estrogens may improve or aggravate type III hyperlipidemia.

A second step in the remnant removal process is the removal of triglyceride from the remnant by hepatic lipase (1). Hepatic lipase activity is reduced by estrogen (*e*Table 8.2.1 and *e*Table 8.2.3), causing lipoproteins in pregnancy, oral contraception, and postmenopausal hormone replacement to increase in triglyceride content. Clinically, hepatic lipase deficiency looks like remnant removal disease, but estrogen makes it worse, not better. Progestins have the opposite effect to increase hepatic lipase activity—an effect that is associated with increased cardiovascular risk in non–hormone-exposed persons with coronary disease (79).

Adapted from Knopp RH, Zhu X, Bonet B. Effects of estrogens on lipoprotein metabolism and cardiovascular disease in women. *Atherosclerosis* 1994;110:S83–S91.

Low-Density Lipoprotein Metabolism

Decreased LDL-C concentrations with estrogen treatment are greatest with orally administered estrogen formulations due to increased LDL receptor activity. LDL reduction with patch formulations is due less to the lack of the first pass of estrogen through the liver that is associated with oral hormone administration.

Typical estrogen replacement doses are 0.625 mg of equine estrogen (Premarin) or 17b-estradiol (Estrace) 1 or 2 mg daily, both orally. Typical patch doses are Estraderm or Vivelle, 50 or 100 µg changed every third day; Climara, 50 or 100 µg changed every seventh day; or sublingual Estrace for women with patch sensitivity (see the section Clinical Advice). Costs range from $15 to $25 per month or more. Oral administration of estrogen replacement therapy appears to be preferable to patch or systemic administration for effects on LDL and HDL (see the section Postmenopausal Sex Steroid Hormone Effects on Lipoproteins, Carbohydrate Metabolism, and Clotting). However, oral estrogen can exaggerate hepatic synthesis of many other proteins, including VLDL and clotting factors. Thus, patch estrogen, which mimics the systemic entry of ovarian estrogen, may be preferable.

In contrast to estrogens, high-dose androgens increase LDL-C by diminishing the LDL receptor activity (*e*Table 8.2.2 and *e*Table 8.2.3). If the androgen is testosterone, which is partly converted to estradiol by tissue aromatases, no effect is seen on LDL levels (73).

Lipoprotein(a) Metabolism

Lp(a) is associated with LDL and exaggerates its inherent atherogenicity. Lp(a) is a nonfibrinolytic plasminogen homologue that is carried on LDL apoprotein B, thereby forming Lp(a) (40,43). Estrogen reduces Lp(a) levels in moderate to high doses (72,73). The selective estrogen receptor modulators raloxifene and tamoxifen also lower Lp(a) (72,73,77). Even more paradoxically, Lp(a) also is lowered by androgens (73).

High-Density Lipoprotein Metabolism

A well-known effect of estrogen is to increase plasma HDL cholesterol (HDL-C) concentrations—an example of which is shown in *e*Table 8.2.1. The HDL-C increase is confined to the more buoyant, lipid-rich HDL(2)-C. HDL(3)-C concentrations are unchanged. Because HDL(2)-C is also selectively increased with hygienic measures such as exercise, it was originally thought that HDL(2)-C was the only beneficial fraction of HDL-C. This conclusion no longer appears to be valid, but an increase in HDL(2)-C is associated, nonetheless, with a reduction in CVD risk. The increase in HDL(2)-C concentration is due to an increase in apoprotein A-I secretion from the liver and a reduction in hepatic lipase-mediated uptake of HDL(2)-C and phospholipid—quantitatively the two most important HDL lipids.

Cholesterol from HDL can also be recycled back to LDL and VLDL, where it is made available again to cells by the plasma enzyme that accomplishes this process: lipid transfer protein, which is estrogen dependent. With estrogen also reducing hepatic cholesterol uptake by a decrease in hepatic lipase activity, the overall effect is to enhance cholesterol transport and recycling in the bloodstream (see references 1, 72, and 73 for reviews). The effects of sex hormones on lipoprotein metabolism are summarized in *e*Table 8.2.3.

VASCULAR EFFECTS OF GONADAL STEROIDS

Some animal studies of estrogen effects on lipoprotein levels in plasma show little impact on the extent of atherogenesis and suggest that direct arterial wall effects of estrogen are more important (80). Whether this observation applies to humans is doubtful, but it is clear that estrogen has direct arterial wall effects. These effects include diminished penetration of arterial wall by LDL (80), diminished arterial wall LDL retention (81), and diminished inflammatory response (82) involving a diminished cytokine release and generation of inflammatory response molecules in arterial endothelium and intima-media (see reference 83 for review and Figure 8.4).

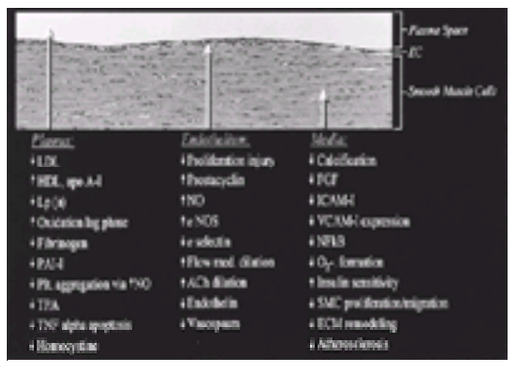

FIGURE 8.4 Beneficial effects of estrogen on arterial wall biology. In this scenario, estrogen-mediated events in plasma, endothelium, and intima-media are beneficial to the arterial wall. ACh, acetylcholine; apo, apoprotein; EC, epidermal cell; ECM, extracellular matrix; eNOS, endothelial nitric oxide synthase; FGF, fibroblast growth factor; HDL, high-density lipoprotein; ICAM-1, intercellular adhesion molecule-1; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); NFkB, nuclear factor kappa B; NO, nitrous oxide; PAI-1, plasminogen activator inhibitor-1; Plt, platelet; SMC, smooth muscle cell; TNF, tumor necrosis factor; TPA, tissue plasminogen activator; VCAM-1, vascular cell adhesion molecule-1.

Some of these effects may be related to the antioxidant effect of estrogen, a non–receptor-mediated effect of estrogen believed to inhibit atherogenesis (83). Alternatively, estrogen effects may be mediated via genomic or nongenomic effects on estrogen receptors or macrophages and arterial walls (84,85). Importantly, estrogen receptors are found in diminished amounts or are absent in areas of atherosclerosis, which may explain the lack of vascular benefit from estrogen in recent clinical trials (86) (see the section Effects of Postmenopausal Hormone Use on Coronary Disease).

A moment-to-moment effect of estrogen increases endothelial nitric oxide synthase activity, nitric oxide generation, and vasodilation. This effect can reverse the paradoxical vasoconstrictor response to acetylcholine in arteriosclerotic arteries (87) (*e*Table 8.2.3 and Fig. 8.5). In fact, estrogen administration can reverse clinical vasospasm within minutes and may be a useful treatment in cardiologic syndrome X (88,89). Some of this benefit may also be due to the antioxidant effect of estrogen, which may slow the rate of oxidative destruction of endothelial nitric oxide (1,72,88,89 and 90). In addition, estrogen is associated with lower plasma levels of the vasoconstrictor endothelin (91). Surprisingly, testosterone and other androgens also have a vasodilatory effect in healthy arteries that is mediated directly and by an acetylcholine mechanism (92,93).

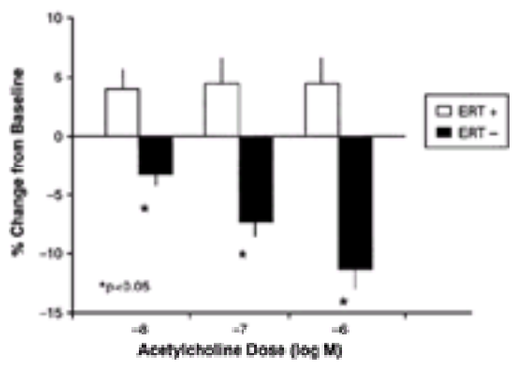

FIGURE 8.5 Mean percent change in coronary diameter after graded doses of acetylcholine. Vertical lines indicate standard error of the mean. Actual *p* values for comparison of estrogen replacement therapy (ERT)+ versus ERT– for each dose of acetylcholine are .03, .001, and .0004, respectively. (From Herrington DM, Braden GA, Williams JK, et al. Endothelial-dependent coronary vasomotor responsiveness in postmenopausal women with and without estrogen replacement therapy. *Am J Cardiol* 1994;73:951–952, with permission.)

Most recently, vasoconstrictive effects of progestins on arterial vasomotion have been reported (94), and medroxyprogesterone acetate (MPA) has been reported to abolish the antiatherosclerotic effect of estrogen in cholesterol-fed monkeys and rats (95,96). Testosterone and one androgenic progestin also promote atherogenesis in cholesterol-fed monkeys (97). We have found that progestins and androgens also have a weak prooxidant effect and oppose the antioxidant effect of estrogen (98).

Another way in which sex hormones affect arterial wall physiology is through the arterial wall–prostaglandin system, which can favor vasoconstriction and platelet aggregation if thromboxane formation is dominant and vasodilation and diminished platelet aggregation if prostacyclin is dominant. Consistent with its effects on nitric oxide metabolism and probably arterial wall redox state, estrogen favors prostacyclin dominance, whereas testosterone favors thromboxane formation, diminishes prostacyclin formation, and enhances platelet thromboxane receptor binding on platelets (see reference 93 for review). Again, the estrogen-androgen antagonism is borne out in another physiologic system.

In summary, ample evidence exists for the presence of estrogen receptors in healthy arterial walls and direct, almost moment-to-moment regulation of endothelial nitric oxide generation, vasomotion, arterial wall LDL penetration and metabolism, and underlying inflammatory response. Whether these effects are all estrogen receptor–mediated is unknown, but the fact that progestin and androgen can oppose some of the effects suggests receptor-mediated mechanisms.

ORAL CONTRACEPTIVE STEROID EFFECTS ON LIPOPROTEIN METABOLISM AND ATHEROGENESIS

The antagonism between estrogenic and progestogenic-androgenic effects on lipoproteins is played out in the three generations of OCs. The first generation contained high doses of estrogens and progestins, of which some were androgenic and some were not. Thus, some OCs were estrogen predominant with high triglyceride, high HDL-C levels, and normal LDL-C levels, whereas the progestin-androgen–dominant form had lower triglyceride, higher LDL-C levels, and lower HDL-C levels, consistent with antagonism of the two hormone classes described above.

The second-generation formulations showed less marked effects on triglyceride, LDL-C levels, and HDL-C levels, although the estrogen-versus progestin-androgen–mediated differences could still be seen. The third-generation pills now in use are associated with normal LDL-C levels and increased HDL-C levels and are believed to be estrogen dominant. As a result, triglyceride elevations of 30% to 40% are still seen. As mentioned above, a tendency to venous thrombosis (99) persists, but diminished risk from arteriosclerosis may be attained (100). In addition, estrogen-progestin balance affects insulin sensitivity and clotting factor levels (101), with estrogen dominance favoring insulin sensitivity and a reduction in plasma fibrinogen levels (101).

The main point is that OC steroids, depending on their composition, can affect several arteriosclerotic risk factor axes. It makes good sense for women taking OCs to have their lipoprotein and glucose levels checked at least once after starting because not all women respond the same, and sometimes the hormone-induced changes in lipoproteins can be marked. It also makes sense for women using OC steroids to manage aggressively concomitant heart disease risk factors.

ORAL CONTRACEPTIVE USE AND CARDIOVASCULAR DISEASE RISK

Shortly after the introduction of oral contraception in the early 1960s, a flurry of reports appeared of venous thrombosis and stroke among OC users. In light of today's experience, the occurrence of venous thrombosis is not surprising because the earliest OCs contained between 100 and 150 µg of ethinyl estradiol, which is approximately 20 to 30 times the postmenopausal replacement amount! Reports of an excess of coronary artery disease among OC users appeared in 1975, in which British epidemiologists found an approximately threefold excess of coronary disease among OC users (102,103). Most importantly, these researchers found that a basic tenet of the risk factor theory of arteriosclerosis applied to women and OC users, with single risk factors increasing coronary disease risk approximately threefold and combinations of risk factors increasing risk geometrically (102,103).

The doses of OC estrogen have declined over the ensuing decades to 20 to 35 µg daily of ethinyl estradiol, which is approximately 1.3 to 2.0 times postmenopausal replacement levels. Even at these doses, venous thrombosis still occurs (100) and may actually be somewhat promoted by the reduced androgenicity of certain third-generation OCs; this androgenicity allows the formulation to be more estrogenic, even though the estrogen dose is unchanged (101). The preferred initial formulations contain 35 µg of ethinyl estradiol and 0.250 mg of norgestimate (Ortho-Cyclen) or 0.250 mg of desogestrel and 30 µg of ethinyl estradiol (Ortho-Cept). The triphasic form of Ortho-Cyclen contains less progestin (0.180, 0.215, and 0.250 mg weekly). Other formulations containing less ethinyl estradiol or stronger progestin can be used—depending on gynecologic symptoms or requirements—such as Alesse 21 or 28 (20 µg ethinyl estradiol and 100 µg levonorgestrel).

Several studies in the mid- and late 1980s have verified the earlier epidemiologic surveys that show that, even with lower estrogen–dose OCs, the risk of coronary disease in a cigarette-smoking OC user is increased approximately 20- to 30-fold from baseline and approximately six- to eightfold above the risk of cigarette smoking alone for coronary disease (104,105). The data of Croft and Hannaford in *e*Table 8.2.4 (105) and Rosenberg et al. in Figure 8.6 are representative of the danger of combinations of risk factors for MI, even in young women (104).

***e*TABLE 8.2.4** RELATIONSHIP OF SMOKING TO MYOCARDIAL INFARCTION (RELATIVE RISK)

	Oral contraceptive use		
	Never	Former	Current

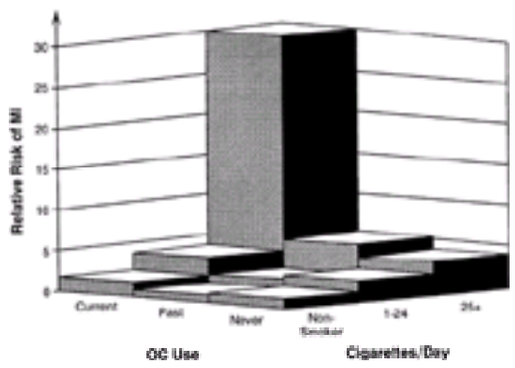

FIGURE 8.6 The effect of smoking and oral contraceptives (OCs) on the risk of myocardial infarction (MI) in women younger than 50 years. (Adapted from Rosenberg L, Kaufman DW, Helmrich S, et al. Myocardial infarction and cigarette smoking in women younger than 50 years of age. *JAMA* 1985;253:2965.)

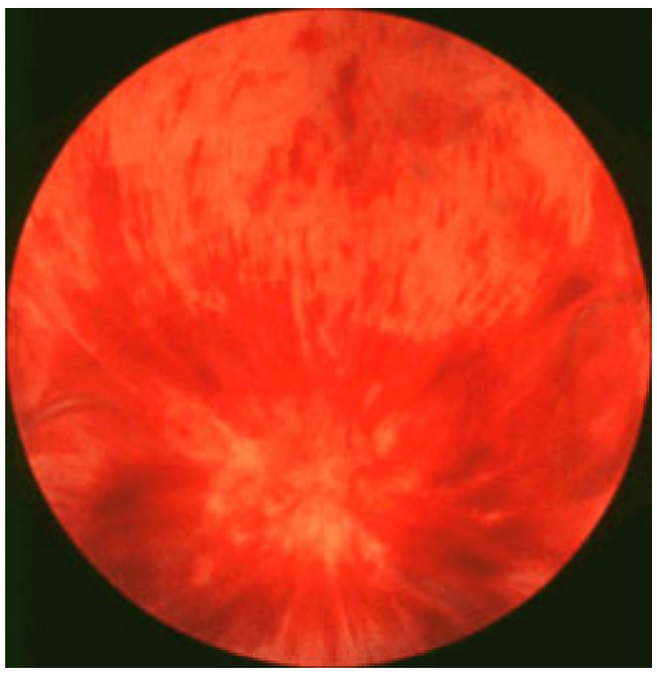
The pathophysiologic mechanism for the increased risk for CVD with high- and mid-dose estrogen pills, especially with smoking, probably reflects the propensity for thrombosis at a site of arterial wall injury such as an endothelial erosion. Such erosion might arise from a toxic effect of cigarette smoke, smoke-induced depletion of antioxidant defenses, or enhanced LDL oxidation in the absence of major atherosclerosis. On the other hand, arteriosclerotic plaque rupture and thrombosis (106) and advanced arteriosclerotic disease (107) have been reported among OC users; this seems to be the situation in the case presented in the introduction to this chapter.



Retinal vein occlusion. There is severe venous congestion with an extensive exudate. The optic disc is nearly completely obscured.

Young women with high degrees of CVD risk should avoid the use of OCs, especially after the age of 35 years, unless the risk factors can be modified. It is the standard of clinical practice that OCs not be prescribed to cigarette-smoking women who are older than 35 years. A schema that takes this and other risk factors into account as a function of initial LDL-C is presented in *e*Table 8.2.5, which is modeled on the NCEP guidelines (108). The important message is that CVD risk factors must be considered seriously when prescribing OCs and that every woman should have her lipid profile checked when OC use is contemplated and then instituted. CVD risk factors in women are summarized in Table 8.2. Obviously, venous thrombosis due to an estrogen-containing OC is a separate contraindication to continued use of the drug. In the case mentioned in the introduction, the combination of cigarette smoking, OC use, and severe combined hyperlipidemia was nearly lethal, even at age 25 years. Had the patient's lipids been checked before OC use, her high-risk status might have been appreciated.

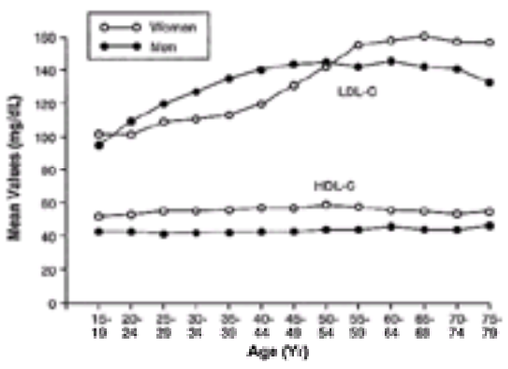
EFFECTS OF HRT ON LIPOPROTEINS

LDL-C levels are higher in postmenopausal women than in younger women—a condition likely due in part to the absence of endogenous estrogen (1,72,73) (*e*Fig. 8.6.1). When women have been studied through menopause and estrogen deficiency develops, the LDL-C level increases by 12.0 mg per dL (0.31 mmol), and HDL-C decreases by 3.5 mg per dL (0.09 mmol) (109). These differences reflect the absence of endogenous ovarian estrogen secretion into the systemic circulation. It is also noteworthy that plasma insulin, glucose, and body weight all increase more in women becoming menopausal than in those not becoming menopausal; this is consistent with a loss of insulin efficacy (discussed earlier).



***e*FIGURE 8.6.1** Lipoprotein cholesterol fractions and age trends in women and men. HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol. (Adapted from Kannel WB. Nutrition and the occurrence and prevention of cardiovascular disease in the elderly. *Nutr Rev* 1988;46:68–78.)

When hormone users are compared to nonhormone users, estrogen treatment raises the HDL-C level as much as 8 mg per dL (0.2 mmol). Compared to the smaller difference associated with menopause, the greater difference with hormone replacement may be due to higher doses of estrogen or to the oral route of administration. The Postmenopausal Estrogen-Progestin Intervention trial showed a 6-mg-per-dL (0.16-mmol) HDL-C increase above control in women given 0.625 mg of Premarin daily, as shown in *e*Table 8.2.6 (110). Premarin given with MPA (10.0 mg given cyclically or 2.5 mg given continuously) resulted in HDL-C increases to 1.6 and 1.2 mg (0.04 and 0.03 mmol) above baseline, respectively. Most interestingly, when micronized natural progesterone was given cyclically with Premarin, the Premarin effect on HDL-C was almost entirely preserved (5 mg per dL or 0.13 mmol increase above baseline). On the other hand, all of the postmenopausal hormonal formulations examined were associated with reductions in LDL-C concentrations of approximately 14.5 to 17.5 mg per dL (0.37 to 0.45 mmol) without any distinctions among the groups. Finally, the triglyceride elevations were minor, ranging from 11.4 to 13.7 mg per dL (0.13 to 0.15 mmol), and less than the triglyceride elevations associated with oral contraception.

In the Postmenopausal Estrogen-Progestin Intervention study (*e*Table 8.2.6), plasma glucose and insulin levels were lowest with estrogen alone and highest with high-dose progestin plus estrogen (110). Thus, the antagonism of estrogen and progestin on carbohydrate metabolism is seen with postmenopausal hormone replacement, as with OC steroids of varied composition.

The estrogen-progestin antagonism is also seen in the levels of clotting factors. Fibrinogen concentration is diminished among postmenopausal estrogen users, as with OC users (101), despite lower doses. Addition of natural progesterone or increasing doses of Provera (MPA) oppose these effects. Although the range of these effects is small, the data indicate that progestins can oppose the effect of estrogen on the clotting system. Recent work from our own laboratory indicates that progestins are prooxidants, opposing the antioxidant and anticytotoxic effects of estrogen (83,98).

An unexpected effect of estrogen—increased CRP levels—has been seen in several studies (111). This increase is said to drive an increase in activity in the complement pathway and favor inflammatory processes (112), and it may explain the strong predictive effect of CRP on atherosclerosis in women (47).

EFFECTS OF POSTMENOPAUSAL HORMONE USE ON CORONARY DISEASE

More than 30 case-controlled and prospective cohort studies have been performed over the last 20 years comparing arteriosclerotic vascular disease in estrogen users versus nonusers (1,72,73,113,114 and 115). These studies indicate that the incidence of coronary artery disease among estrogen users is approximately one-half of that among nonusers. Even before the recent negative clinical trials of estrogen efficacy on heart disease, it was postulated that the putative estrogen benefit was due in part to a “healthy user effect” (i.e., healthier women use estrogen). Barrett-Connor and associates (113) estimated that 50% of the lower rate of coronary artery disease among estrogen users might be ascribed to this selection bias.

Nonetheless, it was a great surprise that the Heart and Estrogen/Progestin Replacement Study (HERS) showed no benefit of equine estrogen (Premarin) 0.625 mg plus MPA (Provera, Cycrin) 2.50 mg continuously versus placebo (116). The results showed a hazard ratio of 0.99 with 95% confidence interval (CI) of 0.80–1.22, p = .91. Various CVD subgroups showed no significant differences with hormone replacement, but the number of subjects with unstable angina tended to be fewer with estrogen, whereas the number of individuals with CHF or cardiac death tended to be greater with estrogen (*e*Table 8.2.7). Because unstable angina involves plaque rupture and nonocclusive thrombus formation, it is hard to argue that the lack of overall benefit from estrogen was due to an enhanced susceptibility to thrombosis. It seems that the sicker or more vulnerable persons were at slightly greater risk from estrogen plus progestin therapy.

[c]Primary CHD events include nonfatal myocardial infarction and CHD death.
From Hulley S, Grady D, Bush T, et al. Randomized trial of estrogen plus progesterone for secondary prevention of coronary heart disease in postmenopausal women. *JAMA* 1998;280:605–613, with permission.

Contrary to popularly held view, equine estrogen plus MPA was without benefit over the entire course of the study, particularly concerning CHD death (Fig. 8.7). Only in a secondary hypothesis-generating analysis was a downward trend detected in nonfatal coronary events, but this analysis included an adverse trend of excess nonfatal CHD events in the first year (116). The results of a HERS follow-up study will be reported in late 2001 and will address the questions of whether the downward trend in CHD events among hormone users continued after the conclusion of the main trial. At present, the conclusion is that coronary disease is not prevented by estrogen among older women (average age, 67 years) with established heart disease (116).

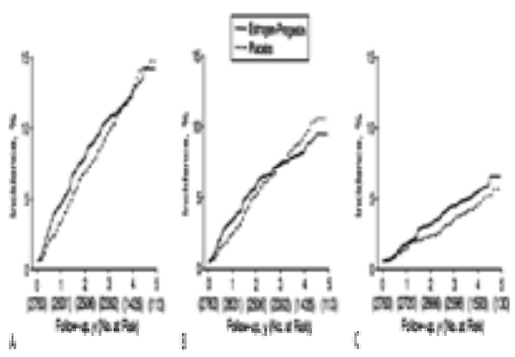

FIGURE 8.7 Heart and Estrogen/Progestin Replacement Study Kaplan-Meier curve estimates of the cumulative incidence of primary coronary heart disease and its constituents. **A:** All events. **B:** Nonfatal events. **C:** Fatal events. Numbers in parentheses are subjects followed to each time-point. Curves are fainter where the sample size falls to less than one-half of the original cohort. (From Hulley S, Grady D, Bush T, et al. Randomized trial of estrogen plus progesterone for secondary prevention of coronary heart disease in postmenopausal women. *JAMA* 1998;280:605–613, with permission.)

A similar negative result was observed on angiographically quantified coronary atherosclerosis after 3.2 years in 309 women randomized to placebo, 0.625 mg equine estrogen alone, or with 2.5 mg medroxyprogesterone acetate daily in the Estrogen Replacement Atherosclerosis trial (117). Again, these were women with established coronary disease, with mean ages ranging from 65.6, 66.3, and 65.5 years, respectively, in the three groups. Minimum coronary diameter change and change in percent stenosis were indistinguishable in the equine estrogen and placebo groups and slightly worse with the equine estrogen plus MPA group (Table 8.3).

				p values

TABLE 8.3 EFFECTS OF POSTMENOPAUSAL HORMONE REPLACEMENT ON CORONARY LUMEN DIAMETER[a]

Possible reasons why neither the HERS nor the Estrogen Replacement Atherosclerosis studies were successful are listed in Table 8.4. These reasons range from too high an estrogen dose in older, estrogen-naïve women to an inflammatory effect of CRP. Not listed among these possibilities is an enhanced sensitivity to arterial thrombosis, because unstable coronary syndromes that are thrombotic in nature tended to be *less* frequent in the HERS hormone-treated group. Other possibilities include an adverse effect of progestin. In animal models, MPA completely blocks the cardioprotective effect of estrogen (95,96), and estrogen seems to be without benefit in animals who have been fed cholesterol and have established atherosclerosis (118,119).

The observational case-control and cohort studies are wrong and do not control for the "healthy user" effect (i.e., there may be no real benefit).
C-reactive protein is increased with estrogen and *may activate* complement and inflammatory response.
Estrogen receptors are reduced or absent in arteriosclerotic tissue.
Estrogen prevents atherosclerosis only in early animal models of atherosclerosis and not established disease.
The progestin opposes diverse effects of estrogen, possibly those that may benefit the arterial wall.
Too high an equine estrogen dose was given too late in secondary prevention studies in menopausal women (late 60s).
Estrogen appears to aggravate cardiovascular risk factor effects, whereas "statins" as an example yield extra benefit in women with high risk.
The oral estrogen route induces first pass effects on hepatic protein synthesis, including lipid and clotting effects; this route is not the systemic ovarian route and may actually diminish effective systemic estrogen delivery.

TABLE 8.4 REASONS WHY ESTROGEN MAY NOT PREVENT CORONARY DISEASE IN RANDOMIZED CLINICAL TRIALS

Another argument against arterial thrombosis being a factor in the negative HERS trial results is the rather low occurrence of venous thrombosis in the hormone-treated groups: 25 versus 8 cases in the placebo group and pulmonary embolism in 11 cases in the hormone-treated group versus 4 in the placebo group for totals of 34 and 12, respectively. These totals are well below the 172 and 176 primary CHD events in the two groups, respectively. Whereas these totals are low relative to coronary disease events, the approximately threefold increased rate of venous thrombosis is similar to that reported recently in a number of observational studies of postmenopausal estrogen use (120,121,122 and 123).

Notwithstanding the above data, Psaty et al. have reported association between a prothrombin polymorphism (20210 G→A) and first MI in hormone-treated postmenopausal women who are hypertensive (124). However, the patients are relatively few. Factor V Leiden was not a predictive factor.

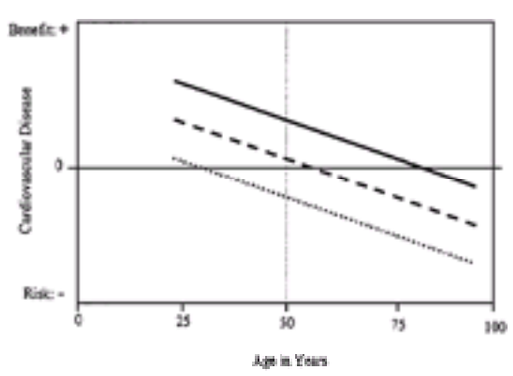
A much longer-term prospective randomized trial of estrogen and estrogen plus progestin replacement therapy is being conducted by the Women's Health Initiative in at least 40 centers nationwide. The larger number of 40,000 to 50,000 subjects is required because of the lower incidence of coronary disease in a primary prevention setting. This study will be reported in approximately 2004.

Clinical Advice

In the meantime, what do we tell patients? It does not seem possible dogmatically to recommend estrogen replacement therapy to prevent existing coronary disease, given the negative results of two prospective randomized trials. On the other hand, many reasons can be given for offering or suggesting estrogen replacement therapy, including sense of well-being, prevention of osteoporosis, preservation of skin turgor, prevention of senility and even Alzheimer's disease (1,72,73), preservation of vaginal mucosa, metabolic benefits (see below), and higher intellectual function (1,72,73). Most women come to this decision aware of at least some of these benefits and some of the side effects and often have their own well-established viewpoint about whether to take estrogen.

As to androgen effects on human atherosclerosis, more than 20 case reports of coronary artery disease have been documented among athletes taking androgen (125). This clinical experience and the atherogenic effects of androgens in animal models provide evidence against the use of excessive or pharmacologic amounts of androgen in young athletes and provides evidence for minimizing the exposure to androgenic progestins in hormone replacement and OC therapy.

The most frequently prescribed dose of postmenopausal estrogen replacement therapy is equine estrogen (Premarin) 0.625 mg daily. Whether generic equine estrogen is equivalent in the 8 to 10 estrogenic steroids of pregnant mares' urine is hotly debated. Occasionally, 0.9 or 1.2 mg daily of equine estrogens is necessary to control hot flashes in women entering menopause. Doses of 2.5 mg daily of equine estrogens have little or no use and may be associated with MI excess, especially in association with cigarette smoking, as found in the Framingham study—one of the few observational studies in which postmenopausal estrogen replacement was associated with an increased rate of coronary artery disease (126). This effect resembles the increase in coronary disease among men given 2.5 or 5.0 mg of equine estrogen in the Coronary Drug Project (127). These data are compatible with the idea that coronary disease is *worse* with high-dose estrogen and major CVD risk factors, as in the OC experience. Thus, one might predict diminished estrogen benefit or even harm with increasing estrogen dose, older age, and multiple CVD risk factors (eFig. 8.7.1).



***e*FIGURE 8.7.1** Postulated benefit or harm of estrogen on cardiovascular disease (CVD) as a function of age and inherent CVD risk. This hypothetical scenario takes into account the possibility that estrogen benefit diminishes with age (142), increased CVD risk (102,103), and high dose of estrogen with risk factors (102,103,126). Solid line, healthy women; dashed line, women with CVD, multiple risk factors, or possibly adverse progestins; dotted line, women with high-dose estrogen and risk factors for CVD.

Alternatives to equine estrogens are pure 17b-estradiol (Estrace), which is given in 1- to 2-mg-per-day doses, or estropipate (Ogen), which is estrone sulfate given in

doses ranging from 0.75, 1.50, or 3.00 mg daily (Ogen: 0.625, 1.250, or 2.50 mg). Ogen does not appear to be quite equivalent to equine estrogen, and doses higher than 0.75 mg daily may be needed to relieve flushing symptoms.

When women have oral intolerance to estrogens or have a metabolic contraindication (chiefly hypertriglyceridemia), then systemically administered estrogen is indicated by one of three routes: patch, injection, or sublingual. There are 3-day patches in the form of 50- or 100-µg doses of Estraderm or Vivelle or 7-day patches of Climara in 50 or 100 µg delivered daily. Most women prefer the longer duration patch, but, often, use is dictated by sensitivity to the patch adhesive. In this respect, Vivelle may be better tolerated. When no patch can be tolerated, sublingual estrogen in the form of Estrace (1 mg) is a viable alternative or 17b-estradiol valerate in oil (10 to 20 mg intramuscularly), although injectable preparations do not yield an even blood level over a month's time. Side effects of estrogen are most typically breast tenderness and, possibly, pelvic fullness. In postmenopausal women, and especially in elderly women, lower doses of estrogen are advisable to start (e.g., 0.3 mg of equine estrogen daily or every other day) to avoid these symptoms. Another advantage of patch estrogen is that a higher systemic dose can be obtained with better control of symptoms than the oral route, in which hepatic inactivation can limit symptom control.

Estrogen can be used without a progestin only in women without uteri. All other women require progestin in some form. The most popular form is 2.5 mg of MPA (Provera, Cycrin, or the combination formulation Prempro) given continually. This regimen is associated with vaginal spotting and bleeding in more than 50% of users during the first months of treatment and does not decline to a few percent until after 24 to 36 months of use. The unpredictability of this bleeding is the most troublesome aspect for older women. Cyclic progestin given 12 days out of each month can produce vaginal bleeding on a predictable basis in approximately 50% of the women who resume bleeding, but most women do not want this regimen, and the higher MPA doses of 5 and 10 mg daily have deleterious metabolic effects, as described above. Micronized natural progesterone taken cyclically in doses of 100 to 200 mg daily is an alternative form, as are 1 mg micronized 17b-estradiol with norgestimate (Ortho-Prefest) and 5 mg ethinyl estradiol with 1 mg norethindrone acetate (Femhrt)—a more androgenic progestin.

Side effects of progestins are not negligible and include weight gain, fluid retention, headache, and symptoms resembling premenstrual tension. Fortunately, most women are not bothered by these symptoms, but they can be virtually incapacitating when these symptoms are present. Oral progestin can be given with estrogen by any route. An alternative to oral progestin is Depo-Provera administered intramuscularly.

DEHYDROEPIANDROSTERONE

The adrenal and ovarian androgen precursor dehydroepiandrosterone (DHEA) has a divergent association with arteriosclerotic disease, depending on gender. In men, it has been shown that DHEA levels decline with age and are lower in subjects prone to coronary artery disease (128). On the other hand, female subjects with higher DHEA levels are obese and have overproduction of testosterone by the ovary, insulin resistance, and PCOS (65,66,129)—all markers of increased CVD risk in women. At the very least, in female subjects, DHEA seems to be a marker of the insulin resistance syndrome, which is associated with ovarian dysfunction, or it could be a risk factor in its own right as an androgen precursor. In contrast, DHEA may actually be beneficial to male subjects. When DHEA is given to animal models fed cholesterol, it prevents arteriosclerotic progression (73).

The clinical implication of these observations is that DHEA may protect against arteriosclerosis, at least in men. However, this hypothesis requires much more research and does not justify the almost black-market commerce in DHEA use.

CHOLESTEROL-LOWERING INTERVENTIONS AND REDUCTIONS IN CORONARY ARTERY DISEASE IN WOMEN

Diet

As mentioned earlier, some studies have found a diminished effect of diet on LDL-C and HDL-C levels in women compared to men. However, in a recent study of the largest group of free-living men and women studied to date, LDL-C lowering was equivalent in men and women, but the HDL-C lowering was greater in women (6% to 7%) than in men (1% to 3%)—even after 6 to 12 months, when the acute HDL-lowering effects of diet had worn off (70,71). These percentage differences are small in the aggregate but could be meaningful for atherosclerotic risk among individuals with marked HDL-C reductions. Monounsaturated fat supplementation is under investigation as a means to minimize this HDL-C decrease. The new NCEP guidelines favor a 35% fat diet, with only saturated fat restriction (71a).

Drug Therapy Efficacy

LDL-C reductions are at least as good in women as in men with heterozygous familial hypercholesterolemia treated with reductase inhibitor, niacin, and bile acid–binding resin. In the author's clinical experience, familial hypercholesterolemic women are more often successfully managed with single lipid-lowering agents (almost always reductase inhibitors) than are men, who often require combination therapy. The better response in women is not understood but could relate to lesser body mass.

Arteriosclerosis Prevention and Regression

In keeping with the usually good response of women to lipid-lowering drugs and equivalent LDL-C response to diet, studies of angiographic regression and heart disease prevention also show better responses in women than in men. In the SCOR study, the angiographic response of coronary arteries to lipid lowering in familial hypercholesterolemic women and men was analyzed in response to combination therapy (9). At baseline, the mean percent coronary artery stenosis was approximately 48% in women and 55% in men at equivalent ages (40 to 43 years), reflecting the later onset of disease in women. The angiographic improvement after several years of triple-drug therapy (reductase, resin, and niacin) was also greater in women (–2.1%) compared to men (–0.9%) (negative signs connote vessel enlargement). These were the first data to show that lipid-lowering treatments were as good as or better in women compared to men in attaining angiographic arteriosclerosis regression.

The prevention of clinical manifestations of coronary disease in men and women in the recent CARE study confirm and extend the angiographic study (130). In this investigation, a greater percentage of reduction in coronary artery disease was observed in women (46%) compared to men (20%) at equivalent doses (40 mg daily) of the reductase inhibitor pravastatin. The better preventive effect in women may be related to a less advanced stage of disease, to a greater LDL-C reduction, to a fixed reductase inhibitor dose, or to other inherent biologic differences. It is known that arteriosclerotic plaques in women are less fibrotic and contain more lipid-filled foam cells (131), implying greater potential for reversibility but also potentially greater vulnerability for plaque rupture and thrombosis. The main point is that impaired responsiveness to therapy cannot be used as a reason not to treat women at high risk for arteriosclerotic vascular disease.

Lipid Screening Guidelines for Hyperlipidemic Women

Based on the lack of association between coronary artery disease mortality and total plasma cholesterol levels in pooled epidemiologic surveys and the low CVD mortality rates of women before the menopause (132), it has been recommended by some that cholesterol screening not be done in premenopausal women unless a family history of coronary artery disease is present (133). In keeping with the lower expectation of coronary disease events and mortality, the previous NCEP recommendation was that premenopausal women be treated with lipid-lowering agents only if the LDL-C is >220 mg per dL, which means usually that only women with heterozygous familial hypercholesterolemia are candidates for treatment before menopause. Fortunately, the ATP-III guidelines remove this language (71a).

Additional factors must be kept in mind regarding the above guidelines. With respect to screening, other issues are in play besides CVD risk in women. One needs to know whether plasma triglyceride levels are elevated in the context of using sex hormones—either for oral contraception in the reproductive years or for therapy as ovarian function wanes, even before the menopause. In addition, combined hyperlipidemia is a real threat for coronary disease in middle-aged women (see the section Cardiovascular Disease Risk Factors in Women Compared to Men). This condition is now prominently addressed in the NCEP ATP-III guidelines (71a). Finally, it seems that knowing one's lipid profile is an important piece of basic health information that can influence one's health practices such as diet and exercise. Given these arguments, a triglyceride cholesterol, HDL-C, and calculated LDL-C measurement seems as reasonable to obtain as a hematocrit, urinalysis, blood pressure, or physical examination and is appropriate for all general health evaluations. Fortunately, the ATP-III guidelines recommend a full lipid panel in all initial screenings (71a).

Lipid-Lowering Treatment Guidelines

The NCEP guidelines for lipid lowering specify that risk factors apply equally for men and women—except for family history, in which, in contrast to men younger than 55 years, CVD under age 65 in a female relative is considered to be premature and a risk factor (71a). Likewise, age as a risk factor is later in women (age 55 years) than in men (age 45 years). Formerly, male gender was a risk factor at any age, but this guideline no longer applies. Finally, an unwritten difference exists in the application of the HDL-C <40 mg per dL rule as a risk factor. Because women have a mean HDL-C of approximately 55 mg per dL and men have a mean HDL-C of 45 mg per dL, fewer women qualify for low HDL-C as a risk factor than men. Similarly, more women qualify for subtracting one risk factor on the basis of HDL-C >60 mg per dL, yielding a significant number of women in population surveys (especially premenopausally) having a risk factor total of –1. Otherwise, the less than 160-, 130-,

and 100-mg-per-dL LDL-C target values apply equally to men and women, with the gender differences in risk being embodied in the risk factor assessments.

Gender Differences in Drug Treatment

Bile Acid–Binding Resin

Most patients object to the gustatory, upper gastrointestinal, and constipating side effects of bile acid–binding resin. Based on common sense, perhaps the most important point to keep in mind is that when resin is necessary, lower doses might be tried in women compared to men because of a woman's smaller size. Bile acid–binding resin tablets in the form of colestipol, although large, offer a somewhat more palatable alternative (1 capsule = 1 gm, 4 capsules = one scoop or packet). Recently, colesevelam (WelChol) has become available, which is the first well-tolerated, high-affinity bile acid–binding resin.

Niacin

In addition to the usual flushing, side effects of niacin include acanthosis nigricans, ichthyosis, thickening of the skin, and, more subtly, winter dryness. Most of these skin symptoms are more poorly tolerated in women than in men. Apart from scrubbing with pumice, there is no good solution except to tailor the dose to the level of tolerable side effects. Clinical experience indicates that lower doses of 1 to 2 gm daily are worthwhile because a beneficial effect on HDL and triglyceride levels can still be obtained at these doses, whereas the need for LDL-C lowering can be met by adding reductase inhibitor agents in combination. The tendency for plasma glucose levels to rise with niacin therapy does not have a known gender specificity, nor does it have a direct deleterious effect unless it provokes frank diabetes (134).

Fibric Acid Derivatives

Fibric acid derivatives are almost essential in the management of hypertriglyceridemia associated pancreatitis (>1,000 to 2,000 mg per dL). Whether these agents cause cancer in humans is moot in male subjects, and studies in women are lacking. More clear is the tendency of all fibrates to increase gallbladder bile saturation with cholesterol and cause gallstones (134). Because overweight, middle-aged women are more prone to this condition, gallstone disease from fibrate use adds to the reasons to try to find other approaches to high-triglyceride management, which includes weight-loss agents, insulin-sensitivity improvers such as metformin, and weak triglyceride lowerers such as fish oil and a low-fat diet.

Reductase Inhibitors

The largest available study of a reductase inhibitor is the Excel study of lovastatin. Results show a greater degree of lipid lowering in older women (135). As higher doses of reductases are being recommended (134), it may be anticipated that more hepatotoxicity and myotoxicity may occur in women because of their smaller body mass relative to dose than that of men. However, high-dose therapy may not be as necessary in women compared with men.

Reductase and Fibrate Combination Therapy

Myotoxicity is more common among women with impaired renal function who take the combination of gemfibrozil and lovastatin than among men (136). Clofibrate alone is highly myotoxic in renal failure because of its renal elimination. It is no longer manufactured. Gemfibrozil seems less so, but it can also produce myotoxicity under the conditions described above and with the additional potential for rhabdomyolysis and acute renal failure (136).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Postmenopausal Hormone Replacement Therapy

The view is still held by some that all women should be placed on sex hormone replacement therapy postmenopausally and, conceivably, supplemental estrogen premenopausally. Those who hold this view argue that the lipoprotein effects, the direct arterial wall effects, the antioxidant effects, the benefit on vasomotion, and the epidemiologic surveys are sufficient information and that the proposed cardiologic benefit is so great that side effects, some of which could be fatal, such as pulmonary embolism, can be ignored. This line of reasoning is flawed because, according to epidemiologic surveys, the benefit of estrogen may be overestimated by 50% due to the healthy user effect (113), side effects may possibly be underestimated, and clinical trials in women with advanced coronary disease do not show benefit. Younger women may benefit. The take-home message is that estrogen currently cannot be prescribed for CVD prevention with any assurance, especially in women with coronary disease. Nonetheless, I certainly prescribe hormone replacement to women for specific noncardiovascular indications, which are many.

When counseling patients, I tell them what I know, but I also listen to their concerns, fears, and family history, especially when it involves ovarian and breast cancer, venous thrombosis, and heart disease. If a patient declines to use postmenopausal hormone replacement therapy, she may be making the right decision for her! If hormone replacement therapy is initiated, it must be in conjunction with annual gynecologic evaluation, breast examination, and mammography.

Oral Contraceptives and Vascular Health

Over the years, the argument has raged over whether "undesirable" lipoprotein effects of androgenic progestin-dominant OCs have any material effect on the arterial wall. Given the absence of any arteriosclerotic carryover effect of prior OC use on subsequent risk for arteriosclerotic vascular disease, the possible deleterious effects of the progestin have been dismissed, especially in light of animal studies that show no arteriosclerotic effect in conjunction with estrogen administration (72). The reservations about this point of view are as follows: the monkey studies may not apply to humans, and the older, high-estrogen–dose OCs may have been sufficiently estrogen dominant to overcome any arterial wall progestogenic effect. We must recognize that our understanding of the interaction between estrogen and progestin in OCs and metabolic and vascular physiology is developing, as is our understanding of postmenopausal hormone replacement effects. For now, the clinical message is to minimize the estrogen exposure, the androgenicity of the progestin, and the presence of concomitant risk factors. In this context, not measuring a young woman's cholesterol because CVD mortality is not high enough to justify the expense (132,133) overlooks a vast area of biology and pharmacology that is pertinent to women's health. Greater refinement of our knowledge of new third-generation OC effects on vascular health is needed to secure the possibility that these OCs may be noninjurious and even beneficial to the arterial wall.

Future Directions

Clinical trials currently under way will better define the effects of postmenopausal hormone replacement therapy on cardiovascular health in healthy postmenopausal women without heart disease. We can also expect future development of estrogenic compounds that have hybrid or chimeric effects of estrogen and progestin or that only act on certain, but not all, estrogen-sensitive systems (e.g., the selective estrogen receptor modulators). A heart disease prevention study of one of these agents, raloxifene (Evista; 60 mg q.d.), is under way in high-risk women. These specific therapies may eventually be directed to the arterial wall or bone, for instance, without effects on clotting, hepatic lipoprotein production, or breast metaplasia. Knowledge is also developing rapidly in understanding the postreceptor signaling system of the estrogen receptor (137) and the specificities it entails that may eventually be used for pharmacologic benefit.

Female-Male Cardiovascular Disease Issues

As is apparent from the foregoing text, the epidemiology, management, risk predictors, and subsequent morbidities of CVD are incompletely distinguished in women compared to men. Although better descriptions are constantly appearing (17,36,37 and 38), we will never discover a better way to treat CVD in females without listening to and looking for the ways that early CVD presents differently in women than in men. In this regard, the basic skills of the practitioner must be joined with those of the epidemiologist, the clinical trialist, and the clinical and basic researchers to carry this field forward.

CONCLUSIONS

CVD can occur in women of all ages, depending on risk factor burden. The insulin resistance syndrome (syndrome X) appears to be more important as a risk factor in women than in men. Triglyceride and HDL levels are more important in women than in men until late in life, when the relationships are reversed. Because almost every category of CVD carries worse morbidity and mortality in women compared to men, it seems very important to use every means at hand to prevent its occurrence. The interplay of estrogen and progestin bears on this issue in all stages of life and has to be considered, along with all other cardiovascular therapies.

In general, estrogen at replacement hormone–dose levels is associated with a favorable effect on lipoprotein metabolism, arterial wall penetration of LDL, insulin

sensitivity, and plasma glucose concentrations; some clotting factors and progestins oppose these effects (138,139,140 and 141). The best available information from clinical trials is that estrogen is without cardiovascular benefit in women with established heart disease. It remains to be seen if estrogen or its selective estrogen receptor modulator relatives will have benefit in a primary prevention setting in younger women or those without heart disease.

Caution is also advised for clinicians giving estrogen in any case in which the patient has underlying hypertriglyceridemia or a history of thrombosis. Should hypertriglyceridemia result from estrogen administration or if the patient has a baseline plasma triglyceride level >300 mg per dL (3.38 mmol), an estrogen-patch regimen should be used as an alternative.

With the recent growth in understanding of the effects of sex steroid hormones on many body functions and of the many differences between the genders in arterial physiology and pathophysiology, there is an excellent prospect that this knowledge can be used to minimize coronary disease in both men and women if the undesirable side effects can be avoided.

THE FUTURE

The following statements are as much hopes as predictions. First, physicians and caregivers will remember that coronary disease and arteriosclerotic vascular disease are the most prevalent causes of death in women as well as in men but that the symptomatologies and presentations are likely to differ. Second, physicians and caregivers will have the patience to let patients tell us the story as they see it, so that we can better appreciate and describe the male-female difference and treat appropriately. The third expectation is that ongoing clinical trials will further refine the nature and extent of the heightened vulnerability of women for certain morbidities associated with coronary disease. The fourth expectation is that we will learn the reasons for these excessive morbidities and find better ways to prevent and treat them. The fifth hope is that caregivers will recognize that treatable CVD risk factors—especially hypertension, diabetes, and, in all probability, syndrome X with its associated dyslipidemia—are consistently more common among women with CVD than among men. The sixth expectation is that we will learn to use metabolic treatments more effectively and in combination to treat these risk factors. These treatments will include use of antihypertensives without adverse metabolic effect, agents to minimize insulin resistance, cautious use of existing and forthcoming appetite suppressants, and more informed, target-oriented treatment of diabetes and dyslipidemia. Treatments will also include management of female hyperandrogenic states premenopausally and hormone replacement postmenopausally, avoiding or minimizing the androgenic side effects of certain progestational agents. The future of hormone therapy of arteriosclerotic vascular disease may include the use of chimeric agents combining estrogenic and progestogenic effects and estrogens that are selective for specific tissues and organs. Seventh, women and men should be treated aggressively with lipid-lowering agents to target (while awaiting resolution of) the estrogen–heart disease enigma.

OVERVIEW

The influence of ethanol on the cardiovascular system generally has been attributed to its toxic action rather than to malnutrition. Whereas many individuals addicted to ethanol have subclinical diastolic dysfunction presumably related to interstitial fibrosis of the myocardium, a minority goes on to develop symptomatic cardiac problems such as heart failure and arrhythmias. In addition to supraventricular arrhythmias that often normalize spontaneously, there is an increased incidence of sudden death that apparently peaks at approximately 50 years of age in the alcoholic population. The combined use of tobacco and alcohol increases the risk of many of these clinical abnormalities. A significant degree of blood pressure elevation occurs in individuals who abuse alcohol. This tends to be transient and is normalized in most individuals during abstinence from alcohol. In addition to these risks, there is also a preventive effect of mild to moderate drinking on coronary heart disease.

GLOSSARY

Alcoholism: a disorder characterized by a pathologic pattern of alcohol use and resulting in serious impairment of social and occupational functioning.

Holiday heart: an acute arrhythmic process that appears after an episode of heavy drinking.

Light alcohol consumption: one to two drinks per day in women, two to three drinks per day in men.

PERSONAL PERSPECTIVES

Recent decades have seen a growing public awareness of the multiple negative consequences associated with excess intake of ethyl alcohol. Moreover, there has been some progress in the long-term management of this addiction. At the other end of the spectrum is the realization from multiple studies that low-dose alcohol intake can have positive effects in terms of prevention of cardiovascular disease in middle age and beyond.

HISTORICAL PERSPECTIVE

During the 1860s, controversy existed among members of the British medical profession on the therapeutic effects of alcohol, which had a prominent place in medical practice at the time. The debate focused mainly on the scientific basis that would support this practice (1). During the same period, new investigations called attention to the potential toxic effect of alcohol on the heart. Early studies in the nineteenth century demonstrated a relationship between excessive consumption of beer and the presence of cardiomegaly at autopsy (2). Clinical heart disease related to ethanol abuse was later described in the British medical literature (3). Since then, ethanol has been recognized as a toxic agent affecting different organ functions, both acutely and chronically.

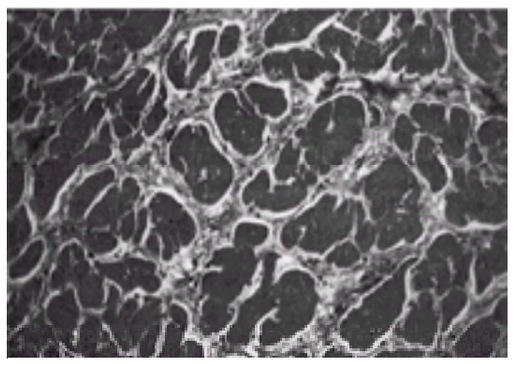
The discovery of the beriberi heart syndrome drew attention to the role of thiamine deficiency as an underlying factor in alcoholic heart disease. Diminished thiamine intake was common among alcoholics in a period when vitamin supplementation was uncommon. Since the middle part of the twentieth century, this confusion between the direct effects of alcohol and the effects of nutritional deficiency has been reduced by evidence of the direct deleterious effects of alcohol on the heart. Numerous studies performed during the late 1960s and early 1970s have confirmed the role of ethanol in the genesis of low-output heart failure, as opposed to the high cardiac output of wet beriberi (4,5). There is persistent controversy, however, about the roles that concomitant risk factors (e.g., tobacco) and lack of trace elements have in the development of cardiac abnormalities.

Recently, epidemiologic studies have reported beneficial effects of light to moderate alcohol consumption on cardiovascular risk. However, further evidence is required to recommend the use of alcohol as a general health policy.

ANATOMY

Specimens from autopsies and biopsies of alcoholic hearts have shown varying degrees of morphologic abnormalities, depending on the stage and progression of the disease. During the preclinical phase, left ventricular mass may be normal or moderately enhanced due to increased wall thickness. With progression of the disease, varying degrees of cardiomegaly reflecting chamber dilatation are seen, particularly when there is concomitant mitral insufficiency as part of the cardiomyopathic picture. On gross observation, the heart appears flabby, large, and pale.

Microscopic characteristics found in alcoholic hearts include focal and diffuse interstitial fibrosis, myocytolysis, and cardiac myocyte hypertrophy (6) (*e*Fig. 9.0.1). On electron microscopy, the sarcoplasmic reticula are dilated, and the mitochondria are swollen with fragmentation of the cristae and deposition of glycogen-filled vacuoles (*e*Fig. 9.0.2). Replacement fibrosis and loss of myofibrils appear with disease progression.



***e*FIGURE 9.0.1** Trichrome stain of left ventricular myocardium in a chronic alcoholic with heart disease (× 100).

***e*FIGURE 9.0.2** Electronic microscopy from the left ventricular myocardium of a long-term alcoholic animal highlights the dilatation of the sarcoplasmic reticulum. The mitochondria appear to be within normal limits. There is a diffuse distribution of glycogen particles. (From Regan TJ, Thomas G, Haider B, et al. Progression of myocardial abnormalities in experimental alcoholism. *Am J Cardiol* 1980;46:233, with permission.)

The degree of coronary atherosclerosis among these patients tends to be minimal. However, microscopic studies may show significant changes at the level of the microvasculature. The alterations noted in the microvascular compartment are, in order of frequency, vascular edema, perivascular fibrosis, vascular sclerosis, and subendothelial humps (7). These changes have prompted some investigators to consider chronic ischemia as a triggering factor in the development of this process, although histologic evidence of ischemia in tissue perfused by the abnormal vasculature has not been described.

PATHOPHYSIOLOGY

Acute ingestion of ethanol is responsible for a direct negative inotropic effect due to diminished ventricular contractile force. A modest increase in heart rate is commonly observed secondary to increased autonomic activity (8). Because these actions of ethanol tend to have opposing effects, evidence of direct acute damage from alcohol can be minimal in healthy individuals or asymptomatic alcoholics. However, clear demonstration of diminished contractility secondary to acute ingestion of alcohol has been shown in human and animal models under conditions of autonomic blockade (8,9 and 10).

The hemodynamic changes that alcohol produces are of greater clinical significance in the chronic user, especially in those with underlying cardiac disease. A potential morphologic basis for the increased diastolic stiffness observed early in the alcoholic heart is related to the accumulation of myocardial collagen in the extracellular matrix. Collagen accumulation has been associated with greater intermolecular cross-links, translating into an increased diastolic stiffness of the ventricle. Staining with Alcian blue shows the deposition of glycoprotein-like material in the interstitium of the ventricular wall (Fig. 9.1). The role of ethanol in the accumulation of collagen can be enhanced by the use of tobacco (11), which is commonly a coaddiction.

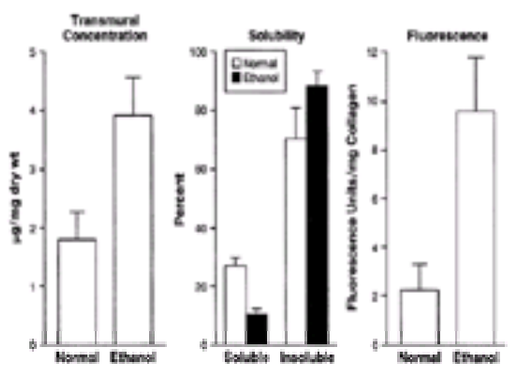


FIGURE 9.1 Differences in the concentration and solubility of collagen found in left ventricular muscle in comparison of healthy and ethanol-fed animals.

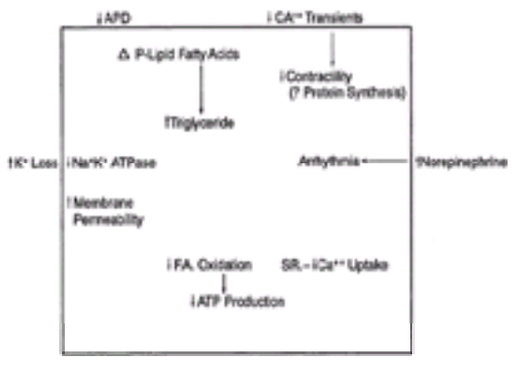
Whereas multiple biochemical mechanisms are altered, the specific pathways involved in clinical events are a matter of debate. Several steps in the excitation-contraction coupling system have been found to be acutely affected by ethanol: reduced capacity of the sarcoplasmic reticulum to accumulate calcium, direct inhibition of the interaction of actin and myosin, and an inhibition of the adenosine triphosphate–dependent Na^+/K^+ pump in the sarcolemma. A reduction of the respiratory ratio in mitochondria has also been described (12). Moreover, the synthesis of cell protein can be significantly reduced, thus suggesting that the appearance of hypertrophy must involve reduced protein degradation.

Ethanol is metabolized to other compounds with concomitant adverse effects on cardiac contractility. Acetaldehyde in high concentrations decreases the action potential of muscle fibers and inhibits the Na^+/K^+ adenosine triphosphatase activity. Abnormal fatty acids derived from ethanol, such as ethyl esters, can decrease mitochondrial activity in the affected cells (*e*Fig. 9.1.1). Phospholipase D catalyzes a transphosphatidylation between ethanol and natural phospholipids present in the myocardium, resulting in the formation of phosphatidyl ethanol, a compound that disrupts the properties of biologic membranes.



***e*FIGURE 9.1.1** Mechanism of action of ethanol and its metabolites on the cardiac cells. APD, action potential duration; ATP, adenosine triphosphate; ATPase,

adenosine triphosphatase; FA, fatty acids; SR, sarcoplasmic reticulum.

Electrolyte abnormalities are a common feature in the alcoholic patient, particularly hypomagnesemia, hypokalemia, and abnormal levels of selenium and cobalt. Changes in magnesium level are due to decreased intestinal absorption and increased renal excretion by a direct effect of ethanol on tubular reabsorption (13). Experimentally, the cardiac abnormalities seen in rats fed a low-magnesium diet are similar to those observed in alcoholic animals. Microscopic changes found in these specimens are mainly mitochondrial damage and myofiber degradation (13,14). Deficiency of the trace metal selenium can be observed in alcoholics. Selenium is known to be an essential component of glutathione peroxidase (15)—an enzyme considered to prevent oxidative cellular damage. A deficit of selenium may play a role in the enhancement of myocardial damage caused by ethanol toxicity.

Some beverage additives have been considered to play a role in the development of alcoholic cardiac disease. In the mid-1960s, outbreaks of an acute and fulminant form of cardiomyopathy were described among heavy beer drinkers (16,17). Cobalt chloride had been added to the beer as a foam stabilizer and was suspected to be the agent responsible for this presentation. Studies of the addition of cobalt salts failed to reproduce these manifestations (18), so it was hypothesized that concomitant nutritional deficiencies were required for the appearance of cardiac abnormalities secondary to cobalt. Alterations in the quality of protein intake may play a role, because amino acids such as cysteine decrease the uptake of cobalt ions by the myocardium. Lead has also been implicated in the pathogenesis of cardiac disease observed in “moonshine drinkers” (19). This effect has been shown in animals fed a combination of alcohol and lead: significant mitochondrial changes were seen in rats receiving this diet (20).

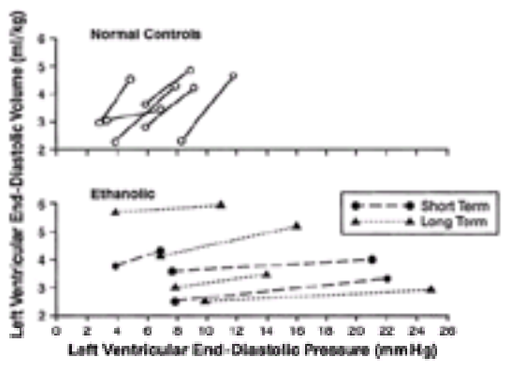
EPIDEMIOLOGY

Two-thirds of the population of the United States consume alcohol, and approximately 10% of these are considered heavy users. Among the identifiable etiologies of nonischemic dilated cardiomyopathy, alcohol is the most common in industrialized countries, accounting for almost half of those diagnosed at autopsy. Prevalence of alcohol consumption differs between genders; however, the risk of alcoholic cardiomyopathy is greater in women than in men.

CLINICAL PRESENTATION

Subclinical Cardiomyopathy

The development of cardiomyopathy is time dependent, with an early period characterized by a lack of symptoms or signs of disease. Evidence of early diastolic dysfunction has been demonstrated as an abnormal increase in left ventricular filling pressure during afterload increments (eFig. 9.1.2).



***e*FIGURE 9.1.2** Left ventricular response to saline in alcoholic and healthy individuals with no evidence of cardiac disease. Alcoholics exhibit a threefold increase in left ventricular end diastolic pressure with minimal stroke output increase. (From Regan TJ, Khan MI, Ettiger PO, et al. *J Clin Invest* 1974;54:740, with permission.)

Noninvasive methods have also demonstrated the existence of ventricular dysfunction during this early period of disease. Findings using these techniques require a stable state for valid assessment. Artifactual results, which can be obtained as a result of neurohormonal changes common after acute ethanol use, may obscure the underlying myocardial dysfunction.

Common echocardiographic findings in the asymptomatic individual include an increase in mean left ventricular and left atrial dimensions, as well as an increase in estimated ventricular mass (21). Characteristic of this stage is an increased mean septal and posterior wall thickness, while a normal percent fractional shortening of the left ventricle is maintained (22,23). Thus, studies of the subclinical state can indicate impaired diastolic function, impaired contractility index, and evidence of ventricular hypertrophy or dilatation, either singly or combined.

The importance of identifying this stage lies in the potential beneficial effect of abstinence. This has been partially demonstrated during serial studies of ejection fraction measured by radionuclide-gated heart scans and echocardiography (24,25). Patients at a rehabilitation center were assessed on the first days of admission, once a basal state was reached and after a 4- to 9-month period of abstinence. Follow-up radionuclide ventriculography after several months of abstinence revealed improved ventricular systolic function.

Congestive Heart Failure

With continuing ethanol abuse, the initial subclinical process eventually deteriorates in many patients with the development of heart failure (Fig. 9.2). Continuation of alcohol consumption at this stage produces a marked decrease of left ventricular function compared to normals (eFig. 9.2.1). Abstinence still plays a role during this period, resulting in evidence of partial improvement in ventricular function and reduced mortality. Cardiac decompensation commonly affects patients in the age range from 30 years to the mid-50s. Intake history averages 80 g of alcohol per day (approximately 8 oz of 86-proof whiskey or 1 L of wine) for a minimum of 10 years. Occasionally, an episode of intense drinking is reported before the development of symptoms, but a particular pattern of drinking has not been found to be associated with the onset of heart failure.

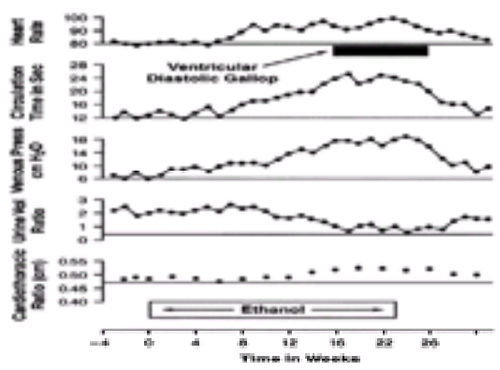


FIGURE 9.2 Evidence of cardiac depression developing as a result of chronic ethanol abuse. The various parameters became progressively abnormal after 8 weeks of alcohol ingestion. The abnormalities disappeared with abstinence.

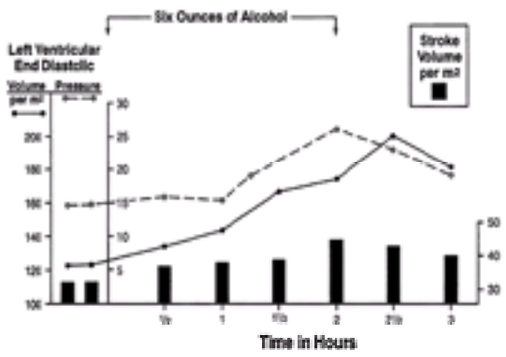
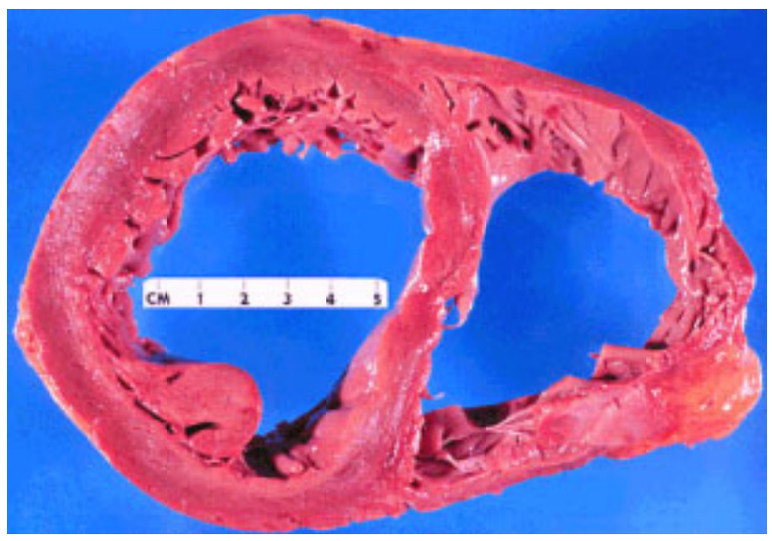


***e*FIGURE 9.2.1** Observations made during the ingestion of 6 oz of scotch by an alcoholic patient with left ventricular failure, demonstrating a depressant effect on cardiac function at a dose that does not affect function in the addicted individual without heart failure. (From Regan TJ, Haider B. Ethanol abuse and heart disease. *Circulation* 1971;44:957, with permission.)

Physical findings and symptoms of left ventricular dysfunction are similar to those produced by other cardiac diseases. Fatigue and weakness secondary to reduced output may be part of the initial complaints, although these symptoms can be attributed to concomitant myopathy common in alcoholics (26). As the process progresses, dyspnea on exertion and orthopnea appear. Due to the fact that many alcoholics fail to seek medical attention early in the course of the disease, it is not uncommon to find evidence of right-side failure at the time of presentation, with jugular venous distention, leg edema, hepatomegaly, and ascites.



Dilated congestive cardiomyopathy. Both the left and right ventricles are significantly enlarged. In this example, the left ventricular wall thickness falls within normal limits.

VIDEO

Video 9.1 Apical long-axis view of a patient with severe left ventricular dysfunction and annular dilatation causing 4+, centrally directed mitral regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Cardiomegaly may be moderate during the early stages. A greater degree of cardiac enlargement is found when there is concomitant mitral regurgitation secondary to papillary muscle dysfunction. Partial regression of ventricular dilatation can be achieved with therapy. An early diastolic gallop is frequently heard during this period. An atrial gallop can be auscultated if the patient is in sinus rhythm; on occasion, an atrial gallop is present in the absence of failure, indicating the existence of myocardial disease. The murmur of mitral insufficiency is rarely pansystolic, usually confined to one portion of systole, and tends to disappear as cardiac compensation is restored. A pansystolic murmur of tricuspid regurgitation, best heard in the third and fourth intercostal spaces, is found during signs of right-side failure and diminishes with effective therapy.

Electrocardiographic findings are, for the most part, nonspecific. Loss of septal Q waves and poor R-wave progression in the absence of coronary disease are common findings. Also noted are signs of left atrial and left ventricular enlargement, as well as varying degrees of intraventricular conduction defects. Low magnesium levels found frequently in the alcoholic produce characteristic electrocardiographic changes: tall, peaked T waves (not as narrow as the wave seen in hyperkalemia) and a normal QT interval. Prolonged hypomagnesemia produces an increased PR interval, wide QRS complexes, ST depression, and low-amplitude T waves.

A 41-year-old patient with hyperkalemia.

Hemodynamically, symptomatic subjects present with higher end diastolic pressures and volumes as compared to the subclinical stage. As might be expected, the ejection fraction and contractile indices are also more depressed. Another clinical manifestation described during this stage is the development of peripheral arterial or pulmonary embolism related to the formation of thrombi in the atrial or ventricular wall.

Thiamine Deficiency (Wet Beriberi)

Thiamine deficiency should be considered as a factor contributing to alcoholic cardiomyopathy. Approximately 15% of asymptomatic alcoholics are moderately deficient in thiamine, as determined by dietary history and excretion of vitamin metabolites (27). There has been no survey of patients with clinical heart disease. The physiologic derangements observed in beriberi heart disease are different from those seen in alcoholic cardiomyopathy; the hallmark is the existence of a hyperkinetic state affecting the cardiovascular system, characterized by decreased peripheral resistance, increased cardiac output, tachycardia, and biventricular failure. In addition to the findings of congestion, on physical examination, there is a wide pulse pressure with a bounding arterial pulse. Frequently, an early diastolic gallop and a systolic murmur can be heard in the apical area. A machinery-type murmur is heard in the peripheral arteries as a manifestation of the arteriovenous shunts that are common in this disorder. The electrocardiogram may show low voltage with an increased QT interval and nonspecific T-wave abnormalities. Cardiomegaly is the common finding in chest radiography.

For the diagnosis of beriberi heart disease, several criteria are required, including a history of thiamine deficiency for more than 3 months, absence of another etiology

of heart failure, evidence of peripheral neuropathy, and a therapeutic response to thiamine (28).

Arrhythmias

Dysrhythmias in the heart are associated with underlying changes in myocardial composition and electrophysiology as a consequence of chronic alcohol ingestion. Healthy subjects do not appear to be affected after mild to moderate intake. Arrhythmias tend to appear in the late stages of an episode of excessive drinking or in the subsequent hours. These episodes of intense drinking are particularly more prevalent among the middle-aged population, as compared to older individuals. A seasonal variability has been described, but similar episodes may not appear in the same individual, despite a similar drinking pattern. Frequent clinical presentations of alcoholics are dizziness and syncope, which are usually attributed to the individual's inebriated state. However, the arrhythmia is detected by electrocardiography.

The most common arrhythmia is atrial fibrillation. This condition can revert spontaneously to normal sinus rhythm, but, on occasion, electrical or pharmacologic cardioversion is required. With sustained abuse of alcohol, chronic atrial fibrillation can develop. *Holiday heart* describes the development of an acute arrhythmic process, generally atrial fibrillation, after an episode of heavy alcohol consumption (Fig. 9.3). These episodes frequently occur during long weekends or annual holidays, during which there is a rise in the consumption of spirits—thus the name *holiday heart* (29).

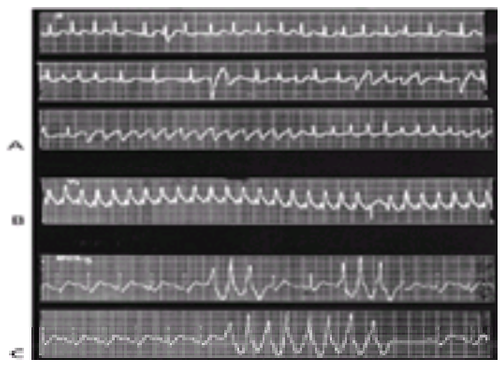


FIGURE 9.3 Electrocardiographic manifestations in alcoholic patients. **A:** The first strip demonstrates rapid atrial fibrillation with one aberrant beat (Ashman phenomenon); the following two strips show increased rate in the same patient with wide complex tachycardia (rate of 240 beats/min). **B:** Atrial flutter with 1:1 conduction (verified after carotid massage) at a rate of 250 beats/min with right bundle branch block aberration. **C:** Nonsustained ventricular tachycardia.

An increased incidence of sudden death has been found among the alcoholic population. It has been postulated that this increased incidence might be due to rapid degeneration of ventricular tachycardias anto ventricular fibrillation, because the former are rarely described in clinical practice. Two European studies have confirmed these observations. Cases of witnessed cardiac arrest were evaluated at the Pathology Institute of Moscow, showing that 17% of the deaths were related to alcohol abuse (30). The majority of the cases were in men younger than the age of 50 years and with alcoholemia. Autopsy revealed no significant coronary artery disease (CAD), but there was evidence of subclinical cardiomyopathy on light and electron microscopy. A large prospective study using a registration system established by the Swedish social authorities for alcoholism examined the role of alcohol as a general and specific cause of mortality (31). In a period of 11 years, the incidence of sudden death between the group registered for alcoholism was double that of the nonregistered group. This association was observed in men with and without coronary disease.

Dose is an important factor in determining the relationship of alcohol to the development of sudden death (Table 9.1). No effect on mortality was found with doses of <80 g of ethanol per day in an epidemiologic study (32). The mortality rate rose threefold with increased intake compared to that of those taking less alcohol. This finding was confirmed in an analysis of the Framingham population. Individuals consuming more than 2,500 g of alcohol per month had an increased risk of sudden death without evidence of CAD (33).

Whiskey (90 mL)	36 g

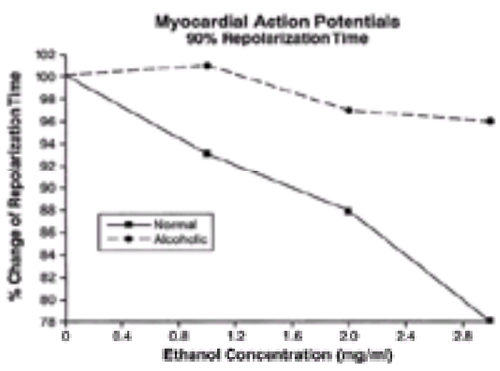
[a]1 oz = 30 mL.

TABLE 9.1 AMOUNT OF ALCOHOL IN DIFFERENT BEVERAGES[a]

High-fidelity electrocardiography has been performed in patients to determine the existence of occult disease. Varied conduction abnormalities have been found during sinus rhythm—mainly prolongation of the corrected PR, QRS, and corrected QT intervals. Also noted was notching and slurring of the QRS complex, indicating the existence of low-grade myocardial disease. In the absence of a dilated heart, these conduction disturbances appeared to be independent of ventricular mass (29).

Acute and chronic alcohol ingestion may trigger cardiac arrhythmias by several mechanisms. Smoking, electrolyte abnormalities, or sleep apnea may also contribute. Acute alcohol ingestion inhibits antidiuretic hormone–producing water diuresis with concomitant loss of sodium, potassium, and magnesium, which have a putative relationship with the development of a variety of arrhythmias. As described above, the existence of scarring, interstitial fibrosis, and cardiac autonomic dysfunction can act as a substrate for the genesis of dysrhythmias (7).

Effects on myocardial action potential are determined by the degree of ethanol intoxication and by the action of major metabolites of alcohol, such as acetaldehyde (34,35) (eFig. 9.3.1). Acute intoxication in alcohol-naïve animals affects the action potential differently within the cardiac tissue, with increases of the action potential at the level of the Purkinje system and decreases at the ventricular muscle (34). In chronic ethanol-exposed animals, acute ethanol administration does not alter the action potential, possibly because of an absence of acetaldehyde, which can produce adrenergic stimulation, or because of the unavailability of sarcolemmal receptors. The latter is thought to be secondary to downregulation because the receptors are occupied by high levels of circulating norepinephrine, thus reducing receptor uptake of exogenous catecholamines. Paradoxically, a decreased sensitivity to administered catecholamines is observed in terms of ventricular vulnerability (36).

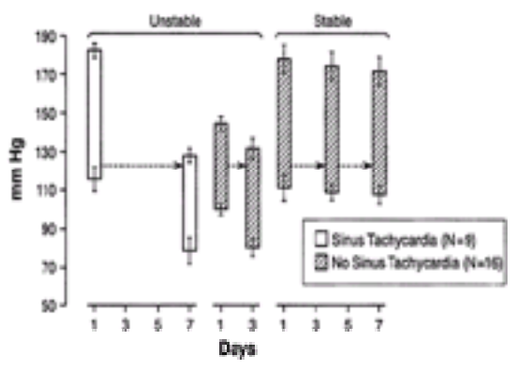


***e*FIGURE 9.3.1** Response of repolarization time in isolated superfused tissue to different doses of ethanol in alcoholic and healthy animals.

Reduction of basal repolarization time secondary to alcohol may be due to opening of voltage-sensitive calcium channels. This hypothesis has been confirmed by normalization of repolarization during calcium-channel blockade. A decrease in repolarization is also related to activation of adenosine triphosphate–sensitive potassium current by a potassium-channel opener.

Hypertension

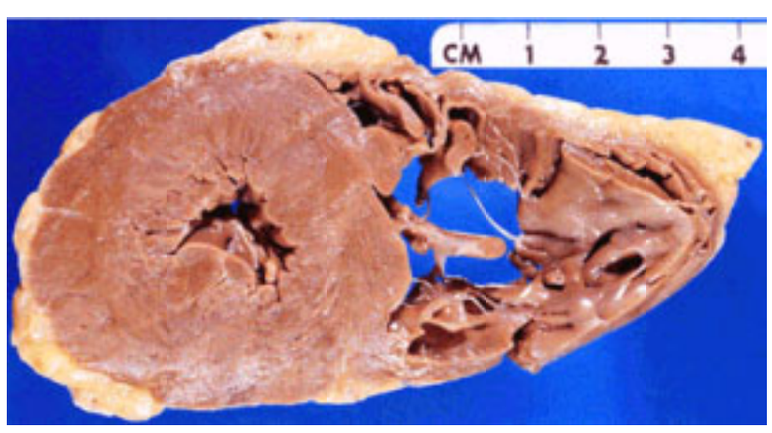
Elevated blood pressure is found in the majority of chronic alcoholics during late intoxication and during early withdrawal periods after acute ingestion. It is unclear whether bursts of elevated blood pressure during withdrawal eventually cause chronic hypertension. However, after a period of abstinence, no increase in blood pressure or end-organ damage was found in patients, irrespective of their underlying cardiac status (*e*Fig. 9.3.2).



***e*FIGURE 9.3.2** Arterial pressure in post–ethanol consumption state. The panel on the left indicates substantial elevation of arterial pressure, which declined without antihypertensive medication in 7 days. The middle panel shows that the moderate pressure elevation normalized in 3 days. The panel on the right indicates that in the essential hypertensive who is alcoholic, the blood pressure may remain stable.

A series of concomitant factors may play a role in the development of alcoholic hypertension, although the definite mechanism through which alcohol causes hypertension remains unclear. Hypertension may be due to a central nervous system (CNS) imbalance related to baroreceptors and CNS control of cardiac output and peripheral effects (37). Some researchers have found that alcohol induces increased postganglionic efferent sympathetic nerve activity accompanied by increased systolic and diastolic blood pressure (38). Stimulation of the renin-angiotensin-aldosterone system is controversial, but stimulation leads to increased extracellular fluid and hypertension. Elevated cortisol levels may occur with ethanol consumption and may be correlated to hypertension. Alcohol may cause increased intracellular calcium with increased vascular reactivity (39). There may be stimulation of endothelium to release endothelin or inhibit nitric oxide (NO) production. Reduced levels of circulating magnesium or changes at the level of the smooth muscle can affect intracellular calcium activity and promote vasoconstriction. Chronic subclinical withdrawal has been postulated as related to sympathetic overactivity.

Acute hypertensive episodes do not result in the development of ventricular hypertrophy, and it is unknown if there is a cumulative effect. Once a cardiomyopathic picture is established, hypertrophy eventually ensues; at that point, a similar pattern exists as in chronic hypertension. Echocardiography has shown that in the nonalcoholic hypertensive, left ventricular mass increments occur in 20% to 45% of patients. Consequently, the hypertrophy seen in some alcoholics may be at least partially related to coexistent hypertension.



Left ventricular hypertrophy secondary to chronic hypertension with secondary ectasia of the right ventricle.

Chest Pain

Underlying cardiac or gastrointestinal processes are often the cause of chest pain in alcoholics. Minimal CAD typically is found among these patients. However, transmural myocardial infarction associated with perivascular fibrosis of subepicardial vessels has been described (40). This fibrosis may limit the coronary blood flow during a period of high myocardial diastolic and systolic tension (Fig. 9.4). No evidence of spasm or embolization has been found.

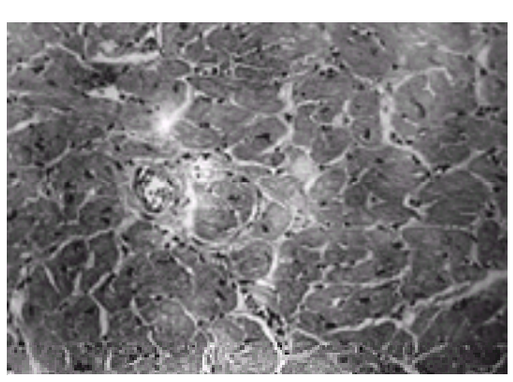


FIGURE 9.4 Periarterial interstitial collagen accumulation with distribution between myofibers (Alcian blue staining), graded as 2 to 3+, indicating increased deposition of glycoprotein material in the extracellular matrix. (From Regan TJ, Wu CF, Weisse AB, et al. Acute myocardial infarction in toxic cardiomyopathy without coronary obstruction. *Circulation* 1975;51:453, with permission.)

Elevations of creatine kinase (CK), CK-MB isoenzyme, troponin I, and lactate dehydrogenase have been described in individuals with alcoholic heart disease, both in clinical and in subclinical stages. Whereas its significance is debatable, the elevation of creatine kinase and CK-MB has been attributed to the existence of skeletal muscle myopathy that is common in alcoholics. Despite the absence of electrocardiographic changes, a cardiac origin is still possible because myocardial enzyme release is induced by acute alcohol administration (41,42 and 43). To make the diagnosis of coronary ischemia related to alcohol, physicians cannot rely entirely on

enzyme levels but must consider the entire clinical picture.

DIAGNOSIS AND MANAGEMENT

Identification of the alcoholic patient can often represent a challenge, because denial of the underlying problem is a common characteristic. It is estimated that approximately 60% to 80% of cases of alcoholism are undiagnosed. Physicians rarely use any screening method to identify the addiction. Screening tests have a sensitivity and specificity of 70% to 90%. Clinician specialists use the criteria established by the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* (44). These criteria require a maladaptive pattern of alcohol use associated with other typical characteristics (eTable 9.1.1).

***e*TABLE 9.1.1** *DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS* DIAGNOSTIC CRITERIA FOR ALCOHOL ABUSE
Characteristics required to be present in a 12-mo period of a maladaptive pattern of alcohol abuse:
Recurrent drinking resulting in failure to fulfill major duties at work, school, or home
Recurrent drinking in hazardous situations
Recurrent alcohol-related legal problems
Continuation of alcohol use despite persistent social or interpersonal problems caused or exacerbated by alcohol

In clinical practice, there are clues that aid in the diagnosis: unexplained hepatic dysfunction, parotid enlargement, hypertension, seizures, anxiety, depression, tremors, and alcohol on the breath. Laboratory data have a low sensitivity and specificity, but they provide a hint of the existence of an alcoholic disorder when used in combination with the history and physical findings. Abnormal laboratory values include a high or slightly elevated mean corpuscular volume, aspartate aminotransferase, g-glutamyl transferase, serum uric acid, triglycerides, and high-density lipoprotein (HDL).

Development of withdrawal and delirium tremens are serious but relatively infrequent in alcoholic patients with heart failure (eTable 9.1.2). These complications are best managed in a hospital environment—especially if tremor, anxiety, tachyarrhythmias, fever, clouded sensorium, or concomitant medical problems (e.g., hepatic failure, pancreatitis) are present. In addition, patients who lack an adequate social support system or those who need psychiatric care benefit in an inpatient setting.

***e*TABLE 9.1.2** EFFECTS OF ABSTINENCE VERSUS CONTINUATION OF ALCOHOL USE ON MORTALITY OVER A 4-YEAR PERIOD

	Abstinent (22 patients; %)	**Active alcoholism (42 patients; %)**
Improved	44	5
Unchanged	36	28
Worse	9	10
Mortality	9	57

Acute withdrawal usually begins 6 to 8 hours after the reduction of ethanol consumption. Delirium tremens occurs in only 5% of these patients; a hallmark is the significant alteration of the patient's sensorium associated with dramatic CNS and autonomic hyperactivity. Seizure activity is of the tonic-clonic type and appears 7 to 48 hours after cessation or relative abstinence. In approximately 40% of these cases, the seizure is limited to a single episode. However, bursts of two to six events with normal sensorium between seizures are not an uncommon finding. Recurrent seizures lasting more than 6 hours are very rare and should raise the suspicion of other diagnoses (e.g., infection, trauma, subclinical hematoma). The seizures are treated with phenytoin or phenobarbital intravenously. Patients developing seizures as their initial manifestations may not have demonstrated earlier signs of withdrawal.

A basic strategy of the management of patients in withdrawal includes alleviating symptoms and prevention of the progression of the process and complications. To maintain a patent airway, care must be taken in patients with decreased mental status. Wernicke's encephalopathy and hypoglycemia have to be recognized, because they may appear concomitantly in alcoholics. The early administration of 100 mg of thiamine intravenously followed by 50 g of glucose (after quick evaluation of blood glucose level by fingerstick) is necessary. Aggressive hydration and correction of electrolyte abnormalities (e.g., of magnesium, potassium, and phosphate) is an important part of this therapy. A cornerstone in this process is the achievement of adequate sedation to prevent the development of complications secondary to agitation, such as trauma, rhabdomyolysis, and hyperthermia. Benzodiazepines are the drugs of choice to achieve this goal; chlordiazepoxide (Librium) at a dose of 25 to 100 mg orally or intravenously every 6 hours is recommended. Because lorazepam (Ativan) is the only benzodiazepine that can be given intramuscularly, it should be used in cases of liver disease or advanced age (>65 years old) or if the patient cannot tolerate oral medications. The use of beta-blockers or alpha$_2$-blockers has been proposed for control of the increased sympathetic tone present during the withdrawal period. However, these agents do not control hallucinations, seizures, or agitation. Experimental studies suggest that NO mediates part of the alcohol withdrawal syndrome and that inhibition of NO synthase during this period can diminish some of the signs and symptoms associated with withdrawal (45), although such therapy is not currently available.

The therapy of heart failure in alcoholic patients is guided by the same principles as other forms of cardiomyopathy. Initial management with diuretics and bed rest may be the only treatment required in patients with minimal clinical symptomatology. Although no clinical investigation has evaluated the efficacy of angiotensin-converting enzyme inhibitors or beta-blockade in the alcoholic heart, these medications' beneficial effect on heart failure patients in general should encourage their use.

Abstinence can result in reversibility of the underlying cardiomyopathic process, provided that the disease is not advanced. Once overt alcoholic heart disease develops, there is more than a 50% 4-year mortality with continuous use of ethanol (eTable 9.1.3). Recognition of the etiologic role in the development of heart disease and other organ failure may encourage abstinence from alcohol. Emphasis on the potential reversibility of the pathologic process may motivate the patient. Referral to addiction control groups such as Alcoholics Anonymous or Alanon (Alcoholics Anonymous groups for family members) can provide important support in the short- and long-term management. Pharmacologic agents such as disulfiram can be used in special situations.

***e*TABLE 9.1.3** RISK FACTORS FOR DEVELOPMENT OF SEVERE ALCOHOL WITHDRAWAL
Daily consumption of a fifth of liquor, a case of beer, or more than 3 L of wine
Heavy drinking for more than 5 mo
Poor nutrition
History of severe withdrawal
Use of other drugs

Reduction in the amount of alcohol consumed lowers blood pressure in the hypertensive alcoholic. A period of 2 to 4 weeks of abstinence should be allowed before considering antihypertensive medications in this population. In the absence of any specific data demonstrating the efficacy of any particular drug in the treatment of alcohol-induced hypertension, angiotensin-converting enzyme inhibitors could be considered the drugs of first choice due to the possibility of concomitant cardiomyopathy. It is important to note that a substantial portion of these patients may experience some degree of autonomic dysfunction secondary to alcohol, resulting in the development of orthostatic hypotension and making alpha-adrenergic blockers the least desirable drug in this population.

There are two objectives in managing patients who present with arrhythmias secondary to ethanol: control of the ventricular response and alcohol cessation. Control of the ventricular response in rapid atrial fibrillation or flutter is best achieved with medications that block atrioventricular nodal conduction, such as beta-blockers and calcium-channel antagonists. Atrial fibrillation in holiday heart tends to revert to sinus rhythm spontaneously, but chemical or electrical cardioversion should be considered if the arrhythmia persists. Ventricular tachycardia or fibrillation require aggressive management with electrical cardioversion or defibrillation. Individuals who are unresponsive to drug therapy or have experienced an episode of sudden cardiac death need to be considered for an implantable defibrillator. Correction of electrolyte abnormalities—especially potassium and magnesium—should ideally be done via intravenous infusion, because many patients present with clouded sensorium or gastrointestinal symptoms that limit oral therapy.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Light to Moderate Alcohol Consumption and the Prevention of Cardiovascular Diseases

A series of epidemiologic studies have suggested that one to two drinks a day of any alcoholic beverage helps protect against CAD (46,47,48 and 49,54). The low incidence of CAD seen in France (French paradox) (50,51) compared to other countries with similar dietary habits has been well publicized. This difference was initially attributed to red wine and its antioxidant components (e.g., tannins, anthocyanins, and flavonoids) (51). However, similar findings have been reported with the use of other alcoholic beverages (52,53).

This beneficial effect of moderate drinking also appears to have a secondary prevention effect by reducing total and cardiovascular mortality in individuals with a history of previous myocardial infarction (55). In this regard, a study of the myocardial response to ischemia in guinea pigs is of interest (56). Low-dose ethanol feeding for several weeks was followed by 45 minutes of no-flow ischemia in the isolated heart with a similar period of reflow. Compared to controls, the ethanol-fed group had

lower ventricular diastolic pressure and decreased myocardial damage measured as the level of creatinine-kinase. Adenosine A_1 receptors were required for this effect.

A biologically plausible basis for the effect of ethanol in reducing CAD is the rise of circulating HDL2 and HDL3 with moderate use. Both subfractions have been associated with a decreased incidence of CAD (57). Complementing this effect may be the increased incidence in thrombolytic activity secondary to enhanced endogenous tissue plasminogen activator (58,62), downregulation of plasminogen activator inhibitor-1 (59), prevention of mononuclear-macrophage activation (60), decreased platelet activity (61), and reduced fibrinogen levels after ethanol ingestion (62). A study by McConnell et al. demonstrated only increasing levels of HDL and its subfractions but no effect on hemostatic parameters in individuals exposed to light drinking over a period of 6 weeks (63).

Prospective studies on the relationship of ethanol consumption and incidence of CAD have demonstrated, in general, a U-shaped or J-shaped pattern with a lower risk among light to moderate drinkers. The increased incidence of cardiac mortality observed in heavy drinkers may be secondary to alcohol-related arrhythmias, hypertension, or cardiomyopathy. The benefit of moderate drinking compared to abstaining has been challenged on the basis that these studies did not separate true abstainers from ex-drinkers.

Major contributions to this field have been made by the Physicians' Health Study, which showed cardiovascular benefits of light ethanol consumption in men. These researchers have recently indicated that no further benefit was achieved above two drinks per day in men. Of greater interest is recent evidence showing no difference in benefit between the consumption of one drink per week and intake of one to two drinks per day. This evidence applies to cardiac events (64), stroke (65), and total mortality.

These findings have prompted others to evaluate the relationship of ethanol use and other cardiovascular diseases. A recent examination of carotid atherosclerosis by ultrasound did not find a significant difference in the wall thickness between patients with moderate drinking habits and the control group (66). In contrast, a recent prospective study on the relationship between alcohol use and peripheral artery disease among American physicians demonstrated that moderate ethanol intake appears to decrease the risk of peripheral artery disease in men (67). This inverse relationship is not affected by other known cardiovascular risk factors, except for smoking. Similarly, in a retrospective analysis of patients with mainly ischemic cardiomyopathy, light to moderate alcohol consumption was not associated with an adverse prognosis and decreased the risk of fatal myocardial infarction. However, a trend towards increasing hospitalization was seen with light to moderate alcohol intake among patients with nonischemic heart failure (68). In a large prospective study of apparently healthy males, a decrease in the incidence of sudden cardiac death was observed in those who reported a light consumption of ethanol. The nadir in risk occurred in those individuals who consumed two to six drinks per week (69).

An association between stroke and alcohol consumption has also been analyzed. In a study by Berger et al., approximately half of those individuals consuming alcohol were also using aspirin, making the absolute effect of ethanol *per se* unclear (65). The association with total stroke incidence showed a risk reduction of 20% after adjusting for important confounders. Benefit was observed among those consuming only one drink per week, and the degree of protection did not increase with higher doses.

The question of who may benefit from moderate alcohol consumption revolves around determinants such as age, gender, the influence of risk factors for disease, and the concomitant use of other drugs (70) (Table 9.2). Young adults have minimal risk for CAD but are at risk for vehicular accidents, which are commonly related to ethanol use. Individuals older than 50 years with coexisting cardiovascular risk factors may benefit from moderate ethanol intake (49). In fact, a major study in the United States indicated that a significant preventive effect was present only in subjects older than 60 years (48). Analysis of population subsets among women has revealed that only those with coronary risk factors experience a significant benefit from low-dose ethanol consumption (71,72) (*e*Table 9.2.1). Recent data also have shown a significant decrease in the risk of coronary disease among diabetics consuming one drink per week. The apparent lack of influence of light to moderate drinking on the regulation of blood glucose is especially important. In contrast to results of the Physicians' Health Study, these diabetics obtained apparent benefit with only one drink per day.

TABLE 9.2 FACTORS THAT CONTRIBUTE TO THE DEVELOPMENT OF ALCOHOLIC CARDIOMYOPATHY

***e*TABLE 9.2.1** NUMBER OF DEATHS FROM ALL CAUSES AND RELATIVE RISK (RR) OF DEATH ACCORDING TO CARDIAC RISK STATUS AND ALCOHOL INTAKE

Average alcohol intake (g/d)	**0**	**0.1–1.4**	**1.5–29.9**	**³30.0**
No risk factors				
No. of deaths	144	38	153	17
Multivariate RR (95% CI)	1.0	0.75 (0.52–1.00)	0.95 (0.75–1.10)	2.2 (1.3–3.7)
>1 Cardiac risk factor				
No. of deaths	693	283	1,088	242
Multivariate RR (95% CI)	1.0	0.93 (0.8–1.0)	0.84 (0.7–0.9)	1.1 (0.9–1.2)

CI, confidence interval.
Adapted from Fuchs CS, Stampfer MJ, Colditz GA, et al. Alcohol consumption and mortality among women. *N Engl J Med* 1995;332:1249.

At issue in the prevention of CAD by alcohol is the question of increased premature mortality rates from other alcohol-related causes, even at moderate doses. The risk-benefit ratio concept has been used to indicate the public health utility of a recommendation for light ethanol use. In a prospective study of 276,000 men aged 40 to 59 years, there was a benefit for reduction of coronary heart disease, but this was only at low dose (i.e., two to three drinks per day) (73). No additional benefit was achieved at higher levels of alcohol intake. Over the 12 years of follow-up, beginning at two drinks per day, there was a progressive increase in the risk of cancer (colon and breast), stroke, accidents, violence, and overall mortality with increasing use of alcohol (Fig. 9.5). Thus, the benefit was limited to low-dose consumption of alcohol. Particularly relevant is a French report that included a prospective cohort study of middle-aged men for nearly a decade and national mortality data from a single year. Whereas consumption of >60 g per day of ethanol correlated with an increase in mortality, lower levels of 26 to 60 mL per day (i.e., two to five drinks) were not associated with reduced total mortality (74).

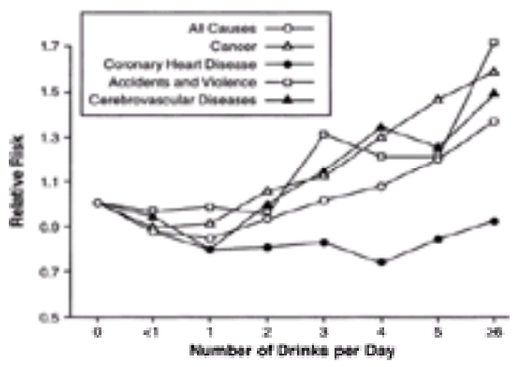

FIGURE 9.5 Alcohol consumption and relative risk of death over 12 years in an American Cancer Society prospective study of 276,802 men, ages 40 to 59 years. Mortality ratios are adjusted for age, smoking habits, the four most common causes of death, and death from all causes. (From Boffetta P, Garfinkel L. Alcohol drinking and mortality among men enrolled in an American Cancer Society prospective study. *Epidemiology* 1990;1:342–348, with permission.)

In the context of the positive epidemiologic message for moderate ethanol use, the statement of Castelli (75) provides a sobering perspective: “With 17 million alcoholics in this country, we perhaps have a message for which this country is not yet ready.” Moreover, the use of alcohol for cardioprotective purposes has been discouraged by some as a general public health measure, because alcohol abuse appears to correlate with overall ethanol consumption in the general population (76). Although the body of evidence supporting the cardiovascular benefits of light to moderate alcohol drinking appears to be reassuring, hazards of moderate intake must be weighed on an individual basis; even modest doses of two drinks per day are associated with an increase in blood pressure. Because of age-related body changes, the National Institute on Alcohol Abuse and Alcoholism recommends that individuals older than 65 years consume no more than one drink per day (77). Extrapolation of these epidemiologic findings to the general population has to take into account several issues: the potential beneficial effect of ethanol is likely to occur over several years; these reports are based on self-reporting habits, which tend to be inaccurate; consumption of ethanol varies among different cultures and societies, which, in turn, reflect different types of diet and lifestyles. Until the precise mechanisms by which ethanol affects cardiovascular diseases are determined, no public health recommendations should be established.

Cardiotoxicity of Alcohol in Women

A gender difference in the left ventricular function has been found among alcoholics (78), suggesting that there may be a varied prevalence of alcoholic cardiomyopathy between men and women, especially during the subclinical period. A lower prevalence of alcoholism among women may be responsible for the lower incidence of cardiac involvement. It is estimated that, currently, one-third of the alcoholics in the United States are women. Alcoholic heart failure is observed in postmenopausal women, but statistical data are lacking in terms of younger women.

However, a similar or slightly greater propensity for developing cardiomyopathy was seen in women, despite their consumption of lesser amounts of alcohol (79,80). In the study conducted by Urbano-Marquez et al. (80) in ethnically homogeneous and adequately nourished women, a decrease in the mean left ventricular ejection fraction was present, compared to that in a control group (men). However, the group was small (n = 4), and the women were at an age approximating menopausal years. Kupari et al. (79) found that the development of subclinical cardiomyopathy, as established by echocardiographic findings, was similar in alcoholics of both genders. The caveat to this study is the lack of data indicating whether the younger women ever developed clinical heart failure.

THE FUTURE

In the next decade, further diagnostic refinement should be developed for identification of cardiac patients who abuse alcohol. These developments include biochemical alterations in blood and specific histochemical changes identified on cardiac biopsy. Progress is needed in promoting abstinence in such patients. Pharmacologic interventions to reverse or impede progression of the pathophysiology in myocytes and extracellular matrix are likely to be forthcoming.

Although the research to demonstrate ethanol’s beneficial effect at low to moderate doses has been provocative (81), further extensive study is required to define the mechanisms involved and the precise subgroups of patients who may benefit.

KEY CONCEPTS

1. Nontraditional risk factors are now recognized as important determinants of coronary heart disease.
2. Hyperhomocysteinemia confers an independent risk for coronary heart disease, probably by imparting oxidative stress-induced endothelial dysfunction and inducing atherothrombosis.
3. Many patients with elevated homocysteine concentrations in plasma are relatively deficient in folate or pyridoxine; the possible benefits of treating patients with vascular diseases using vitamins is now being evaluated in clinical trials.
4. Lipoprotein(a) [Lp(a)] confers an independent risk for coronary heart disease in selected populations and may do so by impairing fibrinolysis, promoting thrombosis, or stimulating vascular smooth muscle cell proliferation.
5. Fibrinogen and other prothrombotic risk factors, including plasminogen activator inhibitor-1 (PAI-1) excess and factor VII, confer independent risk for coronary heart disease.
6. Thrombosis is a major determinant of atherogenesis; thrombin stimulates smooth muscle cell proliferation, activates platelets, and promotes plaque growth. In addition, a prothrombotic state in the vasculature supports thrombus propagation at sites of vascular injury.

OVERVIEW

Traditional risk factors are commonplace in patients with coronary artery disease. Their absence in many patients with vascular disorders provides a stimulus to search for other abnormalities that may also confer an increased risk of atherosclerosis. Several such abnormalities have received more widespread attention recently as their possible roles in the genesis of atherosclerosis and thrombosis become more evident. A high plasma homocysteine concentration has been proposed as a risk factor in most case-control studies and some prospective studies. Elevated levels of this sulfur-containing amino acid may cause vascular damage, perhaps by increasing intracellular oxidative stress in endothelial cells. High concentrations may be readily reduced by folic acid, either alone or combined with vitamin B_6 or vitamin B_{12}. The effects of such treatment on prognosis are being evaluated by a number of secondary prevention studies in patients with vascular diseases. An elevated Lp(a) level is also a recognized risk factor for atherosclerosis. The mechanism of vascular damage is unclear but may be related to enhancement of the toxicity of low-density lipoprotein (LDL) cholesterol or, because of structural homology to plasminogen, interference with normal thrombolysis. Although high Lp(a) levels may be reduced by certain drugs and LDL apheresis, such measures are not always successful, and no prognostic benefit has been demonstrated. High fibrinogen and factor VII concentrations are also independently linked with coronary artery disease by mechanisms that remain obscure. Prospective studies are needed to clarify the precise role of the elevated concentrations of PAI in patients with atherosclerosis and thrombosis. Levels of fibrinogen may be lowered by exercise and modest alcohol intake, but a specific fibrinogen-lowering agent is not yet available. The effect of reducing the levels of these prothrombotic clotting factors on prognosis is unknown. This chapter outlines the relationship between these risk factors and coronary artery disease.

HISTORICAL PERSPECTIVE

Associations between vascular disorders and traditional risk factors (e.g., diabetes, cholesterol, blood pressure, and smoking) are well known. Several plasma constituents discovered many years ago have undergone more extensive evaluation recently as their possible role in the development of atherosclerosis and thrombosis receives greater recognition. Although it was discovered in 1959, homocysteine began to receive greater attention only when patients with homocystinuria developed vascular abnormalities. Approximately 15 years later, these observations were broadened when higher homocysteine levels were detected in patients with coronary artery disease and other vascular diseases. Lp(a) was discovered in 1963 and has since been extensively investigated as a risk factor for atherosclerosis. Abnormalities of the clotting cascade are also associated with arterial occlusion. Indeed, more than 40 years ago, high fibrinogen concentrations were noted in patients with acute myocardial infarction (MI). It is now known that other clotting disorders—including excesses of prothrombin, factor VII, and inhibitors of plasminogen activation—may also contribute to thrombosis. These links with atherosclerosis and thrombosis are analogous to the early observations of elevated risk associated with hypercholesterolemia and hypertension. Concepts of risk associated with the latter have undergone considerable refinement and redefinition with time and may provide useful direction for the future evaluation of the risk factors discussed here.

HOMOCYSTEINE

Homocysteine, a sulfhydryl-containing amino acid, was first discovered as a product of demethylation of methionine (1), which is essential as a methyl donor (2).

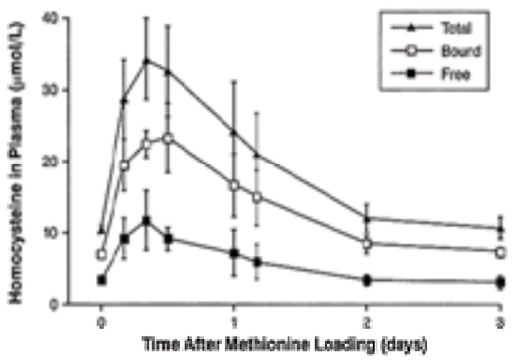
Excessive quantities of homocysteine were noted to accumulate in the blood of patients with homocystinuria—a rare disease characterized by skeletal, neurologic, and vascular abnormalities (3). From this initial observation, a link has been established between more moderate elevations of plasma homocysteine concentrations and atherosclerosis (4,5,6,7,8,9,10,11,12,13,14,15,16,17,18 and 19), even in patients without any apparent defined genetic trait for homocystinuria.

Nomenclature

P> The term *total homocysteine* refers to all species of this amino acid circulating in the blood (4,5,20) and may be abbreviated to *tHcy*. Approximately 80% of homocysteine is protein bound, principally to albumin. The sulfhydryl group of free, unbound homocysteine reacts readily with other sulfhydryl groups to form disulfides. Thus, homocysteine may combine with itself (forming homocystine) or with cysteine to form the mixed disulfide homocysteine-cysteine. Approximately 1% of all circulating homocysteine exists in the free, reduced state. The range of fasting homocysteine currently reported as normal is 5 to 15 µmol per L and includes all free, disulfide-linked and protein-bound species (4,5). Some evidence exists that this range may be too high, because concentrations as low as 12 µmol per L have been associated with atherosclerosis (4,5) and thrombosis in many of the studies of patients with vascular disease (4,5,11,12,13,14,15 and 16). A concentration above this range defines hyperhomocysteinemia; this is sometimes written as *hyperhomocyst(e)inemia* to emphasize the inclusion of all disulfide-linked bound and free species of the amino acid. Standard measurement is usually performed on blood drawn in the fasting state. Concentrations may increase if whole blood is stored at room temperature, as homocysteine may be exported from red blood cells (21). Therefore, blood should be placed on ice and centrifuged as soon as possible after collection for proper determination of fasting concentrations.

Methionine Loading Test

Homocysteine concentrations may also be measured after the administration of methionine (4,5). Methionine administration may be useful in identifying patients with normal fasting levels (*e*Fig. 10.0.1) but with latent abnormalities of homocysteine metabolism and a propensity for the achievement of higher concentrations under certain circumstances. The methionine loading test may also identify additional patients at risk for vascular disease (4,5,14) when combined with a fasting level alone, although the test is time consuming and expensive, which somewhat offsets its broad clinical applicability.



***e*FIGURE 10.0.1** The methionine loading test. After administration of a standard dose of methionine in the fasting state, homocysteine concentrations rise for several hours to a peak. Basal or fasting levels are usually restored after 24 hours. (From Ueland PM, et al. Plasma homocysteine and cardiovascular disease. In: Francis RB Jr., ed. *Atherosclerotic cardiovascular disease, hemostasis and endothelial function*. New York: Marcel Dekker, 1992:183–236, with permission.)

Homocysteine Metabolism

Following ingestion, methionine is converted to *S*-adenosylmethionine and then to *S*-adenosylhomocysteine, from which homocysteine is formed (Fig. 10.1). Methionine may be regenerated by the recycling of homocysteine via two remethylation pathways (2). One pathway uses vitamin B_{12}–dependent methionine synthase, using 5-methyltetrahydrofolate as a methyl donor; the presence of 5,10-methylenetetrahydrofolate reductase is also required. An additional pathway exists for methionine remethylation involving the enzyme betaine-methionine methyltransferase (2). This route is independent of folate and vitamin B_{12}, but it requires trimethylglycine (betaine) as a methyl donor. When methionine stores are adequate, homocysteine enters the transsulfuration pathway, where it is converted to cystathionine by vitamin B_6–dependent cystathionine b-synthase. Cystathionine, in turn, serves as a source for the generation of cysteine, which is required for the synthesis of many major biologic compounds, including glutathione—the most important and abundant intracellular thiol (Fig. 10.2). Ultimately, sulfur-containing amino acids are metabolized to water and sulphate and are excreted in the urine. Activity of cystathionine b-synthase is low or absent in classical homocystinuria. From a review of this metabolic pathway, it can be seen that plasma homocysteine concentrations may increase, owing to decreased activity of certain enzymes, reduced vitamin cofactor availability, or both.

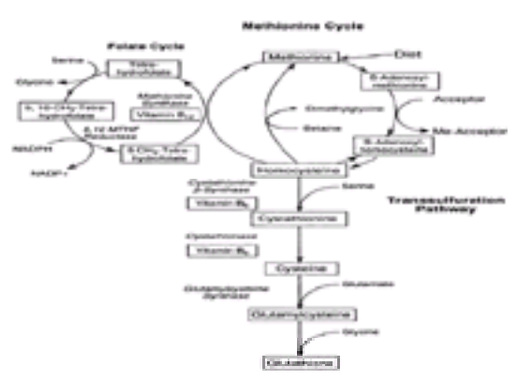


FIGURE 10.1 The metabolic pathway for the metabolism of methionine and homocysteine (see text for discussion). Me, methyl; MTHF, methylenetetrahydrofolate; NADP+, oxidized form of nicotinamide adenine dinucleotide phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

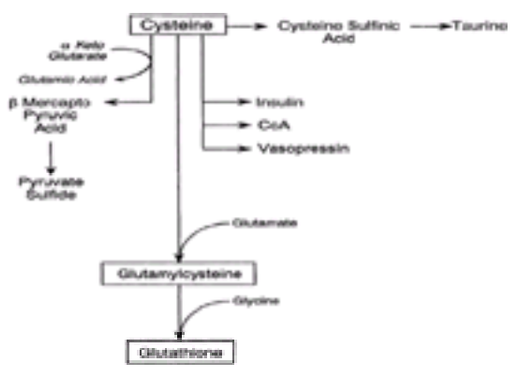

FIGURE 10.2 Pathways showing the fate of cysteine and its central role in the synthesis of essential metabolic compounds, including insulin, coenzyme A (CoA), and glutathione.

Causes of Altered Homocysteine Concentrations

See Table 10.1 for the causes of hyperhomocysteinemia.

Inherited causes
Disorders of transsulfuration
Cystathionine β-synthase deficiency
Disorders of remethylation
Defective vitamin B_{12} transport
Defective vitamin B_{12} coenzyme synthesis
Defective methionine synthase
5,10-methylenetetrahydrofolate reductase deficiency or defects
Acquired causes
Diseases
Chronic renal failure
Hypothyroidism
Chronic inflammatory bowel disease
Some malignant disorders
Systemic lupus erythematosus
Psoriasis
Vitamin deficiencies
Vitamin B_{12}
Folate
Vitamin B_6
Drugs
Cholestyramine, colestipol, and metformin (affect folate and cobalamin absorption)
Methotrexate (inhibits dihydrofolate reductase)
L-Dopa (increases transmethylation)
Niacin and theophylline (induce vitamin B_6 deficiency)
Androgens
Cyclosporine (reduces renal function)
Fibric acid derivatives (possibly after renal function)
Phenytoin and carbamazepine (antagonize folate)
Nitrous oxide (inactivates of methionine synthase)

TABLE 10.1 CAUSES OF HYPERHOMOCYSTEINEMIA

Genetic Factors

Classical homozygous homocystinuria is associated with low or absent activity of cystathionine b-synthase and leads to extremely high (>250 µmol per L) plasma concentrations of homocysteine (3). The heterozygous state is also associated with higher levels of the amino acid. Rare mutations in the remethylation enzyme methylenetetrahydrofolate reductase—which may be associated with excessively high homocysteine concentrations and early death—have also been reported (22). A more common abnormality yielding a temperature-sensitive enzyme (C677T mutation) is also associated with high homocysteine levels (23,24 and 25). Importantly, this abnormality leads to a requirement for high concentration of folate for optimal enzyme activity, and folate supplementation can correct the hyperhomocysteinemia observed in these individuals (26). Uncommon inherited abnormalities of cobalamin metabolism may produce similar clinical disorders (4,5). A genetic influence on plasma concentration has been observed in healthy subjects (27) and in patients with vascular disease (28).

Age

Plasma homocysteine levels rise with age in both men and women (4,5). This age-dependent increase may be secondary to decreases in vitamin cofactor levels or coexisting renal impairment; both are common in this age group. An age-related reduction in the activity of cystathionine b-synthase has also been reported (29).

Gender

Homocysteine concentrations are higher in men than women (4,5), which may be due to differences in muscle mass, renal function, essential vitamin cofactors, or even protein intake. Homocysteine levels are also higher in postmenopausal women than premenopausal women. Sex steroids play an important role in modulating homocysteine concentrations, as illustrated by one study of transsexual males and females in which homocysteine concentrations rose in the subjects treated with androgens but fell in the subjects treated with estrogens (30).

Lifestyle

Lifestyle is also an important determinant of plasma total homocysteine concentrations. In the Hordaland Homocysteine Study, gender, age, folate intake, smoking status, and coffee consumption were the strongest determinants of homocysteine concentration in apparently healthy subjects. A lifestyle of low folate intake, smoking, and higher coffee consumption was associated with a higher homocysteine concentration. Conversely, a high folate intake, nonsmoking status, and low coffee consumption were associated with a median homocysteine concentration that was 3.0 to 4.8 µmol per L lower (31).

Vitamin Deficiencies

Folate and vitamin B_{12} are required for remethylation of homocysteine to methionine. Concentrations of homocysteine rise with decreasing levels of these vitamins (4,5). Frank deficiency can give rise to a markedly increased homocysteine concentration (32). Levels also rise with a decreasing concentration of vitamin B_6 (4,5).

Drugs

Total plasma homocysteine concentrations may also be increased by drugs that affect the metabolism of folate or vitamin B_{12}, including methotrexate, phenytoin, carbamazepine, and nitrous oxide (4,5). Several preparations commonly used in patients with vascular disease—including the cholesterol-lowering agents cholestyramine and colestipol, niacin, and fibric acid derivatives—have also been shown to be associated with an increased homocysteine concentration (4,5). Metformin, theophylline, and L-dopa may have similar effects. A lower homocysteine concentration may be seen in patients taking hormone replacement therapy or penicillamine (4,5).

Renal Dysfunction and Other Disease States

Total plasma homocysteine concentration rises with declining renal function (4,5,33,34 and 35). The reasons for the increase remain unclear, as filtration and metabolism of homocysteine by the kidney are slight in humans (36,37). Some evidence exists that extrarenal metabolism of homocysteine may be impaired in uremia (38). Levels also rise in renal transplant patients (39). A high plasma homocysteine concentration has also been observed in patients with psoriasis, leukemia, systemic lupus erythematosus, hypothyroidism, and inflammatory bowel disease (4,5).

Homocysteine and Vascular Disease

Homocystinuria

Homocystinuria has been the paradigm of homocysteine-related atherosclerosis since the early work of Mudd and coworkers (20). The classical disorder—characterized by complete, or almost complete, absence of cystathionine b-synthase—is rare and occurs in the United States once in every 400,000 births (20). The condition is transmitted in autosomal recessive fashion. Reduced enzyme activity is observed in heterozygotes for the disorder and may be demonstrated by administering a methionine challenge. A markedly elevated plasma homocysteine concentration is typical and is accompanied by an increase in urinary homocystine. The clinical manifestations include skeletal abnormalities, ocular lens dislocation, and mental retardation. The other major complications of early atherosclerosis and a tendency to thromboembolic events soon became evident after the disorder was first described in a survey of mentally retarded children from Ireland (40). The plasma homocysteine concentration can be reduced by dietary methionine restriction or by the administration of vitamin B_6, which may protect against vascular complications (20).

Vascular Pathology

The premature atherosclerosis occurring in homocystinuria involves large, medium, and small arteries in any vascular territory. Pathologic features include marked intimal thickening, medial muscular fiber splitting and fraying, an increase in interstitial collagen, and changes in the internal elastic lamina (41). These lesions are associated with an increase in perivascular connective tissue and increased numbers of fibroblasts, collagen bundles, and small elastic fibers. Intimal and medial thickening may result in severe luminal narrowing. Similar findings have been reported in patients with homocystinuria secondary to the rarer remethylation defects (42). In these individuals, high homocysteine concentrations are also noted. In patients with a deficiency of cystathionine b-synthase, methionine levels are low, suggesting that homocysteine—not methionine—is responsible for the vascular damage.

Pathophysiology of Vascular Disease Due to Hyperhomocysteinemia

Although a high circulating level of homocysteine is associated with atherosclerosis and thromboembolic disorders, the underlying mechanism of vascular damage, if any, remains obscure (*e*Table 10.1.1). Most attention now focuses on possible endothelial dysfunction or damage related to hyperhomocysteinemia. Cystathionine b-synthase activity is absent from cultured endothelial cells and may predispose to intracellular homocysteine accumulation (43,44), especially with a lack of essential nutrients impairing remethylation.

***e*TABLE 10.1.1** HOMOCYSTEINE AND ATHEROTHROMBOSIS: POSSIBLE MECHANISMS

Vascular endothelium
Cytotoxic damage at high doses
Increased macrophage adhesion
Abnormal prostacyclin synthesis
Altered cytokine production
Changes mediated through adhesion molecules
Platelets
Increased synthesis of thromboxane B_2 and other eicosanoids
Increased levels of platelet-derived thromboxane A_2
Increased platelet adhesion and aggregation
Decreased platelet survival
Clotting factors
Activation of factor XII
Decreased antithrombin III levels
Factor V activation by a homocysteine-induced endothelial cell factor
Decreased activation of protein C
Inactivation of thrombomodulin production or activity
Increased affinity of lipoprotein(a) for plasmin-modified fibrin
Inhibition of vWF processing and secretion
Blocking of tissue-type plasminogen activator binding to endothelial cells
Reduction in plasma homocysteine is associated with a decrease in vWF, thrombomodulin, and endothelin

vWF, von Willebrand factor.

In vitro studies have shown the toxic effect of homocysteine on cells in culture; in animal models, homocysteine has been shown to cause vascular endothelial damage, resulting in desquamation and early atherosclerosis (45,46 and 47). Homocysteine is readily oxidized, leading to the formation of superoxide and hydrogen peroxide, which may cause endothelial damage. This oxidant stress may play an important role in endothelial cell damage (48) before the development of overt structural heart disease (49).

Welch and colleagues (50) have shown that homocysteine exposure produces a dose-dependent increase in intracellular reduced glutathione concentrations. An increase in the concentration of oxidized glutathione, however, was also observed. Overall, there was a decrease in the ratio between the two, consistent with an increase in oxidant stress. A number of mechanisms may protect against this oxidant stress, including release of nitric oxide, which may detoxify homocysteine by formation of *S*-nitrosohomocysteine, thereby inhibiting further generation of hydrogen peroxide. Endothelium-derived relaxing factor may be protective against the effects of homocysteine, but the protection may be lost with progressive endothelial damage (51). Catalase may also protect against the adverse effects of hydrogen peroxide, as may glutathione peroxidase. However, the expression of the latter enzyme may be inhibited by homocysteine (52).

In animals, reduced bioavailability of endothelial nitric oxide has been observed with a methionine-rich, folic acid–poor diet, which resulted in hyperhomocysteinemia (53). Human studies have also shown that high levels of homocysteine are associated with impaired endothelium-dependent vasodilation in healthy subjects (54). Endothelial damage may subsequently be expressed in various ways. Inhibited synthesis of prostacyclin by arterial tissues has been noted, which, in addition to a loss of bioactive nitric oxide itself, can predispose to thrombosis (55,56). Endothelial desquamation after homocysteine infusion in animals is associated with decreased platelet survival, suggesting that homocysteine-induced endothelial injury may cause a secondary increase in platelet consumption (46). In addition, homocysteine may promote procoagulant activity by inactivation of the endothelial cell anticoagulant protein C (57) or by disruption of the processing and secretion of von Willebrand factor (53). Increased factor V expression has also been observed (58), and tissue factor expression may be increased as well (59). Recent data also show that homocysteinylation of factor V impairs its inactivation by activated protein C (60). Other mechanisms by which homocysteine may promote thrombosis include inhibition of the cofactor activity of thrombomodulin and enhanced thrombomodulin expression in human umbilical vein endothelial cells (61), suppression of the expression of the anticoagulant heparan sulfate (62), modulation of tissue-type plasminogen activator (t-PA) binding to its endothelial cell membrane receptor (63), alteration of fibrinogen structure (64), and promotion of vascular smooth muscle cell growth (65). Homocysteine also enhances neutrophil adhesion and migration across the endothelium (66). These pathophysiologic mechanisms have been reviewed by Welch and colleagues in detail (67).

Major Clinical Studies of Homocysteine and Vascular Disease

In 1976, Wilcken and colleagues undertook the first studies of patients younger than 50 years with angiographically proven coronary disease (6) and found higher homocysteine concentrations in patients than in controls. In a later study, the same investigators were unable to confirm these results (68). However, many other studies have since been performed (7,8,9,10,11,12,13,14,15,16,17,18 and 19) that have reached conclusions similar to the initial investigation. In the study by Malinow and coworkers (8), after controlling for conventional risk factors, the odds ratio for vascular disease in patients with hyperhomocysteinemia was 3.3, which was higher than the ratio associated with smoking or hypercholesterolemia. In addition, the increased risk does not have a threshold and is present over much of the range of plasma homocysteine concentrations (Fig. 10.3). A European multicenter case-control study using an internationally accepted methodology and definitions of vascular disease has confirmed other case-control studies (14). Although some prospective studies have confirmed these findings (18,19), a number of major investigations have not (69,70), raising the question of whether an elevated homocysteine level may be causally related to the development of vascular disease or may simply be an epiphenomenon. There are a number of useful recent reviews of studies in this area to which we refer the interested reader (4,5).

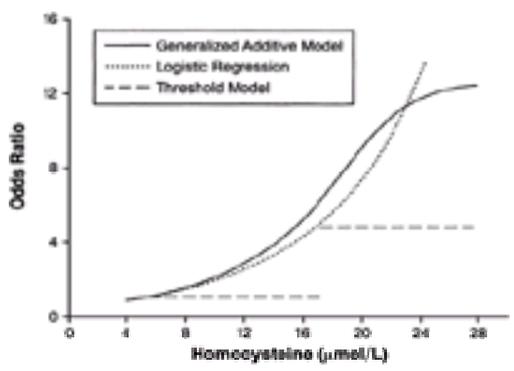

FIGURE 10.3 The relationship of rising plasma homocysteine concentrations to the risk of coronary heart disease. A higher risk is noted with higher concentrations. When homocysteine values are analyzed across the range of plasma concentrations, no threshold effect is evident. (From Robinson K, Mayer EL, Miller D, et al. Hyperhomocysteinemia and low pyridoxal phosphate: common and independent reversible risk factors for coronary artery disease. *Circulation* 1995;92:2825–2830, with permission.)

Interactions with Other Risk Factors

Large epidemiologic studies have also shown a correlation, albeit weak, between homocysteine and other risk factors (14,71) and significant interactions between high homocysteine concentrations and traditional risk factors. These findings are consistent with the enhanced oxidation of LDL in the presence of thiols, including homocysteine (72). Glueck and colleagues (73) have reported interactions of homocysteine with triglycerides. Harpel and colleagues have reported increased binding

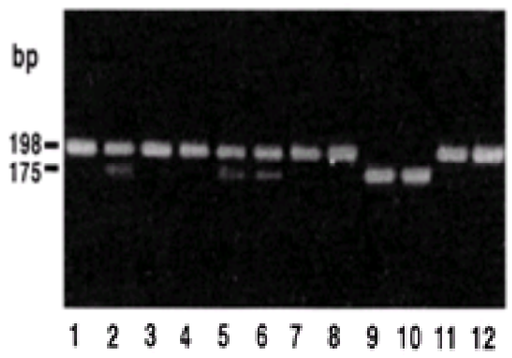
of Lp(a) to fibrin after homocysteine exposure (74).

Effect of Homocysteine on Prognosis in Patients with Atherosclerosis

An elevated homocysteine concentration is associated with an adverse prognosis in patients with established coronary artery disease. In patients with angiographically confirmed coronary artery disease, Nygard and colleagues found a graded relation between plasma homocysteine levels and overall mortality. After 4 years, 3.8% of patients with homocysteine levels below 9 µmol per L had died, as compared with 24.7% of patients with homocysteine levels of 15 µmol per L or higher (75). Stubbs and coworkers evaluated the relationship between plasma homocysteine and short-term (28 days) and long-term (median 2.5 years) prognosis in patients with acute coronary syndromes. Although the event rate within the first 28 days was unrelated to the homocysteine concentration, an apparent threshold effect was noted on long-term follow-up, with a 2.6-fold increase in the risk of cardiac events for patients in the upper two quintiles compared with the lowest three quintiles (76).

Mechanisms of Elevated Homocysteine Concentrations in Atherosclerosis

Wilcken and colleagues and other investigators (7,8) hypothesized a possible carrier state for cystathionine b-synthase deficiency to explain the high homocysteine concentrations in patients with atherosclerosis. The rarity of the genetic frequency for this condition and data from other recent studies, however, make this conclusion unlikely. In 1991, Kang and coworkers reported a thermolabile variant of the remethylation enzyme, methylenetetrahydrofolate reductase, in patients with coronary artery disease (*e*Fig. 10.3.1), which was associated with elevated homocysteine concentrations (23); other investigators have made similar observations (24,25,26 and 27), although a metaanalysis has shown no apparent increase in risk of vascular disease associated with this polymorphism (77). Nutritional abnormalities have also received attention. Because folic acid, vitamin B_{12}, and vitamin B_6 are important for the metabolism of homocysteine, concentrations of these substances have been measured in patients with vascular disease. Negative correlations with homocysteine have been found in many studies (4,5), demonstrating important links between plasma homocysteine, low B-vitamin concentrations, and vascular disease risk. In one study (78), higher homocysteine levels were noted in patients with vascular disease and correlated negatively with all three B vitamins. Low folate status was found in approximately 10% of patients and was associated with an increased risk of vascular disease explicable on the basis of higher homocysteine concentrations.



***e*FIGURE 10.3.1** Determination of 5,10-methylenetetrahydrofolate reductase genotypes. Results from 12 subjects are shown. The normal allele gives a fragment of 198 base pairs (bp), whereas the thermolabile allele gives a fragment of 175 bp. Subjects 1, 3, 4, 7, 8, 11, and 12 are homozygous for the normal allele (–/–); subjects 2, 5, and 6 are heterozygous (+/–); and subjects 9 and 10 are homozygous for the thermolabile allele (+/+). (From Adams M, Smith PD, Martin D, et al. Genetic analysis of thermolabile methylenetetrahydrofolate reductase as a risk factor for myocardial infarction. *QJM* 1996;89:437–444, with permission.)

Vitamin B_6 plays an important role in the metabolism of homocysteine. Early *in vivo* work showed that animals chronically deprived of vitamin B_6 also developed arteriosclerotic lesions (79). Epidemiologic studies have demonstrated a relation between vitamin B_6 deficiency and atherosclerosis in humans (10,15,78,80,81), and this association has been confirmed by prospective observation (70). The apparently common deficiency of vitamin B_6 in patients with vascular disorders may explain the high homocysteine concentrations observed after a methionine challenge in patients with vascular diseases previously ascribed to cystathionine b-synthase deficiency (7,9). This focus on the role of lower B-vitamin levels in hyperhomocysteinemia highlights the importance of functional vitamin deficiencies in the development of vascular disease.

Venous Thromboembolism

In homocystinuria, venous thromboembolic episodes are common; therefore, several studies have addressed homocysteine as a risk factor for venous thrombosis (82,83,84,85 and 86). Although not all of these case-control studies have reached similar conclusions, two metaanalyses have suggested that hyperhomocysteinemia may indeed be a risk factor for venous thrombosis (87,88). The mechanisms underlying this, however, require further study.

Renal Failure

High homocysteine concentrations occur frequently in patients with renal failure (89). Case-control studies have shown that higher levels of homocysteine are associated with an increased risk of atherosclerosis independent of traditional risk factors in dialyzed patients with end-stage renal disease (35). In addition, high homocysteine levels are closely related to B-vitamin metabolism in these patients. Prospective studies have also demonstrated a relationship between vascular complications of end-stage renal disease and elevated homocysteine concentrations (89,90). Recently, Suliman and colleagues (91) have shown that elevated homocysteine concentrations are a predictor of adverse outcomes in patients with end-stage renal disease and that nutritional status may also be an important determining factor of homocysteine concentrations.

Cardiac Transplantation

After cardiac transplantation, homocysteine concentrations rise (92,93 and 94) and are associated with abnormalities of B vitamins and renal function, suggesting a multifactorial etiology. Follow-up of these patients, however, has shown that low vitamin B_6—but not high homocysteine concentrations—predicted cardiovascular morbidity and mortality in this patient group (95).

Therapeutic Implications

Metabolism of homocysteine requires vitamin B_6, vitamin B_{12}, folate, and betaine. Vitamin B_6 and folate reduce homocysteine concentrations in homocystinuria, and vitamin B_6 may reduce the incidence of vascular complications in patients with atherosclerosis (20). The treatment of homocystinuria is reviewed extensively elsewhere (96).

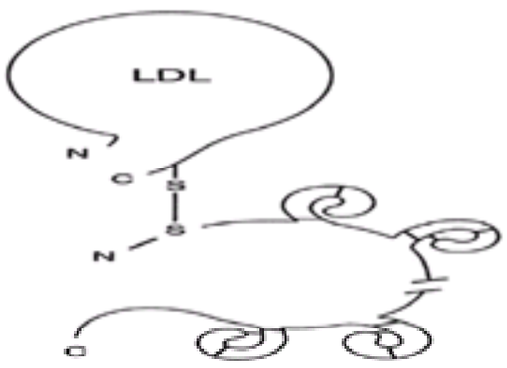
In healthy subjects and in patients with atherosclerotic vascular disease, homocysteine concentrations may be reduced by folic acid alone or in combination with vitamins B_6 or B_{12} (4,5,97,98). The effect is greatest with folic acid, which, in doses of only 0.5 mg per day, may reduce homocysteine concentrations by approximately 30% (98). Vitamin B_{12} may produce a more modest 10% reduction. Vitamin B_6 is most effective in reducing homocysteine concentrations after a methionine challenge. Other agents that may reduce homocysteine include betaine, choline (13), estrogen (99), and *N*-acetylcysteine (100). The use of penicillamine has also been associated with a reduction in homocysteine concentrations. A number of clinical trials are ongoing in patients with coronary artery disease and stroke using folic acid, vitamin B_6, and vitamin B_{12}. In addition, other studies are in progress using high-dose folic acid in patients with end-stage renal disease. These studies may help provide more definitive answers concerning the contribution of homocysteine to the development of atherosclerosis and whether the routine use of B-vitamin supplements is justified in these patients.

At the current time, measurement of homocysteine concentrations and use of these vitamins in patients with vascular disease remains speculative, although the American Heart Association has suggested that the measurement of homocysteine concentrations in high-risk individuals—such as those with a positive family history or the development of early atherosclerosis—may be reasonable. Until the ongoing treatment trials have been concluded, the benefit of routine use of vitamin supplements in these patients remains unproven (101).

LIPOPROTEIN(A)

Structure

Lp(a) was discovered in 1963 by Berg (102) and consists of two major components: an LDL particle containing the apoprotein B-100 molecule and an apoprotein(a) molecule (*e*Fig. 10.3.2) linked by a single disulfide bond to apoprotein B (103). Apoprotein(a) is a large protein with an amino-acid sequence similar to that of plasminogen. It contains several cysteine-rich domains of 80 to 114 amino acids in length that are referred to as *kringles*. Five kringles occur in plasminogen, and most of those in apoprotein(a) are largely similar to the fourth kringle of the plasminogen molecule. Lp(a) is synthesized in the liver, and its molecular weight varies from 400 to 700 kd. This range is due to variation in the number of copies of kringle 4 in apoprotein(a) and is inversely associated with Lp(a) levels in plasma. Plasma levels are determined by the balance between production (104) and removal (105). Variation in concentrations has also been noted in patients with the same apoprotein(a) isoform, which may be due to differences in the rates of production (105). It is unclear if this variation is caused by differences in gene transcription, protein translation, or assembly (106). The concentrations in plasma range from 1 mg per dL to 100 mg per dL. Most values lie below 20 mg per dL, and the concentration distribution is, therefore, markedly skewed in most populations [see the section Effects of Age, Gender, and Race on Lipoprotein(a) Levels]. The normal function of Lp(a) remains unclear.



***e*FIGURE 10.3.2** The structure of lipoprotein(a). The apolipoprotein(a) moiety is located in the lower portion of the diagram, together with four of its representative kringle (triple-loop) domains. Apolipoprotein(a) is linked to low-density lipoprotein (LDL) by a single disulfide bridge. [From Loscalzo J, Weinfeld M, Fless GM, et al. Lipoprotein(a), fibrin binding, and plasminogen activation. *Arteriosclerosis* 1990;10:240–245, with permission.]

Genetics

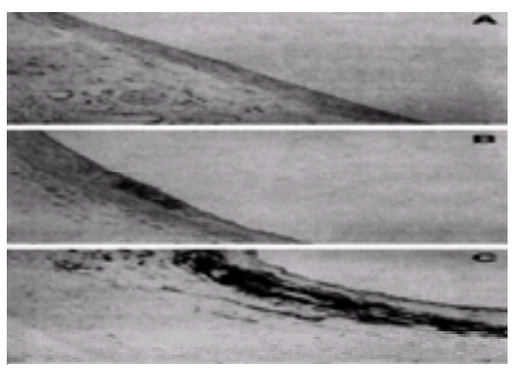
The gene for the apoprotein(a) is located on the long arm of chromosome 6 and is closely linked to the gene for plasminogen (106,107). There is a high degree of homology between these two genes. Utermann and colleagues (103) reported six size isoforms of Lp(a) that were inherited, but more than 30 isoforms have now been reported (106,108).

Effects of Age, Gender, and Race on Lipoprotein(a) Levels

Plasma levels of Lp(a) do not bear any clear relationship to age or gender, although levels are higher after menopause (109). Concentrations also increase with the levels of LDL cholesterol (109). A weak correlation with age in men and women was reported by the Northern Sweden World Health Organization (WHO) MONICA project investigators (110). Lp(a) levels vary substantially among ethnic groups and are higher in American and African blacks than in whites; levels are normally distributed rather than skewed in blacks. Despite the higher levels, the risk of coronary artery disease may not be increased in blacks compared with whites (110). In Asian populations, Lp(a) has also been associated with an increased incidence of coronary artery disease (111). Recent studies have shown that dietary fat content may increase Lp(a) concentrations, perhaps by modulating apoprotein(a) mRNA levels (106). Levels are higher in patients with nephrotic syndrome and chronic renal failure and may be three times higher than normal controls in patients undergoing dialysis (112). Higher levels have also been noted in patients with diabetes mellitus and immediately after MI (113,114). Lp(a) concentrations are higher in patients who have undergone renal transplantation treated with cyclosporin than in patients taking azathioprine or prednisone (115).

Epidemiologic Links with Coronary Artery Disease

Numerous case-control studies have shown a relationship between Lp(a) and coronary artery disease. Seed and colleagues (116) demonstrated that an elevated level is a strong risk factor for CHD in patients with familial hypercholesterolemia. There have been similar findings in a number of prospective and nested case-control studies. In one such study, serum Lp(a) was an independent risk factor for MI and CHD death (117). In another, the subsequent development of “severe” cardiovascular events was fourfold greater after 11 years of follow-up in randomly selected Swedish men with the highest levels (118). In an Icelandic study (119), 1,332 men were followed for 8.6 years, during which 104 patients experienced MI. Higher concentrations of apoprotein(a)—representing greater Lp(a) concentrations—were independent risk factors for developing MI (119). These findings were not reproduced in the Helsinki Heart Study, in which no relationship was noted between baseline levels of Lp(a) and subsequent development of fatal and nonfatal MI (120). An elevated risk of CHD associated with Lp(a) was not seen in the U.S. Physicians Health Study, although it should be emphasized that this was an unusual and narrowly defined population in which not even cholesterol conferred an increased risk of MI (121). This outcome could reflect biases related to the population studied, storage conditions for plasma, or even the use of aspirin. High levels of Lp(a) combined with high LDL cholesterol appear to confer a particularly high risk of coronary artery disease. There are conflicting reports concerning the relationship of Lp(a) and graft occlusion rates in patients who have undergone coronary artery bypass surgery (122,123). Lp(a) is found in atherosclerotic plaque (125,126; *e*Fig. 10.3.3), where it localizes with fibrinogen (127). Because of the heritability of Lp(a), Berg and colleagues (128) explored the frequency of this trait in siblings or offspring of patients with early coronary artery disease. Higher levels of Lp(a) combined with high LDL cholesterol appear to be associated with a particularly high risk of coronary disease and were found in patients with siblings or parents with CHD. Other studies have also shown higher levels of apoprotein(a) or Lp(a) in individuals with a positive family history of coronary artery disease.



***e*FIGURE 10.3.3** Photomicrographs showing immunohistochemical identification of lipoprotein(a) in early and advanced coronary atherosclerosis. Immunoperoxidase staining of coronary arteries with antilipoprotein(a) adsorbed with plasminogen from **(A)** normal monkey, **(B)** monkey fed an atherogenic diet (at necropsy, total plasma cholesterol = 200 mg/dL and high-density lipoprotein cholesterol = 45 mg/dL), and **(C)** monkey fed an atherogenic diet (at necropsy, total plasma cholesterol = 400 mg/dL and HDL cholesterol = 65 mg/dL). (× 150.) [From Nachman RL, Gavish D, Azrolan N, et al. Lipoprotein(a) in diet-induced atherosclerosis in nonhuman primates. *Arterioscler Thromb* 1991;11:32–38, with permission.]

Mechanism of Thrombosis and Atherosclerosis

The mechanism of thrombosis and atherosclerosis is unknown (*e*Table 10.1.2), but the structural similarity of apoprotein(a) to plasminogen suggests that high levels of Lp(a) may inhibit endogenous fibrinolytic activity (129). Unlike plasminogen, apoprotein(a) cannot be converted to a plasmin-like molecule. Indeed, it inhibits plasminogen activation by streptokinase and competitively inhibits plasminogen activation by t-PA. In addition, owing to its kringle-like domains, apoprotein(a) binds and displaces plasminogen from sites on fibrin and fibrinogen (130). Lp(a) may increase the endothelial release of PAI and downregulate plasmin generation (131). In one study, the rate of plasmin generation was most effectively inhibited by low-molecular-weight isoforms of Lp(a). However, it is important to point out that there is extraordinary polymorphism in apoprotein(a) with respect to kringle number and sequence heterogeneity within kringles—both of which can affect fibrin(ogen) binding properties (132). Alternatively, Lp(a) may affect the delivery of LDL cholesterol to the vessel wall, favoring atherogenesis by binding to plaque elements and enhancing cholesterol deposition (133). Recently, additional potential proatherothrombotic actions have been identified, including induction of monocyte chemotaxis by endothelial cells (134) and, possibly, control of angiogenesis (135).

***e*TABLE 10.1.2** LIPOPROTEIN(A) AND ATHEROTHROMBOSIS: POSSIBLE MECHANISMS
Binding to fibrin and cell surfaces where it competes with plasminogen for binding and reduces plasminogen activation
Inhibits transforming growth factor-b and promotes smooth muscle cell growth
Uptake by evolving foam cells
Stimulation of plasminogen activator inhibitor-1 release from endothelial cells
Induction of monocyte chemotactic activity in endothelial cells
Participation in control of angiogenesis

Treatment

Niacin and neomycin (136) may lower Lp(a) levels, as may stanozolol (137) and *N*-acetylcysteine (138). In one study, the angiotensin-converting enzyme inhibitor fosinopril lowered Lp(a) levels in patients with mild to moderate renal impairment, including blacks and diabetics (139). In a study of 31 postmenopausal women given conjugated equine estrogen for 3 months, Lp(a) concentrations fell by approximately 15% (140). In men with prostatic cancer, large doses of estrogen reduced Lp(a) concentrations by approximately 50% (141); androgens and androgenic progestins have similar effects (141,142). The effects of estrogen may be mediated by accelerated LDL-receptor–mediated clearance (140), as may the effects of the fibric acid derivative bezafibrate (143). Despite the potential for lowering Lp(a) levels, there are no data showing the clinical benefit of this treatment approach (144). In patients with a borderline LDL cholesterol level, an elevated Lp(a) level may provide a rationale for more aggressive LDL-lowering therapy (144). In one study (145), higher levels of Lp(a) did not confer greater cardiovascular risk if LDL had been lowered (Fig. 10.4).

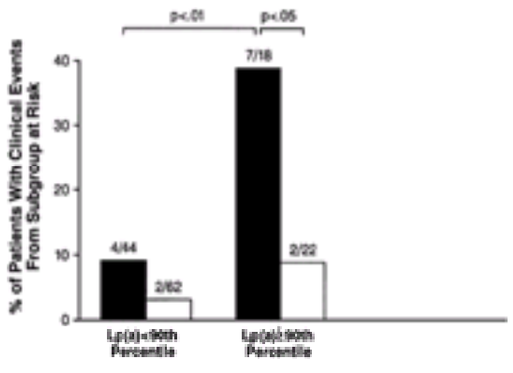


FIGURE 10.4 Relationship of in-treatment lipoprotein(a) [Lp(a)] level and low-density lipoprotein cholesterol (LDL-C) response to occurrence of clinical events. Dark bars indicate LDL-C reductions of £10% (i.e., minimal); light bars indicate LDL-C reductions of >10% (i.e., substantial). The number of clinical events divided by the number of patients at risk in subgroup is listed above each bar. It is assumed that patients dropping out of the study (n = 26) had LDL-C reductions £10%. [From Maher V, Brown BG, Marcovina SM, et al. Effects of lowering LDL cholesterol on the cardiovascular risk of lipoprotein(a). *JAMA* 1995;274;1771–1774, with permission.]

COAGULATION AND FIBRINOLYTIC ABNORMALITIES

Fibrinogen

As long ago as 1954, levels of fibrinogen were noted to be high in patients with acute MI (146). A large body of evidence has now accumulated that links fibrinogen independently to cardiovascular disease.

Structure

Fibrinogen is a glycoprotein synthesized in the liver and has a molecular mass of 340,000 d. The circulating concentration ranges from 200 to 400 mg per dL. Levels are higher in women than in men and increase with age, after menopause, and with increasing body fat. Elevated fibrinogen concentrations occur as a consequence of increased hepatic production or reduced clearance from the circulation. The fibrinogen molecule consists of three pairs of polypeptide chains (a, b, and g) linked by disulfide bonds (147).

Genetics

The three polypeptide chains are encoded by three separate genes on chromosome 4 band 4q32 (148). Genotype may be associated with significant differences in fibrinogen levels (149).

Function

Formation of a fibrin clot and support of platelet-platelet associations are the principal functions of fibrinogen. The proteolytic fragments of fibrinogen have several other functions, including stimulating hematopoiesis, promoting smooth muscle proliferation, and having a possible role in containing bacterial infection.

Effects of Race, Age, and Gender on Fibrinogen Levels

Fibrinogen levels are higher in blacks than in whites by approximately 0.2 g per L (150), and levels increase with age. Concentrations are also higher in women than in men and increase after menopause (151). Fibrinogen concentrations increase with body weight and are lower with exercise and in individuals who consume alcohol (151). Levels also correlate positively with other risk factors for vascular disease, increasing with concentrations of LDL cholesterol and Lp(a) and decreasing with increasing HDL cholesterol (151). Higher levels are found in the setting of stress, overweight status, and physical inactivity (152). Smoking also increases fibrinogen concentration (153), which may be reversible with smoking cessation (151,154).

A specific interaction of smoking and fibrinogen genotype has been observed (155). Higher concentrations of plasma fibrinogen have been observed in smokers with the T148-A455 allele compared with homozygotes for the common C148-G455 allele. The increased risk of vascular disease and smoking may be at least partially explicable by the higher fibrinogen concentrations in smokers (156). Fibrinogen levels are also higher in patients with hypertension (157) and diabetes mellitus (158). In addition to these diseases, fibrinogen is an acute phase reactant (151) that increases in a variety of acute disorders, including stroke (159), MI (160), acute infection, neoplasms, and hepatitis. Levels are higher in patients with end-stage renal disease on hemodialysis and peritoneal dialysis (161); these levels decrease after dialysis (162). A polymorphism in the beta-fibrinogen gene recently has been found to be associated with a progression of asymptomatic coronary atherosclerosis (163).

Epidemiologic Links with Coronary Artery Disease

Many studies have shown a link between fibrinogen and cardiovascular disease. In the Northwick Park Heart Study (*e*Table 10.1.3), an association was noted between fibrinogen and fatal or nonfatal MI, independent of other risk factors (164). Higher levels of factor VII coagulant activity also conferred an increased risk of ischemic heart disease in this study population. In this prospective study of 1,511 white men aged 40 to 64 years, the association between elevated levels of these clotting

factors and subsequent ischemic episodes was stronger than for cholesterol. Similar findings (eFig. 10.4.1) in relation to fibrinogen have been reported in other studies (165), including the Framingham study (156) and, more recently, the Bezafibrate Infarction Prevention Study (166). In a metaanalysis of six prospective population studies (167), odds ratios for cardiovascular events for the upper versus the lowest tertile were between 1.8 and 4.1 for the different studies. Despite the differences in design, sample sizes, and periods of follow-up, the summary odds ratio for all of these studies was 2.3. Only one of these studies involved women. Further work is needed in this area to determine the risk of vascular disease conferred by high fibrinogen and factor VII concentrations in black, Asian, and other populations.

***e*TABLE 10.1.3** FACTORS ASSOCIATED WITH ISCHEMIC HEART DISEASE (IHD) FOR EVENTS OCCURRING WITHIN 5 YEARS AND IN A 13-YEAR TOTAL FOLLOW-UP PERIOD OF THE NORTHWICK PARK HEART STUDY[a]

Event	Age	Cholesterol	Systolic blood pressure	Fibrinogen	Factor VII
IHD death £5 yr					
SRE	1.92	1.36	1.21	1.67	1.55
p	.006	NS	NS	.02	.04
Total					
SRE	2.00	1.27	1.17	1.39	1.32
p	<.0001	.07	NS	.02	.03
Nonfatal IHD £5 yr					
SRE	1.48	1.16	1.14	1.68	1.28
p	.04	NS	NS	.004	NS
Total					
SRE	1.43	1.12	1.35	1.60	1.00
p	.02	NS	.04	.002	NS
All IHD £5 yr					
SRE	1.54	1.17	1.27	1.57	1.37
p	<.006	NS	.09	.003	.03
Total					
SRE	1.65	1.18	1.32	1.41	1.14
p	<.0001	NS	.008	.0002	NS

NS, not significant; SRE, standard regression effect.

[a]All five variables were included in the regression analysis, regardless of whether they were significantly associated with IHD in stepwise analyses. The SREs for different variables are comparable with each other and indicate the increased risk of an event for a 1 standard deviation rise in the variable in question. Thus, an SRE of 1.50 means that for a standard deviation rise in the variable concerned, the risk of an IHD event increases by 50%.

***e*FIGURE 10.4.1** Myocardial infarction (MI), stroke, and death from cause other than MI or stroke among 792 men grouped according to quintile of fibrinogen levels. There was no clear trend for deaths other than those from MI or stroke. (From Wilhelmsen L, Svardsudd K, Korsan-Bengtsen K, et al. Fibrinogen as a risk factor for stroke and myocardial infarction. *N Engl J Med* 1984;311:501–505, with permission).

Mechanism of Thrombosis and Atherosclerosis

The mechanism of thrombosis and atherosclerosis is unknown and reflects the complex interactions among plaque development, lipid abnormalities, and derangements of endothelium and the coagulation system (167) (*e*Table 10.1.4). Fibrinogen is the major determinant of plasma viscosity and binds to platelet glycoprotein IIb/IIIa receptors, which is a necessary prerequisite for platelet aggregation (168). In patients with type II hyperlipoproteinemia and familial hypercholesterolemia, fibrinogen binding to platelets is increased (169). In addition, fibrinogen is incorporated into arteriosclerotic plaques and stimulates smooth muscle cell proliferation and growth (151,170,171).

***e*TABLE 10.1.4** FIBRINOGEN AND ATHEROTHROMBOSIS: POSSIBLE MECHANISMS
Activation of factor XII
Promotion of platelet aggregation
Increased plasma viscosity and erythrocyte aggregation
Liberation of serotonin and platelet factors
Stimulation of smooth muscle proliferation and migration

Treatment

Several drugs lower plasma fibrinogen concentrations, including some beta-adrenergic blocking agents, platelet inhibitors (172), and fibric acid derivatives (especially bezafibrate) (167), but lifestyle interventions such as increased exercise and modest alcohol intake may be the most satisfactory initial treatment choice (172). A specific fibrinogen-lowering agent is not yet available.

Plasminogen Activator Inhibitor-1

Plasminogen activator inhibitors (PAIs) are specific inhibitors of t-PA and urokinase-type plasminogen activator. There are several PAIs: PAI-1, PAI-2, and PAI-3; the most extensively investigated in relation to atherosclerosis is PAI-1.

Structure

PAI-1 is a glycoprotein that belongs to the a_1-protease inhibitor class of serine protease inhibitors (i.e., serpins) (173). The gene for PAI-1 is located on chromosome 7 (174). PAI-1 has a molecular mass of 52 kd and consists of 379 amino acids. It is found in plasma, platelets, and extracellular fluid. The relatively high circulating levels of PAI-1 activity in pregnancy may be explained by the high concentrations in the placenta (173).

Synthesis

Synthesis and secretion of PAI-1 can be modulated by various substances that may exert their effects at the level of gene transcription (173,175). Some substances, such as insulin, may have a posttranscriptional effect by modification of mRNA stability (176). When synthesized in endothelium, PAI-1 is rapidly secreted, although it may also be stored in the alpha-granules of platelets and is released on activation (173).

Function

Under normal circumstances, fibrinolysis is tightly regulated by the balance between activation of plasminogen and inhibition of plasmin—the active serine protease derived from plasminogen. Inhibition of fibrinolysis may occur through inhibition of plasminogen activation. Plasma PAI-1 circulates bound to vitronectin (176); its

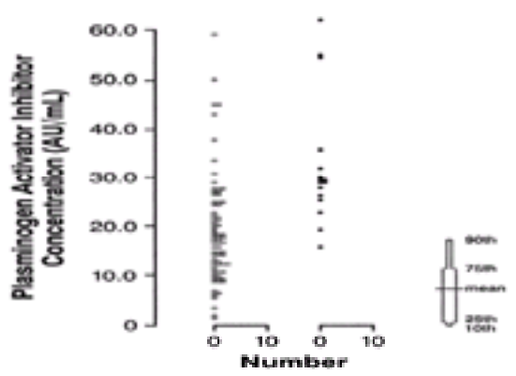
plasma levels exhibit a circadian variation reaching a peak in the morning and a trough in the evening. Importantly, this variation is opposite that for t-PA (173).

Age and Gender

Levels of PAI-1 increase with age (177,178) but are not related to smoking or cholesterol levels (179). Levels rise with increasing systolic blood pressure and are higher in patients with higher triglyceride and insulin concentrations and with higher body-mass indices (180). There is a correlation of PAI-1 with insulin resistance and with the components of this syndrome (181). Endothelial synthesis of PAI-1 may also be enhanced by Lp(a) (131), although plasma levels of these substances do not correlate with one another (182). The clinical value of measurement of PAI concentrations may be enhanced by drawing blood samples before and after venous occlusion for 10 minutes, using a blood pressure cuff inflated to 100 mm Hg (137). This maneuver should produce an increase in fibrinolysis expressed as increased plasminogen activator level and a fall in the concentrations of PAI-1. The test requires further evaluation, as it conceivably could be a better marker for vascular disease than the fasting value alone; the test has already been applied in therapeutic studies in which the fibrinolytic properties of drugs are being evaluated (137).

Epidemiologic Links with Coronary Artery Disease

Increased levels of PAI-1 have been reported in several thrombotic disorders, including venous thrombosis, coronary artery disease, and especially MI (*e*Fig. 10.4.2), although the mechanism remains unclear (*e*Table 10.1.5). Korninger and colleagues (183) described 121 patients with venous thrombosis or pulmonary emboli in whom impaired fibrinolysis was evident, although it was unclear if the findings were due to reduced release of t-PA or increased PAI-1. In addition, although other studies have shown higher levels of PAI-1 (184) in patients with venous thrombosis than in matched controls, confounding variables (e.g., obesity) may explain the findings. These studies of venous thrombosis recently have been reviewed, and the design of many may be flawed by the selection of inappropriate controls or the measurement of fibrinolytic activity after the thromboembolic event (185). Decreased fibrinolysis from increased PAI-1 is associated with an increased risk of postoperative thrombosis (185). Because PAI-1 is also an acute phase reactant, it remains unclear whether this increase is an effect of the surgery. Higher PAI-1 concentrations also have been noted in patients with coronary artery disease than in matched controls (186,187,188,189,190,191,192,193,194,195 and 196). An insertion/deletion polymorphism in the PAI-1 gene locus (5G/5G) has been associated with a family history of coronary artery disease (197), but this association has not been observed consistently (198). There are conflicting findings in relation to recurrent MI (196,199); in patients with angina, PAI activity was not predictive of increased risk of MI (199). Decreased levels of PAI-1 are actually associated with decreased rates of restenosis after coronary angioplasty (200). In addition, higher PAI-1 concentrations also have been noted within the vessel wall, although plasma levels do not correlate with the extent of atherosclerosis (201). Ridker and coworkers (202) have observed elevated plasma concentrations of t-PA in a prospective study of white men with stroke in the United States; these concentrations may simply be a marker of endothelial cell activation or dysfunction. Further prospective studies are required to explore the relationship between activators and inhibitors of plasminogen and the subsequent development of atherothrombotic disorders.



***e*FIGURE 10.4.2** Distribution of values for plasminogen activator inhibitor concentrations in plasma from patients with an uneventful course (*open dots*) and with recurrence of myocardial infarction (*solid dots*). (From Hamsten A, Walldius G, Szamosi A, et al. Plasminogen activator inhibitor in plasma: risk factor for recurrent myocardial infarction. *Lancet* 1987;2:3–9, with permission).

***e*TABLE 10.1.5** PLASMINOGEN ACTIVATOR INHIBITOR AND ATHEROTHROMBOSIS: POSSIBLE MECHANISMS
Interaction with lipoprotein(a)
Coincident expression of plasminogen activator inhibitor-1 and tissue factor may initiate and prolong thrombotic events in the vessel wall
May regulate extracellular proteolysis during growth or migration
Increased expression in atherogenic lesions may increase vessel wall damage

INFLAMMATORY MARKERS

Inflammatory responses within coronary atheromata are important determinants of plaque activation and subsequent acute atherothrombotic events (203). Systemic inflammation is also associated with atherogenesis and its acute thrombotic complications. Recent data suggest that circulating systemic markers of inflammation can identify subjects at high risk for clinical atherothrombotic events (204,205). In this regard, the acute phase reactants serum amyloid A protein and, more important, C-reactive protein (CRP) have been identified as independent risk factors for cardiovascular events among both apparently healthy individuals and patients with unstable angina pectoris (206,207). In addition, the increase in CRP after acute MI (208,209 and 210) or in the setting of unstable angina pectoris (211,212) correlates with adverse outcome. The association between CRP and cardiovascular disease is believed to be indirect, because circulating CRP reflects the extent of acute phase response to nonspecific stimuli that induce acute inflammation, including ischemia, plaque rupture, vascular injury, and necrosis. Nevertheless, CRP has been demonstrated to be an independent risk factor for atherothrombotic events (207) and may, therefore, be a direct mechanistic determinant of outcome by as yet poorly defined molecular processes. Importantly, aspirin suppresses CRP levels, and this effect may account, in part, for the benefits of aspirin in prevention (207).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Research into the relationship between homocysteine and vascular disorders has uncovered important links between folic acid and atherosclerosis. Although folate is important, it is not the sole determinant of plasma homocysteine levels. It is essential to realize that high homocysteine concentrations may reflect reduced activities of a number of enzyme systems and several B vitamins. By extension, the relationship between vitamin B_6 and atherosclerosis—although proposed almost 50 years ago by Rinehart and Greenberg (78) and since developed by others (79,80,216)—is largely unknown by clinicians and requires greater recognition. Controversy also surrounds the relationship of mutations in methylenetetrahydrofolate reductase and cystathionine b-synthase to hyperhomocysteinemia and vascular disease. Treatment of high homocysteine levels by the routine use of multivitamins in patients with atherosclerosis remains entirely speculative, although trials are now ongoing. Indeed, even the routine measurement of homocysteine, Lp(a), or the concentrations of fibrinogen, factor VII, or PAI-1 in patients with atherosclerosis cannot be recommended until controlled intervention studies have demonstrated a clinical benefit of therapy.

THE FUTURE

Whereas the elevated concentrations of homocysteine, Lp(a), and prothrombotic clotting factors may confer increased risk of atherosclerosis and thrombosis, much additional investigation is required before their role in these disorders can be fully understood. For example, the underlying abnormalities that lead to high homocysteine levels in patients with vascular disease are complex and involve nutritional and genetic factors (25,26,203,204,205,206,207,208,209,210 and 211). The cellular mechanism, if any, leading to vascular damage in patients with high homocysteine levels is also unclear. Interactions with traditional risk factors (e.g., smoking, hypercholesterolemia, and hypertension) may predispose to a greater likelihood of vascular disease (14,72), but attention should also focus on interactions with nontraditional risk factors. The increased risk of thrombosis in patients with homocystinuria possessing the R506Q (Leiden) mutation of factor V (212) highlights the possibility of multiple coexisting genetic abnormalities predisposing to atherosclerosis and emphasizes the evolving concept of disease-modifying genes as an explanation for the diverse manifestation of complex phenotypes. Perhaps the most important issue is whether reduction is associated with an improved prognosis in primary or secondary prevention studies, and these issues should now be tested by clinically appropriate trials.

The role of Lp(a) in atherosclerosis and thrombosis remains unclear, but complex interactions with nontraditional risk factors are evident. There is increased binding of Lp(a) to fibrin by homocysteine (73). In addition,Lp(a) regulates PAI-1 expression in endothelial cells (131) and accumulates with fibrinogen in atherosclerotic plaque (127). It is also possible that Lp(a) may be more atherogenic in the presence of specific cholesterol subfractions and that certain Lp(a) phenotypes may be more atherogenic than others. Different populations may be at varying risk; this also requires further study. Reduction of high Lp(a) levels is possible, but, at present, this may not confer any benefit if LDL is maximally reduced. Future development of more specific and effective treatment may alter this perspective.

High circulating levels of fibrinogen and PAI are frequently seen in patients with atherothrombotic disorders, but their origin is obscure. Genetic determinants and their relationship to environmental factors require further study. Newer genetic polymorphisms in platelet glycoproteins (213,214) and procoagulants (215) and other prothrombotic determinants are likely to gain importance as we unravel the complexities of gene-gene interactions in atherothrombotic risk. Therapeutic studies are also needed but are made more complex, as in the case of fibrinogen, by the lack of a specific agent that selectively reduces levels of this clotting factor. As with other heritable abnormalities, the atherosclerotic and thrombotic tendency associated with specific phenotypic abnormalities—alone or combined with other risk factors—requires further evaluation. Additional prospective study is required to define the specific role of high levels PAI in atherosclerosis and thrombosis.

OVERVIEW

Behavioral medicine integrates behavioral sciences with the science of medicine. Thus, the behavioral medicine approach to cardiac disease includes evaluation of behavioral, psychological, and social functioning in relation to the etiology and treatment of disease. Behavioral and psychological factors associated with coronary artery disease (CAD) include personality [e.g., Type A behavior pattern (TABP)], affective state (e.g., depression, anxiety), and social or work environment.

Although global Type A (TA) behavior previously was found to be strongly associated with the development of CAD, refinements of the TA construct have indicated that hostility and cynicism may be the most toxic components of the TABP. In addition, negative emotions other than hostility, especially depression, and environmental factors such as work strain (high demand, low control) have been associated with the development of CAD. Social support, on the other hand, appears to mitigate the negative effects of stress and environment on CAD.

Comprehensive evaluation of stress usually includes a subjective appraisal of stress, as well as physiologic indicators of stress as measured in laboratory studies of cardiovascular (CV) function. Stress-related hemodynamic alterations are important to evaluate because CV reactivity of the sympathoadrenal and pituitary adrenal-cortical systems is thought to be a pathophysiologic mechanism linking stress with development of CAD. Recent data also reveal stress-related changes in neuroendocrine function and blood lipids, which may contribute to CAD.

Intervention studies suggest that relaxation training may have beneficial effects on CV reactivity to laboratory stressors and that stress-management training may be beneficial for reducing components of the TABP. Stress-management interventions can minimize the impact of depression on future cardiac events among post–myocardial infarction (MI) patients, and stress management is a central component of multimodal treatments for patients with CAD. Studies have not yet demonstrated the optimal components or dosage of stress-management interventions among patients with CAD, but ongoing research is documenting various aspects of stress-management interventions that may be important in the treatment of cardiac patients.

GLOSSARY

Appraisal: The mechanism by which social support is thought to mitigate the effects of stress on health. *Primary appraisal* refers to support that helps to prevent the individual from viewing an event as stressful. *Secondary appraisal* refers to social support facilitating reappraisal (in a less stressful way) after an event that was viewed as stressful.

Biofeedback-assisted relaxation training: The use of auditory and visual feedback from electromyographic sensors to enhance individual awareness and control of muscle tension.

Cognitive-behavioral counseling: An approach to stress management that includes increasing the patient's awareness of negative and stressful ways of thinking that are likely to result in unhealthy behavior and negative social interactions. Cognitive counseling is directed toward increasing the frequency of positive, rational thinking.

Health behavior model: A theoretical model linking hostility with CAD and suggesting that hostile individuals are less likely to engage in good health habits.

Progressive muscle relaxation (PMR): A technique for reducing muscle tension and subjective stress by means of focused, systematic relaxation of muscle groups throughout the body.

Psychophysiologic (CV) reactivity model: A theoretical model linking hostility with CAD and suggesting that individuals high in hostility manifest larger increases in heart rate, blood pressure, and stress hormones than individuals with low hostility.

Psychosocial vulnerability model: A theoretical model linking hostility with CAD and suggesting that hostile individuals experience a more conflict-laden environment with less available social support.

Self-efficacy: The individual judgment of one's ability to achieve a goal. This is a widely studied concept in health psychology literature that has been proved to be an important psychological factor in behavioral change (e.g., exercise, smoking cessation, diet).

Structured Interview: An interview assessment of TABP and related characteristics (e.g., potential for hostility) that is widely regarded as the best assessment tool for evaluating TA characteristics.

Thought stopping: A stress-management technique in which patients are trained to stop the rapid succession of negative thoughts and feelings associated with stressful circumstances and to substitute alternative behaviors (e.g., relaxation) or thoughts.

Type A behavior pattern (TABP): Also described as *coronary-prone behavior*, TABP includes a constellation of behaviors and personality traits (e.g., excessive

competitiveness, chronic feelings of time pressure and urgency, chronic feelings of anger and hostility) associated with increased rates of CAD.

HISTORICAL PERSPECTIVE

For more than 50 years, clinical researchers have acknowledged the importance of behavioral, psychological, and social factors in the pathogenesis, assessment, and treatment of physical illness. The past several decades have witnessed a proliferation of research evaluating behavioral aspects of medical conditions and describing the direct and indirect effects of behavior and psychological functioning on incidence and progression of disease. Due to the widespread prevalence and profound impact of cardiovascular disease (CVD) in our society, research into the behavioral and psychological aspects of CAD has received an exceptional amount of attention and has flourished. In an effort to explore the multidetermined nature of behavioral and psychological factors in CAD, research in this area has addressed a broad spectrum of topics, including stress effects, personality (e.g., TABP, hostility, neuroticism), affective function, social support, health behavior, cognitive function, and CV reactivity.

In the 1950s, cardiologists Friedman and Rosenman first suggested the probability of a coronary-prone personality (1). More recent work has identified specific affective states (e.g., depression, anxiety, chronic anger) that are predictive of CAD (2,3), as well as relevant social and environmental factors associated with CAD (4,5). In addition, psychophysiologic researchers during the past two decades have successfully documented important individual differences in physiologic and behavioral responses to stress and the relevance of CV reactivity for the etiology of CAD (6,7). This multidisciplinary approach to the study of CAD typifies the field of behavioral medicine. Behavioral medicine involves the integration of behavioral sciences with the practice and science of medicine to promote and maintain health, prevent and treat illness, and identify etiologic and diagnostic factors in illness and health (8).

This chapter elaborates on the historical perspective by delineating the contribution of each area of research toward understanding behavioral and psychological factors in CAD. Subsequent sections of the chapter address biobehavioral factors in the etiology of CAD, behavioral and psychological interventions, and select issues and controversies relevant to future behavioral medicine research.

Stress

Stress has been broadly defined as an experience in which the demands of a situation exceed the perceived ability to cope with the situation (9), most often resulting from a person-environment transaction and leading to overarousal or underarousal of the organism (10). Much research has been directed toward elucidating the nature of the *stress response*, first described by Cannon (11) and characterized as an innate “fight-or-flight” response in animals when confronted by a threatening situation of a physical or social nature. Although this fight-or-flight response is an adaptive response to physical threats, it is not adaptive in most modern social circumstances and often is suppressed. In human beings, the stress response is marked by a cognitive appraisal of a situation as threatening, followed by physiologic changes such as increases in blood pressure, heart rate, respiratory rate, output of stress hormones, blood homocysteine levels (12), and blood platelet activity. It has been hypothesized that stress-associated physiologic arousal may contribute to chronic elevations in blood pressure and increased risk of cardiac disease (6). Thus, the stress response is a function of personality and individual differences that may affect the appraisal of the situation, as well as influence person-environment interactions.

An expanded view of the stress response was proposed in a recent review (13), in which it was observed that the majority of studies describing the fight-or-flight phenomenon has included only men. After extensive review of animal and human research, Taylor and colleagues (13) have postulated that women respond to stress with a “tend-and-befriend” pattern of behavior. *Tending* is described as nurturing activities that enhance safety and alleviate distress to protect the self and offspring; *befriending* involves the development and maintenance of social relationships that facilitate tending.

The tend-and-befriend pattern is thought to be a product of the biobehavioral attachment-caregiving system involving oxytocin, estrogen, and endogenous opioid mechanisms, which, in turn, down-regulate sympathetic nervous system responses. Taylor and colleagues suggest an evolutionary basis for this behavioral pattern, speculating that the tend-and-befriend stress response may help to explain gender differences in CV reactivity and life span. At a minimum, this view of the stress response indicates the importance of evaluating responses to stressful circumstances in the context of gender.

Several studies provide data suggestive of the importance of stress—physical or mental—in the onset of cardiac symptoms. Stressful, frustrating interpersonal relations may elicit anger and general excitement among CAD-prone individuals (14). In addition, epidemiologic research suggests that the onset of symptoms of acute MI are triggered by external factors (e.g., heavy physical work, violent quarrel, unusual mental stress) in a substantial minority of cases (10%) (15).

Work environment has become one of the most commonly studied environmental precipitants of stress-related cardiac disease, and it has been argued that work environment is more important to evaluate than individual factors (16). Johnson and Hall (17) found that job strain (high demand and low control) was associated with increased rates of CVD prevalence and that workers with the lowest level of social support had higher prevalence rates, regardless of level of job strain. Figure 11.1 provides a schematic of relative job strain associated with various common professions.

FIGURE 11.1 Illustration of the Karasek job strain model. Based on a job characteristics scoring system, occupations are characterized according to level of job demand and control. Workers with high demand and low control are at greater risk for cardiovascular disease. (Adapted from *The New York Times*, 3 April 1983.)

This research shows promise in providing evidence of the complex interaction of factors (e.g., work stress and social support) associated with CAD. Longitudinal data from a 14-year follow-up study revealed that working Swedish men with low control in their jobs had a significantly elevated risk for CVD mortality compared to men with high-control jobs (5). CV risk factors may also be affected by work stress. A study of 715 male shipyard workers found that the threat of job loss was associated with increased serum cholesterol, especially among those men reporting sleep disturbance (18). Thus, data suggest that work and related environmental stressors may have a significant influence on the development of CAD. However, individual differences in the frequency and magnitude of the stress response also suggest the importance of personality variables such as the TABP.

Type A Behavior Pattern

The TABP was first described in the late 1950s by cardiologists Meyer Friedman and Ray Rosenman, who observed in their patients a number of common behavioral characteristics and personality traits, including excessive competitiveness, extreme desire for recognition and achievement, chronic feelings of time pressure and urgency, as well as chronic feelings of anger and hostility (1). Although early research suggested a strong association of TABP with development of CAD (19), more recent data suggest that global TABP may not be associated with CAD (20,21). Thus, there remains controversy regarding the prognostic importance of TABP in primary and secondary prevention settings. Data from a recent metaanalysis indicate that global TABP may not be as relevant as more specific aspects of TABP, especially hostility (2).

Hostility and Heart Disease

Epidemiologic data evaluating personality traits associated with CAD suggest that chronic hostility and cynicism are the most pathogenic components of the coronary-prone personality (22). Smith has reviewed evidence for several models to explain the association (23). The psychophysiologic reactivity model is founded on the notion that individuals high in hostility are more likely to manifest larger increases in heart rate, blood pressure, and stress hormones in response to stressors than individuals with low hostility (22). However, the nature of the stressor may be important, as demonstrated by studies finding no association of hostility with reactivity in the context of nonsocial stressors (24) but significant associations in the context of interpersonal stressors (25). Other theoretical models linking hostility with disease

include the psychosocial vulnerability model (i.e., hostile individuals experience a more conflict-laden environment with less social support) and a health behavior model (e.g., hostile individuals may engage in poor health habits). The transactional model—representing a synthesis of the psychophysiologic and psychosocial models—posits that hostile individuals tend to respond to daily stressors with heightened CV and neuroendocrine reactivity and that these individuals experience more frequent, extreme, and enduring episodes of stress due to their hostile cognitions and overt behavior (23). Thus, all of the models linking hostility with CAD emphasize the interaction of the hostile individual with environmental stressors; this interaction supports the importance of individual constitutional variation and environmental factors.

Gender

Several studies suggest that gender differences may mediate the relationship between hostility and psychophysiologic reactivity. Davidson et al. (26) examined correlations between hostility scores from a Structured Interview assessment (27), scores on antagonism and neuroticism scales, and resting blood pressure among 193 undergraduate women and men. Whereas hostility was related to antagonism and higher resting blood pressure in men, hostility was related to neuroticism and lower resting blood pressure in women. Siegman et al. (28) explored the relationships between Structured Interview component scores and CAD status among 196 men and women undergoing thallium stress testing. Results of separate logistic regressions suggested that men with overt anger expression were at greater risk for CAD, but women with indirect expression of antagonism were at greater CAD risk. Similar results were observed by Lahad et al. (29) in a study comparing 277 women with a history of nonfatal MI with 988 case-control women without CAD. Lahad and colleagues found that hostile affect (i.e., the experience of negative affect in relationships) was associated with increased risk for MI, but aggressive responding (i.e., the tendency toward anger and aggression in response to problems) was associated with reduced MI risk.

Blood Serum

Recent studies have explored the relationship between hostility and lipid reactivity. In a study of 77 healthy women, Suarez et al. (30) observed significant elevations in total serum cholesterol and low-density lipoprotein cholesterol among women assessed as high in cynical and antagonistic hostility. Among healthy men (n = 98), Richards et al. (31) found significant associations between angry reactions (i.e., the tendency to experience and express anger in response to criticism or unfair treatment) and elevated total serum cholesterol and low-density lipoprotein cholesterol levels. Data also indicate that healthy women and men with high levels of hostility and men with inhibited anger expression may have higher levels of blood homocysteine (32). One hypothesized mechanism for this effect may be increased hemoconcentration associated with stress (33).

Depression and Anxiety

Although much early research was devoted to the relationship of CAD to TABP and its components, more recent data have suggested additional important psychological factors associated with CAD, especially anxiety and depression. In a metaanalysis of studies evaluating psychological functioning and CAD, it was found that the effect size for depression was as great as that of TABP or other known risk factors for CAD (2). Although anxiety was related to CAD, it was not as strongly related as depression. Thus, the traditional image of the coronary-prone individual as time pressured, impatient, and work oriented is not consistent with the data. Instead, a more appropriate image is that of someone harboring negative emotions, such as depression, anxiety, hostility, or aggression. Thus, hostility or anger would be supported as the most important component of TABP, but depression and anxiety also may be important predictors of CAD (2).

Depression has been implicated as an important factor in the initial onset of CAD (34), as well as among patients with previously diagnosed CAD. Frasure-Smith and colleagues (35) confirmed the importance of negative emotions, including depression, anxiety, and history of depression, for prognosis of post-MI patients. Results from their longitudinal study, included in Figure 11.2, suggested that post-MI depression was more strongly associated with arrhythmic deaths (3), whereas anxiety was more strongly associated with acute coronary syndromes (30). Carney et al. (36) found that major depressive disorder was the best predictor of cardiac events during the 12 months following catheterization among patients with CAD. It has been suggested that dysregulation of the autonomic nervous system—particularly, elevated resting heart rate and decreased heart-rate variability associated with reduced parasympathetic nervous system activity—may be one mechanism explaining the association of major depression with CAD (37). In a study of medically stable patients with CAD, heart-rate variability was significantly lower among subjects with moderate to severe depression than among mildly depressed and nondepressed patients (38). Also, depressed patients have been found to manifest elevations in heart rate at rest and under orthostatic challenge (39).

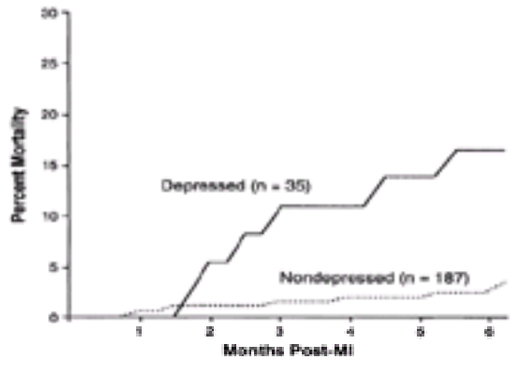

FIGURE 11.2 Cumulative 6-month mortality for depressed and nondepressed post–myocardial infarction (MI) patients. Depression was assessed with structured interviews during inpatient hospitalization (approximately 7 days post-MI). (Adapted from Frasure-Smith N, Lesperance F, Talajic M. Depression following myocardial infarction. Impact on 6-month survival. *JAMA* 1993;270:1821.)

The association of depression and CAD has continued to receive considerable attention and has led to current investigations of pharmacologic and behavioral interventions to treat depression among post-MI patients. Given the recent data indicating that exercise may be as efficacious as pharmacotherapy in the treatment of depression among healthy, older adults (40,41), exercise may be especially useful among cardiac patients in alleviating the physical and psychological symptoms associated with CAD. In addition, data from the Enhancing Recovery in Coronary Heart Disease (ENRICHD) trial should soon be available to evaluate the efficacy of cognitive-behavioral interventions among depressed patients with CAD. The ENRICHD trial is a multisite, randomized controlled clinical trial sponsored by the National Heart, Lung, and Blood Institute to examine the effect of cognitive-behavioral treatment for depression and poor social support on morbidity and mortality among post-MI patients. Participants were recruited for the study on the basis of having experienced acute MI and having clinical depression or being deficient in social support. Although results of ENRICHD and other clinical trials are not yet available, recent data underscore the importance of distinguishing long-standing depression and personality traits from acute, reactive depression after a cardiac event (34,42) and the relevance of examining interactions of depression with other psychosocial factors (e.g., social support). Acute depression in reaction to a cardiac event may be more amenable to relatively brief psychological intervention, whereas chronic depression is likely to involve a broader range of precipitating factors (e.g., other major life stressors in addition to health problems) and may require more intensive, long-term treatment.

Additional Psychological Factors

Numerous other studies have documented psychological and personality dimensions related to CAD. Among post-MI patients, data indicate that patients who experience distress and inhibited expression of emotion may have a higher rate of death than other personality types (43). Powell and Thoresen (44) found that the intensity of experiencing emotion was associated with reinfarction among coronary patients in the Recurrent Coronary Prevention Program, and Shekelle et al. (45) suggest the possibility of greater emotional susceptibility among post-MI patients based on data from a 10-year follow-up. Thus, the prospective data suggest that negative emotions, including hostility, depression, and anxiety, are predictive of coronary events. Among post-MI patients, inhibition of emotion and negative emotions, including cynicism, have been predictive of mortality. In addition, post-MI patients may be more emotionally vulnerable, potentially leading to greater intensity of emotional experience, which, in turn, is associated with cardiac events. The degree to which heightened emotional vulnerability is a cause or an outcome of MI remains unclear, based on the literature to date.

Social Support

During the past two decades, increased attention has been devoted to understanding the effects of social support on health, health behavior, and adherence to behavioral change programs. Cohen and Wills (46) have suggested that social support may have a beneficial effect on physical health by buffering the individual from the potentially pathogenic effects of stress. These researchers posit that the buffering effects of social support may act in two ways: (a) by preventing the appraisal of

stress immediately after an event (primary appraisal) or (b) by facilitating reappraisal (secondary appraisal) or inhibiting an emotionally linked physiologic response after an event is perceived as stressful. Cohen and Wills (46) note that social support may buffer stress by providing enhanced self-esteem, companionship, assistance in problem solving, and material aid. Several epidemiologic studies provide evidence to suggest that social support may act to mitigate the effects of chronic stress on the development of CAD. Population-based studies in Sweden have provided evidence that (a) low social support is associated with total and CV mortality in adults over the age of 35 (4); (b) men who reported feelings of loneliness had higher CV mortality rates than men not reporting loneliness (47); (c) low social activity, along with traditional risk factors, was associated with CV mortality (48); and (d) in a 3-year follow-up study of a CV risk reduction intervention, subjects who maintained health behavior changes had a larger support network and tended to be more family centered (49). A recent review of the literature suggested that social network is an important, independent risk factor for CVD in white middle-aged men and that the impact of social support is comparable to that of traditional risk factors for CVD (50). The effects of social support also have been found to interact with other risk factors for CAD among patients with symptoms of cardiac disease. In a sample of patients undergoing diagnostic coronary angiography, Blumenthal and colleagues (51) found that severity of CAD was negatively associated with perceived social support for TABP individuals, but no association of CAD and social support was found for type B participants.

In addition to its influence on appraisal of potentially stressful situations, social support may also affect CAD via the influence of caregivers and friends (a) encouraging appropriate health behavior change and use of medical care and (b) providing direct comfort and aid in tasks of daily living, thereby minimizing potential physical stresses (46,52). Relatedly, marriage may be an important source of social support associated with decreased risk of CAD. In a recent population-based study of risk factors for stroke among older adults in Australia, it was found that unmarried men had relatively low high-density lipoprotein cholesterol and relatively high systolic blood pressure, but widowed women did not have similar risk factors (53). In a population-based study pooling data from the Minnesota Heart Survey and the Minnesota Heart Health Program, separated or divorced persons had higher rates of hospitalization for heart attack or stroke than did married or widowed persons. However, separated or divorced persons also reported higher levels of smoking, drinking alcohol, and physical inactivity than did married persons (54). Thus, although spousal support may be important for facilitating health behavior changes in patients who are at risk of CAD and for supporting early identification of cardiac symptoms, data also indicate that hostile and antagonistic marital interactions may contribute to greater risk for CAD (55).

Psychophysiologic influences of social support on CV functioning via neuroendocrine or hemodynamic function also have been demonstrated. For example, among college-aged women, Kamarck et al. (24) found that CV reactivity (blood pressure and heart rate) to a mental stressor was attenuated by the presence of a friend. However, the study did not evaluate the extent to which this effect was cognitively mediated (i.e., the friend's presence minimized the cognitive stress of the task). A subsequent study (56) found that social support (e.g., the presence of a friend) influenced CV reactivity only in the presence of social threat and that the effect was most prominent among socially avoidant individuals. Thus, social support may interact with environmental or situational variables and individual personality dimensions to influence CV function.

Adherence and Risk-Factor Reduction

As awareness of risk factors for CAD has become more widespread through community education efforts, the need has grown for programs to support health behavior change. Most of the risk factors for CAD are behaviorally mediated and, thus, may be readily influenced and modified. For example, smoking, diet, and exercise activity all involve modifiable behaviors. However, it may be difficult to reach high-risk individuals in primary prevention, because it has been found that high-risk CAD groups (e.g., men, older adults, and individuals with less education) are less likely to make use of educational materials regarding CVD risk (57).

As shown in Figure 11.3, adherence to a behavioral program may be influenced by a number of factors, both individual and environmental. Among the most clearly identified individual factors affecting adherence are self-efficacy (i.e., the patient's belief that he or she will be able to achieve the behavioral goal) and self-motivation (58). Hellman (59) used a Stages of Change in Exercise Adherence (60) model to examine predictors of exercise adherence among cardiac patients who completed an inpatient rehabilitation program. This model consists of five stages of change in exercise adherence: (a) *precontemplation*—not exercising at present with no intent to begin exercising; (b) *contemplation*—not exercising at present but considering exercising in the future; (c) *preparation*—starting to exercise on a limited basis; (d) *action*—less than 6 months of regular exercise; and (e) *maintenance*—more than 6 months of regular exercise. Several predictor variables were shown to differentiate the stages of change in exercise adherence: perceived self-efficacy, perceived benefits of exercise, interpersonal support for exercise, and perceived barriers to exercise, with group means for exercise predictor variables increasing in a stepwise fashion from precontemplation to maintenance stages. Bock et al. (61) also used a stages of change model (60) to assess predictors of exercise adherence among 62 men and women who completed a 12-week cardiac rehabilitation program. At posttreatment assessment, 68% of patients had progressed at least one stage, with significant increases in self-efficacy and use of behavioral processes of change (e.g., reinforcement management, stimulus control) and significant reduction in ratings of the cons of exercise occurring from pre- to posttreatment. At a 3-month follow-up assessment, results indicated that patients who regressed toward earlier stages (42%) rated the cons of exercise higher than the pros, had decreased self-efficacy, and were less likely to use behavioral processes of change compared to patients who did not regress. Hershberger et al. (62) found significant associations between scores on a personality measure [e.g., Well-Being, Socialization, and Communality (i.e., similar views of self and others)] and percentage of exercise appointments kept among patients in cardiac rehabilitation.

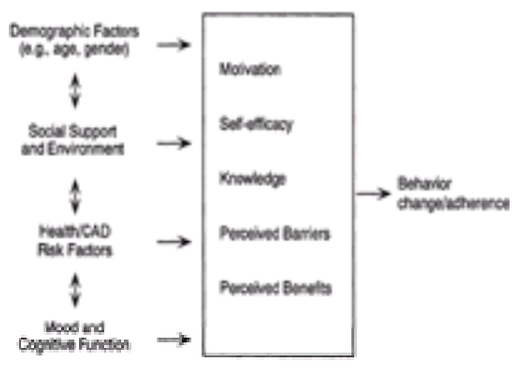

FIGURE 11.3 Hypothesized model of factors associated with adherence and behavior change. CAD, coronary artery disease.

Although studies of exercise adherence have been conducted among patients in cardiac rehabilitation programs, few studies have evaluated predictors of adherence outside of cardiac rehabilitation programs or adherence to health behaviors other than exercise. For example, environmental factors such as stress in the home or workplace may be associated with negative health behaviors (e.g., patient may resume smoking, overeating, or drinking to cope with stress at work) through the patient's reliance on previous maladaptive coping strategies. In a study of 118 healthy men enrolled in a CAD prevention program, Naslund et al. (63) noted that poor compliance with increased consumption of dietary fiber was associated with hostility, perceived barriers to diet modification, and little knowledge of CAD risk factors. Poor compliance with a low-fat diet was related to younger age, smoking, and negative family history of CAD. Poor compliance with exercise was associated with younger age and having children living at home. Further study is required to evaluate the complex interaction of psychological and social variables affecting adherence.

BIOBEHAVIORAL FACTORS IN THE PATHOPHYSIOLOGY OF HEART DISEASE

As theoretical advances have been made in evaluating physiologic mechanisms of behavioral and psychological effects in CAD, the major thrust of research has been directed toward studies of CV reactivity.

Cardiovascular Reactivity

Studies suggest that stress may contribute to the development of CAD via stress-associated, chronic, exaggerated reactivity of the sympathoadrenal-medullary and pituitary adrenal-cortical systems, triggering hemodynamic changes or biochemical alterations that lead to damage of artery walls (6). The impact of CV reactivity is thought to be cumulative, contributing to injury of the endothelium and to deposition of cholesterol on the artery wall. Among patients with CAD, CV reactivity may also contribute to myocardial ischemia and arrhythmias (23). Studies generally confirm an association of elevated CV reactivity in individuals with symptoms of CAD or hypertension (6). Indeed, among post-MI patients, CV reactivity to a cognitive task (the Stroop test) predicted subsequent clinical events (i.e., MI and stroke) (7). Furthermore, among mildly hypertensive subjects, CV reactivity was associated with elevated total cholesterol levels, as well as elevated low-density lipoprotein cholesterol and lower levels of high-density lipoprotein cholesterol (64). In research with cynomolgus monkeys fed an atherogenic diet, it has been demonstrated that monkeys responding to stress with high heart-rate reactivity had significantly greater coronary atherosclerosis than did low heart-rate reactors (65). In humans, laboratory studies have confirmed stress-associated CV and neuroendocrine changes (6), and it has been theorized that stressful interpersonal interactions and work environment may be potent precipitants of increased nervous system reactivity, leading to acute changes in CV or endocrine functioning. Thus, CV reactivity is viewed as a marker of the stress response and as a mechanism in the pathophysiology of heart disease.

In psychophysiologic studies of CAD, CV reactivity is a critical outcome measure that can be evaluated reliably in a laboratory setting. The methodology for measurement of CV reactivity may be specific to the clinical and research questions being addressed, and several methodologies have been summarized elsewhere (66). Because of the limited generalizability of laboratory measurement of CV reactivity, measurement of CV and neuroendocrine functioning in naturalistic settings is increasingly emphasized in clinical research studies.

Health-Damaging Behavior

The health behavior model described by Smith (23) suggests that the association between hostility and CAD is the result of poor health behavior among hostile individuals. In support of this model, Smith summarizes studies that have demonstrated associations between hostility and low physical exercise, low self-care, higher alcohol consumption, higher body mass index, and more cigarette smoking. However, the interrelationship of hostility, health behavior, and CAD has not been evaluated. Frasure-Smith et al. (3) suggest that health behavior change among cardiac patients also may be impaired by affective distress (e.g., depression and anxiety). Although social support may serve to moderate somewhat the negative effects of emotional state and personality on health behavior change, the effect of personality and emotions on adherence to preventive and rehabilitative health behaviors has not been investigated.

Cognitive functioning also may affect an individual's ability to conduct adequate self-care and follow prescribed health care regimens. Although several studies have documented cognitive deficits among cardiac patients (67,68), only one study has evaluated the association of cognitive functioning with health behavior in cardiac patients. In a sample of clinically stable cardiac rehabilitation patients, Barclay and colleagues (69) found that 35% were so cognitively impaired that they were unable to self-administer medications appropriately. The evaluation of interactions of cognitive performance with health and health behavior is especially important among older adults with or at risk for CAD.

Relationship among Areas of Behavioral Medicine

As the research data indicate, it is difficult to define psychosocial functioning by addressing only one of the many psychosocial factors in CAD because these factors are likely to be interrelated. For example, social support may mitigate the association of TABP with CAD, as well as minimize CV reactivity to laboratory stress. Figure 11.4 provides an illustration of the relationships among various behavioral factors suggested by the research data thus far.

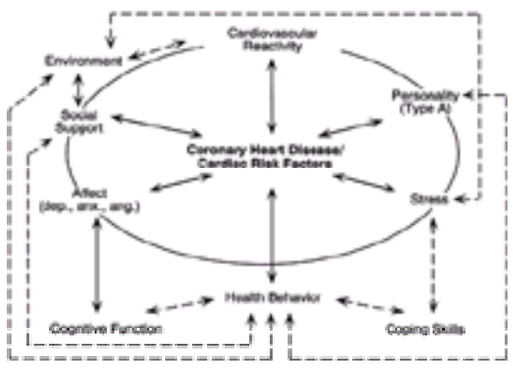

FIGURE 11.4 Psychosocial factors associated with coronary heart disease and cardiac risk factors. Stronger associations are depicted with solid arrows; less strong associations are depicted with hatched arrows. ang., anger; anx., anxiety; dep., depression.

CLINICAL PROFILE AND ASSESSMENT

The historical research data suggest that the typical CAD patient is likely to manifest one or more components of TABP—most likely hostility or cynicism, as well as other negative emotions such as depression or anxiety. In addition, the patient's work and home environments may present obvious or subtle stressors of a chronic nature, and social support may be limited. Although not all CAD patients present with psychosocial problems, the clinician addressing behavioral issues among CAD patients must use adequate assessment techniques to facilitate appropriate treatment strategies.

Several assessment instruments have been used by researchers to measure psychiatric symptoms, physical symptoms, psychological functioning, social support, and stress. A listing of common assessment instruments is included in Table 11.1. The Structured Interview assessment was the first instrument designed to measure TABP and remains the benchmark of global TABP assessment tools (70). In addition, the Structured Interview can be used to evaluate potential for hostility (i.e., tendency to experience anger and resentment, tendency to react to aggravating events with antagonism and rudeness) (71), which has been associated with CV outcomes (23). Use of more specific assessment tools has helped isolate anger and hostility as the potentially toxic components of TABP. The Cook-Medley Hostility Scale (72), derived from the Minnesota Multiphasic Personality Inventory (73), is one of the most widely used self-report instruments to assess hostility. The Beck Depression Inventory (74) is a 21-item, self-report questionnaire that measures severity of depressive symptomatology, although it is not designed to diagnose clinical depression. In a study by Frasure-Smith et al. (3), the Beck Depression Inventory predicted later post-MI mortality in patients who did not meet criteria for major depression. The Social Support Questionnaire (75) consists of a series of items that yield scores for a perceived number of social supports and satisfaction with social supports. Measures of work stress also have been included in assessments of psychosocial risk in CVD. The Job Content Questionnaire, developed by Karasek (76), includes two scales that define job strain: decision latitude and psychological job demands. Job strain as measured by the Job Content Questionnaire was shown to be a risk factor for hypertension and increased left ventricular mass in a sample of 215 working men employed in a variety of jobs at seven urban work sites (76).

TABLE 11.1 PSYCHOSOCIAL ASSESSMENT INSTRUMENTS COMMONLY USED IN CARDIOVASCULAR MEDICINE

These measures represent a sampling of instruments available for assessment of behavioral and psychological factors among patients with CAD. Although there are no firm guidelines for selecting appropriate assessment instruments, it is important that behavioral and psychological evaluation be conducted. Assessment of hostility, depression, social support, and work strain is especially important, given these factors' relevance for patients with CAD.

BEHAVIORAL AND PSYCHOLOGICAL INTERVENTIONS

Most cardiac risk factors are modifiable, with the exceptions of age, gender, and family history. Primary prevention strategies tend to target at-risk behaviors, such as cigarette smoking, poor dietary habits, and sedentary lifestyle. Secondary prevention efforts also aim to reduce health-damaging behaviors and improve compliance with physicians' recommendations; these efforts often include additional therapeutic techniques to reduce the impact of psychological distress and other psychosocial risks that can interfere with a positive prognosis. Among the intervention strategies commonly used are stress reduction techniques, relaxation training, biofeedback, and other psychotherapeutic interventions. However, none of these techniques is mutually exclusive. Most studies of psychosocial interventions among cardiac patients have evaluated the effects of stress-management interventions encompassing relaxation training and selected other techniques, such as cognitive counseling (e.g.,

identifying and challenging irrational, stress-producing thought patterns) or behavioral counseling (e.g., modifying contingencies for desired behavior). Relaxation techniques typically include breathing exercises and PMR—a process of systematic tensing and relaxing of major muscle groups throughout the body. Cognitive and behavioral components of stress management have included specific skills training, such as public speaking training, stress-inoculation training emphasizing positive self-statements, biofeedback-assisted relaxation training with electromyography and heart-rate feedback, and affect regulation, including appropriate expression of anger and hostility. Few studies have been conducted to compare the relative efficacy of the stress-management components. The only study contrasting components of stress management among cardiac patients found no significant differences between a relaxation condition and a no-relaxation stress-management condition (i.e., monitoring negative self-statements) with regard to psychological functioning (i.e., decreases in social anxiety) (77).

Stress Management

The effects of stress management on cardiac outcomes have been studied mainly in secondary prevention. The Ischemic Heart Disease Life Stress Monitoring Program (35) examined the impact of stress monitoring and intervention in 543 male post-MI patients randomly assigned to a treatment condition or no-treatment control. Subjects in the treatment condition received monthly telephone calls from nurses who assessed stress levels. If the subject's monthly stress level was above the standard criterion (i.e., above 4 on the General Health Questionnaire; 78), he would receive individual counseling and advice designed to alleviate stress. Results indicated that the monitored group showed a greater decline in stress levels compared to no-treatment controls. Although the monitored group did not differ from the controls in the incidence and length of hospital readmissions, the rate of mortality for that group was significantly lower. Data from this study are depicted in Figure 11.5. The authors suggest that stress reduction interventions may play a greater role in lowering cardiac mortality than in preventing future nonlethal cardiac episodes. Unfortunately, the investigators did not control for the type of counseling offered to each subject; indeed, they suggested that the phone call itself might have been responsible for lowering stress levels.

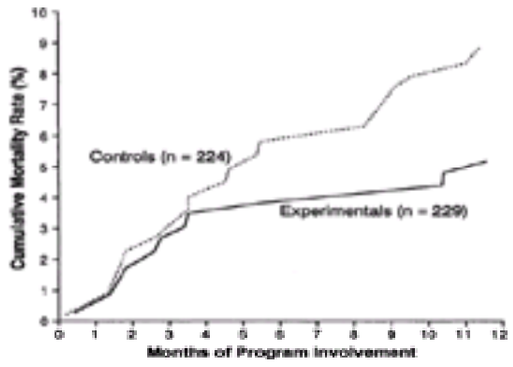

FIGURE 11.5 Life-table cumulative mortality rates for post–myocardial infarction patients randomly assigned to experimental group (stress monitoring) or no-treatment control group. (From Frasure-Smith N, Prince R. The ischemic heart disease life stress monitoring program: impact on mortality. *Psychosom Med* 1985;47:438, with permission.)

Among post-MI subjects, stress-management interventions (e.g., coping skills training, PMR, deep breathing exercises, biofeedback) have been found to provide greater cardiac benefit (i.e., significantly fewer arrhythmias, less chest pain, and better overall cardiac status) than cardiac education alone (79), and the effect of stress management on psychophysiologic reactivity has been found to be comparable to that of drug treatment (e.g., propranolol) (80). Stress management also has been evaluated as an adjunct to exercise rehabilitation in a study of 45 post–coronary artery bypass graft patients randomly assigned to (a) conventional medical therapy and exercise rehabilitation or (b) conventional therapy, exercise rehabilitation, and stress-management intervention (81). Exercise rehabilitation included three 1-hour workouts per week for 18 weeks. Stress-management intervention included eight 90-minute sessions that provided education about TABP, expression of anger and hostility, use of humor, and autogenic training—a form of relaxation training. Subjects received a booster session 1 month after the end of the program. Results indicated that subjects in the stress-management intervention experienced reduced blood pressure reactivity, as well as improved perceived health status and decreased triglyceride levels. The conventional treatment showed a decrease in high-density lipoprotein. Blumenthal et al. (82) compared the effects of stress management or exercise on myocardial ischemia and risk for cardiac events among 107 CAD patients exhibiting ischemia during mental stress tasks or ambulatory monitoring. Patients were randomized to stress management (i.e., psychoeducational group sessions, monitoring and modifying irrational thoughts, PMR, and biofeedback) or an exercise intervention (i.e., riding on a stationary bicycle, walking, and jogging three times per week) for 4 months. Patients residing at a distance from the study site comprised a nonrandom, usual-care control group. Patients were contacted at 4 months, 10 months, and at yearly intervals up to 5 years to assess cardiac morbidity and mortality. Compared to patients in the usual-care control group, patients in the stress-management group had significantly lower relative risk for cardiac events throughout the 5-year follow-up period. In addition, subjects in the stress-management condition experienced reductions in ischemia during mental stress and ambulatory monitoring.

Dusseldorp et al. (83) conducted a metaanalysis of 37 studies to evaluate the effects of stress-management and health-education programs on cardiac morbidity and mortality and risk-factor reduction. Stress-management programs were defined as psychotherapeutic or supportive interventions or as relaxation training. Health-education programs involved contact between professionals and patients for organized instruction on CAD risk-factor reduction and behavioral change. Results of this quantitative review found that stress-management and health-education programs provided an average of 34% reduction in cardiac mortality, a 29% reduction in recurrent MI, and significant improvements in blood pressure, cholesterol, weight, smoking cessation, exercise, and diet. Programs that had greater success in risk-factor reduction showed, in turn, the strongest effects on disease outcome variables.

In a primary prevention study, Patel and colleagues (84) examined the effects of relaxation training—including breathing exercises and meditation techniques—among 192 men and women with two or more coronary risk factors (e.g., high blood pressure, high cholesterol, or cigarette smoking). Subjects were randomly assigned to a treatment group that received health-education leaflets and 8 weeks of relaxation training or to a control group that received only the educational leaflets. In the relaxation group, systolic and diastolic blood pressure were significantly reduced after 8 weeks, as well as at 4-year follow-up. No significant blood pressure changes were observed in the control group; at 4-year follow-up, the control group had a significantly higher incidence of ischemic heart disease, fatal MI, or electrocardiographic evidence of ischemia.

Beneficial effects of relaxation-based stress management also have been observed among patients with diagnosed CAD. Trzcieniecka-Green and Steptoe (85) examined the effects of a 12-week stress-management program on various aspects of psychosocial functioning in 78 patients who had recently experienced MI, coronary artery bypass graft surgery, or coronary angioplasty. Results indicated that subjects experienced a reduction in anxiety, an improvement in activities of daily living and social activities, and greater satisfaction with sexual relationships; these effects were largely maintained at 6-month follow-up.

Relaxation training also has been evaluated as an adjunct to standard exercise-based cardiac rehabilitation programs. Progressive relaxation training among 18 post-MI patients in a cardiac rehabilitation exercise program was associated with lower State Anxiety scores and reduced somatization, anxiety, and depression scores compared with scores of 19 nonrandomized control subjects who were not provided relaxation training (86). Munro et al. (87) examined the effect of relaxation training among 27 subjects in cardiac rehabilitation compared to 30 nonrandomized controls who received standard treatment. At 3-month follow-up, the relaxation group sustained a significant reduction in diastolic blood pressure, but the control group did not. However, relaxation had no effect on psychosocial functioning.

Van Dixhoorn and colleagues examined the impact of relaxation training as an adjunct to exercise-based cardiac rehabilitation programs in a series of randomized trials. Post-MI patients who received exercise training plus relaxation and breathing therapy had less cardiac dysfunction (88) and a significantly lower rate of reinfarction (17%) than patients receiving exercise training alone (37%) (89). Exercise alone did not affect psychosocial variables, but exercise combined with relaxation training resulted in reductions in anxiety and improvements in well-being (90).

Behavioral Counseling and Therapy

The impact of behavioral and psychological factors on CVD outcomes suggests that mental health and behavioral interventions should be part of multidisciplinary treatment programs and secondary prevention strategies (91). Although data indicate that psychological counseling may be associated with improved prognosis, few published studies have examined the effects of psychotherapy in cardiac care. In one early study, a group of six post-MI patients showed improvements in psychosocial functioning after nondirective group therapy (92).

In a randomized block-design study, 46 post-MI patients were assigned to one of three groups: an educational intervention that included cardiac information and relaxation training, an education plus counseling intervention involving six to ten sessions of individual psychological counseling in addition to the educational

intervention, or a control condition of routine medical care (93). After 3-, 6-, and 12-month follow-ups, both intervention groups demonstrated significant improvements in psychological and lifestyle functioning and reported fewer cardiac symptoms compared to the control group.

Cognitive and behavioral counseling appears to have been effective in modifying TA behavior in the Recurrent Coronary Prevention Program (94). Post-MI patients (n = 862) were randomly assigned to group cardiac counseling, group cardiac counseling plus TA behavior modification counseling, or a waiting-list control condition. Cardiac counseling focused on strategies improving behavioral compliance with medical recommendations. TA counseling included relaxation, cognitive therapy, and graded behavioral assignments. The cardiac counseling group met biweekly for 3 months, monthly for 3 months, and bimonthly until the conclusion of the study; the TA behavior modification group met weekly for 2 months, biweekly for 2 months, and monthly through the conclusion of the study. After 1 year, results indicated significantly greater changes in global TA ratings, hostility, and anger in the TA modification intervention than in the cardiac counseling group. At the 41/2-year follow-up evaluation, the TA modification group had a significantly lower reinfarction rate than the cardiac counseling group (13% vs. 21%). The TA modification group also reported greater improvements in self-efficacy and social support and lower levels of depression than the cardiac counseling group. Although the results suggest that TA counseling was associated with a decreased reinfarction risk, the intervention may have affected other psychosocial indicators associated with CAD (95), such as depression and anxiety.

In a recent study, 22 highly hostile CAD patients were randomly assigned to a hostility intervention consisting of eight 90-minute, weekly group meetings or a one-session information control group (96). The intervention addressed behavioral, cognitive, and affective hostility factors, as well as relapse prevention. Immediately after treatment and at 2-month follow-up assessment, intervention patients had lower hostility on self-report and interview ratings and lower resting diastolic blood pressure compared to control patients. Moreover, significant positive correlations were found between reductions in hostility and diastolic blood pressure. Davidson et al. (97) subsequently examined patient interviews from this sample and found that the relationship between reductions in hostility and diastolic blood pressure was mediated by increased ability to express anger verbally in a constructive fashion.

Investigators have developed theories to explain the relationship between hostility, interpersonal interactions, and CV reactivity. Davidson et al. (97) theorize that when hostility and cynicism are minimized, previously hostile individuals' enhanced willingness to participate in problem solving reduces their exposure to interpersonal provocation, which, in turn, reduces blood pressure reactivity. Stoney and Engebretson (98) suggest that expressions of anger be considered in terms of two modes of expression: (a) "communicative" expressions that are nonthreatening or (b) "aggressive" expressions that involve the intent to inflict verbal or physical harm. The notion that verbal expressions of anger can be constructive is supported by the results of a recent study that found a positive relationship between anger expression and quality of social support among 246 undergraduate men and women (99).

Multidisciplinary Interventions

Recent cardiac intervention studies have incorporated several behavioral strategies into multidisciplinary efforts. Ornish and colleagues (100) conducted a randomized controlled clinical study of an intensive multidisciplinary intervention on patients with CAD. Twenty-eight subjects participated in the treatment group, and 20 subjects participated in the usual-care control group. Treatment subjects were provided an intensive 1-week retreat at which they were instructed in numerous areas of lifestyle change, including initiating a low-fat vegetarian diet (i.e., <10% calories from fat), practicing stress management for at least 1 hour per day (e.g., stretching and breathing exercises, meditation, progressive relaxation, and imagery), and exercising regularly (i.e., minimum of 3 hours per week with 30 minutes at target heart rate). After the retreat, intervention subjects participated in group support meetings for 4 hours twice a week. At 12-month follow-up, experimental subjects had reduced cholesterol, fewer angina episodes, and significant regression of coronary atherosclerosis, but control subjects were unchanged. Better adherence to the experimental regime was associated with greater decreases in stenosis of the arteries, as shown in Figure 11.6. Experimental subjects continued to exhibit regression of coronary atherosclerosis at 5-year follow-up; control subjects showed progressive coronary atherosclerosis and had twice as many cardiac events (101). Although the results are impressive, the study has been criticized for several reasons. The intensive nature of the treatment raises questions as to its viability, cost-effectiveness, and generalizability to larger samples. Only half of the 94 original subjects randomized to treatment and control conditions agreed to participate in the study, raising the possibility of selection bias. In addition, the study did not discriminate between the effects of individual components of the multidisciplinary treatment program.

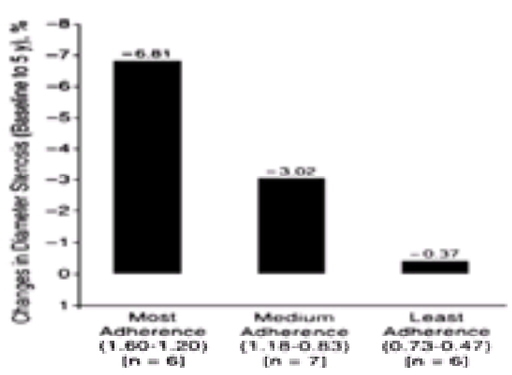

FIGURE 11.6 Percentage change in coronary arterial diameter stenosis over 5 years by adherence tertiles for coronary heart disease patients assigned to intensive lifestyle (exercise, diet, stress management) intervention. (Adapted from Ornish D, Scherwitz LW, Billings JH, et al. Intensive lifestyle changes for reversal of coronary heart disease. *JAMA* 1998;280:2005.)

The Women's Lifestyle Heart Trial (102) used the methodology developed by Ornish et al. (100) in a study of 25 postmenopausal women with CAD. Fourteen women were randomized to the treatment group, and 11 were randomized to the usual-care control group. Results at 4-, 12-, and 24-month follow-up showed significantly greater improvement for the treatment group, as reflected by decreases in body mass, angina symptoms, and hypertension medications, as well as increases in self-reported quality of life. There were also trends toward lower lipids and blood pressure in the treatment group, as well as reductions in lipid-lowering medications.

Spoth et al. (103) assessed a minimal multidisciplinary intervention in 47 patients undergoing coronary angioplasty. Patients were randomized to one of three treatment conditions: minimal intervention (1-day risk-reduction educational workshop plus individual consultation on behavior change), minimal intervention plus biofeedback training (six 1-hour sessions), or waiting-list control. Both intervention groups showed greater increases in knowledge about CVD risk reduction strategies, but the group in the combined program had a greater benefit in self-reported lifestyle behavior change.

Several community-wide primary intervention trials aimed at reducing behavioral and psychosocial risk factors have been studied [e.g., Purdue Stepped Approach Model (104); Stanford Five-Cities Project (105)]. Although clinical interventions are more intensive and responsive to individual cognitive, behavioral, and psychological needs, community interventions have the advantage of reaching a much larger audience (104). The majority of these interventions is based on health-education and health-promotion strategies; the results are generally encouraging, revealing improved use of educational resources and compliance with health-promotion programs.

The intervention strategies reviewed show promising results, but they suffer from methodologic shortcomings. Most strategies are lacking randomized control groups; many have high dropout rates, small samples, and unbalanced sample sizes in treatment conditions and lack assessment of long-term cardiac outcomes. Ethical concerns may contribute to the methodologic problems, such as reluctance to include a no-treatment control group in clinical settings. There may also be a bias toward publishing only positive results. Despite these shortcomings, the findings are encouraging and suggest that stress-management approaches can be an effective component of primary and secondary efforts to minimize the impact of CAD. Specifically, the data suggest that clinical behavioral and psychological management of cardiac patients should include (a) relaxation training, (b) education regarding cardiac risk factors, (c) identification of social and environmental stressors, (d) facilitation of social support mechanisms, and (e) focused cognitive approaches to stressful interactions (e.g., positive self-talk, thought stopping, distraction). The data suggest that such interventions provide additional benefit to cardiac patients beyond the benefits of exercise per se. Although the efficacy of stress management and relaxation has been demonstrated, no studies have evaluated the appropriate "dose" required.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Psychological Influences in Heart Disease

Decades of research have helped to refine the TABP construct and delimit its components (e.g., hostility and cynicism), which appear to be associated with the etiology of CAD. Recent data suggest that depression also may be an extremely important psychological factor in the etiology of CAD, as well as in mortality post-MI. There is acknowledgment of the importance of environmental or interpersonal factors in the manifestation of coronary-prone behavior, as well as the importance of situational appraisal as a hypothesized modifiable link between stimulus and physiologic response. The transactional model described by Smith (23) posits that the hostile individual creates situations that are challenging and stressful. Although no studies have directly tested this model, it deserves further scrutiny to evaluate the full extent

to which the hostile or coronary-prone individual exerts control over physiologic responses and cognitive or emotional responses. In the treatment literature, it is assumed that individuals exert a considerable amount of influence over select aspects of physiology and cognition. However, the parameters of control must be explicated further to help direct future psychosocial interventions among patients at risk for cardiac disease.

Environmental influences also may affect the individual's health-promoting behavior, thereby having an indirect influence on the development or progression of CAD. Although the research literature has addressed various psychosocial components related to CAD, studies have not addressed more complex models integrating psychophysiologic, social, environmental, and personality variables. Thus, despite data suggesting the relevance of several psychosocial variables, there is minimal documentation of the way in which the variables interact or the relative importance of psychosocial variables. For example, O'Neil and Emery (99) found a positive relationship between anger expression and quality of social support among college undergraduates with a family history of CAD. This counterintuitive result of a higher quality of social support for people who express anger may reflect the positive aspects of a greater willingness to discuss problems and emotions with close friends. In addition, the presence of a curvilinear relationship between hostility and quantity of social support in this study suggested the possibility that social relationships may increase with a moderate degree of cynicism but not with a high degree of cynicism (99). Thus, it is important to recognize that factors associated with CAD may interact in unexpected ways.

Brummett et al. (106) found a directly inverse relationship between CAD patients' perceived social support during hospitalization and depressive symptoms 1 month after discharge; hostility was indirectly predictive of postdischarge depressive symptomatology due to its negative association with social support. In a comparative population study of Lithuanian and Swedish men (107), a four-fold higher CAD mortality rate for Lithuanian men was associated with poor social support, low self-esteem and quality of life, depression, vital exhaustion, and poor expectations for health and well-being. Data suggest that social support may have less impact than negative emotions on cardiac events among post-MI patients (3), but further research will help to clarify models describing the relative impact of psychological and social factors in CAD.

In clinical practice, data suggest the importance of teaching relaxation skills, addressing psychological distress, especially depression and anger, and working with patients in identifying social and environmental sources of stress and support. Although none of these areas is easily addressed by the practicing cardiologist, recent data suggest that cardiac patients' satisfaction with health care providers' support is associated with enhanced recovery times (108). Thus, it is important for the cardiologist to attend to the patient's concerns and provide support directed at those concerns while encouraging the patient to make positive steps forward in recovery and health-behavior change. The cardiologist may help the patient view the illness as an opportunity to reevaluate priorities and set new goals, thereby encouraging the patient to remain oriented toward the future instead of dwelling on perceived past mistakes. Perhaps the most important role for the cardiologist is to help the patient identify specific individuals (e.g., spouse, child, friend) who will be supportive of the patient and future behavioral changes. Toward that end, cardiac rehabilitation programs provide an excellent environment for the patient to receive emotional and physical support from staff members and fellow patients, in addition to learning further strategies for exercise, nutrition, and stress management.

Measurement and Data Analysis

Despite the availability of a wide range of psychosocial assessment procedures, implementation of the assessments may be restricted. For example, metaanalysis has indicated that self-report measures of TABP are not adequate and that the Structured Interview is a preferable assessment technique for TABP (2). However, the Structured Interview is a more cumbersome and expensive assessment because it requires a face-to-face interview conducted by trained interviewers and scoring of videotaped interviews. Thus, the Structured Interview may be impractical in many settings, and clinical investigations of TABP and related factors (e.g., potential for hostility) may be constrained by inadequate measurement. Studies of more specific psychological and personality factors (e.g., depression or neuroticism) are likely to be easier because of the availability of valid and reliable self-report measures.

Technological advances have enhanced the reliability of CV reactivity measurement, and CV reactivity may have utility as an outcome for the clinician to document changes over time in physiologic response to laboratory or environmental stress. However, analysis of reactivity data remains controversial due to conflicting methodologies for analysis of the complex data resulting from reactivity studies. In addition, measurement of CV parameters, especially determination of baseline values, may be subject to experimental bias or neglect (66). Although data indicate the importance of the cardiac patient's home and work environment as potential sources of interpersonal conflict and work stress, there is a lack of reliable measurement of environmental factors and a lack of agreement regarding choice of environmental factors to measure. Because the analysis of psychological-environmental interactions in the pathogenesis of CAD remains a critical area for further study, it is important for clinicians working with cardiac patients to help elucidate relevant environmental factors to consider for evaluation.

Implementation of Behavioral and Psychological Interventions

Evidence exists for the importance of psychological factors (e.g., depression, hostility) in the pathogenesis of CAD, as well as for the effectiveness of behavioral and psychological interventions in modifying psychosocial risk factors (109). Although behavioral and psychological approaches are increasingly embraced in the practice of CV medicine, there remains a bias against directly addressing psychological issues. This bias may stem from several sources, including (a) patients and family members who are reluctant to acknowledge that psychological or social factors may play a role in the patient's health and heart condition and (b) inadequate resources available for behavioral assessment and treatment. The result of this bias is that, often, only patients who are most distressed, most difficult to manage, or unresponsive to traditional medical care are referred for behavioral and psychological evaluation. Such patients may be angry at the health care system and less willing to address psychological issues, thereby undermining the efficacy of the intervention. However, data from randomized clinical studies support the utility of behavioral and psychological interventions for the average patient. Thus, the most efficacious approach for addressing behavioral and psychological issues among cardiac patients is to provide all patients with psychological evaluation, group support, and individual follow-up intervention as needed. The accumulated evidence supporting the relevance of behavioral and psychological factors in CAD indicates that a behavioral and psychological assessment and treatment model would be appropriate in primary care settings, as well as in rehabilitation settings. By making behavioral evaluation a routine part of practice, all patients would benefit without fear of being stigmatized.

Factors limiting the ability to implement a behavioral and psychological evaluation and treatment program among cardiac patients are the reluctance of third-party payers to reimburse for behavioral services and the difficulty that most patients have paying for medical costs out-of-pocket. This problem can be addressed, in part, by health care providers who are sensitive and responsive to behavioral issues. More important, systematic collection of behavioral and psychological outcome data can help to clarify the utility of behavioral and psychological assessment and treatment among cardiac patients and patients at risk for CAD. In addition, further clinical studies are needed that compare the effects of established behavioral interventions (e.g. relaxation training, cognitive therapy) and lifestyle interventions on the incidence and progression of CAD and that evaluate psychological factors associated with long-term adherence and behavior change among patients with CV risk factors and CAD. The accumulated evidence to date suggests that behavioral and psychological factors are of critical importance in the etiology and treatment of CAD and cardiac risk factors. By implementing and evaluating behavioral interventions, it is possible to refine intervention techniques and develop symptom- and illness-specific behavioral and psychological assessment and treatment protocols.

THE FUTURE

Empirical studies have documented the potent effects of negative emotions on the development and course of CAD, and studies support the importance of CV reactivity and related neuroendocrine changes as pathophysiologic mechanisms by which stressful events may contribute to the development of CAD. Future clinical research will be dedicated to the task of evaluating the complicated interactions of social, psychophysiologic, and health behavior factors in the development of CAD and the mechanisms explaining interactions of these factors with emotions and coping skills. In addition, future research will further explore the mechanisms by which gender may interact with behavioral, psychological, and physiologic factors in the etiology of CAD. Studies will also address treatment outcomes among cardiac patients to determine the most effective strategies for minimizing the influence of negative psychosocial factors in the epidemiology of CAD.

ACKNOWLEDGMENT

This work was supported, in part, by a grant from the National Heart, Lung, and Blood Institute.

OVERVIEW

Cardiac rehabilitation is a well-defined process that has changed over the years from a narrowly focused, closely monitored exercise program for coronary patients to a widely applied secondary prevention process, available to a broad range of patients with cardiovascular disease. Risk reduction outcomes are closely tied to specific individualized patient goals, often delivered in a case-management format. The greatest benefits are often manifest in the highest-risk patients and extend to women, elderly patients, and patients with chronic heart failure (CHF). The best determinant of patient participation in cardiac rehabilitation is the strength of the primary physician's recommendations, and these physicians should be actively recruited into the rehabilitation process from acute coronary event to participation in long-term preventive care.

Cardiac rehabilitation is highly cost-effective and is associated with a decrease in cardiac hospitalizations. The cardiac rehabilitation facility should be viewed as the clinical site at which systematic secondary prevention services are delivered in an outpatient setting in collaboration with the primary physician. The maintenance of physical functioning, the prevention of coronary disability, and the prevention of recurrent coronary events are the primary outcome goals.

BACKGROUND

Cardiovascular disease is the leading cause of death and premature disability in the United States for both men and women (1). It is also a major cause of disability in the rapidly growing elderly population (2,3). Coronary artery disease (CAD) usually presents clinically as angina pectoris or acute myocardial infarction and affects more than 13 million Americans, with many more cases remaining undiagnosed. More than 1 million individuals survive a myocardial infarction yearly in the United States, and another 750,000 undergo coronary revascularization procedures (4,5). The maintenance of physical functioning and the prevention of second coronary events and rehospitalizations in these populations are major preventive health challenges and require a systematic approach.

The current perspective of cardiac rehabilitation is that of a structured "secondary prevention" center, with on-site and home-based exercise programs, lipid clinics, weight loss programs, and other risk-factor modification components aimed at preventing second coronary events, cardiac rehospitalizations, and cardiac disability in patients with established CAD (6,7). Cardiac rehabilitation services include medical evaluation; prescribed exercise; and cardiac risk-factor modification, education, and counseling. Services are tied to a series of short-term and longer-term outcomes, which include return to work and measures of physical functioning, cardiac symptoms, psychological well-being, risk factors, progression of coronary atherosclerosis, recurrence of cardiac events, and number of rehospitalizations. Cardiac rehabilitation is prescribed for patients with myocardial infarction, coronary bypass surgery or percutaneous angioplasty, chronic angina pectoris, CHF, or heart transplantation and for selected patients who have had valvular heart surgery or exertional arrhythmias (8,9). Debate is ongoing as to whether early outpatient exercise training requires direct supervision or whether it could effectively be more widely applied, for low- and moderate-risk patients, in the home setting (10,11,12 and 13).

HISTORICAL PERSPECTIVE

Cardiac rehabilitation was conceived in an era when postmyocardial infarction activity prescriptions were evolving from 6 weeks of bed rest in the 1930s, to "chair" therapy in the 1940s, to 3 to 5 minutes of walking per day at 4 weeks in the 1950s (14,15 and 16). By the early 1960s, clinicians recognized that early ambulation helped patients avoid many of the complications of bed rest, such as pulmonary embolism and deconditioning, and in-hospital ambulation gradually displaced long-term bed rest as the standard of care (17,18 and 19). As the ambulation process extended beyond hospital discharge, concerns about the safety of unsupervised exercise resulted in the development of highly structured, physician-supervised, electrocardiographically monitored exercise programs in the 1970s. The focus was almost exclusively on exercise. By the 1990s, hospitalizations for acute myocardial infarction had shortened and are now as brief as 3 to 4 days (20), so that deconditioning is minimal. However, so is the opportunity to counsel patients about risk-factor modification. Smoking-relapse prevention programs, initiated in-hospital, have proven effective (21), but therapy and education for other modifiable risk factors are largely left for the postdischarge period.

With the development of a body of literature supporting the benefits of risk-factor modification in coronary patients (called *secondary prevention*), the cardiac rehabilitation center has evolved to become a clinical site for the systematic delivery of secondary prevention services. Recently demonstrated benefits of cardiac rehabilitation and secondary prevention in coronary patients are broad and compelling. Metaanalyses of exercise rehabilitation after acute myocardial infarction have demonstrated a 20% to 25% decrease in the overall mortality rate and in sudden cardiac death in the 3 years after infarction (22,23). Complementary trials of exercise and low-fat diets have demonstrated a slowing of the atherosclerotic process (24,25), and studies that incorporated multiple risk-factor interventions (10), pharmacologic lipid-lowering, or both, demonstrated a decrease in coronary events and a retardation of atherosclerosis (26). Despite these well-described advantages, fewer than 15% of patients who might benefit currently participate in formal cardiac rehabilitation (27).

In view of this, efforts have been made to develop physician-directed, nurse-coordinated home-based rehabilitation programs, with the goal of expanding the delivery of preventive cardiology services (10,11,12 and 13,28). In many cases, these services can be appropriately delivered through a physician's office, with a systematic approach to the detection and modification of coronary risk factors (29) (eFig. 12.0.1).

SCIENTIFIC FOUNDATION OF CARDIAC REHABILITATION AND SECONDARY PREVENTION

In the 1970s and 1980s, the scientific study of cardiac rehabilitation focused primarily on exercise, which was generally delivered in a 12-week program of three hourly sessions of aerobic exercise per week. Studies focused on physiologic mechanisms of conditioning in cardiac patients after 3 months of exercise and on the magnitude of the exercise training response, measured as exercise tolerance, or peak aerobic capacity on the treadmill. Outcomes of interest have gradually broadened to include longer-term effects on clinical parameters such as cardiac symptoms, clinical events, rehospitalization rates, quality of life, and measurement of coronary risk factors, such as blood lipids, that mediate progression of the atherosclerotic process (30).

Determinants of Exercise Capacity and Physical Functioning in Coronary Patients

In the period after a coronary event, when patients are most commonly identified for participation in cardiac rehabilitation programs, the incidence of exertional angina or ischemia is surprisingly low, owing to modern approaches including post-event risk-stratification, angiography, and interventional revascularization techniques aimed at improving coronary blood flow.

The cardinal symptoms of coronary heart disease (CHD), angina, and exertional dyspnea depend on a complex interplay of vascular biologic abnormalities and cardiac hemodynamics, compounded by deconditioning and psychological factors. Angina pectoris and ischemic left ventricular (LV) dysfunction result from an imbalance of myocardial oxygen supply and demand. In the presence of coronary atherosclerosis, exercise-induced increases in blood flow are limited both by the presence of atheroma and by an abnormal vascular endothelial response that paradoxically results in exertional vasoconstriction (31,32).

In the presence of chronic exertional angina, supervised aerobic exercise training programs have clearly been shown to increase the anginal threshold, and at a given workload, myocardial oxygen demand is lower (33) (Fig. 12.1). In one study, after 3 months of aerobic training, 7 of 18 patients who had exertional angina before conditioning could no longer reach their angina threshold after conditioning (34). In the 1-year study by Ornish and associates, a combination of aerobic exercise, a very low-fat diet, and meditation led to a 91% decrease in angina frequency and a 28% decrease in angina severity (25).

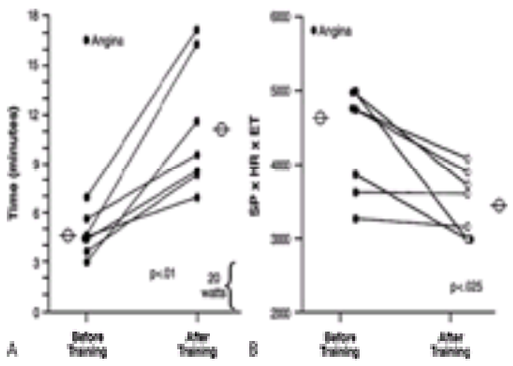

FIGURE 12.1 Effect of 6 weeks of training on exercise capacity **(A)** and triple product **(B)** in patients who have exertional angina. ET, ejection time; HR, heart rate; SP, systolic pressure. (From Redwood DR, Rosing DR, Epstein SE. Circulatory and symptomatic effects of physical training in patients with coronary-artery disease and angina pectoris. *N Engl J Med* 1972;286:959–965, with permission.)

Many patients with CAD are limited by coronary ischemia in the absence of angina, often manifested as dyspnea or fatigue. Furthermore, LV diastolic abnormalities, which are particularly common in older coronary patients, lead to exertional dyspnea, which may be exercise limiting (35,36). A smaller number of patients are limited by exertional arrhythmias, peripheral vascular disease, and comorbidities independent of their CAD.

More than 25% of patients with CAD appear to terminate exercise at treadmill testing before the attainment of a true physiologic maximal effort in the absence of coronary ischemia, heart failure, and arrhythmias (37,38). This effect is particularly notable in the older coronary population, in which as many as one-third of patients terminate exercise prematurely, before significant anaerobic metabolism has been measured, in the absence of angina or ischemia (37). These findings are supported by a study on cardiac disability in which many patients describe limiting their daily activities because of a fear of adverse cardiac consequences, based on advice or misinformation, rather than on account of specific symptoms, such as angina or dyspnea (38) (Fig. 12.2). Rehabilitation programs that counsel patients about the safety of specific employment-related and daily living activities and that reproduce these activities in a monitored setting are designed to facilitate return to premorbid activities (39,40). This is supported by improvements in patient-reported physical function scores after cardiac rehabilitation (11,13,41).

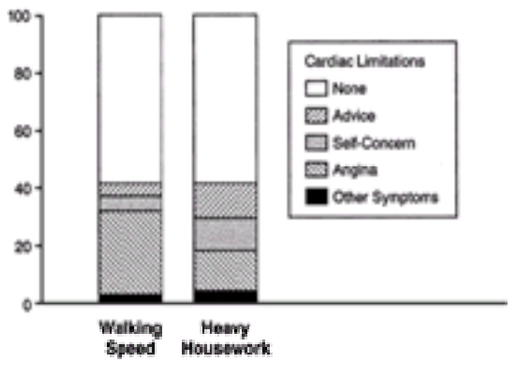

FIGURE 12.2 Patients' perception of reasons why heart disease limited them in walking speed and in heavy housework. (From Neill WA, Branch LG, De Jong GD, et al. Cardiac disability. The impact of coronary heart disease on patient's daily activities. *Arch Intern Med* 1985;145:1642–1647, with permission.)

The reasons for limitation of exercise performance in patients with significant LV dysfunction are complex. Although the initial insult results in a reduction in LV function, with a resultant decrease in rest and exercise cardiac output, secondary neurohormonal, peripheral muscular, and vascular abnormalities often predominate as the cause of exercise intolerance. Neurohormonal abnormalities include elevated circulating catecholamine levels that result in downregulation of cardiac b-adrenoreceptors and a decreased cardiac reserve. A diminished peripheral arterial vasodilatory capacity results in a decreased blood flow to skeletal muscle during exercise (42,43). Several observations suggest that peripheral abnormalities are primary determinants of exercise tolerance in CHF. First, exercise capacity correlates poorly with hemodynamic variables such as LV ejection fraction, cardiac output, and left-atrial filling pressures (44,45). Second, despite rapid improvements in central hemodynamics with medications, rapid parallel improvements in exercise capacity do not occur (46). Third, abnormalities in skeletal muscle histology and biochemistry are similar to those seen with deconditioning and improve with reconditioning (47,48).

In summary, exercise capacity and physical functioning in coronary patients are limited by the direct effects of coronary disease, such as angina and LV dysfunction, the indirect effects of CAD on skeletal muscle structure and function, and patient-centered psychological factors.

Adaptations to Exercise Conditioning in Patients with Coronary Heart Disease

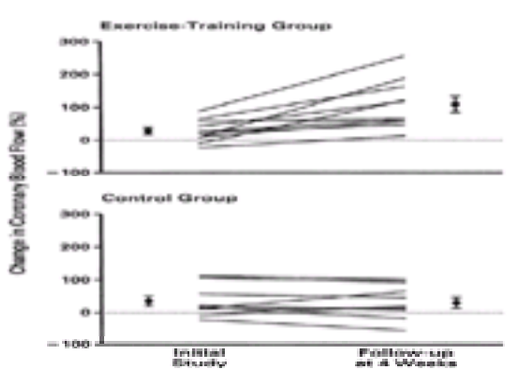
Physiologic adaptations to aerobic exercise training in middle-aged coronary populations include skeletal muscle and vascular adaptations, which result in a widened arteriovenous oxygen difference at maximal exercise (49,50 and 51), and cardiac adaptations, which result in an increased capacity to deliver bloodborne substrate to skeletal muscle (52,53,54 and 55). Peripheral adaptations include an increase in skeletal muscle fiber area, capillary density, and oxidative enzyme capacity (49,50 and 51), in addition to a probable increase in exercise-induced skeletal muscle vasodilatory capacity (56). Cardiac adaptations include increases in cardiac dimensions, stroke work, cardiac output, and afterload-corrected indexes of LV function (52,53,54 and 55). These are similar to training adaptations seen in healthy younger subjects (50). In coronary patients, these adaptations result in a lower heart rate and heart-rate systolic blood pressure product at a given submaximal exercise workload, the primary mechanism by which exercise conditioning decreases symptoms of angina and ischemia during physical exercise (*e*Table 12.0.1) (33,34,57).

***e*TABLE 12.0.1** MECHANISMS OF CLINICAL BENEFITS OF EXERCISE IN CORONARY ARTERY DISEASE

Direct
Decreased myocardial work and oxygen demand
Increased myocardial oxygen supply
Improved myocardial function
Enhanced endothelial vasodilatory capacity
Indirect
Delayed progression of coronary atherosclerosis
Improved lipid profiles
Improved carbohydrate metabolism
Increased fibrinolysis/decreased platelet adhesiveness
Decreased body adiposity
Increased skeletal muscle mass

In older coronary patients, CAD and peripheral vascular disease are superimposed on “normal” aging-related increases in LV and arterial wall thickness and stiffness (35,36). This has been shown to limit cardiovascular adaptations to aerobic conditioning in older coronary patients (58). Accordingly, in these patients, training mechanisms are primarily limited to the periphery and include an increase in arteriovenous oxygen extraction, capillary density, oxidative enzyme capacity, and individual fiber area, without an increase in maximal cardiac output or calf blood flow (58).

Much attention has been focused on whether exercise conditioning increases coronary flow during exercise in patients with CAD. Although several studies have documented improved thallium perfusion after conditioning (59,60), it is not clear whether this reflects an absolute increase in coronary flow in zones of prior ischemia or an improvement in myocardial metabolism during exercise. It has been demonstrated that healthy runners who exercise intensively on a regular basis possess a greater capacity to vasodilate coronary arteries in response to direct-acting vasodilators, such as nitroglycerin (61). A recent study in patients with CHD described improvements in endothelium-dependent coronary vasodilation after 4 weeks of exercise training, which may be a mechanism of the generalized protective effects of exercise in CHD patients (31,62) (*e*Fig. 12.2.1). Experimental studies in dogs similarly document enhanced coronary vasodilation after exercise training in association with an increased transcription of nitric oxide synthase in the vascular wall (63,64 and 65).

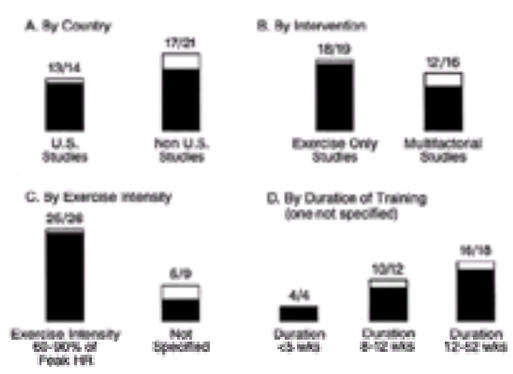


***e*FIGURE 12.2.1** Coronary blood flow in response to acetylcholine at initial study and after 4 weeks; exercise-training group vs. control group. The mean percentage change differed significantly between groups at 4 weeks (*p* <.01). (From Hambrecht R, Wolf A, Gielen S, et al. Effect of exercise on coronary endothelial function in patients with coronary artery disease. *N Engl J Med* 2000;342:454–460, with permission.)

Clinical Effects of Exercise Conditioning in Coronary Patients

Exercise Tolerance

The effect of supervised exercise conditioning programs on exercise tolerance in populations of patients with CAD has been extensively studied. The Federal Clinical Practice Guideline on cardiac rehabilitation describes a total of 35 randomized, controlled trials of cardiac rehabilitation exercise training on measures of exercise tolerance, and the vast majority documents a clear benefit of exercise training on the outcome measure of exercise tolerance (8) (*e*Fig. 12.2.2). These exercise conditioning studies consisted of uncomplicated patients after myocardial infarction who began their exercise program 4 to 52 weeks after the coronary event (22,23 and 24,66,67). After 3 months of aerobic conditioning three times weekly, at an intensity of 70% to 85% of maximal heart rate, exercise tolerance on the treadmill increased by 30% to 50%, and peak oxygen consumption increased by 15% to 20%. It should be noted, however, that in individual coronary patients the relationship between exercise tolerance and home-based physical activity profile is quite complex, with many patients limiting household activities for reasons other than angina, dyspnea, or fatigue (38). For example, many patients limit activities on the advice of family or physicians, not on the basis of objective evidence (38). Other patients develop elaborate support systems that minimize the need for physical activity, contributing to the vicious cycle of inactivity and deconditioning.



***e*FIGURE 12.2.2** Proportion of randomized controlled trials of cardiac rehabilitation reporting improvement of exercise tolerance in intervention groups. HR, heart rate. (From Wenger NK, Froehlicher ES, Smith LK, et al. *Cardiac rehabilitation: clinical practice guidelines*. AHCPR publication no. 96-0672. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research, and the National Heart, Lung, and Blood Institute, 1995, with permission.)

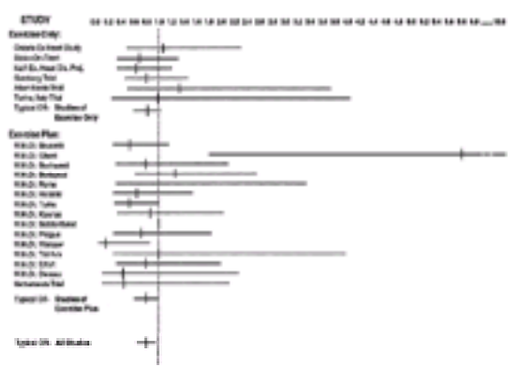
Studies in coronary patients older than 65 years have documented relative improvements in exercise tolerance similar to those seen in younger patients (37,68,69 and 70). Some authors suggest that older patients require longer training programs to attain training effects than younger patients (71), although this is not a universal

finding (72).

Efforts to predict which patients will make the greatest gains in exercise tolerance with cardiac rehabilitation have been somewhat disappointing. Patients with exertional ischemia at baseline appear to benefit somewhat less from a standard 3-month training protocol than do patients without exertional ischemia, although fitness levels and angina threshold nonetheless increase (34,73). The presence of LV dysfunction without exertional ischemia does not predict a lower relative response to conditioning (73). Whereas some studies suggest that patients with the poorest state of fitness show the most improvement with training (74), other studies, particularly in elderly patients, do not show a diminished relative training response in the least-fit patients (37,75). From the point of view of preventing or treating cardiac disability, patients at the lowest levels of physical functioning stand to gain the most if they can exercise at intensities adequate to stimulate a training response (41,76). The use of beta-adrenergic blockers or other pharmaceutical agents does not appear to alter conditioning response in coronary patients (77), despite the attenuation of conditioning in healthy subjects (78,79).

Morbidity and Mortality Rate

The effect of cardiac rehabilitation programs on long-term morbidity and mortality rates, particularly in patients who have experienced myocardial infarction, has been extensively studied. These studies, however, took place in the 1970s and 1980s, before the widespread use of thrombolytic therapy, coronary angioplasty, stents, and angiotensin-converting enzyme inhibitors. Although several individual randomized, controlled trials documented significant decreases in the long-term mortality rate (66,80,81 and 82), metaanalyses have provided the best data on the effect of cardiac rehabilitation on the mortality rate in patients who have experienced myocardial infarction. In the metaanalyses of Oldridge, O'Connor, and their coworkers, which included more than 4,000 patients in 21 randomized, controlled trials, cardiac rehabilitation was associated with a 25% reduction in the mortality rate compared with the rate among control subjects at an average follow-up of 3 years (22,23) (*e*Fig. 12.2.3). More than 80% of the patients in these studies were male, and they were primarily younger than 65 years. Studies in which the intervention involved exercise and risk-factor modification showed a greater benefit than studies in which the intervention was exercise only (23). It should be noted that all of the studies reported in these metaanalyses antedated current aggressive approaches to risk-factor modification, often centered at the cardiac rehabilitation facility. Exercise training per se is nonetheless a contributor to the improvement in mortality rate, because training-induced changes in peak exercise capacity that occur with cardiac rehabilitation are associated with lower mortality rates for patients who have the greatest training effect (83).



***e*FIGURE 12.2.3** Metaanalysis from randomized trials of the effect of cardiac rehabilitation on the mortality rate 3 years after randomization. OR, odds ratio; W.H.O., World Health Organization. (From O'Connor GT, Buring JE, Yusuf S, et al. An overview of randomized trials of rehabilitation with exercise after myocardial infarction. *Circulation* 1989;80:234–244, with permission.)

Studies of the long-term effects of cardiac rehabilitation on morbidity rates, most commonly reinfarction rates, are less clear. Metaanalysis of 15 randomized, controlled trials of primarily exercise-only interventions from the 1970s and 1980s document no significant effects on reinfarction rates (23). These results are perhaps no longer relevant in the 1990s, when multiple studies of secondary prevention, consisting primarily of lowering of lipid levels, often in association with exercise, have documented a clear decrease in coronary events and cardiac rehospitalizations (10,26,84) (see below). A more recent large controlled trial of multifactorial rehabilitation, which included both aerobic exercise and risk-factor counseling, documented reductions in reinfarction rates (18% vs. 33%) and fewer hospitalization days for cardiac problems (11 vs. 16 days) over a 5-year follow-up period (85,86). At 5 years, there was also less smoking, less hypertension, and less use of antianginal medication.

The risks associated with the actual delivery of supervised exercise rehabilitation were well studied in coronary populations of the1980s and 1990s (87,88). A study of 142 U.S. rehabilitation programs reported a nonfatal myocardial infarction rate of 1 per 294,000 patient-hours and a mortality rate of 1 per 784,000 patient-hours (87). A similar study reported in 1998, after the widespread implementation of thrombolysis, beta-adrenergic blockers, and angiotensin-converting enzyme inhibitors, documents similar event rates (88). It should be noted that rehabilitation programs are now actively encouraging participation of higher-risk patients, including patients who have CHF or arrhythmias, elderly patients, and patients who have undergone transplantation, who were often excluded from rehabilitation in past years. Nonetheless, rates of exercise-induced coronary catastrophes in the rehabilitation setting remain exceedingly low.

Effects on Lipid Levels and Obesity

Studies of cardiac rehabilitation exercise programs on serum lipid levels in the absence of focused nutritional counseling document modest, though favorable, effects. Although exercise has no consistent effect on low-density lipoprotein (LDL) cholesterol levels, a consistent favorable increase of high-density lipoprotein (HDL) cholesterol of 8% to 23% has been demonstrated (89,90 and 91). Decreases of 3% to 21% in serum triglyceride levels after 1 to 2 years of exercise have also been demonstrated (92,93 and 94). Numerous studies that combined exercise with behavioral counseling and dietary instruction have documented consistent beneficial effects on serum lipid levels that include decreases in LDL cholesterol and serum triglyceride levels and maintenance or slight increase in HDL cholesterol (10,11,24,25,95). For example, in the diet-exercise studies of Schuler and Ornish, reductions in LDL cholesterol of 11% and 37%, respectively, were attained (24,25). In some patients, lipid-lowering medications are required to meet treatment goals (29), and the benefits of aggressive therapy include a retardation of the atherosclerotic process and a decrease in long-term coronary events (10,26).

Studies on the effect of cardiac rehabilitation exercise without intensive nutritional counseling on measures of obesity have documented only modest benefits (82,90,96,97). This may be because of the surprisingly low exercise-related caloric expenditure noted with cardiac rehabilitation exercise programs, particularly in female and older participants (98,99). A promising intervention that merits further study is the modification of cardiac rehabilitation exercise protocols to maximize caloric expenditure. This involves increasing the frequency and duration of exercise, at slightly lower intensities, and using non–weight-supported exercise such as walking (100). In studies that incorporated a very low-fat dietary intervention in addition to the exercise intervention, consistent improvements in body mass index [(weight in kg)/(height in m)^2] have been demonstrated (10,24,25). Although obesity is an independent risk factor for the development of CAD (101,102), in the setting of established CAD, reduction of obesity, particularly abdominal obesity, acts as a multifactorial intervention with associated improvements in lipid profiles and measures of insulin resistance and a lowering of blood pressure (96,103,104 and 105). Aerobic exercise training alone is associated with a reduction in abdominal obesity, even in the absence of major changes of weight in healthy elderly individuals and in CHD patients (90,106).

Psychological Effects

Many patients state that psychological effects of cardiac rehabilitation programs play a major role in their successful recovery from a cardiac event. In practice, the objective demonstration of measurable improvements in markers of psychological function has been difficult. Studies of exercise rehabilitation without psychological counseling have shown improvements in selected markers of psychological functioning, such as measures of depression and tension (107,108), although these findings have not been universal (109). Group psychological counseling in the rehabilitation setting has demonstrated objective improvements in selected psychological measures, such as depression and social adjustment (110,111 and 112). In addition, a metaanalytic study has noted that the addition of psychosocial treatments to standard cardiac rehabilitation regimens results in a reduction in mortality rates and morbidity over a 2-year period, along with a reduction in psychological distress (113). A randomized, controlled trial of relaxation training in cardiac rehabilitation resulted in a significant decrease in total cardiac events (114).

The magnitude of improvement in dysfunctional behavior in CHD patients is a function of the intensity of the counseling component of a multifactorial rehabilitation intervention. This generally includes group counseling on stress management, relaxation training, and guidance on social adjustment and recovery. Another important role of the group sessions is to identify patients who require more intensive counseling or pharmacologic therapy to avoid psychological symptoms and psychological disability. Depression, in particular, has been demonstrated not only to be a quality-of-life issue, but to predict 6-month mortality rates after myocardial infarction and rate of cardiac rehospitalizations, independent of the severity of cardiac disease (115,116).

Employment

A return to prior employment status is an important integrated measure of successful recovery from a coronary event. Numerous factors independent of the rehabilitation process are important predictors of failure to return to work after a coronary event. These include older age at the time of the coronary event, extended sick leave or unemployment at the time of the coronary event, lower educational level, employment in an unskilled position, or a prior myocardial infarction (86,117,118 and 119). On the other hand, several predictors of return to work may be favorably modified by the exercise rehabilitation process, particularly if work requirements are defined early in the rehabilitation process. These include a low physical function capacity, a lack of confidence in performing physical work, and high levels of depression or anxiety (86,117,118 and 119). A cardiac rehabilitation program that simulates elements of work during the training process has proven to be more effective at returning cardiac patients to work than standard cardiac rehabilitation without job simulation (39,40,117). Studies that have applied a generic exercise training routine to all participants have had little success in enhancing return-to-work rates (67,81,82,85,109,119).

An additional intervention that has been determined to be effective in accelerating return to work in patients with uncomplicated postmyocardial infarction is the performance of a symptom-limited electrocardiographic stress test 3 weeks after the coronary event, with explicit instructions regarding the timing of return to work (120). Patients who are defined as low risk, as determined by an absence of severe exertional ischemia (³2 mm of ST depression), are given explicit instructions to return to work within 2 weeks of the stress test. In a carefully controlled clinical trial, this lowered the time to return to work from 75 to 51 days (120). If the patient then proceeds into a rehabilitation program, a careful determination of work requirements and a training program designed to simulate work-related tasks with monitoring as needed can increase return-to-work rates (39,40). When anxiety or depression is deemed to be preventing a patient's return to work, psychological and vocational counseling may be helpful. Because CAD remains the major cause for premature disability in the United States, continued efforts at refining interventions aimed at returning patients to employment is a major health care issue.

Older Patients

More than one-half of the patients who are eligible for cardiac rehabilitation services are older than 65 years. According to the Framingham Disability Study, which defined disability by work and mobility limitations, disability rates in older coronary patients are extremely high (2). In patients older than 70 years, 79% of women and 49% of men with CAD were found to be disabled (Table 12.1). The direct causes of disability in older coronary patients have received little study, although preliminary work suggests that the best predictors of poor physical function in older coronary patients are a low aerobic fitness capacity and the presence of mental depression, both of which are treatable (121). Despite this, older coronary patients are far less likely to participate in cardiac rehabilitation than younger patients (122,123). The rate of participation for patients older than 62 years is less than one-half that seen in younger patients (122). The primary reason for nonparticipation is a low rate of physician referral (122).

	Men (%)	Women (%)
No CAD or CHF	27	49
CAD	39	61
Angina	56	84
CHF	57	88

CAD, coronary artery disease; CHF, congestive heart failure.

TABLE 12.1 FRAMINGHAM DISABILITY STUDY DISABILITY RATES: AGES 70–88 YEARS

The cardiac rehabilitation literature clearly supports the safety and efficacy of exercise-training regimens in older coronary patients, with relative training benefits similar to those in younger coronary patients (37,68,69 and 70,72,75). Special considerations in the older population include frequent need to adjust training regimens to accommodate the presence of comorbidities such as arthritis, diabetes, and peripheral vascular disease. In addition, the least-fit elderly patients are often unable to sustain exercise for extended periods; these patients do well with intermittent brief bouts of exercise and a longer-term training program. Even patients who use canes and walkers can be exercise tested and trained on a treadmill that has surround bars. Resistance training is a promising intervention for older patients, owing to the frequent presence of sarcopenia and physical disability (see Resistance Training) (124,125). A combination of aerobic and resistive exercise training has been shown to improve physical function scores in both older and younger CHD patients (41).

Women

After menopause, the incidence of CAD rises steadily; by age 65 years, the prevalence of CAD in women approaches that in men (126,127). Despite this, women are a definite minority among cardiac rehabilitation participants (122). The primary reason for this appears to be lower referral rates by primary physicians rather than clinical differences between male and female patients (122). Relatively little study has been made of the relative benefits and special needs of women in cardiac rehabilitation, although women and men improve exercise capacity with training to a similar degree (122,128). Women, however, appear to experience less weight loss, and risk factors improve to a lesser degree, probably owing to a significantly lower exercise-related energy expenditure during cardiac rehabilitation sessions (90,99).

The current model of cardiac rehabilitation was developed primarily for middle-aged male coronary patients in the 1960s and 1970s. Early after myocardial infarction, women have a lower functional capacity than men, they are generally older, they are more likely to have residual angina, and they have more prominent risk-factor profiles; therefore, rehabilitation needs may differ from those of male participants (122,126,129,130). In addition, women are more likely to have a recurrent coronary event during the year after an initial myocardial infarction than are men (122,126,129,130).

Women's preferences in cardiac rehabilitation programming differ from those of men and need to be incorporated into programs designed to maximize adherence and attainment of clinical goals. Although both women and men describe that "frequent progress updates," "encouragement from professionals," and "flexibility in choosing exercise modality" are their most important cardiac rehabilitation features, women preferentially describe that their desires to "not have pain" and "not tire" are less well met than in men (131). As the population ages, the special needs of rehabilitating older female CAD patients will play an increasing role. Because of their high disability rates and diminished muscle mass and strength, older women may benefit from resistance training to a greater degree than other segments of the cardiac rehabilitation population (2,125,132).

Chronic Heart Failure

Patients with CHF are the most highly symptomatic group of patients with cardiovascular disease, and their activities are often limited by low-threshold exertional dyspnea and fatigue. Because of the progressive aging of the population and the improved prognosis of patients with CHF who receive pharmacologic therapy with angiotensin-converting enzyme inhibitors (133,134), the absolute size of the American population with CHF is gradually increasing. At present, more than 2 million Americans experience CHF, with 400,000 new cases diagnosed yearly (135). The mortality rate is high, at a 5-year mortality rate of roughly 50% (135).

Recent studies show that patients with CHF can safely undergo exercise conditioning and that regular exercise improves functional status and decreases symptoms (47,136,137 and 138) (Fig. 12.3). Furthermore, in a randomized, controlled trial, 1 year of moderately intense aerobic exercise improved patient-reported measures of quality of life and decreased overall mortality and hospital readmission rates (139) (Fig. 12.4). Neurohormonal activation and lactate production during submaximal exercise is also diminished by a regular, supervised, home-based exercise program (136), and exercise training augments the symptomatic and functional benefits of angiotensin-converting enzyme inhibitors (137). Peripheral (skeletal muscle) adaptations appear to mediate the improvement in exercise tolerance (47). In addition to improving the peripheral extraction of oxygen, aerobic conditioning in CHF is associated with an increase in cardiac output both during submaximal and maximal exercise (136).

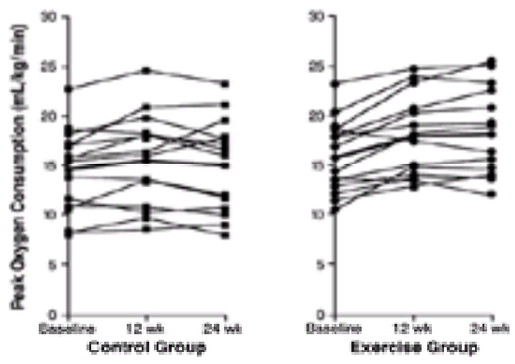

FIGURE 12.3 Peak oxygen consumption in patients with compensated heart failure who do not have exercise training (control group, n = 14) and who did have exercise training (exercise group, n = 15). The heavy line represents the mean value across time, with a significant difference between groups (*p* <.05). (From Keteyian SJ, Levine AD, Brawner CA, et al. Exercise training in patients with heart failure: a randomized, controlled trial. *Ann Intern Med* 1996;124:1051–1057, with permission.)

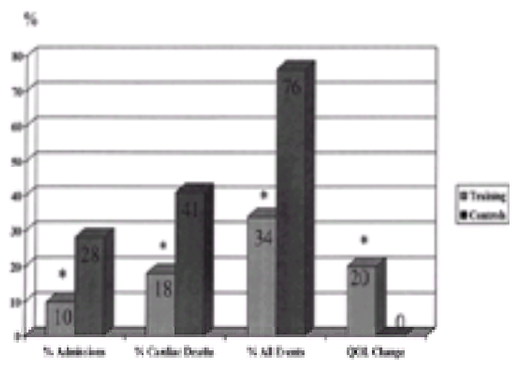

FIGURE 12.4 Randomized, controlled trial of exercise training in patients with chronic heart failure (n = 99; mean follow-up, 3.3 ± 0.15 years). **p* <.05 compared with control group. QOL, quality of life. (Adapted from Belardinelli R, Georgiou D, Cianci G, et al. Randomized, controlled trial of long-term moderate exercise training in chronic heart failure: effects on functional capacity, quality of life, and clinical outcome. *Circulation* 1999;99:1173–1182.)

There is insufficient evidence to recommend a specific type of training program for patients with CHF, although existing studies have focused primarily on aerobic exercises such as cycling or treadmill walking rather than resistance training (47,136,137 and 138). Effects of combined strength and aerobic training in patients with CHF is a promising intervention that improves muscular strength, aerobic capacity, and endothelial-dependent and -independent vasodilator capacity (140,141). In addition to the benefits of supervised exercise training, rehabilitation programs can provide patient and family counseling and facilitate patient compliance with treatment recommendations (135).

An exercise conditioning trial involving CHF patients awaiting cardiac transplantation involved maximal medical therapy and a prescribed walking program. Patients gradually worked up to walking 20 to 30 minutes or 2 miles four times per week at a moderate exercise intensity for 6 months. Peak exercise tolerance improved in 38 of 68 clinically stable patients, and after an average of 6 months of follow-up, 31 of those 38 patients had improved sufficiently to be removed from the transplant list (142). After transplantation, exercise tolerance improves with aerobic exercise training, using perceived exertion as a guide to exercise intensity (143,144 and 145).

Resistance Training

Resistance- or weight-training protocols have long been discouraged in coronary patients because of fears of cardiac complications that can be caused by blood pressure elevations during the lifting phase of such exercise (146). However, carefully screened subsets of CAD patients younger than 65 years have safely participated in resistance-training programs, with impressive increases in strength and no adverse cardiac effects (146,147,148 and 149). Recent data also confirm increases in strength measures after 3 months of resistance training in older coronary patients of approximately 19% to 24% (124). It is important to note that when strength is low, it is a limiting factor in endurance activities, such as walking (150). Thus, in elderly patients, walking endurance improves with resistance training in the absence of aerobic training (151).

Resistance training is of particular importance in women, elderly patients, and coronary patients who plan to return to physically demanding employment (132,148). In healthy individuals, the conditioning response to resistance training includes fiber hypertrophy and an increase in oxidative enzyme activity without an increase in peak aerobic capacity (152). An important functional result is a decreased heart-rate response to a given resistive workload (147,151,152).

Cardiac responses to resistance training have been variable. Although cross-sectional studies of recreational weightlifters have generally shown measurable increases in LV mass, this has not been associated with alterations in LV diastolic filling patterns or in LV systolic function (153,154,155 and 156). Systolic blood pressure and heart-rate measures during exercise up to a training intensity of 80% of a single maximal lift have been found not to be excessive and, in fact, are lower than values measured during symptom-limited treadmill testing of the same individuals (157). A number of studies have assessed the safety and feasibility of weight training in middle-aged coronary patients, although no long-term studies of weight training on cardiac morphology or function have been reported (147,148,157). Because measurable increases in diastolic blood pressure during the lifting phase to levels beyond those seen with aerobic exercise have been demonstrated, the primary relative contraindication to weight training in coronary patients is uncontrolled hypertension (146). Although there is a theoretical concern of adverse LV remodeling caused by blood pressure rises during weight training in coronary patients, beneficial effects on skeletal muscle mass and function may override that danger, and LV dysfunction need not be considered a contraindication. The elevated diastolic blood pressure during the lift may, in fact, increase subendocardial perfusion and thereby contribute to the lower incidence of ischemic responses seen with isometric or isodynamic effort (158,159 and 160).

From a practical point of view, the onset of upper body resistance training should be delayed until 3 months after coronary bypass grafting surgery to allow full sternal healing to occur, whereas it can commence as early as 1 month after myocardial infarction or 1 to 2 weeks after a successful percutaneous coronary intervention, after performance of a satisfactory baseline exercise tolerance test. The resistance-training program should include training of the leg extensor muscles to assist with walking and stair climbing and upper body training to aid in the lifting and pushing required for the performance of daily household activities. A report on the results of resistance training in disabled older women with CHD documented increased strength, endurance, balance, coordination, and measures of physical performance during practical activities such as stair climbing and grocery carrying (125).

Secondary Prevention

The relative risk of developing myocardial infarction for patients with clinically manifest CAD is five to seven times higher than in matched individuals without established coronary disease (161). Thus, secondary prevention focuses preventive efforts in patients at the highest risk of recurrent cardiac events and cardiac death. The cardiac rehabilitation center needs to be structured in such a manner that program personnel systematically define and treat modifiable risk factors in participants, in coordination with primary physicians. The American Heart Association has defined “core components of cardiac rehabilitation,” which expand the mandate of cardiac rehabilitation programs to act as “secondary prevention centers” (6) (*e*Table 12.1.1). Individual programs need to develop treatment modules that screen for the presence of risk factors and define counseling, behavioral, and pharmacologic interventions related to the presence of hyperlipidemia, obesity, hypertension, smoking, diabetes, and psychological dysfunction.

***e*TABLE 12.1.1** CORE COMPONENTS OF CARDIAC REHABILITATION/SECONDARY PREVENTION PROGRAMS
Patient assessment
Evaluation
Medical history
Include cardiovascular (including peripheral vascular and cerebrovascular) diagnoses and prior cardiovascular procedures (including assessment of left ventricular function), comorbidities, symptoms of cardiovascular disease, risk factors for atherosclerotic disease progression, medications, and medication compliance (see below for physical activity and psychosocial assessment).

Physical examination
Include vital signs, cardiovascular and pulmonary examination, postprocedure wound sites, joint and neuromuscular examination (see below for specific examinations for hypertension, weight, and diabetes).
Testing
Obtain resting electrocardiogram, assess quality of life using standard questionnaires (e.g., Medical Outcomes Study Short Form 36; see below for specific tests for exercise, lipid levels, and diabetes).
Intervention(s)
Compose written records that reflect the patient evaluation and contain a patient-care plan with detailed priorities for risk reduction and rehabilitation.
Actively communicate this plan to the patient and the primary health care provider.
Expected outcome(s)
Development and implementation of short-term (i.e., weeks to months) and long-term (i.e., years) goals and strategies to reduce disability and subsequent cardiovascular disease risk.
Improvement in quality of life as identified by positive changes on follow-up questionnaire.
Generation of a written summary of patient outcomes on completion of the program that is provided to the patient and to the primary and referring health care providers. Written summaries should identify specific areas that require further intervention and monitoring.

Nutritional counseling

Evaluation
Obtain estimates of total daily caloric intake and dietary content of fat, cholesterol, sodium, and nutrients.
Assess eating habits, including number of meals, snacks, frequency of dining out, and alcohol consumption.
Assess target areas for nutrition intervention as outlined in the core components of weight, hypertension, and diabetes, as well as heart failure, kidney disease and other comorbidities.
Intervention(s)
Prescribe specific dietary modifications that aim to attain at least the fat and cholesterol content limits of the American Heart Association step II diet (9).
Individualize diet plan according to specific target areas as outlined in the core components of weight, hypertension, and diabetes (as outlined in this table), as well as heart failure and other comorbidities.
Educate and counsel patient (and family members) regarding dietary goals and how to attain them.
Incorporate behavior change models and compliance strategies in counseling sessions.
Expected outcome(s)
Patient adherence to prescribed diet.
Patient understanding of basic principles regarding dietary content of calories, fat, cholesterol, and nutrients.
Construct a plan to address eating behavior problems.

Lipid management

Evaluation
Obtain fasting measures of total cholesterol, HDL, LDL, and triglyceride levels. In patients with abnormal levels, as judged by the National Cholesterol Education Program (9), obtain a detailed history to determine whether diet, drug use, and/or other conditions that may affect lipid levels can be altered.
Assess current treatment and compliance.
Repeat lipid profiles at 4–6 wk after hospitalization, and at 2 mo after initiation or change in lipid-lowering medications.
Intervention(s)
Provide nutritional counseling and weight management, aiming for at least an American Heart Association step II diet in those patients with LDL levels ³ 100 mg/dL; consider adding drug treatment in patients with LDL levels 100–130 mg/dL; add or intensify drug treatment in patients with LDL levels >130 mg/dL.
Provide interventions to increase HDL >35 mg/dL. These include exercise, smoking cessation, and consideration of targeted drug therapy.
Provide interventions to reduce triglyceride levels <200 mg/dL. These include nutritional counseling and weight management, exercise, alcohol moderation, and drug therapy according to the National Cholesterol Education Program recommendations (9).
Provide and/or monitor drug treatment in coordination with primary health care provider.
Expected outcome(s)
Short term
Continued assessment and modification of intervention until LDL levels are <100 mg/dL.
Long term
LDL levels <100 mg/dL.
Secondary goals include HDL levels >35 mg/dL and triglyceride levels <200 mg/dL.

Hypertension management

Evaluation
Measurement of resting blood pressure on two or more visits.
Assessment of current treatment and compliance.
Intervention(s)
If blood pressure is 130–139 mm Hg systolic or 85–90 mm Hg diastolic:
Provide lifestyle modifications, including exercise, weight management, moderate sodium restriction, alcohol moderation, and smoking cessation.
Administer drug therapy in patients who have heart failure, diabetes, or renal failure.
If blood pressure is ³ 140 mm Hg systolic or ³ 90 mm Hg diastolic:
Assist in lifestyle modification and administer drug therapy.
Provide and/or monitor drug therapy in coordination with primary health care provider.
Expected outcome(s)
Short term
Continued assessment and modification of intervention until blood pressure is <130 mm Hg systolic and <85 mm Hg diastolic.
Long term
Blood pressure <130 mm Hg systolic and <85 mm Hg diastolic.

Smoking cessation

Evaluation
Document smoking status: never smoked, former smoker, or current smoker (which, because of the high rate of relapse, includes those who have quit smoking in the last 6 mo); specify both the amount of smoking (packs/d) and duration of smoking (number of years).
Assess frequency of cigar smoking, pipe smoking, and chewing tobacco use and exposure to secondhand smoke.
Assess for confounding psychosocial issues.
Determine readiness to change by asking every smoker whether he/she has considered quitting in the last 6 mo.
If the answer is no (precontemplation stage), firmly advise the patient that he/she give it some thought; plan to ask again after several visits.
If the answer is yes (contemplation stage), proceed with interventions below.
Ongoing contact
Update status at each visit during first 2 wk of cessation and periodically thereafter for at least 6 mo.
Intervention(s)
When readiness to change is confirmed, assist the smoker in setting a quit date and select appropriate treatment strategies (preparation):
Minimal
Provide individual education and counseling by program staff, supplemented by self-learning materials.
Encourage physician, staff, and family support.
Provide relapse prevention.
Optimal
Provide formal smoking cessation program using group and/or individual counseling.
Provide and/or monitor pharmacologic support as needed, in coordination with primary health care physician.
Offer supplemental strategies if desired (e.g., acupuncture or hypnosis).
Arrange follow-up by return visits or telephone contact for at least 6 to 12 mo.
Expected outcome(s)
Short term
Patient demonstrates readiness to change by initially expressing decision to quit (contemplation) and selecting a quit date (preparation). Subsequently, the patient quits smoking and use of all tobacco products (action); adheres to pharmacotherapy, if prescribed; practices strategies as recommended; and resumes cessation plan as quickly as possible when relapse occurs.
Long term
Complete abstinence from smoking and use of all tobacco products at 12 mo from quit date.

Weight management

Evaluation
Measure weight, height, and waist circumference.
Calculate body mass index.
Intervention(s)

In patients with body mass index >25 kg/m^2 and/or waistline >40 in. (102 cm) in men and >35 in. (88 cm) in women:
Establish reasonable short-term and long-term weight goals individualized to patient and associated risk factors (e.g., reduce body weight by at least 10% at a rate of 1–2 lb/wk over a period of time as long as 6 mo).
Develop a combined diet, exercise, and behavioral program designed to reduce total caloric intake, maintain appropriate intake of nutrients and fiber, and increase energy expenditure.
Aim for an energy deficit of 500–1,000 kcal/d.
Expected outcome(s)
Short term
Continued assessment and modification of interventions until progressive weight loss is achieved.
Provide referral to specialized, validated nutrition weight loss programs if weight goals are not achieved.
Long term
Adherence to a diet and exercise program aimed at attainment of established weight goal.
Diabetes management
Evaluation
Identify patients with diabetes using initial history, and note medication type, dose, and regimen; type and frequency of glucose monitoring; and history of hypoglycemic reactions.
Obtain fasting plasma glucose in all patients and hemoglobin A_1C in diabetic patients to monitor therapy.
Intervention(s)
Develop a regimen of dietary adherence and weight control that includes exercise, oral hypoglycemic agents, insulin therapy, and optimal control of other risk factors.
Drug therapy should be provided and/or monitored in coordination with the primary health care provider.
Monitor glucose levels before and/or after exercise sessions. Instruct patient regarding identification and treatment of postexercise hypoglycemia. Limit or prohibit exercise if blood glucose ³300 mg/dL.
Refer patients without known diabetes whose fasting glucose is >110 mg/dL to their primary health care provider for further evaluation and treatment.
Expected outcome(s)
Normalization of fasting plasma glucose (80 to 110 mg/dL or hemoglobin A_1C <7.0), minimization of complications of diabetes, control of associated obesity, hypertension (<130/85 mm Hg), and hyperlipidemia.
Psychosocial management
Evaluation
Identify psychological distress as indicated by clinically significant levels of depression, anxiety, anger, or hostility; social isolation; sexual dysfunction/adjustment; and substance abuse (alcohol or other psychotropic drugs) using interview and/or standardized measurement tools.
Intervention(s)
Offer individual and/or small-group education and counseling regarding adjustment to coronary heart disease, stress management, and health-related lifestyle change. When possible, include family members and significant others in such sessions.
Develop supportive rehabilitation environment and community resources to enhance patient's and family's level of social support.
Teach and support self-help strategies.
In coordination with the primary health care provider, refer patients who are experiencing clinically significant psychosocial distress to appropriate mental health specialists for further evaluation and treatment.
Expected outcome(s)
Evidence of emotional well-being indicated by the absence of clinically significant psychological distress, social isolation, or drug dependency.
Demonstration of self-responsibility for health-related behavior changes; relaxation and other stress-management skills; ability to obtain effective social support; compliance with psychotropic medication regimens, if such medications are prescribed; and reduction or elimination of alcohol, tobacco, caffeine, or other nonprescription psychoactive drugs.
Construction of a plan for ongoing management if important psychosocial issues are present.
Physical activity counseling
Evaluation
Assess current physical activity level and determine domestic, occupational, and recreational needs.
Question activities relevant to age, gender, and daily life, including: driving, sexual activity, sports, gardening, and household tasks.
Assess readiness to change behavior, self-confidence, barriers to increasing physical activity, and social support in making positive changes.
Intervention(s)
Provide advice, support, and counseling about physical activity needs on initial evaluation and in follow-up. Target exercise program to meet individual needs (see "Exercise training" in this table). Provide educational materials as part of counseling efforts. Consider simulated work testing for patients with labor-intensive jobs.
Set goals to increase physical activity that include 20–30 min/d of moderate physical activity on 5 or more days each week. Explore daily schedules to suggest how to incorporate increased activity into the patient's usual routine (e.g., parking farther away from entrances, walking up two or more flights of stairs, walking 15 min during lunch break).
Advise low-impact aerobic activity to minimize risk of injury. Recommend gradual increases in intensity over weeks.
Expected outcome(s)
Increased participation in domestic, occupational, and recreational activities.
Improved psychosocial well-being, reduction in stress, facilitation of functional independence, prevention of disability, and enhancement of opportunities for independent self-care to achieve recommended goals.
Exercise training
Evaluation
Obtain an exercise test (or another standard measure of exercise capacity) before participation and repeat as changes in clinical condition warrant. Test should include assessment of heart rate and rhythm, signs, symptoms, ST segment changes, and exercise capacity.
Intervention(s)
Develop a documented individualized exercise prescription for aerobic and resistance training that is based on evaluation findings, risk stratification, patient and program goals, and resources. Exercise prescription should specify frequency (F), intensity (I), duration (D), and modalities (M).
For aerobic exercise: F = 3–5 d/wk; I = 50% to 80% of exercise capacity; D = 20–60 min; and M = walking, treadmill, cycling, rowing, stair climbing, arm ergometry, and others.
For resistance exercise: F = 2–3 d/wk; I = 8–15 repetitions, maximum, for each muscle group (where repetition maximum is the maximum number of times a load can be lifted before fatigue occurs); D = one to three sets of six to ten different upper and lower body exercises (20–30 min); and M = elastic bands, cuff/hand weights, dumbbells, free weights, wall pulleys, weight machines.
Include warm-up, cool-down, and flexibility exercises in each exercise session. Provide updates to the exercise prescription routinely and when patient condition warrants. Structured outpatient or home-based programs are appropriate and may include electrocardiographic monitoring as deemed necessary. Regardless of program site, supplement the formal exercise regimen with at-home activity guidelines as outlined in the "Physical activity counseling" section of this table. Caloric expenditure of at least 1,000 kcal/wk should be a specific exercise program objective.
Expected outcome(s)
As a component of an overall program of cardiac rehabilitation/secondary prevention, exercise assists in lowering cardiovascular risk and improves overall outcomes.
Improved functional capacity through enhanced muscular endurance and strength, flexibility, and weight management improves symptoms and physiologic responses to physical challenges and should assist in the modification of various unhealthy behavior and psychosocial characteristics.
Patient understanding of safety issues during exercise.

HDL, high-density lipoprotein; LDL, low-density lipoprotein.
From Balady GJ, Ades PA, Comoss P, et al. Core components of cardiac rehabilitation/secondary prevention programs: a statement for healthcare professionals from the American Heart Association and the American Association of Cardiovascular and Pulmonary Rehabilitation Writing Group. *Circulation* 2000;102:1069–1073, with permission.

Lipids

It is now well established that lowering blood lipid levels reduces clinical events and mortality rates in patients known to have CHD. Numerous controlled clinical trials, most with quantitative coronary angiography, have demonstrated the efficacy of pharmacologic and diet-induced lipid lowering on slowing the progression of angiographic measures of atherosclerosis and on reducing clinical coronary events (10,24,25,84,162,163 and 164). Low-fat diets, without accompanying drug treatment, have been effective in reducing the prevalence of angiographic progression of CAD when combined with exercise (24,25) and stress management (25), which strengthens the case for widespread institution of lipid-lowering dietary therapy. The reduction in clinical coronary events was most conclusively demonstrated in the Scandinavian Simvastatin Survival Study, which reported a 30% to 35% reduction in deaths and major coronary events (84). Data from these studies suggest that even patients who have mild to moderate lipid abnormalities benefit from therapy in a manner similar to that in patients who have more severe abnormalities. The National Cholesterol Education Program recommends setting an LDL cholesterol level of <100 mg per dL as a goal of therapy for all coronary patients (165).

The cardiac rehabilitation program is an optimal site for systematic screening and treatment of hyperlipidemia. This includes dietary counseling and active participation by the patient in pharmacologic therapy. A rehabilitation-based screening and treatment program has been documented to triple the likelihood that, with the collaboration of the referring physician, patients for whom such treatment is appropriate receive lipid-lowering therapy (166). Affiliation with a clinician who is expert in

lipid management is necessary, and in many cases a lipid clinic can be organized at the rehabilitation facility itself.

Smoking Cessation

Cigarette smoking cessation is associated with a marked decrease in coronary event rates in coronary patients (167,168). In the study of Wilhelmsson and associates, patients who quit smoking after experiencing myocardial infarction reduced their 1-year mortality rate from 10% to 5% and their 1-year reinfarction rate from 18% to 9% (168). Exercise training in and of itself has minimal, if any, effect on smoking cessation rates in coronary patients (82). The best results with smoking cessation after a coronary event have been obtained using a physician-recommended, nurse-managed intervention that takes place during hospitalization for an acute coronary event (while patients are unable to smoke) and is aimed at relapse prevention (11,21). These interventions include teaching skills to deal with high-risk situations, relaxation training, provision of nicotine or bupropion when necessary, and long-term telephone contact. At the end of 6 months (21), and 1 year (11), cessation rates were significantly increased, from 32% to 61%.

Weight Reduction

Although no study has addressed the effect of weight reduction on second coronary events, its well-defined role in the treatment of hyperlipidemia, hypertension, and insulin resistance makes it an important multifactorial risk-factor intervention (97). In the studies of Haskell, Schuler, and Ornish that incorporated a low-fat dietary intervention and exercise, reductions in body mass index were demonstrated in coronary populations (10,24,25). For example, in the Stanford Coronary Risk Intervention Project, a sustained 4% decrease in body mass index was attained with a combination of nutritional counseling and home-based exercise (10). On the other hand, studies of exercise rehabilitation alone have generally not been associated with substantial weight change (82,90). When weight loss is accomplished in the rehabilitation setting, it is generally associated with improvements in lipid profiles, insulin resistance, and blood pressure (96). Nutrition education combined with behavioral interventions and prescribed exercise can achieve modest and sustained weight loss in the rehabilitation setting (169). However, the accomplishment of weight loss in cardiac rehabilitation is not a passive process, and it requires the development of a weight loss module for selected patients, staffed by appropriately trained professionals, with clear definitions of goals and desired outcomes and long-term follow-up. A well-established and effective behavior-based weight reduction program has been adapted to the cardiac rehabilitation setting (170,171). The intervention includes behavioral concepts of stimulus control, self-monitoring, problem-solving, and social support; a daily caloric goal; and a daily calorie count. The weight loss goal is not to reach ideal body weight, but rather to achieve improvements in obesity-related risk factors. In many cases, a relatively modest but sustained weight loss of 5% to 10% of body weight significantly improves risk factors such as lipid measures and insulin resistance. An advantage of cardiac rehabilitation–based weight reduction programs is that patients are already performing the exercise component needed to prevent them from regaining lost weight (172).

Diabetes

No clinical trials involving patients with established CAD have been carried out to determine whether tight control of diabetes, in patients with either type I or type II diabetes, prevents cardiac complications or slows the course of macrovascular disease. Results of a recent multicenter clinical trial of tight glucose control in patients with type I (insulin-dependent) diabetes who did not have CAD demonstrated improved lipid profiles, an increase in body weight, a decrease in microvascular complications (retinal and renal), and a trend toward decreased macrovascular events, with such events (cardiac and cerebrovascular) reduced by almost 50% (173). In patients with type II diabetes, exercise and weight reduction resulted in improved measures of insulin resistance and associated coronary risk factors, such as lipid abnormalities and hypertension (174,175). Poor glycemic control predicts an increased likelihood of cardiac events in type II diabetes (176,177). An important role of the cardiac rehabilitation program, beyond encouraging exercise and proper nutrition, is to assist primary physicians with monitoring and treatment of diabetes. Patients are taught self-monitoring techniques, and medications are adjusted as needed (6,178).

Hypertension

Rehabilitation programs assist primary physicians with the treatment and follow-up of coronary patients with hypertension. Although weight reduction, exercise, and salt restriction have all been associated with modest reductions in systemic blood pressure, definite benefits in the cardiac rehabilitation setting have not been demonstrated. Frequent surveillance of blood pressure, teaching of self-monitoring techniques, nutritional instruction, and adjustment of medications are all useful (6,179).

Psychological Factors

The effect of cardiac rehabilitation counseling and behavioral interventions on measures of psychological stress and psychological well-being has received much study. In particular, the type A behavior pattern, hostility, depression, social isolation, and lack of social resources have been identified as important targets of therapy. Psychosocial interventions in the cardiac rehabilitation setting are associated with lower mortality rates and a lower likelihood of recurrent cardiac events (113). The type A behavior pattern, which includes a heightened sense of time urgency and hard-driving competitiveness, has been the most studied psychological variable. In the Western Collaborative Group Study, men with type A behavioral patterns were five times more likely to have a recurrent myocardial infarction than men with type B behavioral patterns (180). Although other studies did not confirm this finding (181), an intervention trial aimed at altering type A behavior patterns was associated with a decreased rate of recurrence of cardiac events (182). The intervention included stress-management counseling in a group setting and avoidance of stressful situations in the home setting.

Depression is reported to precede myocardial infarction in 33% to 50% of cases. One study of patients hospitalized after myocardial infarction found that 18% had major depression and an additional 27% had symptoms of depression (183). In another study, postinfarction patients who met criteria for a major depressive disorder (16% of 272 patients) were five times more likely to die during the first 6 months after infarction than patients who were not experiencing depression (115). Depressive affect in the absence of a major depressive disorder also conferred a higher risk (115). Whether the treatment of depression is associated with a better long-term outcome is not yet known, but decreased depression would probably lead to better functional outcomes and an improved quality of life, independent of effects on orbidity and mortality rates.

Social isolation is also associated with a poor prognosis after a coronary event. In a follow-up study of patients with angiographically documented coronary disease, a 5-year mortality rate of 50% was noted among the patients who were most socially isolated, versus 17% in nonisolated patients (184). No association was seen in this study between social isolation and the severity of cardiac dysfunction.

Cardiac rehabilitation stress-management programs and psychological counseling are performed both in a group setting and in individualized sessions. Counseling sessions generally focus on stress management and relaxation skills, in addition to reintegration and socialization after a coronary event, both at home and at work. Individuals who are at high risk for prolonged depression or maladaptive recovery patterns are identified and referred for more specific therapy, such as pharmacologic antidepressant therapy or longer-term counseling. Studies in the rehabilitation setting have documented lower levels of self-reported emotional stress, lower levels of type A behavior, and improvements in measures of quality of life and anxiety (181,182).

PRINCIPLES OF MANAGEMENT, PROGRAM STRUCTURE, AND ORGANIZATIONAL ISSUES

Inpatient Rehabilitation

In-hospital rehabilitation, or phase I rehabilitation, has necessarily evolved in recent years in response to ever-shortening hospitalizations for acute myocardial infarction and coronary revascularizations. With many infarction patients hospitalized for only 4 to 6 days (20), and much of this period occupied by acute care and recovery from interventional techniques, it is no longer realistic to expect patients to participate in a comprehensive course providing information about coronary risk factors and cardiac diets, and a graded in-hospital exercise program. However, in addition to the economic benefits of a shorter hospitalization, less deconditioning occurs, and patients are more capable of resuming premorbid physical activities. Many patients report that in the current environment, the most important aspect of phase I rehabilitation is to be directed to the phase II outpatient program (185).

Nonetheless, several important interventions take place during this brief hospitalization. Most important is smoking-relapse prevention. Because essentially all American hospitals now prohibit smoking, the issue is no longer smoking cessation, but planning for continued cessation on hospital discharge. Well-designed studies demonstrate that in the setting of acute myocardial infarction, 32% of patients stop smoking without a program, which can be increased to 61% with a nurse-managed smoking-relapse prevention program, as demonstrated by Taylor and colleagues (21).

It is also important during this brief index admission to define coronary risk factors and to set up an outpatient plan for long-term therapy. Defining lipid profiles early on is of particular importance; studies of aggressive lipid lowering in coronary patients document decreasing secondary event rates beginning 6 months to 1 year after therapy is begun (84,164). Serum lipid values are accurate when measured within 24 hours of myocardial infarction. When they are measured later in a hospitalization for myocardial infarction, they are inaccurate, with total, LDL, and HDL cholesterol levels lower and triglyceride levels higher (186,187,188 and 189). For 1 month after coronary bypass surgery, serum cholesterol levels measure falsely low, and therefore baseline measures should be determined preoperatively, with follow-up

measures performed after 1 month (190).

Before the patient is discharged, a nurse clinician or physician should review a set of “survival skills” to outline proper use of medications, to define a plan for early physical activity profiles, and to review how to deal with symptoms, should they occur. If an exercise tolerance test was performed before discharge, it will be helpful in defining the early activity profile, although the exercise prescription needs to be updated during the physician’s visit or on the patient’s entry into outpatient/phase II rehabilitation. If phase II rehabilitation is not planned, a symptom-limited exercise tolerance test performed 3 to 6 weeks after the coronary event, while the patient is receiving his or her usual medications, is useful in constructing a long-term activity program. It is recommended that patients exercise regularly at approximately 60% to 85% of the intensity attained at the exercise test. Additionally, this stress test assists in making return-to-work recommendations and achieving a more rapid return to work for low-risk patients (104).

Outpatient Rehabilitation

Intake Evaluation

The cardiac rehabilitation intake evaluation is the optimal opportunity to stratify patients into risk categories and to systematically define secondary risk factors for the progression of CAD (Fig. 12.5). Therefore, as part of this evaluation, a fasting lipid profile and a glucose measure should be obtained for all patients. Other risk factors, such as smoking status, blood pressure, obesity, and diabetes-related measures, should also be assessed.

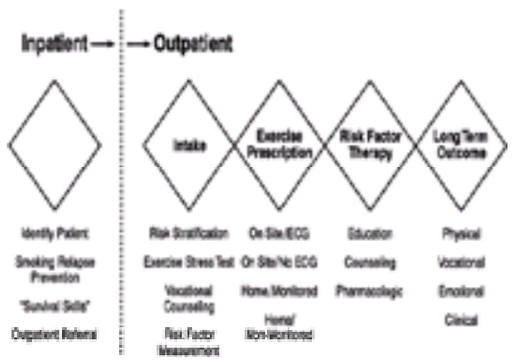

FIGURE 12.5 Elements of cardiac rehabilitation. ECG, electrocardiogram.

An exercise tolerance test needs to be performed so that an exercise prescription can be developed and the risk associated with exercise can be assessed. Patients in whom high-risk characteristics are identified at risk-stratification (Table 12.2) should participate in a supervised program in which electrocardiographic monitoring is available. Patients who are stratified to low- or intermediate-risk groups can be considered for a home-based exercise program. Although the requirements for electrocardiographic monitoring remain poorly defined, the American College of Cardiology, in its “Report on Cardiac Rehabilitation,” recommends electrocardiographic monitoring for high-risk patients (*e*Table 12.2.1) (191).

Risk level	Characteristics
Low	No significant left ventricular dysfunction (i.e., ejection fraction, >50%) No resting or exercise-induced myocardial ischemia manifested as angina and/or ST segment displacement No resting or exercise-induced complex arrhythmias Uncomplicated myocardial infarction, coronary artery bypass surgery, angioplasty, or atherectomy Functional capacity of 8 METs or greater exercise test 3 weeks after clinical event
Intermediate	Ability to moderately depressed left ventricular function (ejection fraction, 31–49%) Functional capacity 5–6 METs on graded exercise test 3 weeks after clinical event Failure to comply with exercise intensity prescription
High	Exercise-induced myocardial ischemia (≥2 mm ST segment depression or reversible ischemic defects seen on echocardiography or nuclear radiography) Severely depressed left ventricular function (ejection fraction, <30%) Complex ventricular arrhythmias while patient is at rest or appearing or increasing with exercise Decrease in systolic blood pressure of >15 mm Hg during exercise or failure to rise with increasing exercise workloads Patient is survivor of sudden cardiac death Myocardial infarction complicated by congestive heart failure, cardiogenic shock, and/or complex ventricular arrhythmias Severe coronary artery disease and marked exercise-induced myocardial ischemia (≥2 mm ST segment depression)

TABLE 12.2 GUIDELINES FOR RISK-STRATIFICATION

***e*TABLE 12.2.1** CRITERIA FOR ELECTROCARDIOGRAPHIC MONITORING

1. Severely depressed left ventricular function (ejection fraction, <30%)
2. Complex ventricular arrhythmia while patient is at rest
3. Ventricular arrhythmias appearing or increasing with exercise
4. Decrease in systolic blood pressure with exercise
5. Patient is a survivor of sudden cardiac death
6. Patient is a survivor of myocardial infarction complicated by congestive heart failure, cardiogenic shock, serious ventricular arrhythmias, or some combination of the three
7. Severe coronary artery disease and marked exercise-induced ischemia (³2 mm ST segment depression)
8. Inability to self-monitor heart rate because of physical or intellectual impairment

From Parmley WW. Position report on cardiac rehabilitation: recommendations of the American College of Cardiology on cardiovascular rehabilitation. *J Am Coll Cardiol* 1986;7:451–453, with permission.

Only 15% of eligible patients in the United States receive cardiac rehabilitation services. In many cases, cardiac rehabilitation programs are not geographically available, whereas in other cases, formal rehabilitation is not recommended by the primary physician. For some patients, insurance coverage is incomplete or unavailable. Whereas cardiac rehabilitation services have classically been delivered on-site at a well-defined exercise training facility, the need to expand preventive cardiology services to include the majority of eligible patients necessitates a redefinition of this model.

The development of alternate approaches to delivery of cardiac rehabilitation services is an ongoing process, aimed at a goal of expanding the base of patients who receive services, at the lowest possible health care cost. Numerous investigators have documented the safety of home-based exercise programs for individuals who are at low to medium risk by use of varying degrees of transtelephonic monitoring (12,13,28,192). Case management (i.e., evaluation and management of risk factors for the individual patient) complements exercise conditioning and allows the individualization of preventive care in health care delivery systems that focus on efficiency and outcomes. Case management, whether delivered in an office practice or in a structured rehabilitation program, should focus on attainment of risk-factor goals (Table 12.3) and identification of highest risk patients (Table 12.2) (10,11). Exercise programs can be individualized for moderate- and higher-risk patients, and patients at highest risk of disability should be referred to a rehabilitation program for closer supervision and monitoring.

TABLE 12.3 RISK-FACTOR GOALS FOR PATIENTS IN RISK REDUCTION GROUP: STANFORD CORONARY RISK INTERVENTION PROJECT MODEL

Exercise Prescription

Classically, exercise programs for coronary patients have involved primarily aerobic exercise, with patients exercising at an intensity approximated by exercise heart rates measured at 70% to 85% of peak exercise heart rate while the patient is receiving his or her usual medications (8). It should be noted that in many cases, the early post–coronary event symptom-limited stress test is a submaximal stress test, and patients are often reluctant at this stage to exercise to a true physiologic maximum (37). Thus, it is useful to supplement heart-rate guided training with estimates of perceived exertion, as described by Borg (193). Lower-intensity training regimens, at 50% to 70% of maximal heart rate, have been shown to result in improvements in functional capacity similar to those produced by more intensive regimens and may be more acceptable for particularly unfit, obese, or older patients (194,195). Clinicians have a tendency to recommend lower-intensity exercise regimens to patients who are exercising in unsupervised settings, and although this appears reasonable, it has not been subjected to study. Probably more important than the absolute training intensity in the early recovery period is the issue of whether patients continue exercise over the long term, and whether they experience long-term improvements in outcomes such as measures of home-based physical functioning, improvement in symptoms, psychological benefits, and physiologic benefits, such as improved lipid profiles and body composition measures.

A baseline evaluation of physical functioning and health-related quality of life, usually using a standardized questionnaire (e.g., the Medical Outcomes Study questionnaire), is extremely helpful in defining a baseline for physical functioning (30,196). Measures of physical functioning improve in all age groups and in both genders after cardiac rehabilitation (41). An evaluation of physical functioning is quite distinct from an exercise tolerance test, and such an evaluation determines the actual activities that a patient can and cannot perform in the home environment. Thus, in the clinical setting, the need for aerobic exercise or resistance training can be determined for the individual patient, based on their at-home work requirements. For example, an older women with CHD is most likely to be limited in the performance of daily activities by decreased muscle mass and strength, and therefore a resistance training program would appropriately supplement an aerobic walking program. Although the exact exercise prescription for resistance training in coronary patients has not been fine-tuned, a common approach is to measure the single-repetition maximum lift for specific exercises after 1 to 2 weeks of acclimatization at low workloads, and then to begin resistance training at roughly one set of eight to ten repetitions at 40% to 50% of the single-repetition maximum. With training, the workload is gradually increased by increasing the number of repetitions and by increasing the resistance so that a steady level of perceived exertion during exercise is maintained. An area of future research is to define the effects of resistance training on physical functioning in specific subsets of patients, in addition to developing low-cost equipment for long-term home use.

Compliance with Exercise and Long-Term Follow-Up

Long-term adherence to cardiac rehabilitation exercise is approximately 50% at 1 year (197,198). This compares to 1-year adherence rates of 64% for antihypertensive medication regimens (199) and 82% for treatment with lipid-lowering agents (200). Several interventions have been shown to optimize compliance with cardiac rehabilitation exercises. A gradual transition to home-based exercise sessions with self-monitoring while the patient was still in the rehabilitation program increased 6-month compliance rates from 76% to 92% (201). The use of lower-intensity exercise (202), participation of nurse case-managers (10,11), and the signing of a written agreement (203) have all been associated with increased long-term compliance with the exercise component of cardiac rehabilitation.

Provisions for the long-term continuation of risk-factor modification also need to be specified. The long-term surveillance and treatment of coronary risk factors is generally transferred to the primary physician, in a case-management format, whereas the long-term surveillance and maintenance of the exercise component is often delegated to the rehabilitation program. Although long-term, institutional phase III programs successfully maintain patients in a supervised exercise program and are particularly useful for older patients because they provide supervision and social interactions, a fully “rehabilitated” patient exercises independently at home.

Strategies to improve participation in cardiac rehabilitation programs are of major importance in view of the relationship between adherence with preventive cardiology recommendations and better clinical outcomes (204,205 and 206). The most important determinant of early post–coronary event cardiac rehabilitation participation, studied in a population of patients ³62 years old, is the strength of the primary physician’s recommendation for participation (207). When the recommendation was graded as moderate to strong (4 to 5, on a scale of 1 to 5), participation was 70%; when the recommendation was weak (1 to 3), participation rate was 2% (Fig. 12.6). Other predictors of poor participation rates included older age; presence of comorbidities, especially arthritis; and the presence of mental depression (207). It should be noted, however, that nonadherence with formal cardiac rehabilitation does not necessarily mean that self-care preventive practices are not in place. It is suggested that successful strategies for enhancing long-term adherence with cardiac rehabilitation and long-term risk reduction include involving the patient and family in clinical decision-making, providing individualized and understandable explanations about regimens that are compatible with the patient’s values, acknowledging the patients’ social and cultural background, and integrating and coordinating patient care with primary providers, particularly during periods of transition (8).

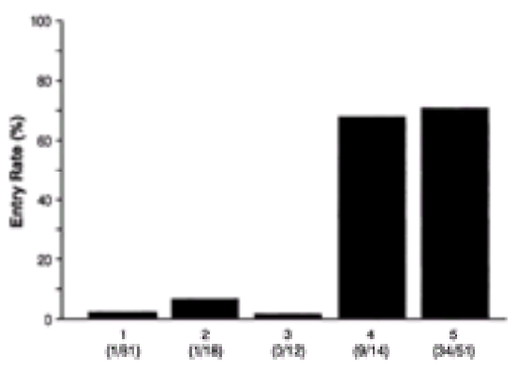

FIGURE 12.6 Cardiac rehabilitation participation by physician’s recommendation. The physician’s recommendation score was graded from 1 (not recommended, or recommended against) to 5 (strongly recommended). (From Ades PA, Waldmann ML, McCann W, et al. Predictors of cardiac rehabilitation participation in older coronary patients. *Arch Intern Med* 1992;152:1033–1035, with permission.)

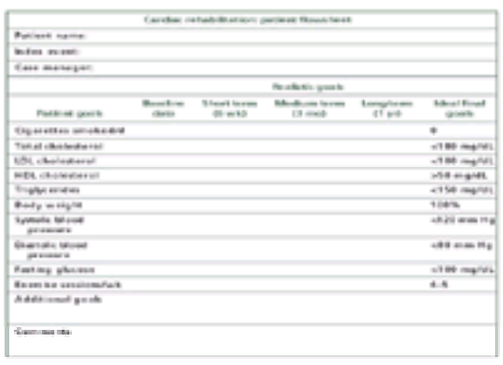
Organizational Issues

Candidates for cardiac rehabilitation are identified in-hospital or referred directly to the outpatient rehabilitation facility. The cardiac rehabilitation program is usually physician directed but managed by a nurse, nurse-practitioner, or exercise physiologist. Patient care is individualized by a case manager who coordinates the implementation of the exercise prescription and the risk-factor treatment plan. Long-term risk-factor goals are set with regard to lipid measures, body weight, diet, and exercise (eFig. 12.2.2), but individualized short-term goals are realistic, with periodic adjustment (eFig 12.6.1). Consultants who have expertise in lipid management, nutrition, psychology, physical therapy, and exercise physiology supplement the expertise of the medical director and clinical coordinator. Outcome measures, such as exercise tolerance, employment status, recurrence of cardiac events, quality of life, and risk factors are updated periodically in coordination with the primary physician.



***e*FIGURE 12.6.1** Patient flowsheet: risk-factor goals.

Home-Based Cardiac Rehabilitation

So that cardiac rehabilitation services can be extended to increasing numbers of patients, the development of home-based programs is essential. The same principles of management described for facility-based rehabilitation apply. Specifically, an on-site intake evaluation is required, with risk-stratification, development of an exercise prescription, and delineation of long-term preventive cardiology goals (*e*Table 12.3.1). The Stanford Coronary Risk Intervention Project describes a model of health care delivery that has been successfully incorporated into a community setting (10). It is a physician-directed, nurse case-managed, multiple risk-factor modification program with well-defined short-term and longer-term individualized goals for specific risk factors (Fig. 12.3). It incorporates personal instruction, home-based programs, and periodic phone and office follow-up and requires no specialized exercise facilities. It has been successfully adapted for use in community programs (208).

***e*TABLE 12.3.1** HOME-BASED CARDIAC REHABILITATION (CASE-MANAGEMENT MODEL)

Intake	Intervention	Follow-up
Risk-factor assessment	Risk-factor therapy	Risk-factor outcomes
Exercise tolerance test	Education, counseling, medical therapy	Physical activity counseling
Risk-stratification	Exercise prescription	Vocational counseling
Vocational assessment		

Home-based rehabilitation can be coordinated either through a physician's office practice or an established rehabilitation program for patients who are unable to attend a facility-based program. In both cases, a case manager (usually a registered nurse), a physician, or both, coordinate the intake evaluation, which incorporates the same basic criteria as were described for facility-based patients. A baseline stress test is particularly useful for risk-stratification to rule out adverse effects of exercise, such as arrhythmias or ischemia, that may require treatment and to help design an appropriate exercise program. The exercise program should be tailored to the patient's needs, but in most cases exercise includes primarily a walking program. Intensity may be guided by exercise heart rate, with patients learning to take their pulse or using a heart-rate monitor to keep their exercise heart rate in the range of 65% to 80% of their maximal heart rate on the treadmill. Alternatively, exercise intensity can be monitored using the perceived exertion scale developed by Borg (193,209); patients should exercise at a perceived exertion of 12 to 14 Borg units (*e*Table 12.3.2). The importance of long-term exercise should be emphasized more than speed or the intensity of individual sessions.

All but the highest-risk cardiac patients, such as those with exertional arrhythmias or low-threshold angina, may participate in home-based rehabilitation, although patients in the moderate-risk category, such as older individuals, those with exertional angina, or those with stable CHF, require more frequent periodic checks and a slower progression of exercise. New technologies include commercially available heart-rate monitors and transtelephonic monitoring and online nurse supervision for selected patients (13). Patients should be encouraged to keep records of their exercise sessions and to perform home monitoring of other individualized risk factors, such as body weight, dietary intake, and blood pressure measures. Short- and longer-term risk-factor goals should be realistic and individualized based on the current status of the patient, the patient's readiness for change, and the available resources. The use of community resources should be maximized to provide climate-controlled exercise spaces, assistance in measurements such as weight or blood pressure, and support groups. Appropriate consultations in the medical environment, such as nutritional instruction or physical therapy, should be available for selected patients to aid them in meeting risk-factor goals. The nurse case-manager should be capable of providing the majority of the necessary education about risk factors related to diet, exercise, and smoking cessation. Patients should be referred as needed to the physician director or the primary health care physician for medical therapy for lipid abnormalities, diabetes, and other risk factors.

COST-EFFECTIVENESS ANALYSIS

Expenditures for the treatment of patients with CAD accounts for approximately 7% of total U.S. health care costs in 1995 ($60 billion of $900 billion) (5). In an era in which containment of health care costs is a major goal, documentation of the cost-effectiveness of specific medical care strategies is a high priority. Cardiac rehabilitation is a clinically effective intervention for CAD that has been subjected to several cost analyses (8,210,211,212 and 213).

Economic evaluations of cardiac rehabilitation were performed both in the United States and in Sweden (210,211 and 212). In a randomized U.S. trial of 8 weeks of rehabilitation begun within 6 weeks of myocardial infarction, a mean per-patient increase of 0.052 quality-adjusted life-years was calculated (210). The cost-effectiveness of this intervention was measured at $9,200 per quality-adjusted life-year. A similar analysis performed in 1996 calculated cost-effectiveness for cardiac rehabilitation of $4,950 per life-year saved (213). These compare favorably with cost-effectiveness analyses calculated for other clinical interventions for CAD (*e*Table 12.3.3).

***e*TABLE 12.3.3** COST-EFFECTIVENESS OF SELECTED INTERVENTIONS FOR CORONARY ARTERY DISEASE

Intervention	Patient group	Cost-effectiveness[a]	Time period
Cardiac rehabilitation	Post-MI	$9,200	1980s–1992
Cardiac rehabilitation	Post-MI	$4,950	1980s–1995
Cholesterol-lowering simvastatin (217)	Angina, post-MI	$9,630	1985–1993
Thrombolytic therapy (t-PA) (218)	Acute MI	$32,700	1990–1994
Coronary bypass surgery (219)	Man, age 55 yr, three vessels	$18,700	1970s–1990s

MI, myocardial infarction; t-PA, tissue type-plasminogen activator.
[a]In dollars per quality-adjusted life-year saved.

A controlled trial of multifactorial cardiac rehabilitation performed in 580 U.S. patients documented a lower cardiac rehospitalization rate and a lower cost per hospitalization, over a mean follow-up of 21 months, for patients who participated in such rehabilitation, resulting in lower hospitalization charges averaging $740 per patient (211). These results are supported by a Swedish study that assessed the value of a 4-month nurse-managed intervention of education and exercise, performed after myocardial infarction in patients older than 65 years (214). At 1 year, rehospitalization rates were significantly lower in the group of patients who participated in intervention programs (13%) than in the control group (29%).

Finally, a comprehensive cost analysis of cardiac rehabilitation was performed in Sweden in patients who had experienced myocardial infarction or had undergone coronary bypass surgery (212). The intervention included twice-weekly group exercise and risk-factor counseling. After 5 years of follow-up, cardiac rehospitalizations were decreased in the group of patients who participated in intervention compared with the control group (11 vs.16 days), and patients participating in rehabilitation returned to work more frequently (53% vs. 38% at 5 years) and had lower sick-leave costs. In the overall cost analysis, rehabilitation costs were offset by the lower hospital admission rates and increased work productivity, which resulted in a 5-year cost savings to the Swedish system of $12,000 per patient.

Thus, cost analyses of the value of cardiac rehabilitation are highly favorable. The well-described clinical benefits of cardiac rehabilitation are attained at an economic cost that compares favorably with other medical interventions that are commonly used for patients with CAD.

CONTROVERSIES AND PERSONAL PERSPECTIVES

In a health care environment that is rapidly incorporating the precepts of managed care and other delivery models, cardiovascular services are undergoing a consolidation designed to maximize efficiency and minimize the use of expensive technologies. Advances in knowledge about the development of coronary atherosclerosis and the prevention of acute coronary events will drive continued interest in the delivery of efficient preventive cardiology services well into the new century. Furthermore, the patient population is aging, and the prevention of coronary disability and second coronary events in elderly patients is a major priority. In patients of all ages, costly cardiac rehospitalizations can be prevented, clinical event rates can be reduced, and coronary disability can be treated and prevented by the systematic application of secondary prevention services.

Many physicians question the need for distinct cardiac rehabilitation facilities, arguing that they can effectively measure and treat cardiac risk factors and recommend home-based exercise in the office setting. In reality, it is the rare physician whose practice is sufficiently regimented, who possesses sufficient expertise in preventive cardiology, and who has sufficient time available to meet the multidisciplinary medical, psychosocial, and vocational needs of the complex cardiac patient. Cardiac rehabilitation is a comprehensive process, and the complex patient benefits greatly from the expertise that is concentrated in the rehabilitation program, including specialists in preventive cardiology, exercise physiology, physical therapy, psychology, nutrition, and vocational counseling. The rehabilitation program has methods in place to maximize the likelihood of attaining outcome goals, and patients describe receiving great psychological support from the peer-group exercise and counseling sessions. Well-defined rehabilitation algorithms have been demonstrated to attain risk-factor goals more successfully than “usual care” in several clinical trials (10,11,24).

Successful modification of coronary risk is not a passive process. Care-management systems need to be established so that patients who would benefit from treatment are referred for care. Risk factors need not only to be identified and measured, but also to be actively treated according to systematic algorithms, with transition to primary health care providers for long-term care and follow-up.

Overall, only 15% of eligible patients participate in cardiac rehabilitation programs, whereas more than 30% of patients at academic medical centers participate (8). Alternative modes of delivery of cardiac rehabilitation services need to be developed to increase the availability of programs. These include home-based programs, with and without transtelephonic monitoring, and case-management systems coordinated through rehabilitation programs or physicians’ offices (208). Exercise programs and risk modification need to be individualized, with an emphasis on clinical outcomes.

In summary, the scientific foundations of cardiac rehabilitation and secondary prevention are on firm ground, supported by recent authoritative clinical practice guidelines and clinical trials (8,6,215,216). As is true of many other preventive interventions, we need not await a “magic bullet.” If currently available therapies can be systematically applied to targeted populations, recurrent coronary event rates will plummet, and coronary disability will be minimized.

THE FUTURE

An established body of scientific knowledge exists that supports the foundations of cardiac rehabilitation and secondary prevention for coronary patients. Systems of delivery need to be established so that patients are systematically involved in the prevention process. The future of cardiac rehabilitation will be defined by the medical care delivery system within which it operates and by the aging of the cardiac population. Prevention of costly rehospitalizations will be a high priority, as will preventing coronary disability in elderly patients. Ever-shortening lengths of stay for acute coronary events and interventional procedures will increase the need for prevention in the outpatient setting.

OVERVIEW

The World Health Organization recognizes the two parameters needed to control a disease such as cardiovascular disease (1). First, a 100% efficacious intervention must be developed. Basic science studies and epidemiologic investigations have identified so-called risk factors, which can explain 60% to 80% of coronary heart disease (2,3). Randomized trials have tested and proven that interventions to modify these risk factors can prevent disease. Yet these increasingly efficacious interventions have fallen short of controlling this disease because of less success in the second parameter, namely, the requirement that 100% of the population be covered by the interventions. Our health systems are inefficient, and a portion of the population is not afforded risk-factor reduction because it is considered not cost effective. Risk factors are not assessed, treated, and controlled on current practice, even in high-risk patients. There are many opportunities for risk-factor management, however. These include the inpatient unit, in which risk factors should be assessed and interventions initiated, even at the time of the acute presentation of coronary disease. Risk-factor assessments and goals, as well as plans for their control, should be clearly communicated by the cardiovascular specialist to the primary care provider. Specialized units, including preventive cardiology clinics, cardiac rehabilitation units, and nurse case manager programs, can support the primary care provider's efforts in outpatient risk-factor management. Developments in electronic media open new avenues for patient education. Finally, health care organizations, professional societies, and third-party payers can favorably affect levels of risk-factor control through professional education programs, clinical guidelines, quality assurance standards, and reimbursement policies. The management of risk factors should be viewed as the management of the atherosclerotic disease process itself, emphasizing the role of risk-factor modification as the cornerstone of coronary care.

NEED FOR A SYSTEMATIC APPROACH TO PREVENTIVE CARDIOLOGY

The evidence base supportive of preventive cardiology has steadily become more comprehensive. Studies of vascular biology, natural history studies, and multicenter clinical trials have clearly delineated the role of factors in the atherosclerotic process and the effectiveness of practices to reduce the morbidity and mortality resulting from coronary artery disease. This evidence base has been used by the scientific community and the medical profession to develop a number of comprehensive clinical guidelines and scientific statements, which have been endorsed by the major cardiovascular associations (4,5,6,7,8,9,10,11,12 and 13) (*e*Fig. 13.0.1). But guidelines are not enough. The next step to realize these potential benefits are critical. Evaluations of the performance of health care providers and health care systems to implement prevention and rehabilitation from coronary artery disease have shown continuing deficiencies. This chapter focuses on these gaps, as well as the barriers causing them and the strategies to successfully implement effective preventive care. Although revascularization and thrombolytic interventions continue to revolutionize care of the acute coronary syndromes, preventive cardiology forms the backbone for lifelong management of this systemic disease process.

***e*FIGURE 13.0.1** Quality assurance in preventive cardiology.

Risk-Factor Modification as an Integral Part of Optimal Care of the High-Risk Patient

Cardiovascular disease, including stroke and peripheral arterial disease, has a multifactorial etiology. Most coronary disease patients have two or more risk factors. Yet any single coronary risk factor can contribute to coronary heart disease if left untreated. *e*Table 13.0.1 provides an updated overview of cardiovascular risk factors and the relative strength of evidence that supports their inclusion (14). The important points of note are, first, the sizable list of potentially modifiable risk factors that are strongly tied to the atherosclerotic process on the basis of sound evidence. Several of these risk-factor modifications require the knowledge and skills of a variety of health professionals, including physicians, nurses, behavioral scientists, exercise physiologists, and nutritionists. Thus, effective risk reduction usually requires a team approach. Second, new data suggest interventions such as hormone replacement therapy have shifted in prominence and practice. New factors, such as inflammatory markers, have been linked to clinical disease.

Modified from Pearson TA, Fuster V. Executive summary of the 27th Bethesda Conference: matching the intensity of risk-factor management with the hazard for coronary disease events. *J Am Coll Cardiol* 1996;27:961–963.

The evidence to support risk factors for which interventions have been proven to lower cardiovascular disease continues to grow and change. For example, a Mediterranean-type diet appears to be able to reduce recurrent myocardial infarction (MI) and death in coronary patients by over 60%, compared with the usual French diet (15). This is of similar or greater magnitude of reduction with pharmacologic agents such as lipid-lowering drugs and beta-blockers. Other recent additions to this table include further data emphasizing the importance of high-density lipoprotein (HDL) cholesterol in coronary disease (16). The Veteran Affairs High Density Lipoprotein Cholesterol Intervention trial showed an impressive 22% relative risk reduction in nonfatal MI and cardiac death with the use of gemfibrozil to raise HDL cholesterol (17). This has important ramifications for many patients with features of the metabolic syndrome (diabetes, glucose intolerance, hypertension obesity, high triglycerides or low HDL) who may have *normal* low-density lipoprotein (LDL) cholesterol but remain at high risk for future coronary events because of low HDL. Vitamin E was not found to alter coronary heart disease risk (18), although there is growing data supporting the importance of inflammatory markers such as high sensitivity C-reactive protein (19,20) providing further options for risk-stratification and management of coronary artery disease risk.

A major change in cardiovascular risk management for postmenopausal women occurred after the results of two randomized trials of estrogen and progestin for secondary prevention of coronary heart disease showed no benefit (21,22). This result came in the face of a wealth of observational studies that have found lower rates of coronary heart disease in women taking postmenopausal estrogen therapy. The known thrombogenic effects of estrogen and progestin were postulated as a potential cause, highlighting the complexities of risk-factor modulation of disease. Although estrogen replacement therapy is no longer recommended for women with established cardiovascular disease (7), their use in symptomatic women remains controversial. Results from The Women's Health Initiative and WELL-HART trials should provide better delineation of this problem (23).

Another development in preventive cardiology has been an emphasis on the modification of risk rather than just risk factors. The concept of primary and secondary prevention has become less applicable. High-risk groups have been identified by global risk assessment to identify individuals whose risk of coronary heart disease is so high that they should be treated as having presumptive coronary atherosclerosis. More specific and sensitive cardiac imaging methods are now widely used to identify people with atherosclerosis in a preclinical phase. The goal for the health professional is therefore to accurately place individual patients into categories of risk. The aggressiveness of risk-factor modification is matched to these categories, providing a cost-effective, evidence-based approach to prevention (14). The patient with symptomatic coronary artery disease is easily placed in the category of highest risk. The risk of future events after an ischemic episode is extremely high. Secondary end points of reduced myocardial ischemia and correction of arrhythmias, prompting fewer hospital admissions, leads to the primary objective of reduction of cardiac morbidity and mortality in these symptomatic patients.

The asymptomatic patient without evidence of vascular disease provides the cardiovascular specialist with additional challenges, because many of these patients have a coronary heart disease risk equivalent. Contribution and interaction of multiple risk factors has provided the impetus to globally assess the cardiovascular risk of a patient with multiple risk-factor scoring systems. These have provided better predictive ability for MI and death. An example of this is the Framingham risk scoring system for persons older than 30 years without prior cardiovascular disease (24,25). Points assigned to risk-factor levels are summed to produce a 10-year absolute risk for coronary heart disease end points for an individual patient. The Joint European Societies have established a 20% risk of coronary heart disease over 10 years as warranting aggressive risk-factor modification therapy (26). This is a risk similar to many persons with previous MI or stable angina and is therefore referred to as a *coronary heart disease risk equivalent*. These patients may be increasingly identified and referred to cardiovascular specialists for risk reduction. Risk-factor management will continue to be the primary means to reduce their high absolute risk of MI and death.

Rationale for a Comprehensive Risk Reduction Approach

What form should risk-factor modification take in the management of the high-risk patient? Several scenarios might be entertained, including intervention by a specialty clinic, for example, lipid management or preventive cardiology clinics, referral of this responsibility back to the primary care provider, or integration of modification efforts as part of the overall care of the high-risk patient. Table 13.1 identifies several of the many reasons to support the latter approach for all patients with symptomatic or high risk for atherosclerotic disease.

Treatment of the primary disease process (atherosclerosis) rather than the symptomatic complications of the disease
Long-term efficacy in reducing risk of events
Reduced risk of symptoms from disease in other vascular beds (e.g., cerebral, peripheral)
Improved effectiveness of acute coronary care
Risk-factor interventions efficacious over very short intervals
Risk-factor modifications may be more successful in the acute phases of coronary disease
Benefits additive to those of other cardiologic procedures
Improved safety of interventions
Reduce potentially deleterious interactions between risk-factor modifications
Reduce deleterious interactions between risk-factor modifications and other cardiologic therapies
Improve follow-up care and compliance by considering risk-factor modification as a cornerstone of cardiologic care worthy of initiation early in clinical course

TABLE 13.1 RATIONALE FOR COMPREHENSIVE RISK-FACTOR MODIFICATION INTEGRATED INTO THE OVERALL MANAGEMENT OF THE PATIENT WITH CORONARY ARTERY DISEASE

One important consideration deals with which disease is actually being targeted for intervention. Although acute syndromes of myocardial ischemia and their sequelae demand acute intervention to reduce the risk of death and disability over the short-term, long-term prognosis is dictated by the extent of the atherosclerotic disease in the coronary vasculature and the factors related to it. Perhaps a better concept is that risk-factor modification constitutes the *medical management of atherosclerosis* (14). After alleviation of the acute manifestations of ischemia, the focus of the physician should then turn to those pathophysiologic processes within the arterial wall that allowed the ischemic event to develop. Although invasive or surgical approaches to atherosclerosis have their place in cardiac care, a considerable array of interventions, both behavioral and pharmacologic, are now available. These focus on reestablishing normal endothelial function, inhibiting the initiation and growth of

atherosclerotic plaques, stabilizing these plaques to prevent ulceration and rupture, and reducing thrombogenicity of the blood. This represents the management of the atherosclerotic arterial system, in conjunction with the correction of myocardial ischemia, left ventricular dysfunction, ventricular arrhythmias, and other pathophysiologic processes. Clinical trials have proven the long-term benefits of this approach (eTable 13.0.1).

Second, limiting intervention to atherosclerotic disease that is symptomatic in one vascular bed ignores the fact that atherosclerosis is a systemic disease. Although the relief of symptoms through revascularization is important to the patient, without intervention on recurrence of the systemic atherosclerotic process itself, symptomatic disease in the coronary arteries or in other vascular beds is highly likely. It is well known that the leading cause of death in patients with atherosclerotic abdominal aneurysm or peripheral arterial disease is MI and sudden cardiac death (24). Moreover, reductions in risk factors in patients with symptomatic coronary disease have been shown to reduce events elsewhere in the vasculature. A metaanalysis of clinical trials observed that LDL cholesterol reduction with 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors in patients with coronary disease not only reduced MI and cardiac death but also reduced the occurrence of fatal and nonfatal stroke by approximately 30% (27). Clearly, the management of the atherosclerotic disease process must occur concomitantly with the management of its symptoms.

Third, the traditional approach has been to consider risk-factor modification as adjunctive therapy, to be provided only after the completion of diagnostic and therapeutic steps in the acutely ill patient. This is based on the old notion that risk-factor management acts on the slowly progressive atherosclerotic process, thereby taking months or years to benefit the patient. More recent evidence, suggesting that a number of modifiable risk factors affects endothelial function, plaque stability, and hemostasis, establishes the biologic plausibility for rapid benefits of risk-factor modification in the acute care of a coronary patient (28). Clinical studies corroborate the acute benefits of risk-factor modification. It has long been recognized that smoking cessation reduces the risk of reinfarction and death after MI in a matter of weeks or months (29,30). More recent randomized trials of lipid-lowering agents have demonstrated substantial reduction of myocardial ischemia on ambulatory electrocardiograms within months of MI (31). There is now agreement that these effective behavioral and pharmacologic measures should be instituted before hospital discharge for maximal benefit (32). Studies using HMG-CoA reductase inhibitors suggest that sizable reductions in clinical coronary events can be realized in a matter of weeks or months. The Pravastatin Multinational study showed a 95% reduction in coronary events with pravastatin after only 6 months, with sizable differences discernible at 8 weeks (33). In a prospective cohort study evaluating early statin use post-MI, a relative risk reduction of 25% in 1-year mortality was noted (Fig. 13.1) (34). Likewise, the preliminary results of a randomized trial of a high-dose statin within the first 48 hours after symptom onset showed a significant 16% reduction in events over the next 6 months (35). Several randomized double-blind placebo trials of early initiation of statins are currently being completed to further delineate the best time to introduce statin use. The Diabetes Mellitus Insulin Glucose Infusion in Acute Myocardial Infarction trial showed a mortality reduction in those patients who had more aggressive management of their blood sugars post-MI, again highlighting short-term benefits of effective risk-factor management (36). The magnitude of these benefits is similar to that expected with angiotensin-converting enzyme (ACE) inhibitors or beta-blocker therapies. This shift in preference toward early risk-factor modification again highlights the need for an effective, structured risk reduction strategy to be in place.

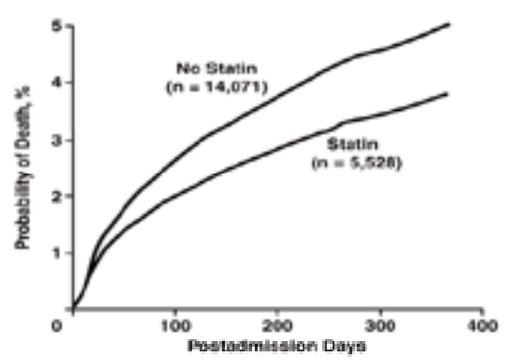

FIGURE 13.1 Statin treatment initiated early in the postinfarction period for patients with acute myocardial infarction. Data were calculated using multiple Cox regression analysis (relative risk, 0.75; 95% confidence interval, 0.63–0.89; *p* = .001). (From Stenestrand U, Wallentin L. Early statin treatment following acute myocardial infarction and 1-year survival. *JAMA* 2001;285:430–436, with permission.)

Next, there are a number of psychosocial benefits of integrating risk-factor modification into the overall management of acute and chronic ischemic heart disease. During acute phases of illness, the patient and his or her family members may be especially receptive to behavioral interventions. This is the concept of the *teachable moment*. For example, during hospitalization for acute ischemia, the coronary disease patient is prohibited from smoking. This may be a propitious time to initiate a program of behavior modification that can extend to the outpatient phases of the patient's treatment.

Another erroneous notion is that traditional cardiac interventions such as revascularization or beta-blocker therapies may somehow negate the need for risk-factor management. Risk factors and clinical factors both strongly influence the natural history of coronary disease (37,38). Although prevention of ischemia, congestive heart failure, and arrhythmia is an important goal in caring for the atherosclerotic patient, stabilization of the atherosclerotic process, slowing its progression, and prevention of thrombosis are discrete benefits of risk-factor management. Subanalyses in large clinical trials such as the Scandinavian Simvastatin Survival Study, for example, were able to examine the benefits of LDL cholesterol lowering in patients who were undergoing a variety of secondary preventive interventions such as treatment with aspirin, beta-blockers, ACE inhibitors, as well as those who were not (39). Consistently, cholesterol lowering was found to have benefits additive to other interventions. Another example is the prevention of saphenous vein bypass graft atherosclerosis. Both the Cholesterol Lowering Atherosclerosis Study (40) and the Post Coronary Artery Bypass Graft Study (41) have shown that the lowering of LDL cholesterol can prevent the initiation and progression of lesions in bypass grafts, preventing the need for repeated surgical revascularization. These observations point to the need to integrate risk-factor modification into the initial stages of therapy, with the expectation of short- and long-term benefits additive to those of traditional cardiac interventions.

On the other hand, another reason for coordination of efforts in comprehensive risk reduction is the potential deleterious interactions between risk-factor modifications and other therapies. Bile acid–binding resins, useful agents for reducing LDL cholesterol, can bind up coumadin, beta-blockers, and digoxin. Similarly, smoking cessation, a major means of reducing risk, can nonetheless lead to postcessation weight gain and deleterious effects on lipids and glucose. A diet that reduces saturated fat and cholesterol may also reduce HDL cholesterol. Proven antihypertensive therapies, namely, thiazide diuretics and beta-blockers, can also reduce HDL cholesterol and raise serum triglycerides in some patients. Clearly, when considering overall risk, a patient's entire risk-factor profile must be considered, especially because most patients with coronary disease have two or more risk factors (39). Intervention on one risk factor should take others into consideration, with the goal being maximal reduction of overall risk.

Finally, the cardiovascular specialist is looked to for leadership and advice in constructing the optimal treatment program for the high-risk patient. Because their care often deals with the acute or emergent management of ischemia, much of the communication to the primary care provider may deal with these interventions only. If a description of a risk-factor reduction program is not included in the overall care program, the impression is given that it is not important. The incorporation of risk-factor modification and other preventive interventions into a well-integrated, comprehensive program that seeks maximal risk reduction should be the mutual goal of both specialist and generalist. Risk reduction is the responsibility of everyone on the health care team.

Evidence for the Underutilization of Interventions to Reduce Risk

The American Heart Association (AHA), American College of Cardiology (ACC), and other organizations have released a number of consensus statements addressing prevention of coronary artery disease (4,5,6,7,8,9,10,11,12 and 13), based on basic epidemiologic and clinical trial evidence (14) (eFig. 13.0.1). Despite the increasing evidence supporting effective preventive therapies, their application has been disappointing. An example is the National Cholesterol Education Program (NCEP) Adult Treatment panel II guidelines for LDL cholesterol management (10). As an evidence-based document, these guidelines established LDL cholesterol thresholds for treatment and LDL cholesterol goals that should be attained for low-risk, high-risk, and coronary heart disease patients. A review of office visits from the National Ambulatory Medical Care Surveys showed that cholesterol screening, both for primary and secondary prevention, was much lower than predicted by NCEP guidelines (42). Cholesterol testing occurred in only 22.9% of office visits and counseling was infrequent (34%) in known hyperlipidemic patients. The Heart and Estrogen/Progestin Study trial enrolled women with coronary artery disease, identifying 91% of participants who had not achieved the NCEP LDL cholesterol goal of less than 100 mg per dL. (43). The Lipid Treatment Assessment Project, a survey to evaluate the proportion of 4,888 dyslipidemic patients receiving lipid-lowering therapy, also provided evidence of a low success rate, especially in high-risk, noncoronary, and coronary heart disease groups (44). Only 18% of patients with established coronary heart disease met the NCEP goal for LDL cholesterol. This was despite surveying 618 physicians who were among the most frequent prescribers of lipid-lowering drugs. The lack of use of medications, an inappropriate choice or dose of medication, or the infrequent use of combination therapy appeared to be the cause of the low success rates. The majority (80%) of participants did not receive dietary counseling.

This treatment gap does not appear to be limited to lipid management. Further review analyzed medication use and showed disappointing rates of use of well-established medications such as beta-blockers (45), ACE inhibitors (46), and aspirin (47), even when clearly indicated. Smoking cessation counseling is addressed

in less than one-half of smokers with coronary disease (48,49). A multicenter study conducted in Europe looked retrospectively at hospital records and conducted prospective interviews of patients to determine whether major coronary risk factors had been addressed (50). There was a striking twofold difference between countries' use of proven beneficial therapies such as beta-blockers post-MI. There was also a threefold variation in ACE inhibitor use in those patients with symptoms of heart failure that could not be explained. Reduced assessment and inappropriate modification of risk factors have also been documented in the elderly (aged 65 years and older) despite their high burden of disease and proven significant risk reduction with these therapies (51,52). An outpatient survey of predominately cardiology practices documented a reluctance to titrate the dose of ACE inhibitors for patients with congestive heart failure and of HMG-CoA reductase inhibitors in patients with lipid disorders (53). Only 26% of patients achieved the recommended target dose as described by a number of studies clearly showing mortality benefit (54). Finally, the majority of patients with premature coronary heart disease were not encouraged to have first-degree relatives screened for cardiac risk. This was further emphasized in a study using the ACC Evaluation of Preventative Therapeutics data, in which less than 1% of inpatient medical records contained a discharge plan detailing recommended screening of family members of patients younger than 55 years (55). Only 17.8% of these patients had their families screened within 6 months of their cardiovascular event, despite NCEP guideline recommendations to screen all patients with a recognized history of premature coronary artery disease (10).

Thus, the gap between the goals of treatment and the actual levels of risk-factor control appears large, and it must translate into considerable numbers of preventable cases of recurrence and death caused by atherosclerotic disease. Table 13.2 illustrates this gap by showing the numbers of lives potentially saved each year if proven preventions were optimally implemented, suggesting that tens of thousands of deaths might be averted merely by following guidelines (56).

Therapy	Ideal–actual use (%)	Relative risk reduction (%)	No. of additional lives saved/yr
Antiplatelet	15	15	13,500
Beta-blockers	10	21	12,600
Angiotensin-converting enzyme 1	30	17	30,600
Statins	20	23	27,600
Total			**84,300**

TABLE 13.2 ESTIMATION OF ADDITIONAL LIVES SAVED EACH YEAR BY IMPLEMENTATION OF PREVENTIVE CARDIOLOGY INTERVENTIONS

BARRIERS TO IMPLEMENTATION OF PREVENTIVE CARDIOLOGY SERVICES

Introduction

Unfortunately, the provision of appropriate and effective preventive cardiology care is affected by a large number of people and institutions, including the patient, physicians (both specialists and generalists), health care facilities (both inpatient and outpatient), and societal and community factors. For example, the motivated patient may not be supported by his or her physician, or the physician and patient may find the hospital environment hostile to preventive care (e.g., high-fat, high-cholesterol meals in the coronary care unit). Finally, all may be frustrated by the lack of reimbursement or standards set by third-party payers. Therefore, it is useful to identify the barriers to implementation of preventive services with proven efficacy and cost effectiveness (*e*Table 13.2.1) (57).

***e*TABLE 13.2.1** BARRIERS TO IMPLEMENTATION OF PREVENTIVE SERVICES
Patient
Lack of knowledge and motivation
Lack of access to care
Cultural factors
Social factors
Physician
Problem-based focus
Feedback on prevention is negative or neutral
Time constraints
Lack of incentives, including reimbursement
Lack of training
Poor knowledge of benefits
Perceived ineffectiveness
Lack of skills
Lack of specialist–generalist communication
Lack of perceived legitimacy
Health care setting (hospitals, practices, and so forth)
Acute care priority
Lack of resources and facilities
Lack of systems for preventive services
Time and economic constraints
Poor communications between specialty and primary care providers
Lack of policies and standards
Community/society
Lack of policies and standards
Lack of reimbursement

Patient Factors as Barriers to Risk-Factor Modification

Often, the tendency is to blame the patient for lack of success with behavioral modifications and noncompliance with pharmacologic interventions. Surprisingly, in surveys of patients ascertaining satisfaction with treatment, preventive services, including counseling, were provided less often than recommended or by patient preference (58,59). For example, studies looking at smoking cessation in the primary care setting have shown that the majority of patients who smoke would attempt to stop if their physicians advised them how to do so (48). Only 40% to 55% reported that this advice was given, despite a number of studies illustrating that timely physician counseling on smoking cessation is an effective preventive intervention (49,60,61). In spite of this knowledge, a review of physician encounters showed that in only 67% of the cases was smoking status documented, and for those who did smoke, discussion in regard to stopping occurred in less than 25% of consultations (48). A number of reasons for these results have been cited by physicians, including a fear of antagonizing patients. However, one recent study has shown that smoking interventions during physician visits were associated with increased patient satisfaction with their care (58).

Coronary heart disease is the leading cause of death in American women (7). Despite this, several studies have documented that women with coronary artery disease were less likely to have invasive management of coronary atherosclerosis (62,63 and 64). Sueta et al. showed women to be less likely to be treated with lipid-lowering drugs (53). Strong associations between a low socioeconomic status and a poor prognosis after the onset of coronary heart disease have been consistently documented (65,66). For example, survival after admission for diagnostic coronary arteriography is strongly related to income, with 24% of patients with an income of $10,000 or less not alive after 5 years, in contrast with 9% mortality in those patients with an income of $40,000 or more (65). A variety of studies have documented a poorer prognosis after the onset of coronary disease in blacks as compared with whites (67,68). Also a major difference in use of medication was noted in the Heart and Estrogen/Progestin Study data, in which nearly one-half of the black women did not use lipid-lowering medication (43). It was postulated that this may have been secondary to cost or reduced access to care. In a review of physician encounters it was also noted that nonwhite populations were less likely to be referred for cardiac stress testing and had lower rates of treatment with medications such as beta-blockers when indicated (45,62). Private insurance was also seen to be an independent nonclinical variable that determined access to treatment for cardiac patients (45,62).

Surprisingly, less is understood about the pathways through which these social and cultural factors act (68). A lack of knowledge or motivation on the part of the patient

is frequently cited. High levels of noncompliance are common in a variety of settings (69,70). For example, a study from Australia noted that 58% of patients prescribed HMG-CoA reductase inhibitors were no longer taking them at the end of 12 months (71). The most frequent reason for this noncompliance was patient related; the patient simply did not understand why he or she was given the medication. Indeed, many patients are less likely to continue cardiac rehabilitation after MI and consequently are less likely to benefit from aggressive risk-factor modification. This has been seen in women (7) and also patients with lower incomes and education who are also less likely to pursue an exercise program on their own, when not enrolled in a cardiac rehabilitation program (72). Similarly, people with lower incomes perceive cost to be a barrier to access cardiac care and emergency care in the United States (73).

Patient confusion over conflicting information is also a significant cause for noncompliance. Unfortunately, the media provides a powerful source of provocative, memorable information that may not entirely provide a balanced picture. Although debate over such issues takes place within the confines of the medical profession, it is important to display a consistent, considered interpretation of the available data. Consensus statements have attempted to address this issue (4,5).

Clearly, a patient well educated and proactive in his or her health influences whether a physician addresses a problem (57). Therefore, efforts to empower patients to seek preventive health services remain a viable strategy. Addressing this imbalance is a key component to optimal preventive care. Laying blame at the feet of the patient is unlikely to remedy this. Targeting high-risk groups with special interventions tailored to their educational level or cultural group will provide better results.

Physician Factors as Barriers to Risk-Factor Modification

Preventive cardiology has indeed become more complex, with increased numbers of issues that should be considered in each patient. First, adequate assessment of patient risk factors and determining the degree of overall coronary heart disease risk is vital. Second, a clear understanding of the clinical guidelines for treatment that are constantly updated provides guidance to effectively manage patients. Frequently a lack of appreciation exists in regard to the benefits and magnitude of cardiac event reduction by risk-factor management (74). Risk-factor intervention rivals or exceeds that of more standard cardiologic intervention, in terms of magnitude of benefit. For example, the lowering of LDL cholesterol has shown reductions in recurrent MI, sudden death, and total mortality in the range of 25% to 40% in a wide variety of clinical subgroups of patients with coronary disease in contrast to a few subgroups of patients undergoing revascularization. Indeed, the Atorvastatin Versus Revascularisation and Treatment trial showed that aggressive lipid management was at least as effective (if not more) as angioplasty in reducing ischemic events in symptomatic coronary patients (75). Angioplasty and bypass surgery generally do not prevent infarction, and bypass surgery improves survival only in certain subgroups of patients.

Both the cardiovascular specialist and the generalist face considerable constraints on their abilities to implement risk-factor modification strategies. Time-consuming interventions, especially those involving behavior modification, place enormous burdens on the ever-shrinking time allotted for interactions with patients. The average length of stay in the hospital has dramatically decreased and in the ambulatory care setting, patient appointments are also brief. These interactions, both in inpatient and in ambulatory care settings, are increasingly focused on the acute problem, with the physician being pressured to treat that problem solely. A preventive therapy is therefore often forgotten and, if remembered at all, there is little continued assessment or progression of treatment (44,76).

High proportions (more than 90%) of physicians have expressed adequate knowledge about various guidelines, such as those related to the detection and management of hypercholesterolemia (77). Nevertheless, there remains a lack of self-confidence in their abilities to effectively implement a cholesterol-lowering diet or to use cholesterol-lowering drugs (78,79). Effective titration of dosages of medications or using combination therapy when goal cholesterol levels have not been achieved have been frequently cited causes of therapeutic failure (44,52). Risk-factor management strategies clearly have not been integrated into many cardiology training programs, and many cardiology trainees lack hands-on experience at risk-factor management in a cardiac rehabilitation or preventive cardiology clinic setting. Without this knowledge, the ability to effectively communicate a preventative strategy to the patient is limited. Furthermore, goals of the treating physician and patient may differ. Patients may be more inclined to seek and use medications that relieve discomfort rather than continue with a medication that lowers cholesterol but provides no detectable symptomatic relief. For both doctor and patient, monitoring of lipid levels as objective evidence of medication success is important to encourage compliance.

There also exist a number of disincentives for the physician to provide preventive interventions. Frequently, risk-factor management services are not recognized as part of the treatment of cardiac problems and are not reimbursed. This is especially true for services by nutritionists and nurses. Furthermore, the feedback to the physician is frequently neutral; the goal of prevention is the absence of further events. This delayed gratification is in stark contrast to the relief of angina or dyspnea brought about by acute interventions.

Finally, the notion persists that risk-factor management is the only legitimate bailiwick of the generalist, and that the specialist's activity in this arena may encroach on the generalist's area of responsibility, resulting in loss of patient referrals. This notion emphasizes the lack of specialist–generalist communication in this area and also the lack of clarity over whose role it is to provide and monitor preventative cardiac care. The real issue is whether risk-factor management is an integral part of the optimal care of the cardiac patient; cardiology societies appear unanimous in their opinion that this is true (14,76). Therefore, risk-factor management should be initiated as part of the management of acute coronary disease and included in the care plan communicated from the specialist to the generalist. Lack of this communication continues to adversely affect patient care (57).

FACTORS IN HEALTH CARE SETTINGS AS BARRIERS TO RISK-FACTOR MODIFICATION

Motivated patients and well-informed, skilled physicians may still fail to implement risk reduction strategies when faced with barriers inherent in acute care hospitals and ambulatory care offices. Today's emphasis on early discharge after treatment of the acute condition places tremendous pressures on the duration and content of inpatient interventions. That time available is frequently taken up by procedures or by periods of convalescence in which the patient is not receptive to health education because of pain or treatment with sedatives. These are clearly not high-quality opportunities for intervention, which formerly may have occurred in the additional day or two available before discharge. Increasingly, discharge occurs before risk reduction strategies can be implemented.

Other barriers in the health care setting may be more amenable to correction. These include a lack of organization and resources dedicated to achieving risk-factor management. The responsibility for risk-factor management is often not assigned to a specific person or unit within the hospital or clinic, leaving the physician to fend for him- or herself. This haphazard duty assignment, when actually undertaken, is often performed inadequately because of lack of training r experience. Nurses, nutritionists, physical therapists, and other professionals frequently have not received formal training materials or patient education manuals to ensure the quality of their service. Again, laboring under the false assumption that risk-factor management is adjunctive care, these professionals are often reassigned to other duties during times of staff reductions. The infrastructure for an effective preventive program is often not in place, and therefore interventions are sporadic and inconsistent. Finally, there is often little opportunity to monitor the outcomes of inpatient programs, because patients are rapidly discharged to ambulatory care settings without proper follow-up of their risk reduction care plan. Communication of interventions already performed or strongly recommended for outpatient initiation and instructions regarding later titration are often not included in the limited space on discharge summary forms. A lack of opportunity to address preventive interventions in hospital is thus propagated into the ambulatory setting.

SOCIETAL AND HEALTH SYSTEM FACTORS AS BARRIERS TO RISK-FACTOR MODIFICATION

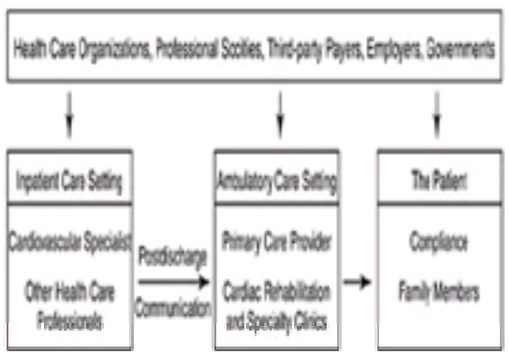
Until relatively recently there has been little impetus from health maintenance organizations to assess the adequacy of risk-factor modification in their patient population. Such an evaluation would be both costly and time consuming. This is especially unattractive without definitive cost-effectiveness data regarding secondary preventive measures. More recent analyses and studies of models for delivering preventive strategies have shown reduced hospitalizations, cardiology clinic visits, and other direct costs as well as improvement in symptoms (80). Frequently, for-profit (and some not-for-profit) health care systems have required a positive return from a preventive intervention within 18 to 24 months, assuming that a substantial portion of patients would be transferring to another health care payer by the end of that time. This in turn has led to lack of reimbursement for preventive services or the lack of designation of positions and resources to provide the risk reduction services. However, more recent studies have focused on initiating preventive interventions in the acute care setting because of early benefits seen (28,29,30,31,32,33 and 34). This has served to increase the importance of guidelines and recommendations that recognize risk-factor management as an integral part of optimal care over both the short- and long-term phases of the disease.

STRATEGIES FOR INTEGRATION OF COMPREHENSIVE RISK REDUCTION INTO CARDIOLOGIC PRACTICE

Introduction

After consideration of the barriers to implementation of risk-factor modification, a chain of opportunities for comprehensive risk reduction might be constructed (*e*Fig. 13.1.1). This would include assessment of the patient's risk factors at the time of admission for an acute coronary disease syndrome, when the cardiovascular specialist or a team of other health professionals might recommend and initiate a risk reduction program. Of special importance would be the communication to the primary care provider about the interventions required and the eventual goals of these interventions, e.g., frequency and duration of exercise, target LDL cholesterol level, and so forth. On an ambulatory care basis, the primary care provider then could initiate or continue the recommended interventions, with or without the help of

specialized entities such as cardiac rehabilitation units, preventive cardiology clinics, and nurse case manager programs. The patient then would be provided with tools to improve compliance with recommended interventions. Finally, health care organizations (e.g., health maintenance organizations and managed care organizations), health insurers and other third-party payers, professional societies, employers, and governments (including the legal system) likely could affect all links in the chain through reimbursement policies, guidelines, and quality assurance programs.



***e*FIGURE 13.1.1** The chain of opportunities for integration of comprehensive risk reduction strategies into the overall care of the patient with vascular disease.

Unfortunately, we have limited direct information on the performance of any of the specific components of this chain of opportunities. What we can infer from large clinical studies is that underuse of preventive interventions and unmet goals of risk-factor reductions currently result in preventable morbidity and mortality. This section discusses the opportunities for intervention at each step of the chain and provides evidence for effectiveness of these interventions to improve levels of risk-factor detection and management.

Opportunities in the Inpatient Care Setting

Role of the Hospital

An inpatient cardiology service can be organized to efficiently and reliably assess the levels of risk factors prevalent in patients admitted with acute coronary syndromes or for revascularization procedures. A convenient tool is the joint AHA–American Association of Cardiovascular Preventive Health statement regarding core components for secondary prevention (26), which includes strategies for optimal risk-factor management. These guidelines include the goals for each risk-factor intervention and have been modified to provide a form to comprehensively document the initial status of the risk factor as well as plans for intervention and follow-up (Fig. 13.2). The checklist format has been used successfully to improve levels of preventive care (81,82). In one study, computer-generated preventive-care reminders, individualized to the patient, increased preventive services provided by 126 physicians by 20% (83). Such a form could be filled out by physicians, nurses, or other health professionals. The AHA has provided a number of Web-based tools to quickly and efficiently document risk-factor assessments and interventions for individual patients (http://www.americanheart.org/CAP, “Get with the Guidelines Program”). These tools track compliance of risk-factor modifications and can even generate letters clearly outlining proposed programs. This provides a time-efficient, vital communication between physicians participating in care. Nurse-generated checklists also have been successful in increasing preventive services (84,85). Similar reminder messages and forms have also been used to implement a variety of acute care guidelines, suggesting their feasibility and desirability even in acute care settings (86). The Cardiac Hospitalization Atherosclerosis Management Program at the University of California Los Angeles has implemented such a system of early risk-factor intervention and has shown increasing rates of use of known effective interventions during long-term follow-up (Table 13.3) (87). Another approach is the development of more elaborate care protocols, or *critical pathways*, that comprehensively define care of a specific problem. The joint AHA-ACC guidelines for management of patients with acute myocardial infarction is an example of this, defining multiple dimensions of acute myocardial infarction management but including risk-factor assessment and management as part of the initial intervention (13).

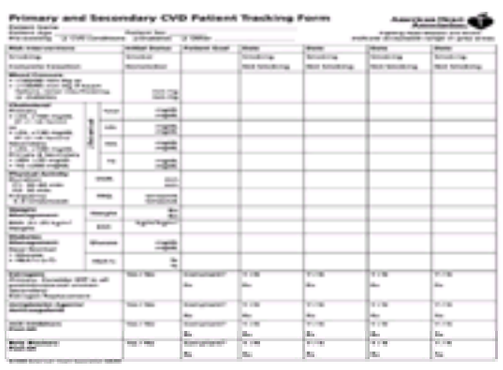


FIGURE 13.2 American Heart Association form to track risk-factor modification and secondary preventive intervention. TABLE 13.3 RATES OF APPROPRIATE AND INAPPROPRIATE CARDIOLOGIC MEDICATION USE BEFORE AND AFTER AN INPATIENT PROGRAM TO IMPROVE ATHEROSCLEROSIS: THE CARDIAC HOSPITALIZATION ATHEROSCLEROSIS MANAGEMENT PROGRAM (CHAMP) STUDY

Hospitals can also provide a variety of other opportunities to identify risk factors. One example is the chemistry laboratory. The AHA-ACC guidelines for management of acute myocardial infarction suggest a lipid profile at the time of admission to the hospital (13). This can be made automatic, so that serum collected for cardiac enzymes such as troponin and creatinine phosphokinase might also be analyzed for serum lipids. The importance of this lies in the observation that serum cholesterol levels (and most lipoprotein cholesterol levels) decrease 24 hours after an MI (88). The routine measurement of a lipid profile in the patient with the presumptive diagnosis of MI would ensure a baseline assessment of lipids and lipoproteins. Furthermore, laboratory reports can include various messages identifying abnormal levels and the steps needed to correct those levels. Cholesterol levels identified as abnormal serve as cues to change physician behavior and are more likely to lead to further diagnosis and treatment of a lipid abnormality than those values not identified as normal (89). This has taken on even more importance with increasing evidence of the benefits of in-hospital preventive interventions.

Another important reason for encouraging early assessment and treatment of risk factors is that hospitalization for an acute ischemic episode often represents an opportunity to change patient attitude and behavior. Patients are unable to smoke in the hospital and are subject to dietary restrictions. This provides as ideal

opportunity to begin the discussion of what permanent changes need to be made in their lifestyles (49,60,61).

Role of the Cardiovascular Specialist

The usual role of the physician admitting the patients acutely ill with vascular disease, or the cardiovascular consultant asked for advice, is to make and confirm the diagnosis, to set goals for treatment, and to formulate the optimal plan to achieve these goals. The same should be true for the modification of risk factors. In this way, the cardiovascular specialist plays a leadership role in the integration of risk reduction strategies into the overall plan. Those patients admitted with symptomatic coronary artery disease already fall into the high-risk group of patients likely to experience further cardiac events. Therefore, risk-factor modulation should aim to meet recommended goals over the next few months after the onset of symptoms and the diagnosis of a risk factor.

After the plan is constructed, the physician may or may not be the person implementing it. However, the physician does need to communicate the overall treatment plan to the patient, including the importance of risk-factor control in the prognosis of disease. Other supporting team members charged with counseling or other behavior-modifying activities need to emphasize the importance of nonpharmacologic life-style changes as well as pharmacologic interventions and revascularization procedures.

The duration of hospital stays is continuing to decrease, with many diagnostic and nonsurgical revascularization procedures being performed on a same-day basis. Much of the care plan, especially that dealing with long-term issues, is carried out by the specialist or by the primary care provider on an outpatient basis. This does not alter the need to integrate risk-factor management into the overall treatment plan of the patient. Rather, it emphasizes the importance of communicating to the ambulatory care provider the need for risk-factor management and the appropriate strategies to achieve specified goals. Frequently, discharge summaries describe findings of diagnostic or therapeutic procedures in great detail, only to ignore altogether the presence of risk factors and any plan to control them. The ambulatory care provider is then led to believe that risk-factor management is not an essential part of the patient's care. Discharge plans and letters to the referring physician should identify risk factors on the patient's problem list, including diagnostic tests performed (e.g., fasting lipid profiles at the time of admission for MI). Furthermore, steps taken, including counseling by members of the multidisciplinary team, should be recorded. Finally, additional interventions and the goals of these interventions, which still need to be completed, should be provided. Again, the emphasis is on communicating the optimal care plan for the patient with vascular disease and this includes risk-factor management.

Role of Other Health Professionals

Interventions on behavioral and physiologic risk factors require a broad range of expertise in such diverse areas as behavioral counseling, nutrition, exercise physiology, pharmacology, and genetics. As noted previously, physicians may not possess specific skills in all of these areas, as compared with the focused expertise of patient education nurses, nutritionists, and exercise physiologists. Therefore, there is much to recommend a multidisciplinary team to implement the care plans for many patients. The team should be well coordinated to ensure communication and avoid confusion between the physician, team members, and patient. This is where the concept of a nurse manager–based cardiac rehabilitation service has become more desirable. In major hospitals this is currently in effect, with the prevention team forming a link between inpatient and outpatient care.

Opportunities in the Ambulatory Care Setting

Role of the Primary Care Provider

The primary care provider plays a variety of important roles in risk-factor management. It is hoped that detailed notes on the recommendations and progress to date will be available from the specialist after discharge from an inpatient unit. Construction of this plan requires the ability to accurately assess an individual patient's risk factors and place them in a category of appropriate risk-factor intervention. Currently, many discharge forms are poorly organized. There are a number of easily accessible forms that provide more comprehensive communication and prompt the physician to consider a number of key issues (Fig. 13.2, http://www.americanheart.org/CAP). The primary care provider needs to integrate these new plans with the overall care plan. Monitoring and feedback of patients' progress are often best carried out by the primary care provider, who has more frequent and regular access to the patient. The primary care provider may also wish to organize his or her practice to provide preventive care more efficiently. The office nurse frequently serves as a counselor on smoking cessation, diet, exercise, medication compliance, and other risk factors. Additional training of nonphysician professionals can expand considerably the services provided by an ambulatory care practice.

In terms of preventive strategies in the patient without symptomatic coronary artery disease, the physician must be able to assess multiple risk factors and estimate an overall risk of future coronary artery disease events. In this instance, the calculation of a global risk-scoring equation using multiple risk-factor variables gives an overall estimate of absolute risk of developing coronary artery disease over a 10-year period (24,25). A variety of risk assessment instruments are available, including wall charts, slide rules, hand-held risk calculators, and software programs. With use of this risk-stratification, the physician is able to provide the appropriate level of risk-factor modification based on accepted guidelines, including the identification of the *coronary heart disease risk equivalent* patient who deserves aggressive risk-factor management.

Role of Specialty Clinics and Cardiac Rehabilitation Units

Larger ambulatory practices, especially those tied to inpatient units, may have the opportunity to develop specialized programs for risk-factor management. The key element is the focus of risk-factor management expertise and resources in a person or team of people to whom problems can be referred. Clearly, most patients with vascular disease should be provided with risk-factor counseling and appropriate pharmacologic therapy as part of optimal cardiology care. However, there will continue to be a subgroup of patients in whom specialized expertise will likely be needed. These include patients who are resistant, recalcitrant, rare, or risky (the four Rs). Patients not responding to usual interventions for dyslipidemia or hypertension may benefit from an additional opinion. Patients who are recalcitrant may benefit from physicians, nurses, nutritionists, and exercise specialists skilled in behavior modification and counseling. Patients with rare risk-factor abnormalities, such as genetic hyperlipidemias, coronary disease without obvious risk factors, or coexisting medical diagnoses, may also require specialist expertise. Finally, patients at extreme risk of bad outcomes may have aggressive risk-factor management programs more successfully implemented by a multidisciplinary team (e.g., the patient with symptomatic vascular disease in the fourth or fifth decade of life and those patients with coronary heart disease and type 2 diabetes mellitus).

These specialized programs may take several forms. A preventive cardiology clinic is likely preferable over a clinic emphasizing a single risk factor, as most patients have several risk factors (90). In general, the staff includes one or more physicians with specialized training and expertise in risk-factor management, a coordinator, a nurse skilled in risk-factor counseling, a nutritionist knowledgeable about lipid-lowering diets, and an exercise physiologist who can develop an exercise prescription. The team may be supported by a variety of data collection tools, including computerized databases, patient education materials, and follow-up protocols.

Cardiac rehabilitation programs are often underused as sites for risk-factor management (see Chapter 12). Their efficacy in reducing total and cardiovascular mortality has been well documented in metaanalyses (91), especially when they include comprehensive risk-factor management services (92,93). Again, a team approach is optimal. Cardiac rehabilitation programs have the added advantage of providing considerable psychosocial support from other patients and their family members.

Nurse case managers are being used widely as a cost-effective means to provide comprehensive risk reduction with excellent continuity between inpatient and ambulatory care settings. Nurse-managed programs have been shown to be effective in the management of single risk factors, including smoking cessation (94), diabetes (95), hypertension (96), and lipid lowering (97). Specially trained nurses have implemented comprehensive risk-factor reduction programs targeting multiple risk factors. An example of such a program, the Stanford Cardiac Risk Intervention Program, is illustrated in *e*Figure 13.2.1 (98,99). During a 1-year period, patients received a combination of visits, telephone calls, and mailing reminders. Nurses formed the central point of contact, interacting with patients and other health professionals and laboratories. There was a clear delineation of professionals' responsibilities. The system successfully enhanced pharmacologic and dietary therapy and improved patient symptomatology and use of health services. DeBusk et al. (98) demonstrated a significantly higher rate of smoking cessation, a tripling of the proportion of patients reaching the LDL cholesterol goal of less than 100 mg per dL, and an improved exercise capacity among those patients managed by nurses trained in multiple risk-factor management (Table 13.4). Nurse case managers appear to be particularly effective in increasing patients' adherence to diet and drugs; in implementing a program of self-monitoring of weight, blood pressure, symptoms, and smoking cessation; and in teaching patients to recognize and respond to changes in their symptoms (100,101). Among the numerous advantages of such nurse case manager programs is the opportunity to initiate contact with the patient while he or she is still in the hospital (98,99), thereby integrating the inpatient and outpatient risk-factor management into a single, continuous program. Furthermore, patient satisfaction has been high, and significant cost savings, even over the short-term, can be realized (101).

Opportunities for the Patient

Patient Compliance and Adherence to Interventions

A detailed discussion of patient compliance and adherence with behavioral and therapeutic regimens is beyond the scope of this review. It is an issue of enormous importance (69). First, the prevalence of noncompliance is exceptionally high, with estimates suggesting that only one-third of patients are fully compliant, another one-third are somewhat compliant, and one-third are fully noncompliant (102). This results in approximately 50% of the 2 billion prescriptions written in the United States annually being taken incorrectly (69). Compliance with behavioral interventions is even lower, with the maintenance of smoking cessation, weight-control diets, and low–saturated fat diets estimated at 10% to 20% over a 1-year period (103). The costs resulting from this noncompliance are staggering, with approximately 10% of hospitalization caused by patients' inability to follow therapeutic regimens (69). In the Beta Blocker Heart Attack Trial, both men and women taking fewer than 75% of their prescribed beta-blocker medication had 2.5- to 3.0-fold higher mortality than those who took their medications more than 75% of the time (104,105). The problem of noncompliance encompasses all diseases, risk factors, and therapies (70). Improving patient compliance and adherence is clearly a major challenge and opportunity for improving the outcome of any intervention program.

The determinants of noncompliance and nonadherence are multiple and complex (106). For example, patient factors (knowledge, beliefs, attitudes, and values), their families, the health care setting, the provider–patient relationship, characteristics of the disease, and nature of the treatment all play important roles (69,107). A 2-year study of patients with hypertension, diabetes, or cardiac disease showed that characteristics of health care providers (physician specialty, number of patients seen per week, willingness to answer patients' questions), the health care facility itself (scheduling a follow-up appointment, number of tests ordered), the seriousness of the illness, and the level of patient distress all have an effect on compliance (70).

Because of the complexity of this issue, no single intervention has been shown to be effective in solving the problem. Although a variety of strategies of varying sophistication have been proposed (102), some rather simple steps can be emphasized (Table 13.5) (107). These include clear communication of goals, simplification of the intervention, and monitoring with feedback to the patient. Special programs, such as those with nurse case managers, may succeed because of their abilities to carry out these compliance-enhancing steps. Increasingly, programs in the electronic media have been developed to ensure compliance. The AHA has also provided several Web-based tools that have a wide variety of applications for physicians, patients, and hospital staff. The *one-of-a-kind* program allows patients to enter data regarding their cardiac risk factors and track their progress as well as compare their values with a composite mean of the database (http://www.onelife.americanheart.org/). This compliance-enhancing, Web-based tool is versatile. Physicians and staff in busy practices can provide their patients with access to cardiovascular services by a brief but strong recommendation to enroll in this program, which prompts a wide range of risk-factor management issues based on current guidelines.

Initiation of treatment
Convey the importance of the recommendations
Emphasize required behaviors to provide the rationale for them
Simplify the regimen
Discuss costs
Record keeping
Use a systematic and consistent tracking form
Send reminders of follow-up appointments
Monitor effects
Follow-up
Reinforce treatment message
Probe about side effects, problems, and adherence

From Luepker RV. Patient adherence: a "risk factor" for cardiovascular disease. *Heart Dis Stroke* 1993;2:418–421, with permission.

TABLE 13.5 RECOMMENDATIONS TO IMPROVE PATIENT ADHERENCE TO TREATMENT

Family Members

Two objectives are served by involving the family unit in a risk reduction program. First, the patient's risk behaviors are subject to a number of influences. The patient's diet, exercise, and smoking habits are usually part of a family's behavior. A lasting behavioral change therefore usually requires family participation. Social support is an important part of any program to improve compliance with behavioral or pharmacologic interventions. Other family aggregating factors, such as diet and environmental tobacco smoke, affect the patient's health directly. Second, the familial aggregation of risk factors is well recognized. The screening of first-degree relatives clearly yields a high prevalence of undetected risk factors (108). A strong recommendation that siblings and children be screened for risk factors should be included in any patient presenting with premature coronary heart disease. Screening in this population has been disappointing (55) and perhaps should form part of the algorithm when documenting family history and risk-factor assessment.

Opportunities by Health Care Organizations, Professional Societies, and Third-Party Payers

Professional Education Programs

The training of physicians, nurses, and other health professionals responsible for the care of patients with vascular disease should include a working knowledge of risk-factor modification, including vascular biology and clinical evidence supporting such interventions. Guidelines for the education of cardiovascular specialists include this training for minimal competence in preventive cardiology (74). Frequently lacking from such programs are didactic and shell-building experiences to organize hospital services or interpret priorities or to improve physician performances in ensuring compliance with both behavioral and pharmacologic interventions.

The continuing education of professionals already in practice presents another set of challenges. In general, successful continuing education programs must identify a specific audience and learning need, express clear learning objectives, target physician performance rather than knowledge, be carried out in clinical settings, and measure changes in physician practices (108). Traditional lectures and mailed materials appear to be less successful unless tied to results of clinically relevant, randomized trials (109,110).

Many studies of continuing education suggest that the effectiveness of these educational programs can be boosted considerably if combined with some form of performance feedback. Forms of feedback include medical records audits (111) or physician knowledge assessment (112). Feedback should be as personalized as possible. In one study, performance feedback boosted the cholesterol management practice in house officers caring for patients with coronary disease, far exceeding the benefits of a reminder system (113).

The AHA and ACC have released a number of clinical guidelines and statements to aid and update physicians on current evidence-based preventive practice (4,5,6,7,8,9,10,11,12 and 13). These should provide ample targets for physician education. Programs to explore professional compliance with guidelines are increasingly available, such as the AHA's "Get with the Guidelines" program (http://www.americanheart.org/CAP).

Clinical Guidelines

Fortunately, the AHA, ACC, and other bodies have issued joint guidelines on risk-factor management in patients with vascular disease (4) and without vascular disease (8), as well as for women (7) and diabetic patients (6). These guidelines are consistent with statements addressing individual risk-factor modification such as hypertension (9), hypercholesterolemia (10), sedentary lifestyle, smoking (11), and obesity (12). The essence of these guidelines has also been incorporated into recommendations for acute cardiac care (13).

Despite good consensus on risk-factor management, the efficacy of guidelines is mixed. It appears that they are least likely to succeed if no incentives (or removal of disincentives) are provided for the practicing physician (114). Guidelines need to be actively disseminated and implemented. They are most effective when coupled with evaluation of physician performance (115). As databases evaluating patient risk-factor modification become increasingly available, this may provide such an opportunity in the future.

Quality Assurance Standards

Some of the components of a quality assurance program are already in place, including substantial evidence from basic science, epidemiology clinical trials, cost-effectiveness analyses (14), and guidelines reflecting broad consensus on criteria for optimal risk-factor management (4). The next component in a quality assurance program is the feedback loop, in which levels of performance toward accepted criteria are linked to incentives, including credentialing, remuneration, or competitiveness (eFig. 13.2.2) (116,117). One performance report has been the Health Plan Employer Data and Information Set (HEDIS), which employers use in contracting for care with managed care organizations (118). Risk-factor management indices have become especially well represented, probably because of the presence of consensus statements and the evidence of nearly universal benefits of many of the interventions. HEDIS 3.0, for example, used a number of risk-factor levels and management practices as end points for the next *report card* (Table 13.6) (119). The National Committee for Quality Assurance is routinely developing new performance guidelines as part of the HEDIS process (118). This now requires a mandatory report from health maintenance organizations, quantifying the percentage of cardiac patients who have met HEDIS criteria. The National Committee for Quality Assurance have defined a difference between clinical and performance goals. Although they endorse the NCEP guidelines, they have stipulated a goal LDL of less than 130 mg per dL, rather than less than 100 mg per dL, in patients with coronary heart disease. The reason for this difference is to provide a realistic, attainable goal that allows physicians room for clinical judgment in individual cases. The important point to note, however, is the change in focus for health maintenance organizations and consequently physician practice in terms of evaluation of efficacy of risk-factor modification (120).

TABLE 13.6 MEASURES RELEVANT TO THE COMPREHENSIVE RISK REDUCTION OF PATIENTS WITH VASCULAR DISEASE PROPOSED FOR REPORTING IN HEALTH PLAN EMPLOYER DATA AND INFORMATION SET

Relatively recent medical-legal actions may be another example of use of quality assurance standards. One settled suit, successfully charging a wrongful death caused in part by the lack of treatment of hyperlipidemia, illustrates the use of guidelines in medical malpractice claims (121).

Reimbursement Policies

The lack of reimbursement can serve as a powerful disincentive to risk-factor management for practicing physicians (122). Statements, guidelines, and accreditation by professional societies and the acceptance of risk-factor management as quality indicators are powerful motivators for third-party payers to reimburse for preventive services. Such motivation will be needed for physicians, clinics, and hospitals to allocate personnel, space, and funds for risk-factor management programs.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The demand for risk modification is likely to continue to expand because of several irreversible trends. First, the prevalence of coronary heart disease and other vascular diseases will continue to expand for at least the next 30 years (123). Currently, among U.S. adults aged 45 years and older, 12% of men and 8% of women carry the diagnosis of coronary disease. Second, cardiovascular specialists are likely to be consulted in the management of a new cohort of patients in whom asymptomatic atherosclerotic disease has been identified by noninvasive means. Third, current guidelines are now identifying, on the basis of a global risk score, a potentially large group of patients who have a coronary heart disease risk equivalent. Thus, the demand for preventive services will only expand, necessitating efficacious, effective, and efficient methods to reduce risk. This chapter has identified gaps in the successful implementation of risk-factor modification. How might we do better? The controversy is not why, whether, or how to do it, but who should do it.

This author's personal impression is that this responsibility is a shared one. Although additional research is needed to identify specific barriers to preventive care and to test strategies to remove them, it is clear that we can organize ourselves to be more effective. For every coronary disease patient admitted to an inpatient service, we recommend an organized, comprehensive assessment of risk factors, which then triggers the development of a plan to manage the patient. Next, a nurse case manager either follows up on the patient from the inpatient to the outpatient setting or clearly communicates the plan to the referring generalist. The plan is then carried out by a coordinated, multidisciplinary team of physicians, nurses, nutritionists, and exercise physiologists either in the inpatient service or in the outpatient clinic. In general, the patient is cared for until risk-factor goals have been met.

Cardiovascular specialists often cite their lack of responsibility in this area. This position is increasingly untenable, because most or all of the goals of revascularization or cardiac pharmacotherapy are the same as those for risk-factor management. Risk-factor management alleviates chest pain, reduces the risk of MI, prevents disability caused by stroke and heart disease, prolongs survival, and, in many instances, reduces health care costs. Few invasive procedure and high-technology interventions can boast of such an effect. The cardiovascular specialist who does not integrate risk-factor management into his or her patient care then has the simple goal of performing procedures, rather than optimizing clinical outcomes.

The bedrock, which is unmoved by contemporary deficiencies in medical education, health care economics, and practice disorganization, will remain the scientific evidence defining the role of risk-factor management in beneficially altering the natural history of atherosclerotic disease. This is likely only to strengthen. In addition to studies of basic mechanisms and randomized clinical trials of new interventions, research on the implementation and maintenance of optimal care practices is needed to ensure the appropriate application of all that we have learned.

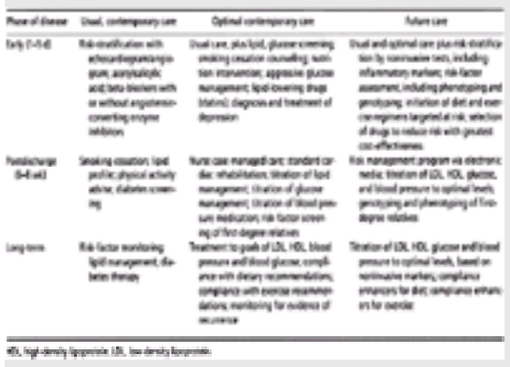
This would then require us to reform our research agenda. The World Health Organization perspective on disease control is illustrated in eFigure 13.2.2 (1). The WHO identified three areas for improvement. The first is to reduce disease currently unavoidable with existing interventions through biomedical research and the development of new interventions. Clearly, there are many opportunities to elucidate new disease mechanisms amenable to intervention, to identify new risk factors, and to test new drugs and technologies with randomized trials. Indeed, the vast majority of our research and development resources go into this activity. A controversial position may be that, as biomedical science advances, further development of interventions will result in only a modicum of disease reduction unless there is attention to two other causes of the disease burden, namely, disease that would be averted with improved efficiency and disease that would be averted if existing interventions were more cost effective. These two areas currently receive a small fraction of research and development funds. To really affect this disease, these sources of avoidable coronary heart disease must likewise be reduced.

THE FUTURE

Applications of the principles of vascular biology to the practice of cardiology will likely be of such priority that the two fields will become one. The concepts of *metabolic revascularization* and *risk-based intervention* will be cornerstones for care.

eTable 13.0.1 provides a view of contemporary interventions as well as those likely to evolve in the near future to become established modes of care. improved intervention and studies to establish their efficiency will be forthcoming in the next decade for diabetes, low hdl and high triglycerides, and obesity. improvements in compliance with physical activity and diet will also take place, it is hoped.

Table 13.7 furthers this vision, starting with current care using known strategies, expanded to optimal evidence-based care projected into the future. several trends clearly stand out. first, risk-stratification will improve through the use of noninvasive imaging and biochemical or genetic markers, such as inflammatory markers. likewise, risk-factor assessment in early and postdischarge periods will be sharpened by use of genetic markers and improved phenotypic indicators, for both probands and their relatives. selection of nonpharmacologic and pharmacologic interventions will be more precise, with clusters of interventions chosen to optimize prognosis and cost effectiveness. these interventions will be guided by knowledge of disease processes and by empirical data from clinical trials. compliance will be strongly emphasized, with the use of multidisciplinary teams led by risk-factor managers supported by a variety of electronic media. titration of drugs and lifestyle interventions may rely less on metabolic or behavioral end points and more on noninvasive measures of altered pathophysiology, such as endothelial dysfunction or disease progression.



Phase of disease	Usual, contemporary care	Optimal contemporary care	Future care
Early (1–5 d)	Risk-stratification with echocardiogram/angiogram; aspirin/clopidogrel; beta-blockers with or without angiotensin-converting enzyme inhibitors	Usual care, plus lipid, glucose screening; smoking cessation counselling; nutrition intervention; aggressive glucose management; lipid-lowering drugs (statins); diagnosis and treatment of depression	Usual and optimal care plus risk-stratification by noninvasive tests, including inflammatory markers; risk factor assessment, including phenotyping and genotyping; initiation of diet and exercise regimens targeted at risk; selection of drugs to reduce risk with greatest cost-effectiveness
Postdischarge (6–8 wk)	Smoking cessation; lipid profile; physical activity advice; diabetes screening	Nurse case-managed care; standard cardiac rehabilitation; titration of lipid management; titration of glucose management; titration of blood pressure medication; risk factor screening of first-degree relatives	Risk management program via electronic media; titration of LDL, HDL, glucose, and blood pressure to optimal levels; genotyping and phenotyping of first-degree relatives
Long-term	Risk-factor monitoring; lipid management; diabetes therapy	Treatment to goals of LDL, HDL, blood pressure and blood glucose; compliance with dietary recommendations; compliance with exercise recommendations; monitoring for evidence of recurrence	Titration of LDL, HDL, glucose and blood pressure to optimal levels, based on noninvasive markers; compliance enhancers for diet; compliance enhancers for exercise

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

TABLE 13.7 PREVENTIVE CARE OF THE CORONARY DISEASE PATIENT: USUAL, OPTIMAL, AND FUTURE

this explosion of knowledge and technology should not lull us into a false sense that cardiovascular disease will be conquered without the continued reliance on interpersonal skills. preventive cardiology will still need to rely on the ability of the preventive cardiology team to modify the patient's behaviors that led to the disease in the first place. it is difficult to conceive of pharmacologic or surgical interventions that will even partially displace the need for effective smoking cessation counseling, the alteration of ingestion of dietary fats and cholesterol, and the increase in physical activity. although patients will benefit from the skills of a variety of health professionals, the cardiovascular specialist will still need to ensure optimal care through his or her implementation. thus, the integration of risk-factor modification will undoubtedly cease to be adjunctive therapy and take its rightful place as the cornerstone of cardiac care.

OVERVIEW

The history is the most essential part of the diagnostic evaluation. A careful interview with the patient not only lays the foundation for an appropriate further workup, but it also serves as the framework for a bond between patient and physician, thereby promoting mutual respect, trust, and understanding. Listening to the patient cannot be adequately emphasized, and this goes beyond what is verbally communicated through gestures and nonverbal language. The major symptoms to review with each patient include chest discomfort or pain, dyspnea or cough, and syncope or palpitations—each of which are discussed in more depth. It is hoped that directly obtaining a meticulous history will become more routine and prioritized in the years ahead.

GENERAL PERSPECTIVE

Obtaining a careful, detailed history is fundamental to the proper evaluation of the patient. This takes time, as it requires listening to the patient and, ideally, his or her family members without interruption. Beyond listening, it is vital to cue in to the patient's nonverbal communication, such as affect and gestures. The time spent with the patient and the attitude displayed set the tone for the whole relationship and, therefore, represent a critical investment for the long-term bond and mutual trust that need to be nurtured. It is important for the patient to understand that the physician is a compassionate person who frankly cares about his or her condition and who genuinely wants to help. The relationship that is built on strong communication with attention to details during the interview leads to a "full disclosure" history that often preempts the need for expensive, potentially hazardous, and certainly inconvenient diagnostic testing (1,2). History taking is a true art that yields unique and valuable information.

Before zooming in on the chief complaint, it is helpful to establish the patient's noncardiovascular history and medications and to query the risk factors for atherosclerosis. Pertinent conditions such as thyroid disease, anemia or gastrointestinal bleeding, asthma or chronic bronchitis, recent upper respiratory or viral illness, prostatitis, or arthritis frequently interrelate to the chief complaint and need to be fully characterized. Similarly, trauma or recent procedures such as oral surgery need to be surveyed. The entire list of medications with corresponding dosages must be known, given the preponderance of symptoms that can arise from side effects of drug therapy. Furthermore, the list of medications often serves as a checkpoint that all relevant medical conditions have been reviewed. Known allergies should be ascertained, and if coronary angiography is even a remote possibility, direct questioning about exposure to contrast dye or shellfish is imperative.

The risk factors for atherosclerosis must be carefully examined. As reviewed in detail in the first section of this textbook, each of the "big five"—hypertension, smoking, diabetes, hypercholesterolemia, and family history—is discussed. In this era of recognition of the primacy of genetics for influencing diseases, it is especially essential to obtain a detailed family history to consider for precocious atherosclerotic coronary disease (presenting at younger than 40 years for men or 45 years for women), any history of coronary artery disease, and other heart disease such as hypertrophic cardiomyopathy, arrhythmias, or other conditions (see Chapter 97 and Chapter 100). As recently noted, a family history of myocardial infarction may not be accurate (3,4).

The patient's weight at the time of graduation from high school and over the next few years (with any significant fluctuations) is helpful information. For women, determination of menstrual status and, if postmenopausal, of whether hormone replacement therapy has been recommended are important to resolve but are too frequently overlooked. The patient's diet and nutritional status are worthy of full review, providing some insight into a patient's level of commitment to a healthy lifestyle. Similarly, the level of physical activity and whether regular exercise is part of the patient's weekly routine frame the symptomatic assessment and corroborate the previous commitment to cardiovascular health. The pattern of alcohol use is a particularly worthwhile item about which to question the patient. Similarly, the potential for drug abuse should be explored in particular circumstances. Considerable revelation about the psychosocial makeup of the patient becomes evident, provided the physician is cueing in to the intensity level and manner in which the words and responses are being conveyed.

EVALUATION OF CARDIOVASCULAR SYMPTOMS

For each patient, a review of cardiovascular symptoms beyond the primary symptom is useful. The major symptoms are chest discomfort, dyspnea, syncope, edema, and fatigue. Other symptoms such as cough, palpitations, orthopnea, and dizziness or light-headedness are supportive and need to be ascertained in relation to the primary complaint. Often, a patient is not in touch with the symptoms or is in such fear or denial that he or she is unlikely to volunteer the information. For this reason, it is imperative to perform detailed questioning about chest discomfort or dyspnea in patients with a clustering of risk factors for atherosclerosis irrespective of the lack of a complaint. Symptoms of atherosclerosis of other arterial beds are systematically surveyed. For the cerebrovasculature, a check on symptoms such as transient loss of speech or motor function (suggesting a transient ischemic attack) or, for the peripheral blood vessels, calf discomfort on exertion that is promptly relieved by rest (suggesting intermittent claudication) help resolve the diffuseness of the atherosclerotic process, if present.

A functional classification of the patient's symptoms should be obtained (5,6). For angina, the Canadian Cardiovascular Society Functional Classification System is usually used (Table 14.1), whereas for dyspnea and other symptoms of heart failure, the New York Heart Association Functional Classification is relied on (Table 14.2).

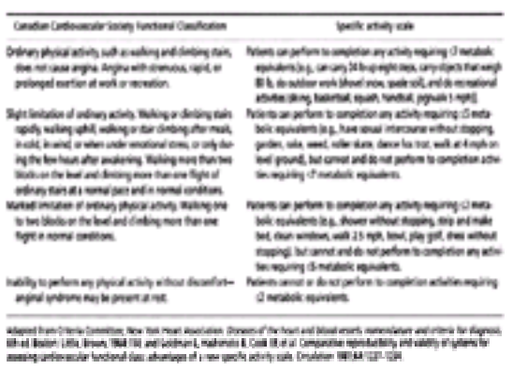

TABLE 14.1 ASSESSING CARDIOVASCULAR DISABILITY

Class	New York Heart Association functional classification
I	Patients with cardiac disease but without resulting limitations of physical activity. Ordinary physical activity does not cause undue fatigue, palpitations, dyspnea, or anginal pain.
II	Patients with cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
III	Patients with cardiac disease resulting in marked limitation of physical activities. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.
IV	Patients with cardiac disease resulting in inability to perform any physical activity without discomfort.

TABLE 14.2 FUNCTIONAL CLASSIFICATION

Chest Discomfort, Pain, and Related Symptoms

One of the most frequent, yet difficult, symptoms to assess is chest discomfort or pain (7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22 and 23). Because this can be so frightening to patients, these symptoms may precipitate emergency evaluation. A variety of cardiac and noncardiac conditions can produce chest discomfort or pain, as summarized in Table 14.3. The key to determining whether the discomfort is cardiac is to review its character, location, and precipitating factors. Because conditions such as esophageal reflux and musculoskeletal abnormalities are quite common, it is not unusual for a given patient to have two or more different types of chest discomfort (22,23). In such instances, a careful assessment of each of the symptom complexes is necessary to determine the underlying condition(s).

Cardiac	Noncardiac
Angina	Esophagitis, esophageal spasm, or reflex
Acute myocardial infarction	Peptic ulcer
Aortic dissection	Gallbladder disease
Pericarditis	Musculoskeletal causes, including osteochondritis or cervical disk, thoracic outlet syndrome
Myocarditis	Hyperventilation
	Anxiety
	Psychogenic causes
Mitral valve prolapse	Pneumonia
	Pulmonary embolus
	Pneumothorax
	Pulmonary hypertension

TABLE 14.3 CAUSES OF CHEST DISCOMFORT AND PAIN

Character and Location

Although *angina* literally means “choking,” most patients with true angina do not use this term to describe their sensation. Despite Herberden’s early description in 1768 of a “painful and most disagreeable sensation in the breast” (24), the unpleasant sensation is more typically characterized as a pressure, tightness, heaviness, or burning. The pressure is not perceived by the patient as “pain,” such that the interviewer who specifically asks about pain may be misled. On the other hand, “pain” is much more apt to be used by the patient to describe a heart attack; on occasion, the patient may clench the fist while describing the discomfort—the so-called Levine sign. The discomfort of angina is usually easy to differentiate from the pain of acute myocardial infarction by the duration, radiation, and lack of precipitating or alleviating factors. As opposed to angina, which usually lasts for 1 to 3 minutes, heart attack pain lasts for longer than 10 minutes; rather than having one focus (usually the retrosternal region), there is commonly radiation of the pain, such as down the arm. Heart attack pain is described in more depth in Chapter 18. Angina most commonly is felt in the midline of the chest, but it can manifest exclusively in the jaw or neck, the left shoulder or arm, and, when present in the arm, particularly on the ulnar aspect of the forearm and hand (Table 14.4). Rather than in the chest, the principal pressure or burning can be perceived in the epigastrium, causing the patient to believe the problem is simple indigestion. More rarely, the back interscapular region or the right side of the chest, shoulder, arm, or forearm is involved. Unlike the chest discomfort of angina, severe pain that radiates to the back is a classic indication of aortic dissection. However, patients with aortic dissection or expanding aortic aneurysm can have predominant anterior chest pain that may be mistaken for acute myocardial infarction. In the course of evaluating patients with chest pain, it is helpful to adopt the philosophy of “aortic dissection until proven otherwise” so that this diagnosis is never missed, even though it is a relatively uncommon entity in the current era of improved control of hypertension.

Dyspnea
Jaw or neck discomfort
Shoulder, elbow, or arm discomfort, particularly along the side of the left forearm and hand
Epigastric discomfort
Back (interscapular) discomfort

TABLE 14.4 ANGINAL “EQUIVALENTS”

Chest pain or discomfort in women is more difficult to assess, and there have been studies to address the issue of whether there is gender bias resulting in inappropriate underinvestigation or undertreatment in women (25,26). A careful history and assessment of risk is especially critical among women, as the correct diagnosis is more elusive—even with noninvasive testing—and pivotal.

Acute pericarditis is a precordial pain that is typically left sided; it is usually worse with inspiration and described as sharp, often referred to the neck. Unlike angina or myocardial infarction pain, this pain is often positional in character such that if the patient sits up and leans forward, the pain may be relieved. Congenital absence of the pericardium is exceedingly rare, but the telltale symptom is chest pain produced by lying on the left side lasting only a few seconds or minutes (27). On occasion, patients with acute myocarditis may present with chest pain, which may be attributed to pericardial involvement or the actual inflammation of cardiac muscle. Mitral valve prolapse often is accompanied by atypical chest discomfort because it is sharp, stabbing, protracted in duration, and associated with a constellation of symptoms (see Chapter 21).

A long list of noncardiac causes of chest pain or discomfort (Table 14.3) is capped by the esophageal disorders of reflux, esophagitis, or spasm—all of which may coexist in certain patients with myocardial ischemia. Esophageal discomfort can fully mimic the character and location of myocardial ischemic symptoms, but, more commonly, the retrosternal burning or epigastric heaviness is brought on by food ingestion and recumbency, with relief by antacids and H_2-blockers. When there is a sour taste in the mouth (so-called water brash) as a result of the acid reflux, this is helpful in differentiating esophageal-induced symptoms from other etiologies. Other gastrointestinal disorders such as peptic ulcer disease, gall bladder disease, and pancreatitis can produce epigastric discomfort and need to be considered in the differential diagnosis.

The symptoms of chest discomfort may be the presenting feature for a host of musculoskeletal conditions. Costal chondritis, or Tietze’s syndrome (11), is characterized

by a chest-wall pain that includes point tenderness and, frequently, is exacerbated by movement or coughing. Chest wall syndromes are particularly common among cigarette smokers and seem to be responsive to cessation of smoking; the etiology remains unclear. A thoracic outlet syndrome is associated with ulnar distribution paresthesias in the arm and forearm that are worsened by arm abduction or lifting. Herpes zoster of the chest wall displays a specific dermatome pattern of the pain with exquisite sensitivity of the skin to touch and, ultimately, the development of characteristic skin vesicles.

In the continuum of musculoskeletal chest discomfort, terms frequently used for discharge diagnosis in emergency departments when the cause is uncertain are *hyperventilation*, *anxiety*, and the *Da Costa's syndromes* (also known as *neurocirculatory asthenia*) (10). Emotional stress precipitates pain characterized by a dull, persistent ache and may be accompanied by point or even diffuse chest-wall tenderness (28,29,30,31 and 32). This pain may last for hours or even days and may be quite localized (e.g., below the left nipple) with a "stabbing" quality. A component of hyperventilation may be diagnosed by eliciting the symptoms of circumoral or fingertip paresthesias with occasional carpal-pedal spasm and the response of the symptoms to breathing into a paper bag. Pulmonary causes of chest discomfort include pneumonia, pneumothorax, pulmonary hypertension, and pulmonary embolus. On occasion, pneumonia can present simultaneously with acute myocardial infarction such that the "either/or" process of ruling out one diagnosis should be considered carefully. Pulmonary hypertension may simulate angina, likely due to right ventricular ischemia. A pneumothorax presents with sudden onset of chest pain in the lateral chest with acute shortness of breath. Pulmonary embolism is also sudden, occurring at rest, and is usually associated with pleuritic chest pain exacerbated by coughing.

Exacerbating and Alleviating Factors

The most helpful aspect of angina is the classic precipitation by exercise or emotional stress. Interestingly, some patients never have angina with peak levels of robust exercise but, rather, experience the tightness or burning during a high-pressure business meeting or a stressful emotional incident. Cold weather, rushing to do an activity, and heavy meals are all common precipitants of angina. When angina occurs nocturnally or in the early morning hours on a cyclic basis, or when it occurs at rest, the possibility of coronary artery spasm or Prinzmetal's angina should be considered. This "variant" angina may be associated with a history of migraine headaches, Raynaud's phenomenon, or both, signifying a vasospastic tendency of multiple arterial beds. Coronary artery spasm, expressed as rest pain or discomfort, can occur concomitantly with classic exertional angina.

Alleviating factors that help in the diagnosis are relief by cessation of the activity or by sublingual nitroglycerin. Getting out of the cold or completing the uphill walk are excellent examples of ways that angina is usually relieved. Interestingly, lying down may not relieve angina and, at times, may precipitate it by the increase in venous return. The response to nitroglycerin is not specific, because esophageal spasm also is alleviated by nitroglycerin. However, the rapidity of relief for angina is quite impressive. The freshness of the nitroglycerin tablets needs to be ascertained in the context of whether the discomfort was responsive; if the tablets are old and did not induce mucosal tingling or a headache, it remains unclear whether a true effect was tested.

Precipitating Factors

There are several key subgroups of patients that deserve particular emphasis. Diabetes mellitus frequently leads to significant atherosclerotic coronary disease, but the symptoms are much less apt to be present and probably are related to a sensory neuropathy (13). Silent ischemia must, therefore, be considered in these patients, but careful interrogation for anginal equivalent symptoms (Table 14.4) is especially worthwhile. Of course, many diabetics have classic angina, but missing the underlying coronary disease in patients who are not fortunate enough to have an intact "alarm system" can have serious or even fatal consequences. Compared with men, women with documented coronary artery disease more often do not have the characteristic symptoms of angina, for unclear reasons. Whereas an exertional or emotional stress component is frequently elicited, the quality of the discomfort can be misleading and seem atypical. A full diagnostic evaluation and extra time to delineate fully the symptoms, precipitants, and risk factors are imperative.

After cardiac transplantation, patients cannot expect to experience chest pain or discomfort due to denervation, except in rare situations in which apparent reinnervation occurs (33,34). Systematic screening for coronary atherosclerosis has to be set up (see Chapter 94). For patients presenting with the chest pain of acute myocardial infarction, women, the elderly, and minority patients (particularly African-American and Hispanic) tend to present later in the course of the event and are more apt to have atypical or nonclassic features (15,16 and 17).

Dyspnea and Cough

Difficulty breathing is one of the cardinal symptoms of cardiac and pulmonary disease. Strictly, *dyspnea* denotes an abnormally uncomfortable awareness of breathing that is easily differentiated from normal, quiet, unnoticed breathing. The history can be particularly important in pinpointing the cause of dyspnea because there are a number of potential etiologies (35,36), including heart failure, pulmonary edema, obstructive airway disease, and pulmonary embolism.

Sudden dyspnea occurs not only with acute pulmonary edema but also with a pneumothorax, pulmonary embolism, or airway obstruction. In congestive heart failure, the onset of dyspnea is insidious and frequently precipitated by exertion. Conditions that simulate the chronic development of dyspnea are chronic obstructive pulmonary disease, pleural effusions, pregnancy, and obesity. Asthma or obstructive airway disease is suggested by inspiratory dyspnea, wheezing, and prior episodes responsive to bronchodilators. Although it is a rare symptom, sudden dyspnea while sitting rather than recumbent suggests the possibility of atrial myxoma, whereas dyspnea relieved by squatting is a classic indication for the congenital lesion of tetralogy of Fallot.

Paroxysmal nocturnal dyspnea is a classic sign of interstitial pulmonary edema and is most commonly due to heart failure. It usually begins 2 to 4 hours after going to sleep; is associated with sweating, cough, and, at times, wheezing; and can gradually improve (over 10 to 20 minutes) by getting out of bed or sitting on the side of the bed. The cough follows the dyspnea in heart failure but occurs in the opposite order in patients with chronic obstructive pulmonary disease. Of lesser severity is orthopnea due to pulmonary venous hypertension, and it occurs in the recumbent position with relief by sitting upright or standing. The number of pillows used by the patient is a good way to semiquantify orthopnea, because patients learn to use one or more extra pillows to combat their sense of breathlessness. Symptoms of heart failure that also cluster with dyspnea and orthopnea are nocturia, edema, and, more rarely, upper abdominal discomfort due to hepatosplenomegaly.

Dyspnea on exertion as a sole symptom may signify an anginal equivalent (Table 14.4); if it occurs with angina, there is an increased likelihood of a large myocardium in jeopardy, compared with angina and no symptoms of breathlessness.

Two alterations of breathing, both with a component of apnea, deserve mention. *Cheyne-Stokes respiration* refers to periods of hyperpnea followed by apnea. The pattern is a feature of the elderly who have heart failure, often with concomitant cerebrovascular disease. Sleep apnea has emerged as an important trigger of pulmonary hypertension and is characterized by episodes of snoring with prolonged periods of apnea due to upper airway obstruction. It typically occurs in patients who are overweight or mildly obese and can be responsive to measures that counter the upper airway obstruction. The diagnosis, however, can only be supported by obtaining a history from the patient's spouse or significant other.

Cough as a symptom is considerably more frequent but equally less specific (37). Perhaps the most common cause of cough today results from the side effect of angiotensin-converting enzyme inhibitors—popularly used for the treatment of hypertension and heart failure—that occurs as a result of activating bradykinin. The dry cough from this class of medications can be difficult to differentiate from that of pulmonary hypertension or mitral stenosis. Both types of cough are irritating and spasmodic, although the heart failure or mitral stenosis cough is more likely to be nocturnal, despite considerable overlap. Cough associated with hoarseness in the absence of upper respiratory disease may suggest a very enlarged left atrium with compression of the recurrent laryngeal nerve. Hoarseness without obvious upper respiratory infection in such patients is known as *Ortner's syndrome*, in which the large left atrium exerts pressure on an enlarged pulmonary artery and peribronchial lymph nodes to compress the recurrent laryngeal nerve. Dysphagia and right posterior chest pain occur only if left atrial enlargement is extreme due to severe chronic mitral regurgitation.

Sputum production and, particularly, hemoptysis are symptoms that tend to localize the disorder in the lungs, except for hemoptysis that is associated with severe mitral stenosis and is characterized by sudden increases in left atrial pressure and rupture of small bronchopulmonary veins. Frank hemoptysis that occurs with pulmonary arterial hypertension due to congenital left-to-right shunts may not share this pathophysiology, as bronchial arterioles rupture, in this case, to cause massive hemorrhage.

In patients with dyspnea and suspect valvular disease, determining whether there is a history of rheumatic fever is customary but can be misleading. Determination of whether there was scarlet fever with a rash, joint pains, chorea (St. Vitus' dance) with twitches or clumsiness, frequent sore throats, prolonged bed rest, or a family history of rheumatic fever are all in this line of questioning. However, frequently, the absence of these symptoms does not rule out rheumatic fever; a positive history can also be inaccurate (38).

Syncope and Palpitations

Syncope is a loss of consciousness due to inadequate perfusion of the brain. The history is fundamental for narrowing down a wide differential diagnosis (see Chapter 71). Sudden loss of consciousness without an aura or warning characterizes cardiac syncope. This condition can result from an arrhythmia such as ventricular

fibrillation, ventricular tachycardia, advanced atrioventricular block, or asystole (38,39). A family history of syncope raises the possibility of a long QT syndrome (see Chapter 97). Beyond arrhythmic causes of syncope, the hemodynamically significant lesions of aortic stenosis, hypertrophic cardiomyopathy, or primary pulmonary hypertension are important causes of cardiac syncope. With these disorders, syncope classically occurs just after exertion, and although hemodynamic lesions are present that can account for the loss of consciousness, serious arrhythmias should not be discounted as the primary trigger. Hypertrophic cardiomyopathy is usually familial such that the family history is important to raise or support this possibility. Besides the postexertional syncope, fainting during prolonged standing, posttussive, or even during exertion can occur with this condition.

The most common cause of cardiac syncope is known as *vasodepressor* and is mediated through the autonomic nervous system, with unconsciousness developing a bit more gradually and lasting for a few seconds; this condition can be induced by emotional stress or pain. It can be preceded by dim vision, sweating, nausea, light-headedness, giddiness, or yawning, reflecting autonomic nervous system hyperactivity, and can be fully alleviated by lying down. After the spell, it is common for the patient to be quite pale and to have a slow heart rate. Closely related in underlying pathophysiology is the syncope due to direct stimulation of the carotid sinus in patients who are “hypersensitive”; this syncope is manifested by fainting spells after sudden head motion or wearing of a tight collar. Hypovolemia in patients experiencing fainting while standing and orthostatic hypotension-related syncope are other possible and related etiologies of cardiac syncope.

Compared with cardiac syncope, neurologic causes often have an aura, as in the case of epilepsy (which, in some cases, is familial and in others posttraumatic) or associated neurologic deficits of transient cerebrovascular ischemia (e.g., vision loss, speech impairment, or motor weakness). Furthermore, after some neurologic causes of syncope such as a grand mal seizure, there is postictal confusion. Importantly, vasodepressor syncope is not typically linked with trauma, but patients with seizures or other forms of sudden cardiac syncope can sustain physical injury with a fainting spell. Near syncope, which is described by the patients as “nearly” losing consciousness or “graying” out, is similar in its differential to actual syncope but, overall, is less likely to be associated with serious pathologic conditions compared with true loss of consciousness.

Calkins and colleagues (39) studied the differentiating symptoms of the history to resolve the etiology of syncope. Features of the history predictive of syncope not due to ventricular tachycardia or atrioventricular block were palpitation, blurred vision, nausea, warmth, diaphoresis, and lightheadedness before syncope and nausea, warmth, diaphoresis, and fatigue after the syncopal event (40).

Palpitations represent an unpleasant awareness of the heartbeat and frequently are described as “skipping,” “jumping,” “pounding,” or “racing.” The skipping is often attributed to the postextrasystolic pause, whereas the pounding or forceful beat is accounted for by the postextrasystolic potentiation of contractility. A variety of rhythm disturbances may be considered, with the full spectrum from bradyarrhythmias to supraventricular or ventricular tachycardias being potential triggers. Palpitations are remarkably common and can simply occur with anxiety (e.g., palpitations occurring with the syndrome of hyperventilation previously described), with tingling around the mouth and in the hands, although the underlying rhythm is sinus tachycardia. Similarly, other benign forms occur with postural hypotension due to the reflex heart acceleration or in response to medications (e.g., amphetamines), cocaine, alcohol, tobacco, and caffeine. With physical exertion, a sense of the heart “pounding” may certainly be anticipated.

However, when the complaint occurs despite lack of exertion or with only minimal effort, other causes need to be surveyed, such as heart failure, anemia, thyrotoxicosis, and atrial fibrillation. A pulse rate of approximately 150 beats per minute suggests atrial flutter, whereas faster rates suggest paroxysmal supraventricular tachycardia. Rates slower than 140 beats per minute (as low as 100 beats per minute) are more suggestive of sinus tachycardia and, therefore, are more likely to be benign.

Edema, Fatigue, and Other Symptoms

Swollen legs manifesting at the end of the day are characteristic of heart failure or chronic venous insufficiency. Early on, this can sometimes be associated only with difficulty in getting one’s shoes on but can also be linked to appreciable weight gain due to fluid retention. Usually, the edema is symmetric and progresses “from the ground up.” In patients with prior bypass surgery who have had saphenous vein grafts harvested, the edema may begin unilaterally on the side of decreased venous competence. In patients confined to bed with heart failure, presacral edema is common. In the presence of hyperpigmentation of the legs, ulcers, and other changes suggesting venous stasis, chronic venous insufficiency may be the likely explanation, but, frequently, the coincident finding of heart failure and chronic venous insufficiency is present. This is especially true in patients who have had long-standing heart failure and other reasons for venous insufficiency (e.g., marked obesity). Generalized edema, known as *anasarca*, can occur with severe heart failure but also with cirrhosis and the nephrotic syndrome. Periorbital edema occurs with hypoproteinemia, myxedema, hereditary angioneurotic edema, and acute glomerulonephritis. Edema localized to the upper body, involving the face, arms, and neck, raises the possibility of a superior vena cava syndrome, which may herald carcinoma of the lung. Edema of cardiac origin that is not associated with dyspnea or orthopnea suggests a right-sided heart lesion such as constrictive pericarditis, tricuspid stenosis, or, for example, a tumor that has invaded the inferior vena cava or right atrium.

Fatigue is a nonspecific and common symptom that may not have cardiovascular basis. However, it may signal poor cardiac output or result from overdiuresis or from the use of beta-blocker drugs. In some cases, episodic fatigue from physical exertion or emotional stress disproportionate to the amount of effort expended may represent an anginal equivalent.

Nausea and vomiting can occur with acute myocardial infarction (see Chapter 18). Fever and chills, along with other constitutional signs, may be associated with infectious endocarditis (see Chapter 25).

CONTROVERSIES AND PERSONAL PERSPECTIVES

It is clear that taking a thorough history has become less of a priority for a few pivotal reasons. First, there is less time available for physician-patient direct contact as a result of the demands placed on a physician’s time. Frequently, a physician extender or nurse obtains part or all of the history to reduce the time burden on the doctor. Under the putative heading of “efficiency,” the priority of the detailed, thorough interview has been markedly reduced. Second, with advances in technology, the history and physical examination have been partially supplanted by rapid use of bedside tools such as the two-dimensional echocardiogram, a treadmill or dobutamine thallium test, a Holter recording, or even diagnostic angiography or electrophysiologic study—all instead of the meticulous history.

These two forces are unfortunate. The history is the most important way to create a physician-patient bond and is precious and irreplaceable. Ideally, the task should not be delegated to a physician extender, except for such perfunctory aspects as the medications and doses, risk factors, and minor details. It is absolutely essential to query the patient directly and in depth for the principal symptoms (e.g., chest discomfort, loss of consciousness, or dyspnea). Only in this way can there be the optimal accuracy and relationship building that are critical. Also, the use of advanced diagnostic technology easily can be imprudent with respect to cost and can uncover findings that, although accurate, have no bearing on the patient’s symptoms. The detailed history preempts or properly guides the use of more refined diagnostic tests. Intuitively, the history is the most cost-effective tool that one can use to lay soundly the foundation of the patient’s evaluation.

THE FUTURE

Although the history has been deemphasized in the past decade, it will become increasingly relied on in the future because of its relatively low cost and pivotal importance in guiding more diagnostic and therapeutic decision making. With the reduced sense of patient satisfaction and bonding with the physician, spending more time with the patient to relay information and develop mutual understanding and trust hopefully will override the forces that have deprioritized such a core component of high-quality cardiovascular medicine.

OVERVIEW

A systematic approach to the bedside examination of a patient is essential in determining the significance of an abnormal physical finding, such as decreased or increased intensity of the first heart sound (S_1), a pathologic third heart sound (S_3), or a systolic or diastolic murmur. Assessment of the abnormalities of the systemic venous pressure and pulse, arterial pulse, precordial impulse, heart sound, and murmurs provides clues not only for the diagnosis of the anatomic abnormalities, but also for the determination of the severity of the hemodynamic abnormalities. It should be emphasized that appropriate investigations (e.g., echocardiography, radionuclide ventriculography and scintigraphy, and cardiac catheterization) should be considered to establish the diagnosis.

In the present era of technological advances, particularly in the various imaging modalities, there is a growing conception among practicing physicians in cardiovascular medicine that bedside physical examination is unnecessary. It should be emphasized, however, that for proper application and interpretation of various new and old tests that are available for cardiovascular evaluation in a given patient, a careful physical examination is essential. Furthermore, a careful, systematic, and methodical bedside clinical evaluation—including analysis of clinical history—can provide enough information to decide whether further investigations are necessary and, if necessary, which investigations are appropriate. Bedside clinical examination should be performed and practiced in the same way after similar sequences and usually begins with *general inspection* of the patient.

INSPECTION

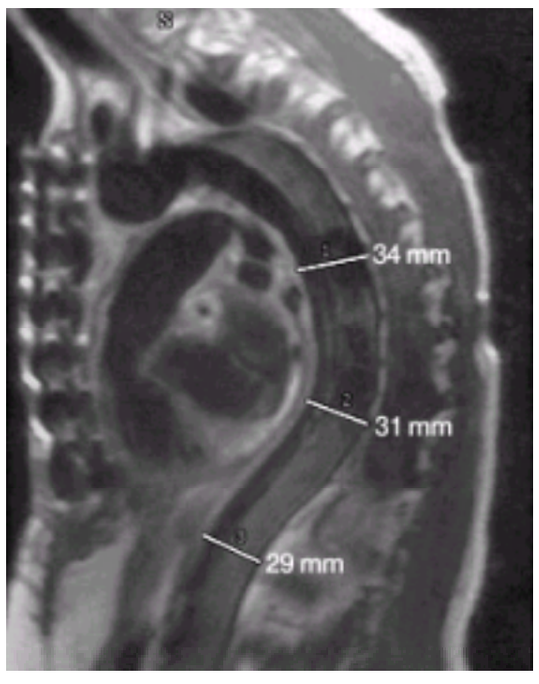
During general inspection (1,2), the stature, body habitus, approximate weight, and presence or absence of obesity are noted. An unusually short stature is seen in patients with osteogenesis imperfecta, which is associated with aortic and mitral regurgitation and calcification of the arterial system. Congenital heart disease, such as Noonan's syndrome, also occurs in association with short stature due to dwarfism. In Noonan's syndrome, short stature is associated with web-neck, dental malocclusion, antimongoloid slanting of the eyes, mental retardation, and hypogonadism. Pulmonary valve stenosis and obstructive and nonobstructive cardiomyopathy are also observed. Dwarfism is an essential phenotypic feature of the various types of mucopolysaccharidosis, which can be associated with various valvular and myocardial dysfunctions due to mucopolysaccharide deposition. An unusually tall stature, however, is seen in patients with Marfan's syndrome, which is frequently associated with aortic aneurysm, aortic regurgitation, and mitral regurgitation. When severe chest pain or back pain is the presenting symptom in a patient with Marfan's syndrome, acute aortic dissection should always be suspected. A tall stature, long extremities, and eunuchoid appearance is observed in patients with Klinefelter's syndrome, which can be associated with congenital heart diseases such as ventricular septal defects, patent ductus arteriosus, and tetralogy of Fallot. During initial cardiac evaluation, it is customary to notice any obvious musculoskeletal deformity, such as kyphoscoliosis, straight back, and pectus deformity of the chest. A higher incidence of mitral valve prolapse is observed in the presence of such musculoskeletal deformities. An increased incidence of mitral valve prolapse is also observed in females with smaller breasts. Muscular dystrophies such as pseudohypertrophic, fascioscapular humoral, or limb-girdles varieties can be suspected during general inspection. These muscular dystrophies may be associated with various cardiovascular abnormalities, including myocardial disease, mitral valve prolapse, ventricular septal defect, and dysrhythmias.

VIDEO

Video 15.1 Coronary ectasia. These angiograms were obtained in a 40-year-old patient with Noonan's syndrome and no coronary risk factors. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Ectopia lentis. This lens dislocation is associated with Marfan syndrome.

Arachnodactylia in Marfan syndrome. The ratio of finger length to hand size is markedly increased.



Magnetic resonance scan of the thoracic aorta in Marfan syndrome. There is dilation of the descending aorta with an average diameter of approximately 3 cm.

Gait

Abnormalities of gait are also noted during inspection. Neurologic deficits resulting from cardioembolic strokes or hypertensive cerebrovascular disease may be associated with abnormalities of gait. A parkinsonian gait may indicate Shy-Drager syndrome, which may be associated with orthostatic hypotension (3). Certain metabolic disorders (e.g., hyperthyroidism, hypothyroidism, Cushing's syndrome, and acromegaly) can be suspected during inspection, and these metabolic diseases may be associated with various cardiovascular abnormalities, including systemic and pulmonary hypertension and myocardial and pericardial diseases.

Body Habitus

During inspection, the general nutritional status of the patient is also noted. Although marked weight loss, wasting, and cachexia occur more frequently from metabolic and neoplastic diseases, they can be manifestations of severe congestive heart failure. Cardiac cachexia (4) does not correlate to cardiac output as usually perceived, but to a marked neuroendocrine abnormality characterized by an activated renin angiotensin system as well as increased levels of cytokines, including tumor necrosis factor and interleukins. The presence and severity of obesity should be noted, as various cardiovascular abnormalities can be associated with obesity. Obesity, particularly abdominal and truncal types, is one of the components of the metabolic syndrome X, which comprises hypertension, hyperlipidemia, and insulin resistance (5,6). In patients with metabolic syndrome, there is increased risk of developing atherosclerotic macrovascular disease, including coronary artery disease. Furthermore, in markedly obese patients, there is increased incidence of sleep apnea, hypertension, and dilated cardiomyopathy. Truncal obesity, if associated with buffalo hump or moon facies, should raise the suspicion of Cushing's syndrome, which may be complicated by hypertension and hypertensive heart disease. In African-Americans, severe obesity and marked increase in body mass index and diabetes are more important predictors of primary diastolic heart failure than hypertension or coronary artery disease.

Respiration

During inspection, presence of respiratory distress and types of altered respiration should be observed. Labored and uncomfortable breathing, however, may be of

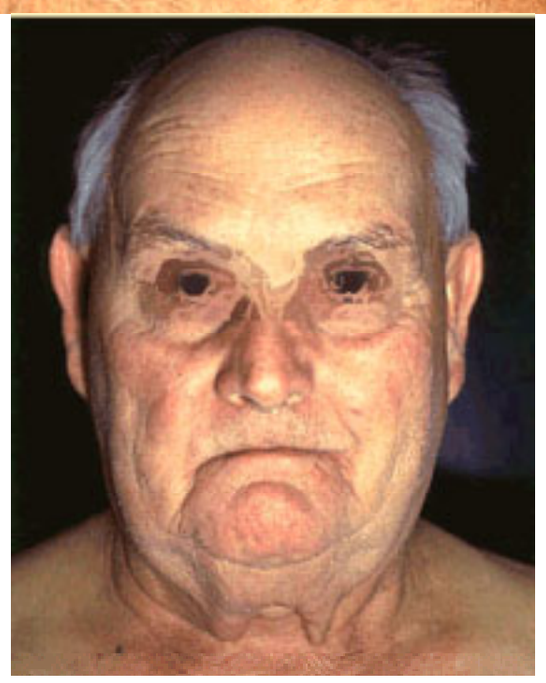
cardiac or noncardiac origin. Inability to lie down or a dry, irritating cough with dyspnea when in the supine position usually indicates pulmonary venous congestion. Sleep-disordered breathing is common in chronic congestive heart failure (7). Typical Cheyne-Stokes respiration with central sleep apnea is observed in 20% to 30% of patients with moderate or severe congestive heart failure with reduced left ventricular ejection fraction and, usually, elevated pulmonary capillary wedge pressure and lower cardiac output. Cheyne-Stokes respiration with central sleep apnea should be distinguished from obstructive sleep apnea, which is associated with inspiratory efforts during apneic phase, because central sleep apnea is a risk factor for increased mortality (7a). Also, patients with only central sleep apnea are likely to benefit from continuous positive airway pressure therapy (7b). Frequent sighing respirations and a restless, anxious look are more frequently encountered in patients with anxiety and neurocirculatory asthenia. The “blue bloater” and “pink puffer” appearances, which can be detected during inspection, usually indicate chronic obstructive pulmonary disease. During inspection, it is desirable to note any obvious changes in the color of the skin. A bluish discoloration of the skin usually indicates cyanosis, which can be either peripheral or central. Peripheral cyanosis is detected in exposed skin (e.g., lips, nose, and earlobes, and in extremities) and indicates impaired peripheral perfusion. A bluish discoloration of the tongue, uvula, and buccal mucus membrane suggests central cyanosis, which results from intrapulmonary or intracardiac right-to-left shunt. When differential cyanosis (i.e., cyanosis in the inferior extremities without cyanosis in the superior extremity) is observed along with differential clubbing, Eisenmenger’s syndrome associated with patent ductus arteriosus should be suspected.

Edema

Generalized edema is easily detected during inspection, usually results from nephrotic syndrome and sepsis, and rarely results from severe heart failure. Dependent edema, on the other hand, is associated with right heart failure. When dependent edema is discovered, careful evaluation of systemic venous pressure and pulse is essential for the diagnosis of right heart failure. The presence of ascites, which also may be a manifestation of right heart failure, can be suspected from the protuberant abdomen. Ascites in the absence of edema of the lower extremities is more frequently a manifestation of liver disease, such as cirrhosis, rather than of heart failure. However, in patients with constrictive pericarditis and restrictive cardiomyopathy, disproportionately large ascites with little or no edema of the lower extremities can be observed (8). Again, careful examination for the presence of systemic venous hypertension, pulmonary arterial hypertension, and physical findings suggestive of restrictive physiology is essential for the differential diagnosis between liver disease and cardiac failure.

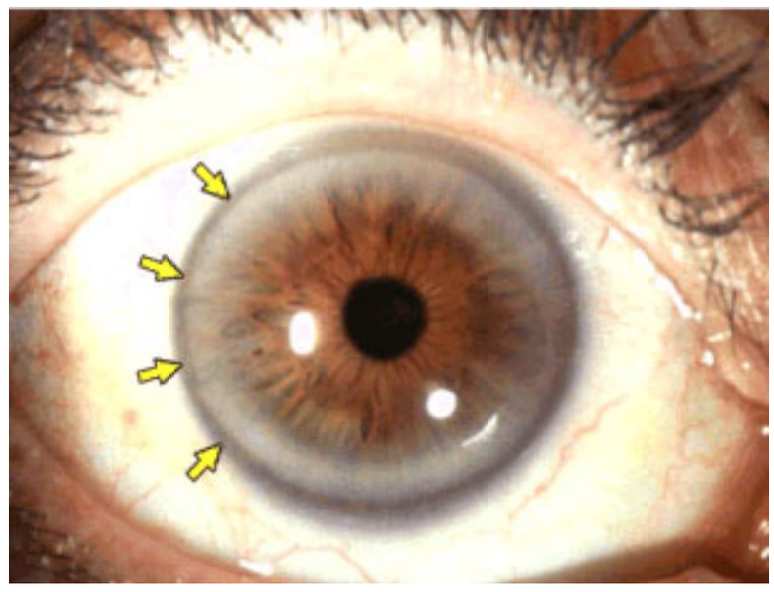
Skin

Slate or bronze pigmentation of the skin may suggest hemochromatosis, which may be associated with various cardiac complications (e.g., restrictive or dilated cardiomyopathy, arrhythmias, and conduction disturbances). It also should be appreciated that patients on chronic amiodarone therapy also develop similar discoloration of the skin with exposure to sunlight (9). Discoloration of the skin similar to marked suntan is also seen in patients with carcinoid syndrome. Mild jaundice may be observed in patients with heart failure with congestive hepatopathy and with pulmonary embolism. Prosthetic valve malfunction should be suspected if jaundice is detected in a patient with artificial heart valves. The livido reticulares with cyanosis of the toes and preserved peripheral pulses (blue toes syndrome) suggest cholesterol emboli (10). Acrosclerosis with taut, thickened, or edematous skin bound tightly to subcutaneous tissue in the hands and fingers suggests systemic sclerosis, which may be associated with pulmonary hypertension, pericarditis, right heart failure, systemic hypertension, restrictive cardiomyopathy, and dilated cardiomyopathy. If malar flush is detected, mitral stenosis with pulmonary hypertension should be suspected. Malar flush, however, can also occur in patients with severe precapillary pulmonary hypertension and may be confused with butterfly rash of lupus erythematosus. The presence of transverse or diagonal earlobe creases in a relatively young person (i.e., under 45 years of age), may suggest the presence of premature atherosclerotic coronary artery disease. The presence of arcus—a circumferential light ream around the iris that begins inferiorly—further increases the risk of premature atherosclerotic coronary artery disease. Arcus is also frequently associated with hypercholesterolemia and xanthelasma (i.e., deposits of cholesterol on the eyelids). When telangiectasia of the lips, tongue, and buccal mucosa are detected, Osler-Weber-Rendu disease, which is associated with pulmonary arteriovenous fistulae, should be suspected. Exfoliative dermatitis, purpura, and petechial rashes usually indicate drug reactions. Although an erythema marginatum is characteristic of acute rheumatic fever, erythema nodosum is a nonspecific finding and occurs in many systemic diseases. In patients with suspected bacterial endocarditis, searches should be made for conjunctival hemorrhages, skin purpuric, and petechial lesions, as well as for splinter hemorrhages. It should be realized that splinter hemorrhages in the nail beds may occur in normal patients after mild trauma and in patients with trichinosis or hemorrhagic disorders.



Jaundice. There is diffuse yellowing of the skin (A,B).

Livedo reticularis. Mottled reddish discoloration of the lower extremities with accompanying multiple ulcerations associated with atheroemboli.



Arcus juvenilis. This ring is associated with premature atherosclerosis.

Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia). Multiple dark red and slightly elevated telangiectasia in the back (*left panel*) and hands (*right panel*) are shown. These represent arteriovenous malformations of dermal microvasculature.

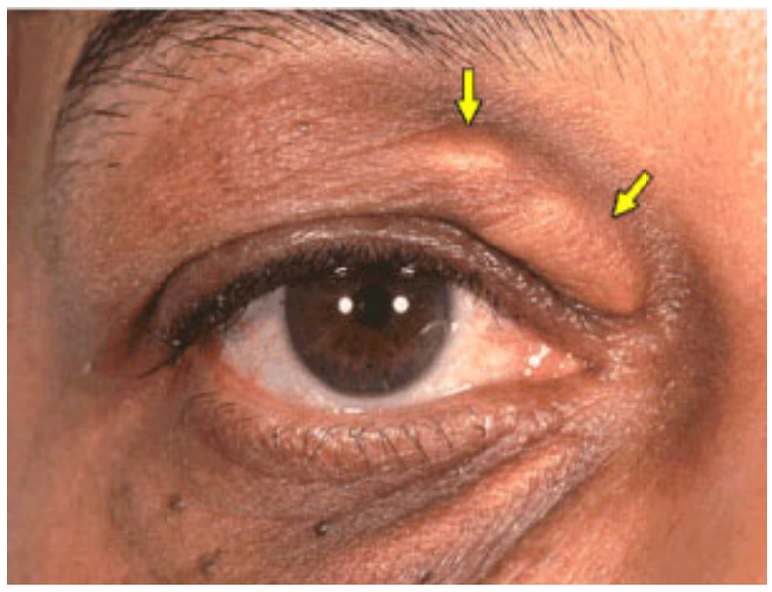
Splinter hemorrhages. Linear hemorrhages on the fingertips (*yellow arrows*) of a patient with infective endocarditis.

During examination of the skin, it is customary to check for the presence of cutaneous and subcutaneous nodular lesions, which may suggest some systemic and metabolic diseases that may also involve the cardiovascular system. The rheumatic nodules associated with acute rheumatic fever are small, nontender, and most frequently seen on the knuckles, extensor surface of the elbows, and suboccipital regions. Rheumatoid nodules, on the other hand, are large, nontender, and characteristically localized over points of pressure or friction—most commonly the extensor surfaces of the proximal forearms. If rheumatoid nodules are detected, attention should be directed to detect the cardiovascular complications of rheumatoid arthritis (e.g., pericarditis, aortic and mitral valvular disease, conduction disturbances, and, rarely, cardiomyopathy). Xanthomas, the cholesterol-filled nodules, occur in different types of abnormalities of lipoprotein metabolism, and recognition of the distribution of xanthomas aids in the diagnosis of these disorders. Tendon xanthomas, xanthomas occurring on digital extensors, and tuberous xanthomas occur in familial hypercholesterolemia (11). Eruptive xanthomas are small yellow papules in the skin that are surrounded by an erythematous halo. They occur in patients with primary familial hypertriglyceridemia that results from lipoprotein lipase deficiency and is associated with recurrent episodes of pancreatitis, but not with premature coronary artery disease. Eruptive xanthomas also occur in patients with endogenous and mixed hypertriglyceridemia, which can be associated with ischemic vascular disease. In patients with suspected bacterial endocarditis, it is desirable to search for Osler's nodes and Janeway's lesions. Osler's nodes are most frequently observed on the palms, soles of the feet, and pads of the fingers or toes. These nodes are tender, nodular, erythematous skin lesions and result from emboli. Janeway's lesions are nontender, raised, hemorrhagic nodules that usually occur on the palms of the hands and soles of the feet. These lesions were initially thought to be due to vasculitis, but they also appear to be of embolic origin. Café au lait spots—sometimes detected only in the axilla—occur in neurofibromatosis, which occasionally is associated with hypertrophic cardiomyopathy.

Xanthelasma. Yellow papules are seen below the eyelid (*arrows*) associated with elevated B lipoproteins.

Xanthoma disseminata. Crops of yellow papules associated with hypertriglyceridemia.

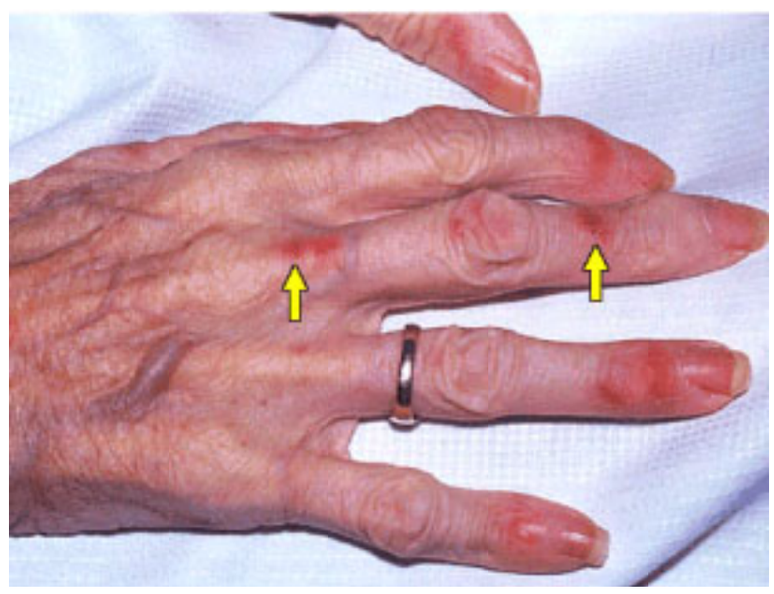
Xanthelasma. Yellowish discreet plaques in the orbital area resulting from hyperlipidemia.



Xanthelasma in association with hypercholesterolemia. The yellow arrows indicates yellowish deposits in this patient with hyperlipidemia.

Xanthoma. Nodular protuberance of the extensor surface of the leg (*left panel*) as well as multiple nodules of the arm (*right panel*).

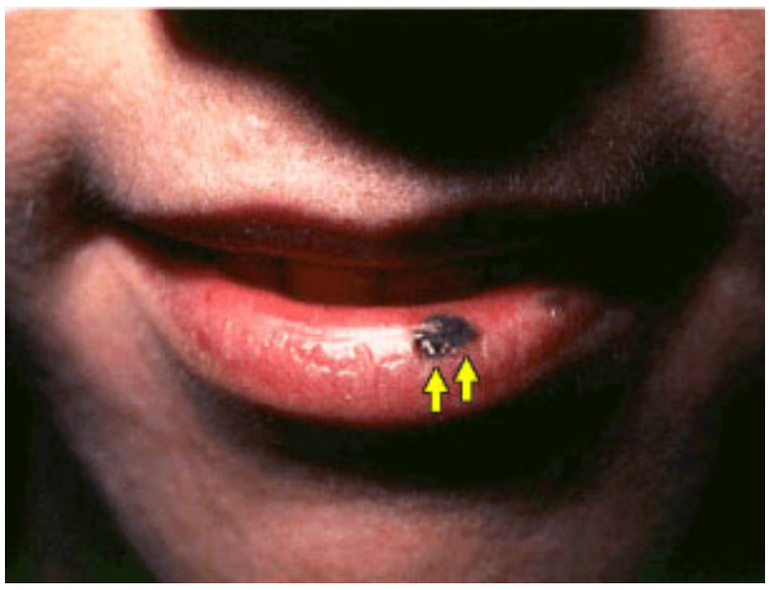
Eruptive xanthoma. Bulbous cutaneous eruptions associated with hyperlipidemia.



Septic emboli from infective endocarditis (*yellow arrows*).

Osler nodes. There are tender nodules on the toe pads (*yellow arrows*) secondary to infective endocarditis.

Janeway lesions of endocarditis. There are hemorrhages with nodular character at the fingertips (*arrows*).



Café au lait spot. There is a flat localized hyperpigmentation that is uniformly light brown in the lower lip (*yellow arrows*) that may be associated with neurofibromatosis, Albright syndrome, or pulmonary stenosis.

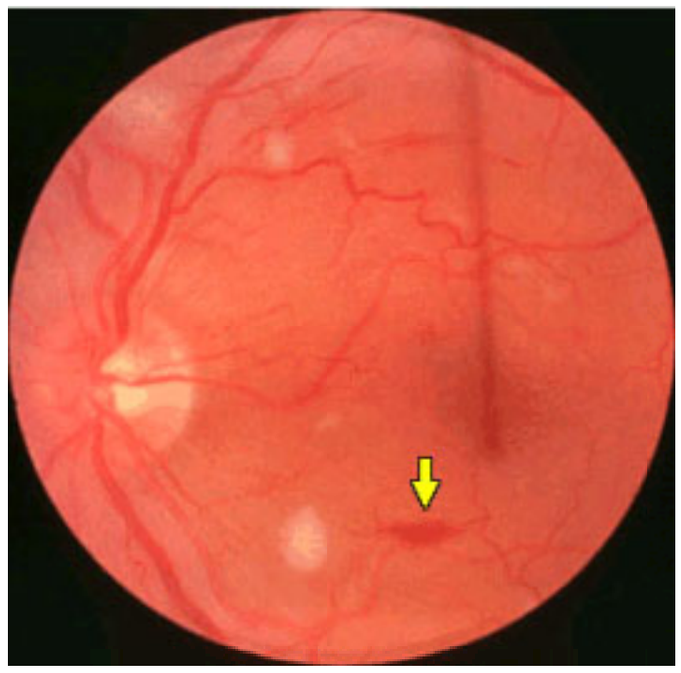
Funduscopy

In patients with established or suspected systemic hypertension, funduscopic examination should be performed. Based on the degree of narrowing or irregularities of retinal artery, the presence or absence of arteriovenous nicking or nipping, hemorrhages, exudates, and papilledema, four grades are recognized (12). Grade 1 consists of minimal irregularity of the arterial lumen and narrowing with increased light reflex. Grade 2 changes consist of arteriovenous nicking, more marked narrowing and irregularity of the arterioles, and distention of the veins. Grade 3 changes are characterized by the presence of flame-shaped hemorrhages and fluffy “cotton wool” exudates in addition to arterial changes. Hard exudates may also be present. Grade 4 funduscopic changes are characterized by the presence of papilledema and any other changes in grades 1 through 3. Generally, grade 1 and 2 changes are present in benign hypertension, whereas grade 3 or 4 changes are seen in accelerated or malignant hypertension. Funduscopic examination should also be performed in patients with suspected bacterial endocarditis and may reveal vascular occlusions and hemorrhagic areas with white centers (Roth’s spots), which result from emboli in the nerve fiber retinal layer. Roth’s spots, however, are not diagnostic of bacterial endocarditis and can be seen in hemorrhagic disorders, including leukemia. Mycotic aneurysms resulting from large emboli occasionally may be discovered in retinal vessels during funduscopic examination. Identification of such lesions should lead to further evaluation for the source of emboli, and appropriate investigations—including transthoracic and, occasionally, transesophageal echocardiography—must be undertaken. Occasionally, funduscopic examination may reveal unusual findings that may provide clues for the diagnosis of the underlying pathophysiology. Beading of the retinal artery may suggest hypercholesterolemia. Microinfarction in the peripheral retina is seen in sickle cell disease, which may also involve the cardiovascular system. Angioid streaks may suggest pseudoxanthoma elasticum, which may be associated with coronary artery calcification, systemic hypertension, intermittent claudication, and arrhythmias. A wreath-like arteriovenous anastomosis around the optic disk is a characteristic of Takayasu’s syndrome. In adult cardiology practice, the abnormal findings that are often detected during inspection, along with their significance, are summarized in Table 15.1.

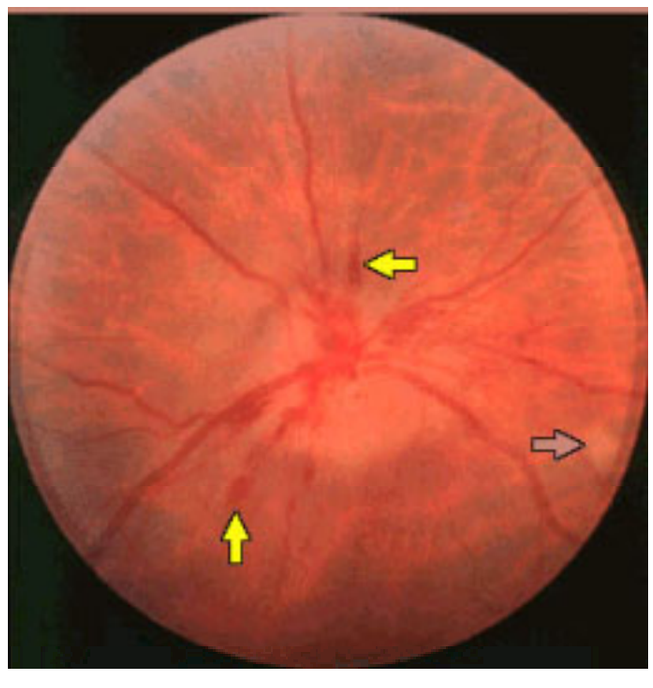
Cyanosis
Peripheral cyanosis only—suspect low cardiac output and impaired peripheral perfusion
Central cyanosis—suspect intrapulmonary or intracardiac right-to-left shunt
Differential cyanosis—suspect Eisenmenger’s syndrome with patent ductus arteriosus
Respiratory distress
Cheyne-Stokes respiration with central sleep apnea—suspect heart failure
Blue bloater and pink puffer—suspect pulmonary disease
Frequent sighing respiration—suspect anxiety syndromes
Nutritional status
Cachexia—suspect severe heart failure with abnormal neuroendocrine profile
Obesity—suspect metabolic syndrome X, sleep apnea, cardiomyopathy
Ascites and peripheral edema—suspect severe heart failure, constrictive pericarditis
Musculoskeletal deformity, kyphoscoliosis, straight back, pectus excavatum
Suspect mitral valve prolapse, aortic and mitral valve regurgitation, congenital heart disease such as atrial septal defect
Abnormal movement of the head and neck
Bobbing of the head coincident with each heart beat—suspect severe aortic regurgitation
Lateral movements of the earlobes with each cardiac cycle—suspect severe tricuspid regurgitation
Slate or bronze discoloration of the skin
Suspect chronic amiodarone therapy, hemochromatosis, carcinoid syndrome

TABLE 15.1 INSPECTION

Arteriovenous nicking in association with hypertension (*yellow arrow*).



Flame-shaped hemorrhage in association with severe hypertension (*yellow arrow*).



Papilledema from malignant hypertension. There is blurring of the borders of the optic disc with hemorrhages (*yellow arrows*) and exudates (*white arrow*).

EXAMINATION OF THE ARTERIAL PULSE

During initial evaluation, all accessible arterial pulses should be examined; in the inferior extremities, dorsales pedes, posterior tibials, and femoral pulses should be examined bilaterally. In the upper extremities, both brachial and radial pulses should be examined, and, in special circumstances, the ulnar pulses and axillary arterial pulses should also be examined. Temporal arteries are examined when temporal arteritis is suspected in patients with headache and jaw claudication. Carotid arteries should be examined sequentially in all patients. Diminished or absent pulses may result from atherosclerotic peripheral vascular disease, which is associated with increased incidence of atherosclerotic coronary artery disease. Loss of or decreased femoral pulse unilaterally or bilaterally most frequently suggests local obstructive lesions due to atherosclerotic disease. However, diminished amplitudes of the lower extremity pulses, including femoral, popliteals, posterior tibials, and dorsales pedes arterial pulsations, also occur from isolated aortoiliac diseases, such as Leriche's syndrome (13), postsubclavian coarctation of the aorta, aortic dissection, descending thoracic and abdominal aortic aneurysms, and abdominal aortic disease such as giant cell arteritis. When coarctation of the aorta is suspected, it is desirable to examine the radial and femoral pulses simultaneously to assess radial/femoral delay. In a normal adult, the pulse transmission time from aorta to the radial artery is approximately 75 ms and to the femoral artery is approximately 70 ms. Thus, in the presence of coarctation, delay in the onset of femoral pulse compared to that of radial pulse can be detected. The radial/femoral delay is rarely observed in patients with Leriche's syndrome and abdominal coarctation. Also in pseudocoarctation, the degree of obstruction is not severe enough to decrease the amplitude of the femoral pulse or to cause delay in the onset of femoral pulse compared with that of radial pulse (14). In patients with radial/femoral delay and suspected coarctation, blood pressure should be recorded in the upper and lower extremities. In the supine position, the inferior extremity pressure is normally slightly higher than that of the upper extremity arterial pressure. In coarctation, inferior extremity pressure is lower than upper extremity pressure. While examining the peripheral arterial pulses, it is desirable to assess the rigidity and elasticity of the arteries. The rigidity of the arterial pulses are best appreciated by examining the femoral, radial, brachial, and carotid pulses. In clinical practice, the thickness and firmness of the arterial walls are examined by rolling the vessel, usually the radial artery, against underlying tissue. The more rigid the artery, the less it is compressible. The appreciation of nonelastic, rigid peripheral arteries may indicate the presence of systolic hypertension. If the significant rigidity of the peripheral arteries is observed, it is desirable to perform Osler's maneuver. Osler's maneuver is performed by elevating the cuff pressure to obliterate the radial pulse; if, after obliteration of the pulse, the radial artery is easily palpable and appears rigid (i.e., a positive Osler's sign), then there might be a significant difference between indirect measurement of arterial pressure by cuff method and directly determined intraarterial pressure.

The peripheral arterial pulses are also examined at the bedside for detection of arrhythmias. If the pulse rate is regular but slow, sinus bradycardia, junctional rhythm, or complete atrioventricular block is suspected. Occasionally, bigeminy may produce an irregular slow pulse because of the nonconducted pulse associated with the ectopic beat. Careful examination of the venous pulse and simultaneous auscultation may be helpful for the differential diagnosis of slow regular pulse. If regular cannon waves with each cardiac cycle are recognized, junctional rhythm is suspected. In the presence of a slow regular pulse, if irregular cannon waves and changing intensity of the S_1 are observed, atrioventricular dissociation due to complete atrioventricular block is the most likely diagnosis. Bigeminy can be diagnosed easily by auscultation, which demonstrates the postectopic compensatory pause. Atrial fibrillation can be suspected if irregularly irregular pulses are appreciated. However, frequent premature beats or multifocal atrial tachycardia can also produce an irregularly irregular pulse similar to that of atrial fibrillation. If atrial fibrillation is suspected, it is desirable to determine the ventricular rate by simultaneous auscultation to assess the degree of pulse deficit. The difference between the heart rate by auscultation and the pulse rate is the pulse deficit. The rapid ventricular responses are the cause of the hemodynamic abnormalities of atrial fibrillation. A fast and regular pulse rate (150 beats or more) should raise the possibility of supraventricular or ventricular tachycardia. It is mandatory to do electrocardiographic evaluation of every patient with suspected arrhythmia.

Peripheral arterial pulses are also examined to detect any alteration of the character of the pulse, which can provide important diagnostic clues. Pulsus alternans is suspected when strong and weak amplitude pulses are appreciated with alternate beats in the presence of a regular pulse. Pulsus alternans can be confirmed by measuring blood pressure by sphygmomanometer. When the cuff pressure is slowly released, phase I Korotkoff's sound is heard initially only during the alternate strong beats; with further release of cuff pressure, the softer sounds of the weak beat also appear. The most important cause of pulsus alternans is left ventricular systolic failure. Pulsus alternans is rarely encountered in patients with cardiac tamponade. In patients with tamponade with pulsus paradoxus, if the respiratory rate is half of the heart rate, pulsus alternans may occur. However, in these patients, when respiration is held transiently, the pulsus alternans is resolved. Pulsus alternans (mechanical alternans) can also occur occasionally in aortic stenosis, in hypertrophic obstructive cardiomyopathy, with sudden increase of afterload, with ischemia, with abrupt fall of preload, and with the onset of a tachyarrhythmia. Rapid atrial pacing may induce pulsus alternans in the presence of normal left ventricular systolic function. However, clinically detectable sustained pulsus alternans almost always indicates left ventricular systolic dysfunction.

In experimental and clinical studies, alternating changes in preload, afterload, and contractility have been suggested as potential mechanisms for mechanical alternans (15); ventricular dyssynchrony with alternating contraction of the interventricular septum, incomplete relaxation in the alternate beats, partial asystole of the left

ventricle, alternating changes in action potential duration, and alternating amounts of Ca^{2+} sparks from the sarcoplasmic reticulum are the other proposed mechanisms (15a). The failing heart is sensitive to altered afterload and resistance to left ventricular ejection. The increased arterial pressure associated with a strong beat increases the resistance to left ventricular ejection for the following beat, which is thus associated with decreased forward stroke volume and decreased arterial pressure. This reduction in arterial pressure lowers the resistance to left ventricular ejection, which allows increase in forward stroke volume and, therefore, increase in arterial pressure. These changes in arterial pressure, reflecting changes in the ejection impedance with alternate beats, can perpetuate pulsus alternans (Fig. 15.1). It should be emphasized, however, that the absence of pulsus alternans does not exclude left ventricular systolic dysfunction. Nevertheless, the pulsus alternans is a reliable and helpful physical finding for the diagnosis of left ventricular systolic dysfunction.

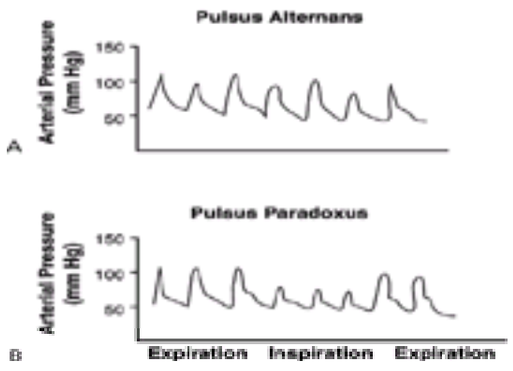


FIGURE 15.1 Schematic illustrations of pulsus alternans **(A)** and pulsus paradoxus **(B)**. In clinical practice, pulsus alternans usually indicates systolic ventricular failure and occurs in patients with chronic ischemic or nonischemic dilated cardiomyopathy, aortic stenosis, and acute myocardial infarction. Pulsus paradoxus, however, is observed in pericardial tamponade, constrictive pericarditis (rare), emphysema, asthma, marked obesity, and severe congestive heart failure (rare).

During examination of the peripheral arterial pulses, if there is a substantial reduction in the amplitude of the arterial pulse during inspiration, pulsus paradoxus should be suspected, and determination of arterial pressure by sphygmomanometry during inspiration and expiration should be performed. Systolic arterial pressure normally falls during inspiration; however, the magnitude of fall in arterial pressure during inspiration usually does not exceed 8 to 12 mm Hg. A more marked inspiratory decrease in arterial pressure exceeding 12 to 15 mm Hg is regarded as pulsus paradoxus and usually is detectable by palpation of the peripheral pulses. However, the magnitude of pulsus paradoxus should be measured by sphygmomanometry. When the cuff pressure is slowly released, the systolic pressure at expiration is noted. With further slow deflation of the cuff, the systolic pressure during inspiration can also be detected. The difference between the pressure during expiration and inspiration is the magnitude of the pulsus paradoxus. The abnormal pulsus paradoxus is an important physical finding of cardiac tamponade (16). The marked inspiratory decrease in arterial pressure in tamponade results from the marked inspiratory decline of left ventricular stroke volume due to a decreased end diastolic volume. In cardiac tamponade during inspiration, there is an increase in venous return to the right atrium and the right ventricle. Due to increased intrapericardial pressure, the intraventricular septum shifts toward the left ventricle during inspiration, which decreases left ventricular preload. There is also an expected decrease in venous return to the left ventricle during inspiration because of increased pulmonary venous reservoir capacity during inspiration. In clinical practice, besides cardiac tamponade, pulsus paradoxus is observed in patients with chronic obstructive pulmonary disease. It should be emphasized that pulsus paradoxus is a rare finding in patients with constrictive pericarditis. Pulsus paradoxus is rarely observed in pulmonary embolism, pregnancy, marked obesity, and partial obstruction of the superior vena cava. In hypertrophic obstructive cardiomyopathy, arterial pressure occasionally increases during inspiration (i.e., reversed pulsus paradoxus) (17). The precise mechanism for this phenomenon is not clear.

The amplitude of the peripheral arterial pulse may provide some information about stroke volume, systemic vascular resistance, and compliance of the arteries. A small-amplitude, rapid pulse usually indicates hypotension, reduced stroke volume, and increased systemic vascular resistance. A large-amplitude, arterial pulse suggests large stroke volume or decreased compliance. A large-volume, bounding pulse is noted after exercise; in high-output states such as chronic anemia, hyperthyroidism, and aortic regurgitation; and in patients with bradycardia (e.g., complete heart block). Decreased compliance and increased rigidity of the peripheral arteries may also increase the amplitude of the arterial pulse, as seen in elderly patients with systolic hypertension. In elderly patients, when the carotid pulse amplitude is decreased, local carotid disease or aortic stenosis should be suspected. Decreased amplitudes of the carotid pulse in elderly subjects should prompt further evaluation, such as echocardiography, to exclude aortic stenosis.
