OVERVIEW

Pregnancy normally induces significant physiologic adaptation in the cardiovascular system, including increases in heart rate, left ventricular size, stroke volume, and left ventricular mass. Systemic vascular resistance decreases during pregnancy. The maximal increase in hemodynamic burden for the pregnant patient is achieved at the end of the second trimester. Uterine contractions and the sympathetic discharge associated with delivery further increase cardiovascular demands on the pregnant patient, with the greatest increase in cardiac output achieved in the final stages of delivery. These alterations are resolved approximately 6 weeks after delivery. Moderate aerobic exercise during pregnancy is safe, increasing maximal aerobic power and the capacity for sustained submaximal exercise, as well as preserving aerobic capacity in late gestation.

Hypertension complicates 10% of pregnancies, is rarely due to secondary causes, and is classified as chronic hypertension, gestational hypertension, or preeclampsia. Preeclampsia, the most worrisome of these disorders, involves hypertension, proteinuria, edema, and possibly coagulopathy and liver dysfunction. If preeclampsia is severe, the condition may lead to eclampsia, a seizure disorder associated with high morbidity and mortality. The HELLP syndrome (*h*emolysis, *e*levated *l*iver function tests, and *l*ow *p*latelet levels) is a preeclampsia variant that has the same potential for malignant degeneration to eclampsia.

Peripartum cardiomyopathy is the presence of a new cardiomyopathy, without any other cause of congestive heart failure or preexisting heart muscle disorder, that appears in the final month of the pregnancy or in the first 5 months postpartum. Older patients, patients experiencing multibirth pregnancies, patients with toxemia, and patients carrying a first child are somewhat more likely to experience this condition. Most patients with this condition present within 1 to 2 months of delivery. Myocarditis is frequently found in patients who undergo endomyocardial biopsy early after presentation.

All forms of chronic anticoagulation may result in bleeding between the uterus and placenta and subsequent pregnancy loss. Heparin may cause osteoporosis if it is administered at a high dosage for long periods, and warfarin (Coumadin) may be associated with an embryopathy or central nervous system abnormality. Patients who require anticoagulants should receive heparin in the first trimester and in the terminal stages of pregnancy. Coumadin can usually be safely administered through the remainder of pregnancy until just before delivery.

Bioprosthetic heart valves frequently degenerate in and around the time of pregnancy and may require replacement. Pregnant patients who have mechanical prostheses have a lower live birth rate and higher incidence of thromboembolic complications.

Myocardial infarctions associated with pregnancy are unusual; however, pregnancy is associated with an increased incidence of vasospasm and coronary dissection. Pregnant patients are also predisposed to aortic dissection, particularly if they have aortic disease, including Marfan syndrome or Takayasu's syndrome.

Patients who have congenital heart disease, even if it is corrected, must be screened carefully before they become pregnant to ensure that their pulmonary vascular resistance, ventricular function, valvular insufficiency, prosthetic devices, and aortopathy will be able to tolerate the cardiovascular strains of pregnancy.

Tocolytic therapy consists of the use of b-sympathomimetic agents to decrease uterine contraction and allow fetal lung maturation. Approximately 5% of exposed fetuses develop pulmonary edema, which appears to be a capillary leak syndrome.

Because antiarrhythmic agents pose a significant risk to the patient and fetus, they must be chosen carefully.

GLOSSARY

Bioprosthesis: An artificial valve made of biologic material, including either homograft (human) or heterograft (pig) tissue.

Embryopathy: Damage to the embryo, usually as a result of maternal exposure, typically in the first trimester of pregnancy.

HELLP syndrome: Hemolysis, elevated liver function tests, and low platelet levels in pregnant patients. Considered to be a variant of preeclampsia.

Myocarditis: Inflammation of the myocardium, characterized by a significant inflammatory infiltrate associated with myocyte necrosis.

Peripartum cardiomyopathy: Cardiomyopathy appearing in the final month of pregnancy or the first 5 months postpartum, with no preexisting heart muscle disorder and absence of any other cause of congestive heart failure.

Preeclampsia: The appearance of hypertension, proteinuria, and edema in a patient of more than 20 weeks' gestation.

Teratogenic risk: Risk of an induced fetal abnormality, usually caused by maternal exposure in the first trimester of pregnancy.

Tocolytic therapy: Sympathomimetic therapy used to decrease uterine contractions; usually initiated to prolong gestation and increase fetal lung maturation.

INTRODUCTION

Cardiologists and internists are more and more often consulted in the management of cardiovascular complications associated with pregnancy. A greater number of women with known or potential cardiovascular disease are becoming pregnant, and cardiovascular complications in pregnant women are increasingly recognized.

This chapter discusses the normal morphologic and physiologic changes that occur during pregnancy, as well as the pathophysiology and management of hypertension associated with pregnancy and peripartum cardiomyopathy. Treatment of pregnant patients who have congenital heart disease or artificial heart valves and of those who require anticoagulation during pregnancy is outlined. Detection and management of coronary artery disease and coronary dissection, as well as the use of a cardiopulmonary bypass during pregnancy, is reviewed. Avoidance of fetal risk factors during pregnancy, including toxic drinking water, is addressed, as are the potential cardiac dangers of the use of tocolytic therapy to retard uterine contraction. Finally, management of both supraventricular and ventricular tachycardia in pregnancy is reviewed.

NORMAL PHYSIOLOGIC AND MORPHOLOGIC CHANGES IN PREGNANCY

Striking adaptations occur in the maternal cardiovascular system in response to pregnancy. An appreciation of these changes is mandatory to allow appropriate treatment of pregnant patients who have cardiovascular disease. Relatively accurate noninvasive techniques for measurement of maternal physiologic changes, including echocardiographic evaluation of the heart structure and function and respiratory gas exchange assessment of functional status, have improved our understanding of these alterations.

In 1992, Hunter and Robson (1) summarized hemodynamic and structural changes in maternal subjects based on many years of echocardiographic studies performed in their laboratory. Longitudinal studies of cardiac output began before conception and continued into the postnatal period. Cardiac output increases as early as 5 weeks after the last menstrual period and rises to 45% above baseline at 24 weeks' gestation. Increased cardiac output is achieved by an increase in heart rate, which rises progressively until 32 weeks' gestation, and in stroke volume, which begins to increase by 8 weeks and peaks as early as 20 weeks (Fig. 32.1). Twin pregnancies result in an additional 15% rise in cardiac output in mothers. The cardiovascular system is taxed further by stage 1 of labor, which is associated with an additional 12% increase in demand for cardiac output. This demand increases to a mean of 34% above the already increased baseline value as labor progresses to its final stages (Fig. 32.2). After-delivery stroke volume decreases by 2 weeks postpartum, but a small further reduction occurs up to 6 months after delivery. Notably, the stroke volume remains at pregnancy levels for the first 2 days postpartum and then falls dramatically. Heart rate remains elevated for 2 days postpartum and returns to baseline by 10 days after delivery. Cardiac output similarly decreases from pregnancy levels to normal levels between 24 hours and 10 days postpartum.

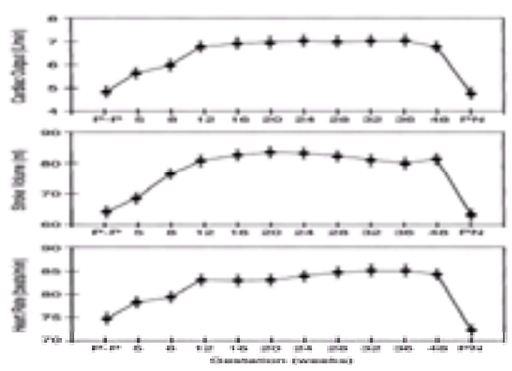

FIGURE 32.1 Serial echocardiographically determined changes in heart rate, stroke volume, and cardiac output during pregnancy and the early postpartum period. P-P, peripartum; PN, postnatal. (From Hunter S, Robson SC. Adaptation of the maternal heart in pregnancy. *Br Heart J* 1992;68:540–543, with permission.)

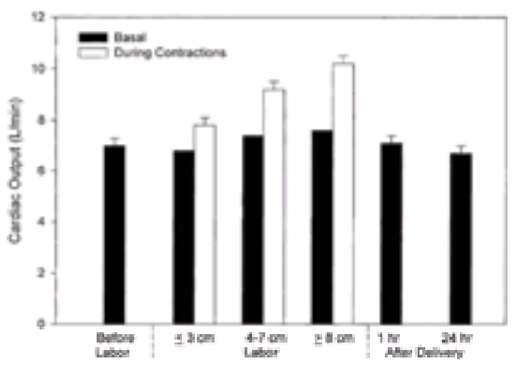

FIGURE 32.2 Normal labor-associated contractions increase cardiac output demands 12% to 34% above an already increased baseline cardiac output. (From Hunter S, Robson SC. Adaptation of the maternal heart in pregnancy. *Br Heart J* 1992;68:540–543, with permission.)

The magnitude of these echocardiographic changes was documented by Mabie and associates (2), who repeated echocardiograms monthly for 18 pregnant patients from 8 to 11 weeks' gestation to 6 to 12 weeks postpartum. Cardiac output, as measured by pulsed Doppler studies, increased from 6.7 L per minute to 8.7 L per minute by 36 to 39 weeks and fell to 5.7 L per minute 2 weeks postpartum. Increases in heart rate and stroke volume of 29% and 18%, respectively, were documented. Additionally, left ventricular mass increased in association with an increased thickness of the left ventricular wall, which was maximal at 24 to 27 weeks. Vered and colleagues (3), in a similar echocardiographic analysis of 15 patients, noted that left ventricular mass increased from 172 to 186 g in association with increased body weight.

The structural changes noted by echocardiography are secondary to the alterations in intravascular volume and neurohumoral stimulation that are associated with pregnancy. Hess and Hess (4) summarized the physiologic fluid changes associated with pregnancy. Plasma volume increases approximately 40% and red blood cell volume 30% above baseline prepregnancy levels, resulting in mild relative anemia. Estrogen-mediated stimulation of the renin angiotensin axis results in increased renal tubular absorption of sodium and an increase in total body salt and water, contributing to the increased plasma volume. Systemic vascular resistance and diastolic blood pressure decrease as a result of changes in aortic compliance and arterial venous shunting in the uterus.

The normal physiologic changes associated with pregnancy result in alterations in the physical examination of the pregnant patient (Table 32.1). It is important to understand findings that are physiologic so that pathologic changes can be distinguished. Because of the increase in total body salt and water, as well as plasma volume, the jugular veins are often full, and the central venous pressure may be slightly increased. Similarly, the pregnant patient may have 1 to 2+ lower-extremity edema. As pregnancy progresses, increased uterus size forces both diaphragms upward, which may decrease pulmonary vital capacity and total lung volume. These mechanical changes may increase the work required for breathing. The previously documented changes in left ventricular size and mass, which are associated with increased volume, result in a mildly displaced and diffuse point of maximal impulse of the left ventricle and increased atrioventricular and aortic as well as pulmonic valve closure sounds. Because of the insulation of the atrioventricular sounds by the abdomen, only the aortic and pulmonic closure sounds are characteristically louder on examination. Increased flow through the pulmonic valve causes a characteristic "functional" early systolic murmur and slight widening of the physiologic variation of closure of the pulmonic component of the second heart sound. Ventricular gallop rhythms and diastolic murmurs are unexpected and serve as clues to anatomic or functional cardiac abnormalities. Occasionally, a normal physiologic diastolic murmur can be heard at the left sternal border in pregnant patients. This physiologic murmur is usually generated by increased diastolic flow through the internal mammary artery, located in the peristernal area and engorged with increased flow to the breasts of pregnant patients. This mammary souffle may persist in lactating mothers, even after delivery. The expected decrease in aortic diastolic pressure during pregnancy that is associated with the decreased systemic vascular resistance results in a widened pulse pressure (systolic pressure minus diastolic pressure) and pulsatile fingertips, warm hands, and occasional Quincke's sign in the extremity nail beds. These findings are also suggestive of aortic regurgitation that may be confused by the diastolic murmur of the mammary souffle at the sternal border. Echocardiography may be required to distinguish the presence or absence of aortic

valve disease.

Mild jugular venous distention
1–2+ Lower-extremity edema
Decreased breath sounds at bases
Upward and leftward deviation of point of maximal impulse
Volume-loaded ventricle (active precordium)
Increased valve closure sounds
"Flow" murmurs (pulmonic and aortic)
Mammary souffle (left sternal border)
Wide pulse pressure
Increased heart rate

TABLE 32.1 PHYSICAL FINDINGS DURING NORMAL PREGNANCY

The physiologic changes associated with pregnancy may also alter the results of noninvasive evaluations of the heart (Table 32.2). The increase in size and left ventricular mass seen by echocardiography has already been described in detail. The electrocardiogram may also be altered. Upward movement of the diaphragm is expected to result in a leftward shift of the electrical axis of ventricular depolarization, and increased ventricular mass may result in increased ventricular voltage. Although changes are altered relative to the subject's baseline values, most changes are not outside the normal limits of variability. Heart rate may be increased, particularly late in pregnancy, and atrial as well as ventricular arrhythmias may increase in frequency in patients predisposed to such events. Chest radiographic studies, which are rarely performed because of radiation risk to mother and fetus, reveal a mild increase in cardiac size, a horizontal shift of the heart that increases with the duration of pregnancy, and fullness of the left cardiac border and pulmonary vascular supply (5).

Test	Change
Electrocardiography	Leftward axis deviation
	Increased ventricular voltage
	Increased rate
	Repolarization changes
Chest x-ray film	Upward diaphragm displacement
	Horizontal heart placement
	Enlarged pulmonary silhouette
Echocardiography	Increased left ventricular diastolic dimension
	Increased left ventricular wall thickness
	Mild increase in contractility

TABLE 32.2 CHANGES IN NONINVASIVE TEST RESULTS THAT OCCUR DURING PREGNANCY

Sophisticated measurements of the cardiovascular response to exercise are now possible, using measurement of respiratory gas exchange during exertion. Sady and coworkers (6) studied nine women at 25 weeks of pregnancy and again at 2 and 7 months postpartum. Their data revealed that the augmented cardiovascular response to exercise associated with pregnancy was reduced by 2 months postpartum but was not completely normal until 7 months after delivery. Lotgering and colleagues (7) studied 33 pregnant women at 16, 25, and 35 weeks of pregnancy as well as at 7 weeks postpartum and proved that pregnant women could exercise maximally without jeopardizing fetal health, and that previous estimates of maximal oxygen exercise capacity, using submaximal exercise values and estimating $\dot{V}O_2$max, were inaccurate. This inaccuracy is due to the altered slope of the relationship between maximal heart rate and percentage $\dot{V}O_2$max in pregnancy. The same investigators later demonstrated that the lower-than-expected peak exercise carbon dioxide production during pregnancy is likely caused by decreased buffering capacity of bicarbonate or increased use of lactic acid by the fetoplacental structures or pregnant liver (8). Wolfe and associates (9) conditioned 18 previously sedentary women during pregnancy with three 25-minute sessions per week, performed exercise stress tests at 17, 27, and 37 weeks' gestation and 20 weeks postpartum, and compared these results with those from a nonexercising control group of pregnant women. Exercise increased oxygen pulse by 17% at peak exercise in the third trimester, with a reduced respiratory exchange ratio. Moderate aerobic exercise during pregnancy is safe; it increases maximal aerobic power and the capacity for sustained submaximal exercise and preserves aerobic capacity in late gestation. Therefore, pregnancy need not limit exercise, and exercise may result in improved conditioning in the pregnant subject.

RADIATION AND PREGNANCY

X-rays produce direct and indirect damage to cells. Direct damage results from the effect of the high-energy radiation beam on cellular and molecular structure. Indirect damage is the result of ionized water and free radical generation. The strength and potential damage of x-rays are measured by the amount of ionic charge created per unit mass of air. One R (roentgen) creates more than 2 billion ion pairs per cm^3 of exposures to air. The absorbed dose of radiation is measured in rad, calculated by the energy imparted to tissue per unit mass of tissue. One rad is equivalent to the deposition of .01 J of energy per kg of tissue. One R of radiation usually produces 1 rad in tissue. Roentgen-equivalent-man (REM) is a measure of absorbed radiation modified by local tissue characteristics, which better delineate the risk of radiation damage to a given organ.

Radiation is harmful to all living tissue and particularly to the conceptus. Increasing radiation exposure is associated with a range of tissue defects, beginning with isolated cellular damage and progressing to growth impairment, structural deformity, neoplasia, and gonadal damage. Environmental radiation results in 50 to 100 mREM exposure during the 9 months of childbearing. The amount of radiation considered to be "safe" is unclear; however, virtually no data have demonstrated significant fetal damage after exposure to less than 1 rad (10).

Several features alter the amount of radiation exposure that occurs during radiologic procedures, including the nature of the radiation source, the equipment used, the size of the patient, the depth of the uterus and conceptus, and the distance from the area being investigated, as well as the extent of the radiologic study. The dose of radiation received by the uterus may vary by 50-fold, depending on these features and whether appropriate uterus shielding is performed.

The increased risk of development of a subsequent malignancy by children receiving radiation *in utero* was reported by the Childhood Cancer Research Group in 1956 and confirmed in 1975 (11). Bithell and Stewart (11) demonstrated a relative risk of 1.47 for the development of subsequent malignancy in children whose mothers underwent radiographs during pregnancy. Furthermore, the relative risk increased progressively from 1.26 for one film exposure to 2.32 for five or more x-rays, indicating a dose response. A first-trimester exposure resulted in a relative risk of malignancy of 8.95, falling to 1.25 and 1.41 in the second and third trimesters, respectively. The risk of childhood cancer from radiation exposure is displayed in *e*Table 32.2.1 (10).

***e*TABLE 32.2.1** PERCENTAGE LIKELIHOOD THAT CHILDHOOD CANCER WILL NOT DEVELOP AFTER PRENATAL IRRADIATION

Gestational age	None	1 rad	5 rad	10 rad
First trimester	99.93	99.75	99.12	98.25
Second and third trimesters	99.93	99.88	99.70	99.48

The risk of radiation must be evaluated relative to the benefit to the mother. It is imperative that the clinician define (a) the dose of radiation to the conceptus, (b) the age and development of the conceptus, (c) the radiation risk from the radiation source, (d) the risk associated with delaying or not performing the test, and (e) the potential for alternative means of answering the question with nonradiation studies.

Standard X-Ray

The estimated exposure to the uterus from standard radiologic examinations is shown in *e*Table 32.2.2 (12).

***e*TABLE 32.2.2** AVERAGE DOSE (MRAD) TO UTERUS BASED ON 1,000-MR EXPOSURE

Cardiac Catheterization

Using the same assumptions noted in this chapter, cardiac catheterization results in exposure of approximately 500 mrad to a shielded uterus, compared with an estimated exposure of 50 mrad for a standard chest x-ray (10). Obviously, the radiation exposure may vary depending on the complexity and duration of the examination. If cardiac catheterization is necessary, brachial as opposed to femoral arterial access should be used, and, where appropriate, noninvasive studies such as echocardiography, transesophageal echocardiography, and contrast echocardiography (13) should be used to define left and right ventricular performance and regurgitant valvular disease, to limit radiation exposure.

Right heart catheterization is occasionally used to monitor cardiac hemodynamics, particularly during delivery and immediately postpartum in patients who have advanced or unstable cardiac disease. This technique can almost always be accomplished without fluoroscopy at the patient's bedside, using an internal jugular approach. Only if the catheter cannot be advanced into the pulmonary artery or if significant atrial or ventricular ectopy occurs with attempted placement should fluoroscopy be used. If fluoroscopy is needed, very limited fluoroscopic visualization is usually necessary.

Computed Tomographic Scanning

Computed tomographic scanning uses circumferential radiation exposure, usually in 1-cm slices. The exposure of the uterus to radiation "leakage" distal to the areas of interest is small but may vary according to (a) the area scanned, (b) proximity of the area scanned to the uterus, (c) the number of images obtained, and (d) the type of machine used. The average skin exposure associated with computed tomographic scanning is 4 rad, with approximately 70% of skin dose still measurable in the midbody. It is estimated that uterine exposure is 1.6 to 4.0 rad and is usually less than 1 rad if examination is confined to the chest cavity.

Radionuclides

Radionuclides are radiation-emitting substances that are injected intravenously and used to image the blood pool or organs of interest. The degree of exposure is correlated with (a) the dose of radionuclide given, (b) the uptake of the radionuclide by organs, (c) the proximity of concentrating organs to the developing child, (d) the type of radiation (g- versus b-emitting), (e) the amount of placental transfer associated with the radionuclide agent, and (f) the length of time that the radionuclide remains in the mother. Several examples are listed in *e*Table 32.2.3 (10).

***e*TABLE 32.2.3** CONCEPTUS DOSE ESTIMATES FROM RADIONUCLIDE EXPOSURE

Radionuclide	Conceptus age (wk)	**Organ**	Dose per unit maternally administered activity (rad/mCi)
^{99m}Tc sodium pertechnetate	1.5–6.0	Whole	0.0027–0.048
^{99m}Tc polyphosphate	1.5–6.0	Whole	0.025
^{67}Ga citrate	1.5–6.0	Whole	0.25
^{131}I	1.5–6.0	Whole	0.1–3.0

From Wegnerckileser RG, Saldana LR. *Exposure of the pregnant patient to diagnostic radiation: a guide to medical management.* Philadelphia: JB Lippincott, 1985, with permission.

Magnetic Resonance Imaging

Magnetic resonance imaging uses strong and weak magnetic fields and radiofrequency waves to image human tissue. This is a relatively new method, and no short- or long-term ill effects of this technology on the fetus or mother are clearly recognized. Until appropriately performed prospective trials are completed, use of the technique should be approached with caution. It is hoped that the lack of radiation exposure will make this technique widely applicable in the future.

It is evident that radiation should be avoided throughout pregnancy and particularly in the early months after conception. Occasionally, medical illness in the mother will mandate investigations using radiation, and it is important for the clinician to have an understanding of the radiation risk involved. The interested reader is referred to Wagner, Leser, and Saldana and their excellent book entitled *Exposure of the Pregnant Patient to Diagnostic Radiation: A Guide to Medical Management* (10).

HYPERTENSION DURING PREGNANCY

High blood pressure may complicate as many as 10% of all pregnancies and remains a major cause of maternal and fetal morbidity and mortality (14,15). In normal pregnancy, diastolic blood pressure falls, often by as much as 10 mm Hg in the first and second trimesters as a result of decreased systemic vascular resistance and increased cardiac output. Blood pressure then increases gradually at or near term and may transiently rise higher than nonpregnant values in the immediate puerperium. Rarely is high blood pressure in pregnancy the result of secondary causes such as intrinsic renal disease, endocrinopathies, or renal vascular obstruction. The currently accepted categories for high blood pressure in pregnancy are (a) chronic hypertension, (b) gestational hypertension, and (c) preeclampsia, with or without preexisting high blood pressure.

Chronic high blood pressure is categorized as preexistent hypertension or a blood pressure of at least 140/90 mm Hg before 20 weeks' gestation. If the diastolic blood pressure is 110 mm Hg or greater, severe hypertension is diagnosed. Pregnant women with a diastolic blood pressure higher than 75 mm Hg in the second trimester and 95 mm Hg in the third trimester should be observed carefully (16). The maternal and fetal outcomes are good unless preeclampsia or abruptio placentae complicates the final stages of gestation. Clear evidence exists (17) that treatment of blood pressure of greater than 110 mm Hg (diastolic) during pregnancy lowers the risk of stroke and cardiovascular complications, although the benefit of lowering blood pressure in mild chronic hypertension during pregnancy is less clearly defined.

Gestational hypertension is defined as asymptomatic blood pressure elevation after 20 weeks' gestation. Unless this elevation of pressure reflects early preeclampsia or unrecognized chronic hypertension, the maternal and fetal outcomes are usually very good, even without treatment.

Preeclampsia is the most feared hypertensive disorder of pregnancy and may lead to life-threatening eclampsia, a convulsive disorder. Preeclampsia is characterized by hypertension, proteinuria (levels greater than 300 mg in 24 hours), and edema but may include coagulopathy and altered liver function in pregnant patients after 20 weeks' gestation (Table 32.3). Preeclampsia may be mild or severe, depending on the degree of blood pressure elevation and proteinuria. In preeclampsia, plasma volume and cardiac output fail to rise, and systemic resistance does not fall. This appears to be related to failure of the uterine spiral arteries to develop, preventing the anticipated arteriovenous shunting. Some researchers believe the primary abnormality causing preeclampsia is the result of prostaglandin deficiency; endothelial cell dysfunction; or immune, genetic, or sodium/calcium membrane disorders. Schobel and colleagues (18) recently demonstrated that preeclampsia is associated with a dramatic increase in sympathetic nervous system activity. This conclusion was reached by evaluation of postganglionic sympathetic nerve activity in the blood vessels of skeletal muscles of preeclamptic patients, compared with those in pregnant and nonpregnant control subjects. Recently, investigators have demonstrated an increased level of platelet-activating factor (19) and plasma levels of prostaglandin isoforms (20) in preeclampsia subjects compared with levels in pregnant and nonpregnant control subjects. Dechend and coworkers (21) demonstrated angiotensin-1 receptor autoantibodies in preeclamptic patients and that these

immunoglobulins may cause vascular smooth muscle cells to express tissue factor that may be responsible for placental infarction (often associated with preeclampsia). These observations may have ramifications for treatment. The maternal risks of preeclampsia include cerebral hemorrhage, pulmonary edema, disseminated intravascular coagulopathy, liver failure, renal failure, convulsions, and death. These risks are correlated with the severity of the complications and level of gestation at the onset of the condition. The fetus may suffer hypoxemia, acidosis, growth retardation, and death.

TABLE 32.3 TYPICAL FINDINGS IN PATIENTS WITH PREECLAMPSIA

Mild preeclampsia may be managed at home; however, development of progressive symptoms such as headache, visual disturbances, and abdominal pain requires hospitalization (*e*Table 32.3.1). The use of antihypertensive or anticonvulsant therapy to treat mild preeclampsia remains questionable. Treatment of severe preeclampsia, on the other hand, may require termination of the pregnancy, regardless of fetal viability, if the mother's life is in jeopardy. Antihypertensive therapy should be initiated with hydralazine, labetalol, or nifedipine to lower mean blood pressure and diastolic blood pressure to 126 and 90 mm Hg, respectively. Because these patients are already volume-depleted, use of diuretics should be avoided. Intravenous magnesium should be given during labor and delivery and for 24 hours postpartum for patients who have severe preeclampsia to avoid convulsions.

***e*TABLE 32.3.1** OMINOUS SIGNS AND SYMPTOMS IN WOMEN WITH PREECLAMPSIA

Blood pressure ³ 160 mm Hg systolic or ³ 110 mm Hg diastolic
Proteinuria of new onset at a rate of ³ 2 g per 24 h or ³ 100 mg/dL in a randomly collected specimen
Increasing serum creatinine levels [especially >177 mmol/L (2 mg/dL) unless the level was known to be elevated previously]
Platelet count <10 × 10^9 cells/L or evidence of microangiopathic hemolytic anemia (e.g., schistocytes or increase in lactic acid dehydrogenase and direct bilirubin levels)
Upper abdominal pain, especially epigastric and right-upper-quadrant pain
Headache, vision disturbances, or other cerebral signs
Cardiac decompensation (e.g., pulmonary edema, usually associated with underlying heart disease or chronic hypertension)
Retinal hemorrhage, exudates, or papilledema (these signs are extremely rare in the absence of other indicators of severity and, when present, almost always indicate underlying chronic hypertension)
Fetal growth retardation

From Cunningham FG, Lindheimer MD. Hypertension in pregnancy. *N Engl J Med* 1992;326:927–932, with permission.

There is no known mechanism for avoidance of preeclampsia, although sodium chloride restriction, diuretics, low-dose aspirin, and increased dietary calcium have been attempted.

A variant of preeclampsia, the HELLP syndrome, is characterized by minimal or no elevation of blood pressure, mild decreases in platelet levels, hemolysis, mild liver function abnormalities, and absence of renal impairment at the onset (*e*Table 32.3.2) (15,17). This syndrome may progress rapidly, resulting in hemolysis, thrombocytopenia, and liver failure. Recognition of this syndrome prepartum should prompt immediate delivery. O'Brien and coworkers (22) have suggested that corticosteroids may be of some benefit in this unusual disorder; however, recommendation of corticosteroid therapy is dependent on the outcome of prospective randomized trials in affected patients. Both the HELLP syndrome and preeclampsia may occur up to 10 days postpartum.

***e*TABLE 32.3.2** CHARACTERISTICS OF THE HELLP SYNDROME[a]

Preeclampsia variant
Minimal blood pressure elevation
Low platelet count
Mild liver function abnormalities
Malignant potential

[a]The HELLP syndrome is a variant of preeclampsia with the same potential for deterioration.
HELLP, hemolysis, elevated liver function tests, and low platelets.

Preeclampsia, the most devastating form of hypertension to affect the pregnant patient, has a unique pathophysiology and requires prompt and appropriate management for avoidance of serious complications to the mother and fetus. Use of antihypertension agents in pregnant women requires special consideration of the effect on the fetus and the uteroplacental unit, as well as on the mother. Cardiologists will likely increasingly be called on to assist in the management of this condition in a usually older, multigravida population.

TREATMENT OF HYPERTENSION DURING PREGNANCY

Medications commonly used to treat chronic, gestational, and preeclamptic hypertension are listed in Table 32.4 and Table 32.5. Appropriate medical management of pregnancy-related hypertension depends on an understanding of the pathophysiology outlined in the previous sections. Some changes are unique to alterations in kidney handling of sodium and water.

Regulation of blood pressure
The degree to which blood pressure should be decreased is disputed; we recommend maintaining diastolic levels between 90 and 110 mm Hg.
Drug therapy
Hydralazine administered intravenously is the drug of choice. Start with low doses (5 mg as an intravenous bolus), then administer 5 to 10 mg every 20 to 30 min to avoid precipitous decreases in pressure. Side effects include tachycardia and headache.
Diazoxide is recommended for women whose hypertension is refractory to hydralazine. Use 30-mg minibolusses, because precipitous hypotension may result if higher doses are used. Side effects include arrest of labor and neonatal hypoglycemia.
The experience with labetalol is growing, and some physicians use this agent, instead of diazoxide, as a second-line drug.
Favorable results have been reported with calcium channel blockers. If magnesium sulfate is being infused, magnesium may potentiate the effects of calcium channel blockers, resulting in precipitous and severe hypotension.
Refrain from using sodium nitroprusside, because fetal cyanide poisoning has been reported in animals. However, maternal well-being should dictate the choice of therapy.
Prevention of convulsions
Parenteral magnesium sulfate is the drug of choice for preventing eclamptic convulsions. Therapy should be continued for 12 to 24 h postpartum, because one-third of women with eclampsia have convulsions during this period.

TABLE 32.4 GUIDELINES FOR TREATING SEVERE HYPERTENSION NEAR TERM OR DURING LABOR

TABLE 32.5 ANTIHYPERTENSIVE DRUGS USED TO TREAT CHRONIC HYPERTENSION IN PREGNANT WOMEN

The mean increase in total body water and sodium during pregnancy is 6 to 8 L and 500 to 900 mEq, respectively, approximately one-half of which is extracellular (23). Many factors alter sodium excretion in pregnancy, of which a 50% increase in the glomerular filtration rate and elevated levels of progesterone and aldosterone are most important. The result is that more than 80% of all healthy pregnant women develop physiologic-dependent or generalized edema.

Edema may be a normal physiologic response; hypertension and preeclampsia are not. Hypertension in pregnancy is associated with increased rates of preterm delivery, perinatal mortality, and probably small-for-date babies and fetal neurologic impairment (16). Preeclampsia is a vascular abnormality, and the earliest manifestation, which occurs well before other manifestations of disease, can be demonstrated as an abnormal pressor response to infused angiotensin. Despite the increase in interstitial volume that occurs with preeclampsia, the intervascular volume is reduced, and oliguria and hemoconcentration are typically present. There is no evidence that sodium restriction or diuretics prevent preeclampsia or other hypertensive complications of pregnancy, and use of such agents may cause additional volume contraction, alkalosis, electrolyte abnormalities, pancreatitis, and bleeding or hyponatremia in the neonate (16,23). Use of diuretics in women with preeclampsia should be avoided, and these agents are of limited benefit for treatment of pregnancy-related hypertension. Patients who have taken diuretics chronically before pregnancy or who are extremely sensitive to salt may derive some benefit from them (23).

Among agents used to treat chronic hypertension in pregnancy, Aldomet (methyldopa) is safe and preferable to other drugs. Randomized trials have demonstrated that Aldomet improves fetal survival significantly, and it is the only drug with long-term follow-up (7.5 years), in which no difference in health, physical, or intellectual outcomes was seen between patients who received treatment with this agent and those who did not (24,25). The use of beta-receptor–blocking agents, including oxprenolol, atenolol, and acebutolol, during pregnancy has been studied. Growth retardation, acute fetal distress, high perinatal mortality, and hypoglycemia, all early concerns, have been found to be nearly nonexistent in controlled trials, and use of these agents is now considered nearly as safe as administration of Aldomet (25,26). Type II calcium channel blockers, including nifedipine, nicardipine, and nitrindipine, are potent vasodilators and have been used to treat hypertension during pregnancy. Nifedipine may induce a rapid fall in blood pressure if given in high dose or sublingually, which may result in reflex tachycardia. Uterine blood flow is minimally affected by nitrindipine and nifedipine, and the drug may decrease uterine contractions as a result of its smooth muscle relaxant properties; therefore, it may serve as a successful tocolytic agent (27).

Angiotensin-converting enzyme (ACE) inhibitors are currently the agents of choice for use in nonpregnant patients who have cardiomyopathy or congestive heart failure and after myocardial infarction, but this class of antihypertensive drugs should *never* be used during pregnancy. Animal and human studies have demonstrated a high degree of morbidity and mortality in infants exposed to ACE inhibitors during pregnancy (28). Complications include growth retardation, renal failure, bone malformations, oligohydramnios, patent ductus arteriosis, pulmonary hypoplasia, respiratory distress syndrome, and neonatal death. The U.S. Food and Drug Administration has issued a warning against the use of ACE inhibitors during pregnancy after the first trimester (29). Most authorities favor avoiding these agents even in patients who are merely contemplating pregnancy.

Preeclampsia requires prompt control of accelerated hypertension. Because of its long history of use for preeclampsia, hydralazine remains the drug of choice for most physicians. The drug can be given intravenously, intramuscularly, or orally and titrated to achieve maximal effect (16). Labetalol combines alpha- and beta-blocking properties, can be given intravenously, and incurs a prompt response. Nifedipine has been used sublingually and, when compared with hydralazine in a small, controlled trial, resulted in improved blood pressure control (27). Type II calcium channel blockers are tocolytic, which may be advantageous for treatment of patients who have premature contractions but deleterious for patients in whom delivery should be hastened. Nitroprusside probably should be avoided because of the potential for thiocyanate accumulation. Magnesium sulfate has been demonstrated to be beneficial during preeclampsia and for up to 24 hours after delivery.

PERIPARTUM CARDIOMYOPATHY

Peripartum cardiomyopathy, a relatively infrequent dilated cardiomyopathy that occurs in women of reproductive age, is defined as “a disorder of heart muscle, which presents clinically with the onset of heart failure in the last month of pregnancy or the first 5 postpartum months” (30,31). Established diagnostic criteria include (a) absence of a determinable cause for cardiac failure, (b) absence of preexisting heart muscle disease, and (c) time limitations of onset of illness. Other causes of congestive heart failure in pregnancy should be ruled out, including congenital, valvular, infectious, metabolic, and toxic etiologies, as well as preeclampsia and pulmonary emboli, which may complicate late pregnancy and delivery. Some recent literature on this topic is tainted by the inclusion of patients who were in the last trimester of gestation rather than the final month. This expansion of the definition encompasses the response of patients with preexistent heart disease to the volume load imposed by pregnancy, which clouds the clinical observations about this unique disorder. Such patients should be excluded.

Peripartum cardiomyopathy complicates 1 in 1,300 to 1 in 4,000 deliveries in the United States (32,33). This condition may affect women of any race, age, or number of prior deliveries; however, pregnancies in older age, multigravida pregnancies, African-American race, and twin pregnancies are thought to represent predisposing features (Fig. 32.3).

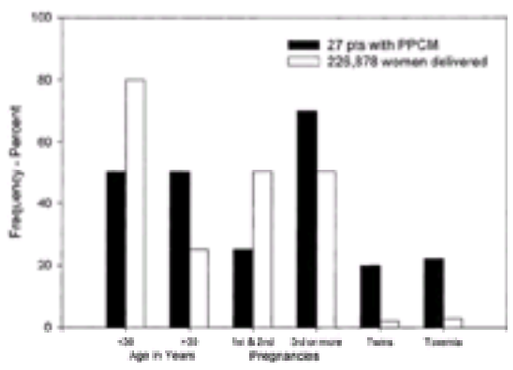

FIGURE 32.3 Risk factors for the development of peripartum cardiomyopathy (PPCM). pts, patients. (From Demakis JG, Rahimtoola SH. Peripartum cardiomyopathy. *Circulation* 1971;44:964–968, with permission.)

The etiology of peripartum cardiomyopathy is unknown (*e*Table 32.5.1). Melvin and associates (34) in 1982 demonstrated myocarditis by endomyocardial biopsy in three of three patients presenting with peripartum cardiomyopathy. All three patients were treated with immunosuppressive therapy, and ventricular function improved in all three. Sanderson and associates (35) performed biopsies on 11 African women with peripartum cardiomyopathy in Nairobi and found healing myocarditis in five. Four patients with myocarditis during follow-up failed to improve, and no immunosuppressive treatment was given. O’Connell and coworkers (36) evaluated 14 consecutive patients with peripartum cardiomyopathy using endomyocardial biopsy, which revealed myocarditis in four (29%); all patients in whom the diagnosis of myocarditis was made underwent biopsy within 1 week of the onset of symptoms. Two of the four patients with myocarditis died, the condition of one stabilized, and the condition of one improved; none was treated with immunosuppressive therapy. Eight of these 14 patients presented before delivery, and these authors extended the window for diagnosis of peripartum cardiomyopathy to the last trimester of pregnancy, rather than to the last month, making their data difficult to interpret.

***e*TABLE 32.5.1** STUDIES OF PERIPARTUM CARDIOMYOPATHY MYOCARDITIS

Reference	Incidence	Immunosuppression	Outcome
Melvin et al. (34)	3/3	Yes	3/3 improved
Sanderson et al. (35)	5/11	No	3/4 experienced congestive heart failure
O'Connell et al. (36)	4/14	No	3/4 experienced congestive heart failure
Midei et al. (37)	14/18	Yes/no	13/14 improved

Midei and coauthors (37) at The Johns Hopkins Hospital reported that 14 (78%) of 18 consecutive patients with peripartum cardiomyopathy had myocarditis found on endomyocardial biopsy. Felker and colleagues (38) expanded their study to include 42 women with peripartum cardiomyopathy who underwent biopsy. Despite a delay in biopsy of 1 to 2 weeks after presentation, the incidence of myocarditis remained high (62%). Additionally, the Johns Hopkins group demonstrated that the prognosis for mothers with peripartum cardiomyopathy is good relative to patients with idiopathic dilated cardiomyopathy (39) (Fig. 32.4). Of 42 patients included in that study, only three died (7%), and three underwent orthotopic heart transplantation (7%) (38). Ventricular function improved in most patients. In our experience, patients presenting early after delivery had more profound congestive heart failure and dramatic myocarditis found by endomyocardial biopsy, but they also had a greater chance of spontaneous resolution, even if they did not receive immunosuppressive therapy. These studies suggest that peripartum cardiomyopathy is immunologic in origin. Whether the inciting agent is an inapparent viral infection or an aberrant immunologic response to a placental or fetal antigen is unknown. As is true of the other cardiomyopathies that present with heart failure, patients with peripartum cardiomyopathy display elevated levels of tumor necrosis factor-a, interleukins, and apoptosis-signaling receptors (40).

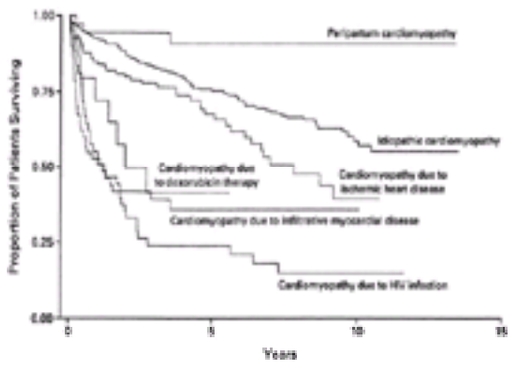

FIGURE 32.4 Adjusted Kaplan-Meier estimates of survival, according to the underlying cause of cardiomyopathy. Only idiopathic cardiomyopathy and cardiomyopathy resulting from causes for which survival was significantly different from that among patients with idiopathic cardiomyopathy are shown. HIV, human immunodeficiency virus. (From Felker GM, Thompson RE, Hare JM, et al. Underlying causes and long-term survival in patients with initially unexplained cardiomyopathy. *N Engl J Med* 2000;342:1077–1084, with permission.)

Patients who have peripartum cardiomyopathy typically present with heart failure, which in our experience has been more profound near the time of delivery and more subtle in presentation when it occurs months later. Approximately 80% of patients present within the first 3 months postpartum (Fig. 32.5). Symptoms of heart failure may be particularly difficult to diagnose for patients in the last month of pregnancy and very early postpartum, when dyspnea, edema, and fatigue may be the result of normal pregnancy and delivery. The physical findings of congestive heart failure are manifest, including jugular venous distention, rales, hepatic congestion, and edema. Patients presenting early may not have cardiomegaly, and the point of maximal impulse is frequently superiorly placed, in our experience.

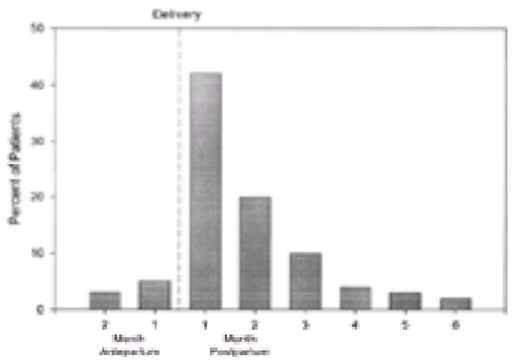

FIGURE 32.5 Peripartum cardiomyopathy. Most patients present with peripartum cardiomyopathy within 2 months of delivery. By definition, those presenting earlier than the last month of pregnancy do not have peripartum cardiomyopathy. (From Homans DC. Current concepts: peripartum cardiomyopathy. *N Engl J Med* 1985;312:1432–1437, with permission.)

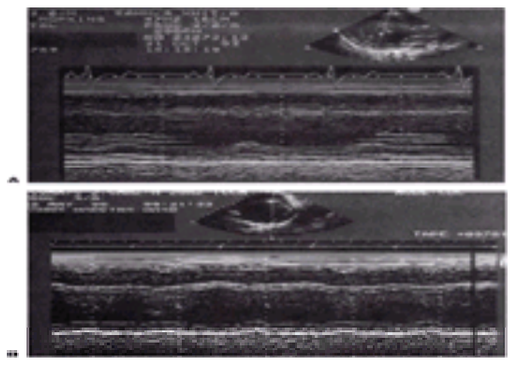
The chest x-ray confirms the presence of pulmonary congestion and usually cardiomegaly. Echocardiography, which is mandatory in the evaluation of these patients, demonstrates markedly decreased contractility with variable degrees of cardiac enlargement (eFig. 32.5.1). The results of electrocardiography are almost always abnormal and show nonspecific ST-T–wave changes. Right heart catheterization (if performed) reveals high filling pressures and decreased cardiac output that are compatible with cardiomyopathy. Only if the patient has multiple risk factors for coronary artery disease or is suspected of having a coronary dissection should coronary angiography be performed.



***e*FIGURE 32.5.1** Echocardiographic appearance of peripartum cardiomyopathy. **A:** Nondilated. Often, in the acute setting, patients present with severe heart failure and nondilated, thickened left ventricles with severe hypofunction. The diastolic dimension of the left ventricle is 5.2 cm, and the systolic dimension 4.8 cm. Left ventricle thickness is 1.5 cm. **B:** Dilated. More traditionally, the left ventricle is modestly dilated, thin walled, and hypofunctional. The diastolic dimension is 6.0 cm, systolic dimension is 4.8 cm, and wall thickness is 1.1 cm.

We do not perform endomyocardial biopsy or right heart catheterization on patients with peripartum cardiomyopathy unless they fail to show improvement in signs and symptoms of congestive heart failure and in echocardiographic ventricular function after 2 weeks of standard management therapy for congestive heart failure. Although endomyocardial biopsy can define the presence and severity of myocarditis in patients who have peripartum cardiomyopathy, it is unclear that this offers any therapeutic advantage, because immunosuppressive therapy is likely ineffective in influencing long-term left ventricular function (K. L. Baughman, *unpublished data*).

Standard management of heart failure should be applied to these patients postpartum, with careful attention to the potential influence of drugs on the uterus and, for patients in the last month of pregnancy, the fetus. Standard treatment includes afterload reduction therapy, diuresis, administration of digoxin (if signs or symptoms of

congestive heart failure persist despite preload and afterload reduction therapy), and anticoagulation therapy (if ventricular compromise persists).

In Demackus and coworkers' initial series (30,31), two groups of patient outcomes were categorized. Approximately one-half of the affected patients recovered normal heart size, and one-half still had cardiomegaly at 6 months' follow-up. Patients with persistent cardiomegaly had the same poor prognosis as patients with dilated cardiomyopathy; 80% died, with an average survival of 4.7 years after presentation. Of patients whose hearts returned to normal size, 14% died, none from cardiovascular disease. This pattern of survival has persisted in all subsequent studies, and, until recently, the prognosis for such patients was poor. Earlier recognition of peripartum cardiomyopathy due to the availability of echocardiography, more sophisticated standard therapy for congestive heart failure, and referral for full cardiac evaluation for patients who fail to respond to early heart failure management have likely improved the prognosis. Cole and associates (41) reported the echocardiographic evolution of peripartum cardiomyopathy compared with peripartum control subjects in 14 patients who presented with this entity. The left ventricular end diastolic volume index was 95 versus 67 mL per m^2, respectively; the end systolic volume index was 66 versus 27 mL per m^2, respectively; and left ventricular wall mass was 139 versus 96 g per m^2, with an ejection fraction of 29% versus 67%, respectively. Despite these findings, 13 of 14 patients improved early and rapidly with standard therapy, despite the fact that none of the five who underwent to endomyocardial biopsy had histologic myocarditis.

We routinely follow patients closely after presentation with peripartum cardiomyopathy. Most patients require hospitalization on presentation because of the severity of congestive heart failure symptoms. Appropriate therapy is administered until the patient's condition is stabilized. This can usually be accomplished with standard medical therapy, but occasionally extraordinary therapy is needed, including intraaortic balloon counterpulsation or use of a left ventricular assist device. Because the degree of reversibility of left ventricular dysfunction associated with peripartum cardiomyopathy is high, and because the patients are young, all means necessary should be applied to ensure the mother's survival. Once discharged from the hospital, patients are followed every 2 weeks with clinical evaluation and an echocardiogram until left ventricular function is stabilized and no longer improving. Echocardiograms are repeated at 3 months and 6 months postpartum. The ventricular function at 6 months will likely be the ventricular performance that the patient maintains. Vigorous activity and nursing are discouraged during this interval to avoid left ventricular stress, which might alter ventricular remodeling during recovery. No other noninvasive tests are helpful in follow-up, in our experience.

Recurrent pregnancies in patients who have experiences peripartum cardiomyopathy remain problematic. Demakis and Rahimtoola (31) reported that in 14 patients whose hearts returned to normal, eight patients attempted 21 subsequent pregnancies. Of these eight patients, three experienced transient cardiac decompensation responsive to heart failure management. Of the 13 patients whose hearts failed to recover, six attempted repeat pregnancy with three experiencing deterioration and death. Through a survey mechanism, Elkayam et al. (42) identified 44 patients who attempted 60 subsequent pregnancies after documented peripartum cardiomyopathy. Patients presenting in the last trimester—as opposed to the last month of pregnancy—were included. Of the 28 patients who normalized ventricular function at rest, there was a significant decrease in ejection fraction (from 56% to 49%), whereas 21% experienced congestive heart failure with subsequent pregnancies. Of the 16 patients with abnormal resting ventricular function, ejection fraction decreased (from 36% to 32%), and 44% developed symptomatic congestive heart failure with repeat pregnancy. Mortality was not noted in those with normalized ventricular function but was 19% in those with persistent dysfunction. Lampert (42a) studied ventricular reserve in patients with peripartum cardiomyopathy who normalized ventricular function. Ten patients were evaluated approximately 9 months after ventricular recovery from peripartum cardiomyopathy. These authors used an echocardiographic load and heart rate–independent mechanism to assess ventricular contractility and reserve in response to methoxamine and dobutamine infusion. Contractile reserve, even in patients with ventricular recovery, was impaired.

There are, therefore, three categories of patients after peripartum cardiomyopathy: those with persistent abnormal cardiac function, those with normal resting but abnormal cardiac reserve with stress, and those with normal resting and stress ventricular performance. For patients who do not recover left ventricular function, standard long-term management for congestive heart failure should be undertaken. For those whose congestive heart failure is unresponsive to treatment, cardiac transplantation can be done (42a,44) with a favorable long-term survival and morbidity comparable to that in age-matched control subjects. For patients with normal resting but abnormal stress ventricular response, pregnancy can be undertaken; however, cardiac decompensation may occur. Fortunately, this decompensation is usually responsive to medical management, and maternal mortality is not expected. In patients with normal resting and stress ventricular response after peripartum cardiomyopathy, repeat pregnancy can be undertaken with less risk of decompensation.

For patients who do not recover left ventricular function, standard long-term management for congestive heart failure should be undertaken. Cardiac transplantation can be done (43,44) for those whose congestive heart failure is unresponsive to treatment, with a favorable long-term survival and morbidity comparable to that in age-matched control subjects.

TRANSPLANTATION

The transplanted heart is denervated and may have limitations in ventricular dilatation, making the hemodynamic burden of pregnancy more difficult to manage (45). Cardiac transplant patients are usually hypertensive and hypercholesterolemic, and they face the potential that accelerated atherosclerosis will develop in the transplanted heart's coronary arteries, increasing the risk of cardiovascular compromise. Pregnancy may interrupt routine surveillance endomyocardial biopsy procedures because of the risk of fetal radiation exposure, thereby limiting the transplant cardiologist's ability to diagnose and treat rejection successfully before hemodynamic compromise develops. Immunosuppressive agents pose a potential risk to the fetus of genetic alterations and to the mother's renal function (cyclosporine) and bone, skin, and adrenal integrity (prednisone). Scott and colleagues (46) reviewed the literature and the University of Utah experience and polled other cardiac transplant centers to gather the experience of 30 posttransplant patients who became pregnant. Overall, 48% had chronic hypertension, 24% had preeclampsia, and 28% had preterm labor. Six episodes of rejection required increased immunosuppressive therapy, and nine required increased cyclosporine dosage to maintain therapeutic levels. Of 27 live births, ten infants were preterm (less than 36 weeks), five infants were small for gestational age, and four infants had neonatal complications. No congenital abnormalities were reported. Data from the National Transplantation Pregnancy Registry compiled by Branch and coworkers (47) confirmed a high incidence of premature and low-birth-weight infants born to 35 transplant recipients with 47 pregnancies. The risks appear to be similar in heart-lung transplant recipients (48). Pregnancy in cardiac transplant recipients must be considered high risk for mother and fetus and is discouraged.

BACTERIAL ENDOCARDITIS PROPHYLAXIS

Vaginal delivery in the presence of infection is thought to increase the risk of bacterial endocarditis in patients who have (a) prosthetic valves; (b) previous bacterial endocarditis, even without organic heart disease; (c) most congenital abnormalities; (d) rheumatic and other acquired valvular abnormalities, even after repair; (e) hypertrophic cardiomyopathy; and (f) mitral valve prolapse with valvular regurgitation. Insufficient data exist that describe the risk of bacterial endocarditis after cardiac transplantation; however, most clinicians favor treatment with antibiotics. No adequate controlled trials have been performed that examine the use of antibiotic regimens for the prevention of bacterial endocarditis in humans, and recommendations are based on animal models and *in vitro* studies (49).The regimens proposed are outlined in *e*Table 32.5.2.

***e*TABLE 32.5.2** DRUG REGIMENS FOR GENITOURINARY AND GASTROINTESTINAL PROCEDURES

Drug	Dosage regimen
Standard regimen	
Ampicillin, gentamicin, and amoxicillin	Intravenous or intramuscular administration of ampicillin, 2.0 g, plus gentamicin, 1.5 mg/kg (not to exceed 80 mg), 30 min before procedure; followed by amoxicillin, 1.5 g, orally 6 h after initial dose; alternatively, the parenteral regimen may be repeated once 8 h after initial dose
Regimen for patients allergic to ampicillin, amoxicillin, and penicillin	
Vancomycin and gentamicin	Intravenous administration of vancomycin, 1.0 g, over the course of 1 h plus intravenous or intramuscular administration of gentamicin, 1.5 mg/kg (not to exceed 80 mg), 1 h before procedure; may be repeated once 8 h after initial dose
Alternate low-risk patient regimen	
Amoxicillin	3.0 g orally 1 h before procedure; then 1.5 g 6 h after initial dose

Note: Initial pediatric doses are as follows: ampicillin, 50 mg/kg; amoxicillin, 50 mg/kg; gentamicin, 2.0 mg/kg; and vancomycin, 20 mg/kg. Follow-up doses should be one-half the initial dose. Total pediatric dose should not exceed total adult dose.

From Dajani AS, Bisno AL, Chung JK, et al. Prevention of bacterial endocarditis: recommendations by the American Heart Association. *JAMA* 1990;264:2919–2922, with permission.

ANTICOAGULATION AND PREGNANCY

Occasionally, pregnant patients require systemic anticoagulation for prophylaxis and treatment of venous or arterial thromboembolic disease or because of the presence of an artificial heart valve. Systemic anticoagulation exposes the mother and fetus to significant risks. Both heparin and warfarin may cause *in utero*placental bleeding, resulting in spontaneous abortion. Long-term systemic heparinization may cause osteoporosis. Heparin does not cross the placental barrier and has no effect on the fetus. Warfarin, on the other hand, does cross the placental membrane and causes fetal anticoagulation. More important, administration of warfarin during the first trimester may cause an embryopathy, and exposure at any time in gestation may cause central nervous system abnormalities in the fetus. Weeks 6 to 12 of gestation appear to be the critical time interval for embryopathy caused by warfarin exposure, resulting in nasal hypoplasia or stippled epiphysis. Central nervous system abnormalities caused by warfarin exposure include hemorrhage and dorsal or ventral midline dysplasia. Data concerning low-molecular-weight heparin are limited. Ellison and coauthors (50) reported a retrospective series of 57 pregnancies in 50 women and found a low incidence of complications with use of 40 mg of

low-molecular-weight heparin once per day. Satisfactory antifactor X_a levels and prevention of thromboembolism were achieved (50).

Systemic heparinization during pregnancy traditionally has been thought to result in high risk to the fetus and mother. Ginsberg and Hirsh (51) reviewed the published literature in 1989 and reported a summary of 106 studies that evaluated 1,325 pregnancies in women who were receiving anticoagulation therapy. After excluding comorbid conditions, the risk of maternal death was 2.5% (7 of 278 patients) for women receiving heparin and 16.8% (95 of 567 patients) for patients treated with oral anticoagulants. These authors and colleagues (52) also carried out a prospective study of 77 women with 100 pregnancies, among whom heparin was given for prevention or treatment of venous thromboembolism in 98 pregnancies and because of a prosthetic valve replacement in two. The rates of prematurity, abortion, stillbirths, neonatal deaths, and congenital abnormalities are similar to those in normal populations. In addition, no symptomatic thromboembolisms and only two episodes of bleeding were seen after a mean of 18 weeks of treatment per pregnancy. As noted, few of these authors' patients received anticoagulation therapy for valvular disease or prosthesis. Osteoporosis is a potential complication of heparin therapy. Barbour and associates (53) performed a prospective study of heparin use in pregnant patients, using bone densitometry to evaluate osteoporosis. Of the 14 pregnant patients given heparin, 36% experienced a greater than 10% decrease in femur bone density measurements from baseline to immediately postpartum, compared with none of 14 pregnant control subjects who were not receiving heparin. The difference in bone density remained statistically significant at 6 months postpartum. These data confirm that one-third of pregnant patients treated with prolonged heparin are likely to develop osteoporosis, even at doses as low as 15,000 units per day. Additionally, patients rarely may develop heparin-associated antibodies during pregnancy, resulting in thrombosis and thrombocytopenia (54).

In their literature review, Ginsberg and Hirsh (51) reported warfarin embryopathy in 45 of 970 exposed fetuses and central nervous system abnormalities in 26 of 970 patients. Of 22 cases of heparin osteoporosis that have been reported, seven have occurred in pregnant patients. Development of osteoporosis may be related to total exposure and has been reported in patients receiving 15,000 to 20,000 units daily for more than 6 months.

Based on these data, most authors recommend systemic heparinization during the critical weeks 6 to 12 of gestation and in the last 2 weeks of pregnancy to allow rapid reversal for delivery. A dosage of 10,000 units twice per day subcutaneously is the recommended treatment. Activated partial thromboplastin time should be measured 6 hours after administration of heparin and should be 1.5 to 2.0 times control. Warfarin can be administered during the remainder of gestation with little risk of embryopathy.

PREGNANCY IN WOMEN WITH VALVE PROSTHESES

Cardiologists are often asked to evaluate and manage the condition of patients with prosthetic heart valves during pregnancy or to advise young women on the selection of an appropriate artificial valve, designed to maximize the potential for a future successful and uncomplicated pregnancy. However, limited data are available to assist in these tasks (*e*Table 32.5.3).

***e*TABLE 32.5.3** STUDIES OF THE USE OF VALVE PROSTHESES IN PREGNANT uwomen

				Thromboembolic complications, %		
Reference	Type of prosthesis	Pregnancies, no.	Live births, %	Valve thrombi	Emboli	Valve degeneration, %
Hanania et al. (55)	Mechanical	95	53	11	9	0
Sbarouni et al. (56)	Mechanical	151	73	9	5	0
Born et al. (57)	Mechanical	35	63	8	3	0
Hanania et al. (55)	Bioprosthesis	60	80	0	0	18
Sbarouni et al. (56)	Bioprosthesis	63	83	0	0	35
Born et al. (57)	Bioprosthesis	25	100	0	5	16

Note: Valve-related risk factors during pregnancy. Both thromboembolic and valve degeneration problems may appear.

Hanania and associates (55) reported a French cooperative study involving 155 pregnancies in 103 women with 182 prosthetic heart valves. Of the 108 pregnant patients with mechanical prostheses, thromboembolic events occurred in 16 patients (14.8%), and 12 of the 16 patients were undergoing subcutaneous heparin treatment. The thromboembolic risk was higher for patients who had undergone mechanical mitral valve replacement (21%) than for those who had undergone mechanical aortic (4.5%) valve replacement. Of the 16 patients who experienced thromboembolic complications, ten were associated with mechanical valves, again affecting mitral (11%) more frequently than aortic (4.5%) prostheses. Four patients with valve thrombosis died, three required cardiovascular surgery, and the remainder were treated with fibrinolytic therapy or heparin. Only 53% of patients with mechanical prostheses delivered healthy fetuses. Eighty percent of patients with bioprostheses had normal deliveries, and the birth weight was significantly higher than in the mechanical prosthesis group. However, 16.7% (13 of 74) of bioprosthesis valves degenerated during pregnancy, an average of 5.9 years (2.5 to 8.0 years) from the time of initial implantation. The risk of premature valve failure attributed to pregnancy was estimated to be 5%. These authors recommended systemic warfarinization, except during the final 2 weeks of pregnancy and during weeks 6 to 12 of gestation, when heparin therapy was thought to be advantageous, to avoid warfarin embryopathy.

Sbarouni and Oakley (56) reported on the outcome of 214 pregnancies in 178 women with prosthetic heart valves who were seen in major European centers. Of these patients, 133 women with mechanical valves sustained 151 pregnancies, and 45 women with bioprostheses had 63 pregnancies. Only 17% of the patients with bioprostheses were receiving anticoagulation therapy, as opposed to all but one patient with mechanical prostheses (one patient with an aortic valve refused anticoagulation therapy). Including spontaneous and therapeutic abortions, 73% of pregnancies in patients with mechanical prostheses and 83% of pregnancies in patients with bioprostheses resulted in healthy babies, born either at full term or prematurely, who ultimately did well. Between the mechanical prostheses and bioprostheses groups, stillbirths (7% vs. 4%) and spontaneous abortions (12% vs. 10%) did not differ significantly. One woman refused anticoagulation therapy and experienced an aortic valve thrombosis. Five additional maternal deaths occurred in the mechanical prosthesis group; four were related to valve thrombosis, and one was related to a fatal cardiovascular embolism. Nine other pregnancies in women with mechanical prostheses were complicated by nonfatal valve thrombosis; five patients required emergency valve replacement, and the conditions of four patients were managed medically. Notably, 10 of the 13 patients with valve thromboses were receiving heparin for systemic anticoagulation, two were receiving warfarin, and one received no anticoagulation therapy. Additionally, 12 of 13 thrombosed valves were in the mitral position. Of seven patients who had major bleeding complications (defined as complications requiring two units of blood for transfusion), five patients were being treated with heparin. In total, complications occurred in 48% of the 34 pregnancies in 29 women who were treated with heparin anticoagulation therapy: valve thrombosis occurred in 24%, bleeding in 12%, and systemic embolic events in 12%. Of the 49 bioprosthetic valves, 17 (35%) deteriorated markedly during or shortly after pregnancy, requiring two emergency valve replacements during pregnancy and 13 electively after delivery. These authors speculated that the increased calcium turnover associated with pregnancy may accelerate bioprosthesis deterioration and wrote that "because of accelerated valve degeneration and the need for early re-operation, bioprostheses should not be recommended to young women who intend to become pregnant" (56).

The outcome of pregnancy in the European study was best for mothers who had prosthetic heart valves and were given heparin for the first trimester, followed by warfarin until delivery. Because pregnancy is a hypercoagulable state, and because of the frequent thrombotic complications of heparin, its use cannot be recommended throughout pregnancy.

Born and associates (57) reported a Brazilian study involving 60 consecutive pregnancies in 49 patients with prosthetic heart valves who were prospectively evaluated. These authors confirm the high risk of valve thrombosis (3 of 35 patients) and cerebral embolism (1 of 35 patients) among patients who have mechanical prostheses and the increased risk of valve degeneration (4 of 25 patients) among those with bioprostheses. In total, four women with artificial heart prostheses died during gestation. Additionally, these authors emphasized the increased incidence of low birth weight and prematurity in infants of mothers receiving warfarin anticoagulation. Mothers with class III or IV congestive heart failure at the time of pregnancy had a 16% rate of spontaneous abortion, 22% rate of prematurity, and 28% risk of bearing low-birth-weight infants. Five of 45 neonatal deaths and four of 45 birth defects occurred in this group of patients. These data clearly demonstrate the fetal and neonatal risks of attempted pregnancy in mothers who have poorly controlled congestive heart failure and valvular prostheses.

Chan and coworkers (58) performed a literature review that compared the use of oral anticoagulation therapy throughout pregnancy, the use of oral anticoagulation therapy throughout pregnancy with the exception of administration of heparin in the first trimester (weeks 6 to 12), and administration of heparin throughout the pregnancy in patients with heart valve replacements. Oral anticoagulation resulted in an embryopathy incidence of 6.4% but the lowest risk of valve thrombosis (3.9%). Heparin administration eliminated the risk of embryopathy but increased the risk of valve thrombosis to 9.2%. The risk of fetal wastage was similar with all approaches, and overall maternal mortality was 2.9%. Use of low-molecular-weight heparin has been limited but does not, even in this small experience, protect against valve thrombosis (59). The use of homographs and newer pericardial prostheses may lower the risk of complications and valve degeneration during pregnancy and delivery (60,61). Finally, percutaneous mitral valvuloplasty is a successful mechanism for relieving critical mitral stenosis in the pregnant patient who would otherwise be unable to complete the pregnancy because of congestive heart failure or arrhythmias (62).

Recently, Vongpatanasin and colleagues (63) recommended that administration of warfarin be discontinued in patients attempting pregnancy and that administration of subcutaneous heparin be substituted, twice per day at a dose that prolongs the activated partial thromboplastin time by more than two times control 6 hours after administration. After week 12 of gestation, warfarin can be safely substituted until "the middle of the third trimester, after which warfarin should be discontinued and heparin resumed until delivery."

In summary, (a) pregnancy in a woman with an artificial valve prosthesis poses significant risks to the mother and fetus; (b) pregnancy is a hypercoagulable state, and valve thrombosis or thromboembolic complications are not rare, particularly in women with mechanical prostheses and especially in women with mitral valve replacement; (c) bioprostheses may degenerate in an accelerated fashion during or shortly after delivery; (d) maternal and fetal risks are increased by the presence of advanced congestive heart failure, and pregnancy is inadvisable for women with artificial heart valves and symptoms of significant heart failure; and (e) heparin cannot be recommended for use as the sole anticoagulating agent during pregnancy and should be combined with warfarin after week 12 of gestation for women with mechanical heart prostheses who require anticoagulation therapy.

CARDIOPULMONARY BYPASS DURING PREGNANCY

Severe native or prosthetic valvular heart disease and, rarely, symptomatic coronary atherosclerosis may require cardiac surgical intervention in pregnant women. A mortality rate as high as 20% may be seen among pregnant patients with native valvular heart disease and class III to IV congestive heart failure (64). Although balloon commissurotomy of mitral stenosis or percutaneous transluminal coronary angioplasty of coronary atherosclerosis may be beneficial for pregnant women who have appropriate mitral or coronary anatomy, most other valve and coronary disease patients require more than medical treatment and should undergo cardiopulmonary bypass.

Pomini and associates (65) examined 59 reports of cardiac surgery performed with the aid of cardiopulmonary bypass from 1958 through 1992. Cardiopulmonary bypass may compromise the placenta and fetus as a result of hypothermia, decreased arterial perfusion, and alterations in coagulation as well as acid-base balance. The reported fetal and maternal mortality rates were, respectively, 2.9% and 20.2% overall, but 0% and 12%, respectively, for the 40 most recently reported subjects (1975–1991). Hypothermia alters placental oxygen exchange and has been demonstrated to initiate uterine contractions. Embryo fetal mortality associated with hypothermic cardiopulmonary bypass was 24%, and mortality associated with normothermic perfusion was 0. Increased rates of pump flow diminished evidence of fetal cardiac distress, and higher-volume cardiopulmonary bypass flow is recommended, with the appropriate fetal monitoring to ensure adequacy. Therefore, normothermic bypass at high-flow volumes is recommended.

Additionally, it is recommended that patients whose pregnancies are past 20 weeks' gestation be positioned in the left lateral decubitus position during surgery to ensure that the uterus does not obstruct venous return as a result of direct inferior vena cava compression. Hyperkalemic arrest solutions may reach the fetal circulation and should be avoided, if possible. Finally, the duration of cardiopulmonary bypass should be minimized, and the operating room must be prepared for emergency cesarean section (65).

In summary, cardiopulmonary bypass may be necessary during pregnancy. To avoid maternal and particularly fetal complications, cardiopulmonary support should be high flow, normothermic, and initiated without hyperkalemic arrest. Surgery should be performed with the patient in the left lateral decubitus position if the pregnancy is past 20 weeks' gestation, and the operating room must be prepared for a potential emergency cesarean delivery.

MYOCARDIAL INFARCTION ASSOCIATED WITH PREGNANCY

Symptomatic coronary artery disease and myocardial infarction occur infrequently during pregnancy (66,67). Nevertheless, because pregnant patients may display spontaneous coronary artery dissection, and because the population of women attempting pregnancy is progressively older, cardiologists must be familiar with this potential problem.

The estimated incidence of myocardial infarction in pregnancy is 0.01%; 125 documented cases were reported in 1996 by Roth and Elkayam (68). The incidence is higher in multigravida, older (>33 years) women (68). The maternal mortality rate is 21%, and the highest rates are reported closer to delivery. Assuming that the patient does not have a hypercoagulable state (such as the antiphospholipid syndrome), Kawasaki disease, or congenital coronary abnormalities and does not use cocaine, the most likely etiologies for myocardial infarction in pregnancy are coronary artery vasospasm (29%), fixed coronary artery disease (43%), coronary dissection (16%), and thrombosis (21%).

Management of an acute myocardial infarction during pregnancy is complicated. Little experience with thrombolytic therapy is available (68); maternal hemorrhage is likely. Aspirin, beta-blockers, and nitrates can be used with caution (69). Although it is of questionable benefit in standard myocardial infarction management, nifedipine may relieve coronary spasm and decrease uterine contractility. Magnesium may decrease myocardial damage and avoid hypertension and uterus hypercontractility. High-dose aspirin may prematurely close the ductus arteriosus, beta-blockers may cause fetal growth retardation and bradycardia, calcium channel blockers (such as verapamil) may cause excessive depression of cardiac function, and diltiazem may be teratogenic (68). Coronary angioplasty has been performed during pregnancy; however, no reports of primary angioplasty for acute myocardial infarction are available (70).

Only 13 cases of postpartum coronary artery dissection were reported until 1994 (71,72 and 73). This represents approximately one-third of the experience with spontaneous coronary artery dissection in women, which may occur up to 120 days after delivery. One, two, or all three major epicardial vessels may be dissected at the time of presentation (74). It is believed that the neurohormonal milieu predisposes the coronary artery tree to mechanical degeneration and vasospasm, which contribute to the artery disruption. There is no accepted form of treatment, although controlling blood pressure and preventing coronary vasospasm seem most appropriate; surgery should be avoided.

Patients who have vasospasm but no fixed coronary artery disease can now be managed successfully with use of nitrates, calcium channel blocking agents, or other therapies directed at reversal of the increased coronary vasoreactivity. Adequate levels of blood pressure must be maintained to ensure placental perfusion, and attention must be directed at ensuring that medical management does not jeopardize fetal growth. Radiographic or scintigraphic investigation should be avoided until after the first trimester, unless it is absolutely necessary. Stress echocardiography or dobutamine echocardiography may be substituted to detect coronary artery disease in the pregnant patient.

The condition of patients with fixed coronary artery disease or prior myocardial infarction who are undergoing pregnancy can usually be managed with medical therapy. Pombar and coworkers (75) reported the cases of 19 women who experienced myocardial infarction before pregnancy and underwent successful completion of gestation without maternal loss and with good fetal outcome. Three patients who had undergone bypass survived subsequent pregnancy and delivery without apparent compromise. Clearly, however, patients with known coronary artery disease should be advised against pregnancy. If these patients do become pregnant, their condition must be managed carefully to adjust for the anticipated increased cardiovascular demands of gestation.

In summary, cardiologists must be aware of the potential for fixed or vasospastic coronary artery disease during pregnancy, as well as the risks of spontaneous coronary artery dissection.

PREGNANCY IN WOMEN WITH CONGENITAL OR ACQUIRED CARDIAC DISEASE

Women who have congenital or acquired cardiac disease with or without surgical correction should approach an obstetrician and a cardiologist for assistance in management of their condition during pregnancy. Siu and colleagues (76) examined prospectively the maternal and neonatal risks associated with pregnancy in

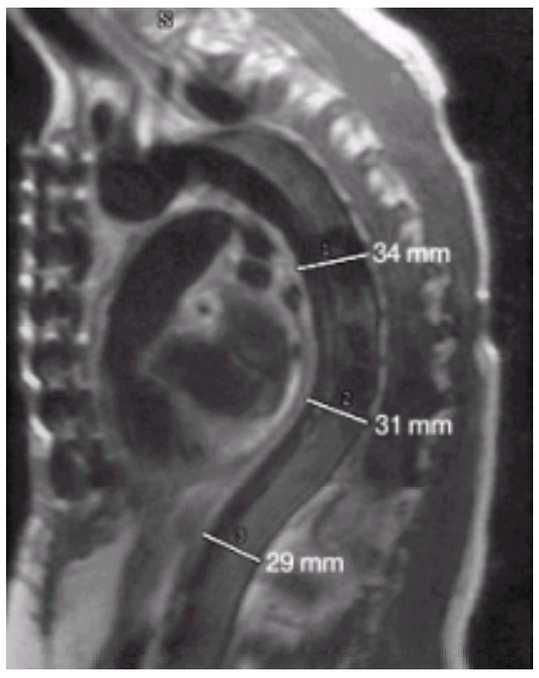
women with known heart disease. Investigators at 13 Canadian cardiac and obstetric hospitals enrolled 562 consecutive patients and determined outcome in 599 pregnancies. Maternal cardiac complications (pulmonary edema, arrhythmia, stroke, or cardiac death) complicated 13% of pregnancies and were predicted by prior cardiac events or arrhythmia, poor functional class or cyanosis, left heart obstruction, and left ventricular systolic function. Patients experienced a 4%, 31%, or 68% risk of primary or secondary cardiac events with 0, 1, and more than 1 predictors. Neonatal complications occurred in 20% of pregnancies and were associated with poor functional class or cyanosis, left heart obstruction, anticoagulation, smoking, and multiple gestations. At the Royal Infirmary of Edenberg University, 50 years of experiences were reviewed; a decreasing incidence of rheumatic heart disease in pregnant women was seen (94% from 1928 through 1947 and 36% from 1968 through 1977). In the same time interval, the incidence of pregnant women presenting with congenital heart disease increased from 3.6% to 70.0% (77). Wooley and Sparks (78) summarized five clinical studies published between 1963 and 1977 that included a total of 490 patients who had congenital heart disease and were undergoing pregnancy, and reported a maternal mortality of 0.53% and a fetal mortality of 18.90%. Certain congenital defects were considered to place patients at a higher risk by these authors, including Eisenmenger's complex, pulmonary hypertension, and cyanotic cardiac defects. Aortopathy associated with Marfan syndrome and coarctation increased risks. Perloff (79) identified potential residual changes after congenital surgical correction that increased concern about maternal and fetal outcomes, including (a) residual elevation of pulmonary vascular resistance, (b) residual aortic stenosis or regurgitation, (c) persistent right or left ventricular dysfunction, (d) aortopathy after aorta or aortic valve repair or replacement, (e) uncertain capability of prosthetic material, and (f) cleft mitral valve residual defects after endocardial cushion repair (eTable 32.5.4).

***e*TABLE 32.5.4** AREAS OF POTENTIAL CONCERN FOR PATIENTS WITH "CORRECTED" CONGENITAL HEART DISEASE WHO ARE CONTEMPLATING PREGNANCY
Residual elevation of pulmonary vascular resistance
Persistent ventricular dysfunction
Residual valvular insufficiency
Prosthetic devices or material
Aortopathy

During pregnancy, Eisenmenger's complex is associated with a maternal death rate of approximately 40%. Coarctation of the aorta, even after repair, may still be associated with aortic valve disease, thoracic aortopathy, adverse affects of long-standing hypertension, and potential aneurysms of the circle of Willis, which may further complicate pregnancy.

Aortic dissection may occur in pregnancy, particularly during the third trimester or the early postpartum interval. Marfan syndrome is associated with increased risks of aortic dissection (eFig. 32.5.2). Pyeritz (80), at The Johns Hopkins Hospital, reviewed this subject, including a retrospective medical literature analysis of 32 patients with Marfan syndrome who were undergoing pregnancy and the course of 26 pregnant patients with Marfan syndrome at The Johns Hopkins Genetics Clinic. Among the retrospective group, one-half of the women died during or shortly after pregnancy; only one of 26 expired in the Genetics Clinic series. Pyeritz recommended that patients with Marfan syndrome and mitral regurgitation who have any degree of left ventricular decompensation and patients with aortic regurgitation or aortic root dilatation greater than 40 mm be advised against pregnancy because of the high risk. Pregnancy appears to predispose other patients with connective tissue disorders to aortic rupture.

***e*FIGURE 32.5.2** Aortic dissection in patient with Marfan syndrome. Massive dissection of the ascending aorta.



Magnetic resonance scan of the thoracic aorta in Marfan syndrome. There is dilation of the descending aorta with an average diameter of approximately 3 cm.

VIDEO

Video 32.3 Aortic insufficiency associated with annuloaortic ectasia of aortic root (oblique-coronal). An "onion-bulb" dilatation of the proximal ascending aorta and the sinuses of Valsalva is observed. A signal-void jet of aortic insufficiency is seen extending from the aortic valve into the left ventricular cavity during diastole. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

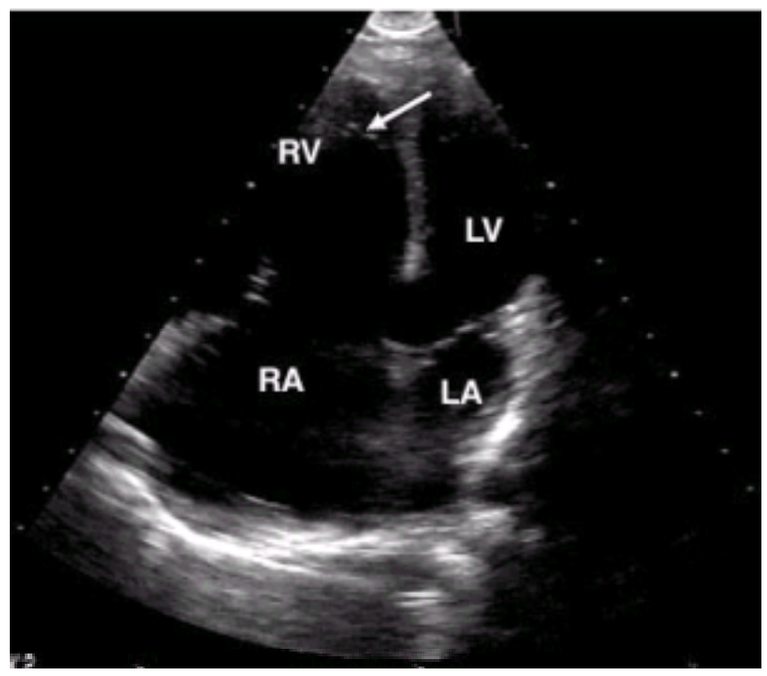
With regard to inheritable myocardial disorders, patients with hypertrophic cardiomyopathy usually fare well, although one sudden death has been reported at 28 weeks' gestation (81). The enhanced volume load associated with pregnancy decreases the symptoms of outflow obstruction and is well tolerated unless myocardial fibrosis has developed, with resultant altered myocardial compliance and high filling pressures. Postpartum blood loss and myocardial hypercontractility of pregnancy may exacerbate the dynamic obstructive characteristics of this disorder, and careful attention must be paid to preload, particularly in the peripartum interval. Oakley and associates (82) reviewed 54 pregnancies in 23 patients with hypertrophic cardiomyopathy; no mother or infant died in the prenatal period. Beta-blockers, diuretics, or both were used as needed for symptoms. Tang and associates (83) reported the outcomes of 37 pregnancies in women who had mitral valve prolapse. No cardiac complications occurred, and only three cesarean deliveries were required for obstetrical complications. There was no maternal mortality, and no congenital defects were noted in the offspring. Pregnant women with these two common inheritable syndromes have relatively good prognoses.

VIDEO

Video 32.4 Aortic dissection (left anterior oblique). Type A dissection of the aorta is manifested on the cine image loop by a mobile intimal flap extending from the mid-ascending aorta to the descending thoracic aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

A number of authors have evaluated specific congenital disorders. Presbitero and coworkers (84) reviewed 96 pregnancies in 44 patients with cyanotic congenital heart disease (excluding Eisenmenger's complex). Maternal cardiovascular complications occurred in 32%, with one death; only 43% of pregnancies resulted in live births. Univariate analysis suggested that maternal disease, hemoglobin, and prenatal oxygen saturation were helpful in discriminating patients who were likely to experience difficulties during pregnancy. Multivariate analysis showed that the prenatal maternal arterial oxygen saturation was the strongest predictor of a live birth.

Connolly and Warnes (85) analyzed the cases of 44 women with Ebstein's anomaly who had 111 pregnancies. Eighteen of these patients experienced cyanosis. No serious pregnancy-related maternal complications were seen, but only 76% of gestations resulted in a live birth, and 23 of 111 deliveries were premature. Patients who have residual atrial septal defects or patent foramen ovale must be monitored for venous thrombosis to avoid paradoxic embolism to the arterial circuit.



Ebstein's anomaly of the tricuspid valve. Note marked apical displacement of the tricuspid leaflets, especially the septal leaflet. The arrow designates the septal leaflet of the tricuspid valve.

Clarkson and associates (86) describe the cases of 23 late survivors of the Mustard operation for transposition of the great arteries. Nine women experienced 15 pregnancies and were asymptomatic before and after the pregnancies. Among these 15 pregnancies, 12 live births, two spontaneous abortions, and one intrauterine death occurred. The greatest risks were right ventricular (systemic ventricle) volume overload or failure, atrial arrhythmias, or both. Patients who are compensated despite corrective congenital heart disease usually fare well during the cardiac challenge presented by pregnancy.

Connolly and coauthors (87) reported the outcomes of pregnancy in 22 patients who had congenitally corrected transposition of the great arteries. Among 60 pregnancies, 50 (83%) resulted in live births, and one patient sustained 12 pregnancies despite toxemia, congestive heart failure, myocardial infarction, and subacute bacterial endocarditis. Another patient required valve replacement for mitral regurgitation and congestive heart failure. Therefore, maternal morbidity is potentially increased for pregnant women who have corrected transposition.

Lao and associates (88) reviewed 25 pregnancies in 13 patients with congenital aortic stenosis and 106 pregnancies in 65 patients (inclusive of their patients) from 11 series in the medical literature with this disorder. In the entire series, a maternal mortality rate of 7 (11%) of 65 patients, 24 therapeutic or spontaneous abortions (23%) of 106 pregnancies, and a perinatal mortality of 3 (4%) of 8 were seen. The risk of fetal congenital heart disease is 5% to 26% in this group, and performance of fetal echocardiography at 20 weeks' gestation to evaluate its presence is justified. An associated coarctation of the aorta was found in 31% of the original 13 patients and may be associated with a high risk of aortic or cerebral vascular complications.

Among patients with rheumatic heart disease, those with mitral stenosis are likely to become symptomatic during the increased volume load and heart rate of pregnancy. There is evidence that management with beta-receptor blocking agents may control heart rate and result in symptomatic improvement and successful term delivery in most patients (89).

Patients with congenital or heritable disorders may attempt pregnancy. The patients at highest risk are those who have residual pulmonary hypertension, right or left ventricular dysfunction, aortopathy, or persistent valvular or intracardiac chamber communication with cyanosis. The potential for miscarriage or premature birth is high, and the potential for fetal congenital heart or vascular disease is increased. A comprehensive noninvasive structural and functional analysis by history, physical examination, and Doppler echocardiography, with or without exercise or dobutamine, should be performed for all women with congenital or heritable cardiovascular disorders who wish to become pregnant to determine their suitability to undergo this challenge.

CARDIOVASCULAR COMPLICATIONS OF TOCOLYTIC THERAPY

Tocolytic agents decrease uterine contractility and are used to prolong gestation, usually beyond week 34, to allow fetal lung maturation. These agents are used in up to 5% of all pregnancies. Drugs used include b-sympathetic agents such as terbutaline, isoxsuprine, ritodrine, salbutamol, and, recently, nifedipine (90). Physiologic effects from this class of agents include tachycardia and antidiuresis. In one study, as many as 4.4% of the female patients exposed to tocolytic drugs developed pulmonary edema (72). The peculiar nature of this life-threatening complication must be understood by the cardiologist for him or her to assist the obstetrician in intelligent management.

Pisani and Rosenow (91) reviewed 22 years of medical literature to report on 58 cases. Thirty-six percent of affected women were primigravida. The most commonly used agent was terbutaline (41%), followed by isoxsuprine (33%), ritodrine (17%), and salbutamol (10%). Corticosteroids were used in two-thirds of the patients to accelerate fetal lung maturation. The average duration of treatment was 54 hours, but the syndrome can appear after less than 24 hours' exposure, and in a few cases, symptoms began after drug discontinuation, although never more than 12 hours after administration of the drug was stopped. Patients complained of dyspnea (76%), chest pain (24%), and cough (17%). Affected women sometimes had fever (temperature higher than 38°C; 14%), were rarely hypotensive, and uniformly had pulmonary rales. Chest x-rays showed bilateral pulmonary infiltrates (81%) and rarely showed effusion. The mean P_{O_2} was only 50 mm Hg in patients in whom it was measured. Echocardiography revealed normal left ventricular function in only seven patients. Right heart catheterization demonstrated elevated filling pressures in only two of nine cases, and the cardiac index was greater than 61 minutes per m^2, on average.

Treatment includes discontinuation of tocolytic therapy and administration of supplemental oxygen and intravenous diuretics. Response is usually gratifying and rapid, within 12 hours. Maternal and fetal mortality is rare, unless the woman's condition is complicated by sepsis or full-blown acute respiratory distress syndrome. The etiology of tocolytic pulmonary edema remains unknown but does not appear to be related to myocardial failure and associated pulmonary congestion.

Other entities that may present similarly include peripartum cardiomyopathy, pulmonary embolism, aspiration with acute respiratory distress syndrome, pneumomediastinum, and amniotic fluid embolization. Amniotic fluid embolization, although rare (incidence of one in 8,000 to one in 80,000 deliveries), is associated with cardiovascular collapse, respiratory distress, disseminated intravascular coagulopathy, and coma and is rapidly fatal in more than 80% of patients (92).

The risks for development of tocolytic therapy pulmonary edema appear to be related in part to the dose, the number of agents used, and the form of delivery (intravenous vs. subcutaneous). Perry and colleagues (93) studied 8,709 women who were given continuous subcutaneous infusions of terbutaline to arrest preterm labor. Patients were followed daily in the hospital or at home. Pulmonary edema developed in only 0.32% (28 of 8,709 patients). Of the 28 patients affected, 17 were receiving one to three tocolytic agents and aggressive intravenous hydration. It appears that tocolytic therapy can be administered relatively safely; however, patients

receiving certain dosages, multiple drug infusions, and supplemental intravenous hydration must be watched carefully.

ARRHYTHMIAS IN PREGNANT WOMEN

Page (94), Cox and Gardner (26), and Rutherford (95) have recently reviewed the treatment of arrhythmias during pregnancy. The hemodynamic stress of pregnancy may exacerbate arrhythmias, and treatment of rhythm disorders poses a risk to the mother as well as to the fetus (96).

Pregnancy significantly alters drug absorption and metabolism as a result of (a) altered gastrointestinal motility, (b) expanded plasma volume, (c) decreased plasma protein, (d) progesterone-induced alterations of hepatic metabolism, and (e) increased renal blood flow. Therefore, frequent measurement of drug levels may be necessary. The teratogenic risk of drug exposure is greatest in the first trimester of pregnancy; use of drugs should be avoided during this time if possible.

*e*Table 32.5.5 lists commonly used antiarrhythmic agents and their adverse effects, teratogenic risks, presence in breast milk, and overall risks. In the Vaughan-Williams classification of antiarrhythmic agents, among the class I agents, the longest experience is with procainamide, quinidine, and lidocaine, and these are at least as safe for use in pregnant women as in the nonpregnant population. Although the pregnant patient is usually younger, with less organic heart disease, it must be assumed that the disappointing results of antiarrhythmic drug trials extend to this population. Little is known about flecainide and propafenone in pregnancy, and dilantin is contraindicated because of its high risk for birth defects.

***e*TABLE 32.5.5** PHARMACODYNAMICS AND ADVERSE EFFECTS OF CARDIOVASCULAR DRUGS IN PREGNANCY

Drug	Classification (Vaughan-Williams)	Therapeutic concentration, mg/mL	Protein binding, %	Fetal/maternal ratio	Breast milk/plasma ratio	FDA pregnancy category	Adverse effects
Digoxin		0.5–2.0 ng/mL	20–25	~1	0.6–0.9	C	Low birth weight
Adenosine		NA	NA	ND	ND	C	None
Quinidine	1A	3–6 µg/mL	70–80	0.24–1.40	0.71	C	Low platelet levels
Procainamide	1A	4–8 µg/mL	15–20	0.28–132	~1	C	None
Disopyramide	1A	2–4 µg/mL	35–90	0.39	0.9	C	Uterine contraction
Lidocaine	1B	1.5–5.0 µg/mL	60–80	0.5–0.6	~1	B	Cardiovascular system side effects
Mexiletine	1B	0.5–2.0 µg/mL	60–75	1.0	0.78–1.89	C	Decreased heart rate, low birth weight, low APGAR score
Tocainide	1B	4–10 µg/mL	10–15	ND	ND	C	ND
Phenytoin	1B	10–20 µg/mL	90	0.65–1.00	0.12–0.45	C	Mental and growth retardation
Flecainide	1C	<0.2–1.0 µg/mL	40	0.70–0.83	1.57–2.18	C	None
Encainide	1C	0.5–1.0 µg/mL	75–85	ND	ND	B	None
Propafenone	1C	0.2–3.0 µg/mL	~95	0.14–0.20	0.14–0.20	C	None
Beta-blockers	2	Variable	Variable	Variable	Variable	C	Possible low heart rate, hypoglycemia
Amiodarone	3	1.0–2.5 µg/mL	96	0.09–0.14	2.25–9.00	C	Low thyroid, growth retardation, premature birth
Sotalol	3	ND	ND	ND	ND	B	Beta-blocker effect
Bretylium	3	0.5–1.0 µg/mL	0–8	ND	ND	—	ND
Verapamil	4	15–30 ng/mL	90	0.17–0.40	0.23–0.94	C	Heart block, hypotension
Diltiazem	4	50–300 ng/mL	80–90	ND	ND	C	Teratogenic?
Furosemide		NA	NA	Placental transfer		C	Low Na^+, K^+, glucose levels
Heparin		NA	NA	No placental transfer		C	Abortion
Coumadin		NA	NA	Placental transfer		D	Abortion hemorrhage

APGAR, activity, pulse, grimace, appearance, respiration; FDA, U.S. Food and Drug Administration; NA, not applicable; ND, not determined.
From Rutherford JD. Management of cardiovascular disease during pregnancy. In: Smith TW, ed. Cardiovascular therapeutics. Philadelphia: WB Saunders, 1996:695–701; and Cox JL, Gardner MJ. Treatment of cardiac arrhythmias during pregnancy. *Prog Cardiovasc Dis* 1993;36:137–178.

Class II Vaughan-Williams agents, the beta-blocking drugs, may cause growth retardation, fetal bradycardia, hypoglycemia, and elevated bilirubin. Beta-1 selective agents have been recommended; they appear to alter vasodilatation and uterine contraction less than nonselective beta-blocking drugs.

Among the class III Vaughan-Williams agents, sotalol is associated with fewer potential long-term fetal and maternal complications, including thyroid deficiency, than amiodarone. None of the agents in this category should be used for treatment of pregnant women, except in the case of severe, life-threatening rhythm disorders.

Class IV agents, the calcium channel blocking agents, may cause hypotension, maternal and fetal bradycardia, and decreased uterine contractility and are used infrequently in pregnancy.

Digoxin is relatively safe in pregnancy, but avoidance of toxicity is important. Adenosine may cause the expected short-term flushing, chest pain, and dyspnea as a result of peripheral and coronary vasodilatation but is effective in terminating supraventricular tachycardia in pregnant women (97).

Nonpharmacologic methods of arrhythmia management may be used, including endocardial pacing and direct current electrocardioversion, without significantly increased risk. Ablation therapy of arrhythmias is best delayed until after pregnancy unless the supraventricular or ventricular tachycardia is incessant and not adequately suppressed by medical management.

Ventricular tachycardia may appear in pregnant women who do not have structural heart disease. Brodsky and associates (98) reviewed reports of 26 patients with ventricular tachycardia during pregnancy, 22 of whom had no apparent ventricular dysfunction or known cardiac disease. Stress and physical exercise exacerbated arrhythmias in 15 patients, anterior myocardial infarction in two, QT prolongation in two, and hypokalemia or mitral regurgitation in one each. Antiarrhythmic agents, including beta-blockers (in 12 patients), class I agents (in 16 patients), and amiodarone (in one patient), were used, and only two maternal deaths were reported. It is presumed that the cardiovascular alterations and enhanced sympathetic tone associated with pregnancy may stimulate repetitive monomorphic ventricular tachycardia or idiopathic left ventricular tachycardia. Diagnosis of early peripartum cardiomyopathy should be considered for patients who develop ventricular tachycardia in the last month or within 5 months of delivery and present with new ventricular arrhythmias.

Wide complex tachycardia. Atrioventricular dissociation confirms ventricular origin.

Arrhythmias that appear during pregnancy may be the result of exacerbation of preexisting, underlying cardiovascular disease or stimulation of de novo arrhythmia as a result of the cardiovascular stress of the condition and the increased sympathetic tone or sensitivity, rather than of organic heart disease. Because of the potential risk to the fetus and mother, use of antiarrhythmic therapy must be carefully weighed, and care must be exercised in the selection of an antiarrhythmic agent.

MATERNAL RISK AND ASSOCIATED FETAL ABNORMALITIES

Cardiologists must be aware of some of the potential dangers of fetal birth defects associated with maternal consumption of toxins. Any medication is most likely to cause fetal malformation if exposure occurs during the first trimester, when embryogenesis and fetal formation are occurring. Cardiac medication risks have already been reviewed.

Physicians should be aware of the potential harm of exposure to the common agents alcohol, aspirin, and drinking water. It has been commonly held that excessive alcohol consumption during pregnancy results in congenital defects stemming from the cranial neural crest cell population, resulting in malformations of the ear, face, neck, and upper heart (ventricular septal defect, transposition of the great vessels, tetralogy of Fallot, truncus arteriosus, and pulmonic stenosis). Werler and associates (99) compared 1,464 infants with these abnormalities to 1,427 infants with other fetal abnormalities using the case-control method and demonstrated a higher-than-predicted risk of cleft lip with or without cleft palate in association with the mother's consumption of five or more alcoholic drinks per day. Aspirin had similarly been thought to increase the risk of certain congenital defects that affect the heart. Werler and coworkers (100) evaluated first-trimester aspirin use by 2,646 mothers whose infants had any structural cardiac defect compared with that in a control group of 6,966 mothers whose infants had other malformations. Interestingly, the prevalence of aspirin use was the same among those with congenital cardiac defects and control subjects. The authors concluded that "aspirin use during the first trimester of pregnancy does not increase the risk of congenital heart defects in relation to that of other structural malformations."

Finally, Goldberg and colleagues (101) reported on the association between congenital cardiac malformations and drinking water contaminants. In an informal survey in 1973, it was noted that a large proportion of the population with congenital heart disease in Arizona lived in the Tucson Valley area. Well water contaminated with trichloroethylene was documented nearby. Using a case registry and a random dialing technique, the authors demonstrated an odds ratio of 3 for congenital heart disease for children of parents who had contact with an area with contaminated water. Therefore, although our focus has been on protecting infants and mothers from medication exposure risks, over which we have some control, it is clear that other contaminants of daily living or over-the-counter medications may influence fetal structural and cardiac abnormalities.

ANTIPHOSPHOLIPID SYNDROME

The antiphospholipid syndrome should be suspected in mothers with arterial or venous thrombosis, thrombocytopenia, neurologic disease, or recurrent abortion. Fetal loss is associated with thrombosis of the uteroplacental vasculature. Antiphospholipid antibodies recognize a plasma cofactor on the trophoblast and/or endothelial cell surface that produces a procoagulant state (102). Women with systemic lupus erythematosus who have the lupus anticoagulant or antiphospholipid antibodies have a greater than 60% chance of pregnancy loss, compared with a 15% loss among women with systemic lupus erythematosus who do not have these antibodies. It is believed that the antiphospholipid antibody results in placental infarction or thromboses, with subsequent pregnancy loss.

Silveria and coauthors (103) treated 11 consecutive patients who had positive anticardiolipin (antiphospholipid) assays and had experienced at least one pregnancy loss with prednisone and aspirin. This resulted in an improved live birth rate, from 15.6% before treatment to 100% after treatment, without significant adverse effects to the mother or fetus. Heparin, low-dose aspirin, and intravenous immunoglobulin have been proposed as treatment options for the antiphospholipid syndrome. In a prospective, double-blind, placebo-controlled trial involving only 50 patients who had antiphospholipid antibodies and three or more fetal losses, 75 mg per day of aspirin had no influence on the live birth rate compared with placebo (80% vs. 85%, respectively) (104). Similarly, Branch and colleagues (105) found no difference in maternal or fetal outcomes when intravenous immunoglobulin was added to a regimen including aspirin and heparin for patients who had antiphospholipid antibodies. Interruption of the anticardiolipin cycle of thrombosis may be important, because patients with this syndrome may develop ventricular diastolic dysfunction over the course of time (106).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Peripartum cardiomyopathy remains a controversial area in the management of the pregnant or peripartum patient. Some authors have inappropriately reported patients in their series who showed evidence of congestive heart failure and cardiomyopathy earlier than the last month of pregnancy or later than 5 months after delivery. Inclusion of patients outside these parameters has tainted some of the data concerning the incidence of myocarditis, response to immunosuppressive agents, and outcome of individuals with this disorder. Not all authors agree that peripartum cardiomyopathy is associated with myocardial inflammation. Even those who believe that myocarditis is a component of peripartum cardiomyopathy have failed to recognize inflammation in all patients who underwent endomyocardial biopsy. Therefore, the etiology of the syndrome remains unknown. Assuming that the condition is associated with myocardial inflammation, the antigen to which the immune response is directed remains unknown. Even more controversial is the potential use of immunosuppressive agents. No prospective randomized trial involving patients with peripartum cardiomyopathy has been carried out on treatment with immunosuppressive therapy of patients with myocarditis proven by endomyocardial biopsy. It is also evident that in a high proportion of patients, peripartum cardiomyopathy, with or without myocarditis, resolves spontaneously. We have, therefore, taken the stance that once peripartum cardiomyopathy is recognized, patients should be treated with standard heart failure therapy for 2 weeks. If clear echocardiographic evidence of improvement in the myopathic state is seen, patients need not undergo endomyocardial biopsy. If the myopathic state does not improve or deteriorates, the patients undergo endomyocardial biopsy, and those with myocarditis are treated with immunosuppressive agents in hopes of improving left ventricular function. Patients with ejection fractions in the exceedingly low range (less than 15%) and those who are more than 4 months from delivery are unlikely to respond, even if myocarditis is demonstrated. Only patients in whom ventricular function does not return to normal after peripartum cardiomyopathy should be should be discouraged from additional pregnancies.

A second controversial area is the use of anticoagulants in pregnant patients. Some authors use heparin throughout the pregnancy to avoid any warfarin-related embryopathy or central nervous system abnormality. Other authors have observed such a low rate of embryopathy and central nervous system disorders with use of warfarin that the agent is used throughout the pregnancy, until delivery. Unless the patient declares her desire for a pregnancy and switches from warfarin to heparin before conceiving, most patients receiving chronic anticoagulants present to their physician already pregnant. These patients have already sustained most of the potential risk for embryopathy by the time the physician is aware of the pregnancy. On balance, the risk to the patient and fetus seems least if warfarin is discontinued before pregnancy is initiated and if heparin is used through at least the first 12 weeks of gestation. Thereafter, warfarin can be used until just before delivery, when heparin must be substituted to allow delivery without substantial bleeding.

The choice of artificial heart valves is a third controversial area of management in pregnant patients. Patients with bioprostheses have a much higher live birth rate and usually do not require chronic anticoagulation. However, the potential for degeneration of bioprostheses is associated with pregnancy and delivery. Mechanical prostheses do not degenerate but are associated with a higher rate of thromboembolic complications, including valve thrombosis and embolic phenomena in the central nervous system and periphery. Most of these thromboembolic complications have occurred in patients receiving inadequate heparin therapy. I favor the implantation of a mechanical prosthesis, even for the patient who desires a subsequent pregnancy. On the patient's declaration of the intention for pregnancy, conversion from warfarin to adequate heparin anticoagulation until after the first trimester, and then careful management of warfarin therapy, should diminish the potential for thromboembolic complications.

Not all clinicians are willing to follow patients who have undergone corrected congenital or acquired heart disease through pregnancy. These patients have often sustained life-threatening complications before surgery, and the surgery itself is usually high risk. Once patients have survived these risks, many clinicians are wary of the patient's decision to incur what some would consider an unnecessary additional risk. There is also the potential that the mother's genetic disorder may be passed on to any children. Other clinicians empathize with the patient's desire to bear and raise children despite the risk to the patient. We ensure that the patient is informed of the potential risk that her cardiac disorder could be transmitted to her offspring. If a patient is willing to accept this risk and we concur, a full cardiovascular evaluation is undertaken to evaluate the patient's cardiopulmonary capability to sustain the cardiovascular stress of normal pregnancy and delivery. Occasionally, the risk is determined to be too great, based on elevated pulmonary vascular resistance, high filling pressures, left or right ventricular dysfunction, or inadequate correction of congenital abnormalities. Most patients are willing to accept the decision to avoid pregnancy after a thorough evaluation.

Little controversy exists about the risks of use of antiarrhythmic agents, regardless of the state of pregnancy. Drugs are infrequently used and when used are carefully chosen to avoid teratogenic and maternal problems.

FUTURE DIRECTIONS

It is likely that an increasing proportion of high-risk pregnancies will be undertaken by older women or women with preexisting heart disease. These factors will result in continued growth and development of the already strong relationships between physicians in cardiology and in high-risk obstetrics.

Because exercise in pregnancy has clear-cut advantages, it is appropriate for a larger proportion of pregnant patients to be involved in aerobic exercise.

It is likely that the etiology of preeclampsia will be discovered in the near future. An increased understanding of vascular biology and alterations of vascular biology that occur in pregnant women will allow an appropriate recognition of the underlying abnormality associated with this potentially fatal complication of pregnancy. Once the

pathophysiology is understood, it is almost certain that an effective therapy can be introduced, significantly reducing maternal and fetal morbidity and mortality.

We are only beginning to understand the pathophysiology of peripartum cardiomyopathy. If the condition is associated with myocarditis, it seems logical that the etiology is immunologic. It is unlikely that the causative agent is viral and more likely that it is related to an altered placental antigen. Understanding the pathophysiology of the condition will allow better recognition and treatment of patients with this disorder. Once the pathophysiology is understood, it is anticipated that almost all patients who have peripartum cardiomyopathy will recover, as opposed to the approximately 50% recovery rate that is currently achieved.

Although new forms of anticoagulants are available, including low-molecular-weight heparin, antiplatelet agents, and platelet IIb/IIIa glycoprotein inhibitors, it is unlikely that any significant improvement will be made in the risk to patients who are pregnant and require anticoagulant therapy. Progress in this regard is again dependent on advances in vascular biology. Estrogen, progesterone, and other pregnancy-related hormone alterations that affect vascular and platelet reactivity may serve as a nidus for thrombus formation. Effective anticoagulant therapy depends on the physician understanding these alterations and providing appropriate interruption of pregnancy-related changes. Once these thrombogenic abnormalities are recognized and understood, it is expected that pregnancy can be more safely undertaken by women with mechanical valve prostheses. There is likely nothing that can alter the increased metabolic and calcium turnover in bioprostheses that are associated with pregnancy, and therefore the degeneration of these prostheses that is associated with pregnancy is likely to continue.

Although earlier correction of congenital and acquired heart disease is possible, it is unlikely that the early repair of these disorders will significantly alter the risk to the patient associated with pregnancy and delivery. More thorough prepregnancy cardiovascular evaluations, including stress or dobutamine echocardiography, and magnetic resonance imaging with or without exercise will likely better identify patients who are capable of proceeding safely with pregnancy and delivery.

Safer doses and durations of tocolytic therapy are already being used. The lack of understanding of pulmonary edema related to tocolytic therapy is the result primarily of inadequate investigation into the condition of these relatively rare patients. Despite the small number of patients who experience this disorder, the nature of the disorder can be ascertained, and appropriate treatment regimens can be designed.

The increased risk associated with use of antiarrhythmic agents has been recognized in nonpregnant patients. This risk is increased further with the pregnant state, because drug absorption and metabolism both alter in association with pregnancy. Therefore, drug therapy should be avoided if possible during pregnancy, and if it is used, agents without teratogenic risk or proarrhythmic potential are favored.

THE FUTURE

An increased understanding of the pathophysiology of disorders such as preeclampsia and peripartum cardiomyopathy will lead to more effective therapies. With advances in vascular biology, more effective anticoagulation regimens can be used in patients who have thrombogenic abnormalities. More thorough prepregnancy cardiovascular evaluations, including stress or dobutamine echocardiography and magnetic resonance imaging, will better identify patients with acquired or corrected congenital heart disease who are able to proceed safely with pregnancy and delivery.

OVERVIEW

The extraordinary increase in the number of older persons and the frequency of cardiovascular disease, coupled with inevitable age-related changes in the cardiovascular system, make the study and understanding of cardiovascular disease in the elderly one of the most important and intriguing scientific endeavors in medicine. The high, and increasing, costs of cardiovascular care also demand a better appreciation of the appropriate use of the many treatments and interventions available for the elderly.

The interaction between age-related changes in the cardiovascular system and cardiovascular disease substantially modifies the presentations and outcomes of diseases in the elderly. The enormous heterogeneity of the aging process complicates the issues and requires a more deliberative approach. Biologic age, not chronologic age, should be the basis for assessment. Lifestyle changes in the elderly further complicate all issues, because lack of exercise, depression, and poor nutrition (among other issues) can masquerade as the aging process or disease. The interaction among disease, age, and lifestyle requires careful analysis when interpreting a patient's complaints and altered functional capacity.

Changes in the pharmacokinetics and pharmacodynamics of many cardiovascular drugs related to the patient's age demand careful monitoring for side effects and the differentiation of side effects from symptoms of new or worsening disease.

For multiple reasons, therapies known to be effective (and sometimes inexpensive and relatively safe), such as aspirin and beta-blockers, are underused in the elderly. Others, such as catheter-based interventions, require additional systematic study, especially because their use is increasing rapidly and they are expensive.

Randomized controlled trials, so useful in gaining knowledge about treatments in younger cohorts, are likely to be of limited value in older patients with cardiovascular disease because of the heterogeneity of this population. Critical data prospectively entered into databases and analyzed with sophisticated approaches should provide the most valuable insights about the most effective use of medical, financial, and other resources in older patients.

Older patients require a comprehensive, highly individualized approach to clinical decision making, because of the heterogeneity of this group and the many complex interactions that exist. In many situations, older patients should be given an active role in clinical decision making, because management decisions often involve a complex set of variables and no clearcut preferred choice is apparent. This requires considerable time and insight on the physician's part and a knowledge of the patient's values and expectations, issues not of such critical importance in younger patients. The older the patients, the more important is this aspect of their care, but data indicate that heterogeneity of the patient group becomes the major issue in patients older than 75 years.

Systematically collected data about outcomes, especially functional status for the several years after a major management decision, are critical to the understanding of the widely disparate practices and costs in caring for elderly patients with cardiovascular disease.

Cost-effective, evidence-based medicine may be seriously explored in the elderly because cardiovascular diseases are so common, the enormous costs for care are paid by public funds (which makes accountability more urgent), and the options for management are multiple. Studies involving prospective formulation of important outcomes can be effective instruments (randomized clinical trials are not practical) for assessing care and costs, which makes the study of practice an appealing approach to improving practice.

HISTORICAL PERSPECTIVE

The number of older Americans—those older than 65 years of age—is increasing at a remarkable rate, both in absolute terms and as a proportion of the population. Since the beginning of the twentieth century, longevity has increased by an average of 28 years (1). In 1994, 33.2 million Americans were at least 65 years old; this number is expected to more than double (to 70.2 million) by 2030 (1,2 and 3). Furthermore, the proportion of the population aged 75 years or older may triple from 1.6% to 4.8% between 2000 and 2050 (4). Due to a significant reduction in the death rate among people older than the age of 85, the greatest rate of increase in the population will continue to occur in this "oldest-old" group (5). Thus, the proportion of very elderly in the population is expected to increase dramatically, whereas that of the young will remain relatively stable over the next 50 years (6) (eFig. 33.0.1).

***e*FIGURE 33.0.1** Distribution of the U.S. population by 5-year age categories for 1900 and 1990 and projections for 2050 (6). The distribution becomes rectangular as the proportion of the population achieving old age increases and (projected) birth rates stabilize. (From US Census Bureau. *J NIH Res* 1995;7:29.)

This increase has been achieved primarily because more people are living to old age, not because the age at which the oldest people die has been greatly extended. In 1900, the life expectancy from birth was 47 years in the United States; today it is 72 years for men and 79 years for women (7). The average maximum length of life during this period has not increased significantly and remains at 85 to 90 years (6,7 and 8). This is an important consideration with regard to the use of resources and expectations in patients older than the age of 80 who have cardiovascular disease, because longevity in many patients is quite limited independent of the outcome of the treatment of their cardiovascular disease.

Never has a society had as many old people and as many who are frail, and never has there been so great a commitment of society's resources to their well-being. Over 40% of noninterest U.S. federal spending is committed to the elderly, especially in Medicare and Medicaid. In 1997, $26.9 billion was paid for hospital care to Medicare beneficiaries with cardiovascular problems (9). Cardiovascular disease is the most common cause of morbidity and mortality among the elderly (10). In 1997, 25.8% of elderly nursing home residents age 65 and older had a primary diagnosis of cardiovascular disease at admission. This was the highest disease category for these residents (11). The 20-year follow-up of participants in the Framingham Heart Study of the National Heart, Lung, and Blood Institute revealed that the average annual rate of a first major cardiovascular event rises from 7 per 1,000 in men between the ages of 35 and 44 to 60 per 1,000 in men between the ages of 85 and 94, nearly a tenfold increase in the risk for cardiovascular events. Comparable rates were seen in women but were achieved 10 years later (12,13). Despite these data, few cardiovascular therapies have been studied systematically in trials in this group. Until recently, older patients were excluded from therapeutic trials, perhaps out of concern that they would skew the outcomes or make complication rates unacceptably high (*e*Table 33.0.1). In large heart failure trials, the average age was 59 to 64 with few elderly patients, yet congestive heart failure (CHF) is the most common diagnosis-related group (DRG) in the Medicare population (14,15,16,17,18,19 and 20). More than 60% of cases of acute myocardial infarction (AMI) occur in patients older than the age of 65, but older patients are underrepresented in clinical trials and average age is usually relatively young, 57 to 62 years (21,22,23,24,25,26,27 and 28). A similar situation has occurred with regard to atrial fibrillation, a condition for which the median age is 75 years (29). This situation is improving, but the medical system commits limited money and energy to the study of the patients who account for most cardiovascular disease and for whom health-care expenditures are growing the fastest. Of great importance, Bayes theorem dictates that data from clinical trials in younger cohorts may not be generalizable to the large heterogeneous elderly diseased population.

In this chapter, three key issues regarding the problems of cardiovascular disease in the elderly are repeatedly cited. First, age-related cardiovascular changes, including degenerative changes in the conduction system (resulting in rhythm abnormalities), alterations in the myocardium and left ventricular function (resulting in diastolic dysfunction), and senile calcification of the aortic valve (with eventual stenosis) are described. These and other changes are the consequences of aging, which occur at a highly variable rate and can substantially alter the clinical presentation and course of cardiovascular disease in the elderly. Management is further altered by changes in the pharmacokinetics and pharmacodynamics of drugs related to patient age. Second, how these age-related changes modify the clinical management and outcomes of therapy is emphasized. The third issue is that heterogeneity is the attribute of aging that has greatest importance in clinical decision making. It is heterogeneity that dictates the need for highly individualized decisions in the elderly, particularly for those older than the age of 75 or 80. This heterogeneity, overtly manifest in the physical and physiologic variation among elderly patients, is especially important when considering patients' preferences and expectations. For many older persons, quality of life rather than longevity, remaining functionally independent (hospitalization results in a total loss of control), and more subtle aspects of their value systems are of key importance, unlike in clinical decision making in the younger population. To evaluate these issues requires major physician involvement and precious time. In addition, these outcomes, generally classified as quality-of-life outcomes, are not easily measured but may be most important from the elderly patient's perspective.

CARDIOVASCULAR CHANGES RELATED TO AGING

Age-related changes in the cardiovascular system occur in parallel with age-related changes elsewhere in the body, but all organ systems do not develop age-related changes at the same rate. Age-related changes in a single organ or group of organs, such as the brain, lungs, or kidneys, may be responsible for the limitations and deterioration of aging, whereas all other organs may remain functionally intact. Age-related alterations in the cardiovascular system tend to be selective; some of the major anatomic and physiologic changes are listed in *e*Table 33.0.2 and *e*Table 33.0.3. Age-related changes must be differentiated from changes that result from alteration in lifestyle. Many older patients become inactive, both physically and mentally, and show major deterioration and loss of function that can be reversed by rehabilitation efforts and treatment of depression, regardless of the patient's chronologic age (30,31 and 32a).

*e*TABLE 33.0.2 NORMAL AGE-RELATED CHANGES IN CARDIAC ANATOMY

Myocardium
Increased heart weight, left ventricular (LV) mass, LV wall thickness
Mild hypertrophy
Fibrosis, collagen accumulation
Chambers
Decreased LV cavity size, shortened long axis
Rightward shift and dilatation of the aorta
Dilatation of left atrium, senile septum
Valves
Calcific and fatty degeneration of valve leaflets and annuli
Coronary arteries
Dilation, tortuosity, and Mockeberg medial calcification (arteriosclerosis)
Conduction system

Fibrosis and loss of specialized cells and fibers
Loss of 75% of pacemaker cells in sinoatrial node
Fibrosis of atrioventricular node and left anterior fascicle

*e*TABLE 33.0.3 NORMAL AGE-RELATED CHANGES IN CARDIOVASCULAR PHYSIOLOGY
Aortic elasticity decreases; aortic impedance increases.
Myocardial relaxation decreases; diastolic dysfunction develops.
Peak exercise heart rate declines.
Peak exercise ejection fraction is maintained by a larger diastolic volume.
Cardiac output and stroke volume are not diminished.
Systolic blood pressure increases.
Valvular regurgitation develops.
PR, QRS, QT are prolonged; left-axis deviation develops.
Reactivity to chemoreceptors and baroreceptors is diminished.
Sensitivity to beta-agonists is decreased.
Pharmacokinetics and pharmacodynamics are altered.

From Kitzman DW, O'Connor CM. Acute myocardial infarction in the elderly. In: Gersh BJ, Rahimtoola SH, eds. *Acute myocardial infarction*, 2nd ed. New York: Chapman & Hall, 1997;602–634, with permission.

Consensus is lacking regarding the gross and microscopic findings in the senescent heart, but some general statements can be made. The weight of the heart increases by 1.0 g to 1.5 g per year between 30 and 90 years of age (33,33a). Ventricular septal thickness increases between the third and tenth decades of life, whereas the base-to-apex dimension decreases, which creates a smaller ventricular chamber. Another morphologic change in the senescent heart is the "sigmoid septum," which probably results from the reduction in the ventricular size and the rightward shift of the dilated ascending aorta (34). The curved ventricular septum has no hemodynamic significance, although echocardiographically it may simulate asymmetric hypertrophic cardiomyopathy. Elderly hearts reveal relative myocyte hypertrophy, most marked in the middle myocardium, and a distinct increase in connective tissue matrix, particularly in the posterior left ventricle (35).

With aging, a progressive reduction of the more distensible form of collagen with an augmentation of the more rigid type may occur. Such an alteration in the connective tissue matrix may cause the greater stiffness of the senescent heart, which requires greater filling pressures to adapt to an increased preload by the Frank-Starling mechanism (36).

Age-related changes in the arteries begin in midlife and accelerate in old age, resulting in alteration in elasticity, distensibility, and dilatation. These changes are believed to be independent of atherosclerosis and hypertension (although exacerbated by those processes) (37,31,32,33,34,35,36,37,38,39 and 40). Histologic changes include irregularity in the size and shape of aortic and endothelial cells and increases in multinucleated endothelial giant cells. The subendothelial layer becomes thick and includes more smooth muscle cells, elastic lamella lipids, and foci of calcification. The media, besides showing the fragmentation of elastic lamellae, reveals increased amounts of collagen and mucopolysaccharides and thus appears thick despite the concomitant dilatation.

Reduced prostacyclin synthesis by endothelial cells may play a role in the development of thrombosis and atherosclerosis (41). Functional changes in small vessels are more difficult to study, but endothelial-derived relaxation factor may not be elaborated as effectively in the old as in the young. Endothelial-dependent responses to agonists such as acetylcholine are reduced (42,43 and 44). Such alterations have important clinical implications for response to stresses and disease. Changes of the aging endothelium per se are difficult to separate from the same alteration (reduced endothelial-dependent relaxation) resulting from hypertension, atherosclerosis, and hypercholesterolemia. In a variety of studies, however, age has been found to be an independent risk factor for loss of endothelial-dependent relaxation.

These processes are probably caused by concomitant disease and possibly by genetics. They generally result in less elasticity and distensibility and progressive dilatation and elongation of the aorta, which reduces its diastolic contraction (the "secondary pump" in the young) and results in higher systolic pressure and a greater pulse pressure. The left ventricle has a greater afterload, which results in mild but definite thickening and increased left ventricular muscle mass in active older patients (45,46,47 and 48).

Myocardial function with aging has been studied extensively. In a wide variety of species, as well as in humans, systolic myocardial function (the ability of heart muscle to shorten, develop tension, or both) remains essentially normal. Extensive investigations have been conducted of age-related changes in systolic and diastolic myocardial function at the cellular and subcellular level, including study of the availability and use of energy stores, intracellular calcium handling, and evaluation of the transmembrane action potential (49).

Some intriguing features of direct clinical pertinence are provided by studies in isolated cardiac muscle. Muscles from older animals show a reduction in inotropic response to catecholamines and digitalis (which require a receptor) but an unchanged response of myofibrils to direct exposure to calcium (after chemical removal of the cell membrane). In addition, postextrasystolic potentiation is maintained in senescent animals, a response that would be predicted by the calcium observations. A diminished response to digitalis is seen in both old rats and old dogs (50). Observational and anecdotal evidence suggests that such changes occur with human aging. Older persons have higher levels of catecholamines and greater release of catecholamines with stress but reduced chronotropic and inotropic responses.

In contrast to systolic function, which overall is preserved (although modified in its response to various agonists), diastolic function is impaired. The changes are usually not dramatic but may be clinically important. Based on study of a variety of senescent animal models, the most striking and predictable change in the function of cardiac muscle is the longer duration of relaxation. This inherent property of senescent myocardium is likely attributable both to the slower intracellular handling of calcium and to the longer action potential that occurs with aging. Diastolic dysfunction in the intact heart is also a result of the age-related left ventricular chamber alterations described earlier and possibly of structural changes in the mitral valve. Age-specific infiltration of amyloid (discussed later) occurs in some patients, producing additional diastolic dysfunction. Echocardiographic Doppler studies have confirmed a slower relaxation phase and diastolic dysfunction in normal old persons compared to young persons (51,52 and 53).

The changes in the myocardium and ventricular performance with aging can be summarized. Peak contractile force and the ability of heart muscle to shorten is not impaired; systolic function is preserved. Agonists such as digitalis and beta-adrenergic stimuli that require a receptor have diminished effect, whereas direct stimulation of the muscle with calcium does not result in diminution. The most consistent change in the aging heart due to myocardial as well as left ventricular chamber alterations is a diminution in myocardial relaxation producing diastolic dysfunction. These changes have major implications in reference to all cardiovascular diseases in which left ventricular filling pressure may be altered substantially due to disease (AMI, hypertension) or to drugs (diuretics).

Overall Integrated Cardiovascular Performance

The age-related changes in the heart and peripheral vasculature alter considerably the integrated response to stress, including that from daily activities such as exercising, standing, and eating. These matters are important in considering the consequences of and response to disease entities such as myocardial infarction (MI) and CHF, as well as responses to drugs.

Differentiation of the effects of aging on integrated cardiovascular performance from those related to disease and lifestyle changes is not always possible. Early studies found a steady decline in overall cardiovascular performance, as judged from exercise training, with aging (54). All studies show a decline in maximum oxygen consumption, but this could be the result of a decrease in muscle mass with aging, rather than being related to reduced overall cardiovascular performance or cardiac output (55).

Afterload increases due to age-related changes in the aorta, and contractility and heart rate response during stress and exercise become reduced due to the reduced myocardial response to beta-adrenergic stimulation.

Rodeheffer (56) evaluated this issue by studying 61 highly motivated, healthy participants, aged 25 to 79 (fewer than ten were older than age 70) with no evidence of cardiovascular disease. The group engaged in vigorous exercise at 125 W and to the point of exhaustion, which indicated that they were well conditioned. Maximum cardiac output did not decrease with advancing age, but data on healthy people older than age 75 are sparse. Measurement of ventricular volumes with radionuclide methods provided insights into the mechanism for maintenance of cardiac output. Increasing age correlated with a decreased heart rate, decreased contractility, and increased impedance to ejection (afterload), which was offset by an increased end diastolic volume (preload). The larger diastolic volume in the older subjects resulted in an increase in stroke volume to maintain cardiac output, according to the Frank-Starling mechanism, in the face of reduced peak heart rate. Acute beta-blockage in young individuals blunts the heart rate response and results in an increase in end diastolic volume with exercise, which simulates what happens in elderly healthy

people and suggests that the exercise-related differences in cardiac performance are due to age-related reduction in beta-adrenergic responsiveness (57).

Hence, motivated fit normal older persons achieve the same peak cardiac output as younger cohorts but do so by different mechanisms. Longitudinal studies of aging are needed to confirm these concepts in a rigorous fashion. Of great importance, older individuals can derive benefit from successful physical training in the same ways as younger persons in terms of increased exercise tolerance, muscle mass, and improved ventricular performance, probably related to reduction in age-related arterial stiffness (58,59,60,61,62,63 and 64).

Age-related changes in cardiac valves and the conduction system are discussed in a later section describing valvular and conduction system diseases in the elderly.

Drug Use in the Elderly

Age-related alterations in both pharmacokinetics (what the patient does to the drug) and pharmacodynamics (what the drug does to the patient) are discussed in Chapter 40. *e*Table 33.0.4 summarizes many of the changes important in treating patients with cardiovascular disease. The general axiom in reference to drug dosing of “Start low and go slow” is a sensible approach. Drug use in the elderly cardiovascular patient, however, is complicated not only by age-related changes in drug kinetics and dynamics but also by the common occurrence of drug interactions because older patients take many drugs, often as many as eight to fifteen (65,66). Age-related changes in the gastrointestinal tract and frequently used drugs such as antacids or anticholinergic agents can reduce the absorption of many drugs. Studies of drug absorption in the elderly are limited, but several alterations might be expected. Estimates are that the absorptive surface of the mucosa of the small bowel is reduced by 30% due to flattening of the intestinal villi. Also, gastric pH decreases as a result of diminished acid-secretory capacity, gastrointestinal motility decreases, and blood flow to the small intestine is reduced by 40% (66,67 and 68).

*e*TABLE 33.0.4 AGE-RELATED PHARMACOLOGIC CHANGES IN THE ELDERLY
General considerations
Three times as many drugs prescribed over age 65
Multiple drugs usual, drug interactions common
Memory problems and confusion (or lack of patient education) a major issue
Pharmacokinetics (bioavailability)
Absorption (usually not important)
Reduced gastric emptying time and gastrointestinal motility
Reduced splanchnic blood flow
Decreased mucosal absorptive surface (small bowel)
Drug distribution
Less lean body mass and decreased blood volume
Changes in volume of distribution depending on lipid solubility (increased for lipophilic drugs, reduced for hydrophilic drugs)
Metabolism (biotransformation)
Less liver mass, reduced blood flow
Reduced cellular enzyme activity (primarily affects oxidation)
Elimination
Glomerular filtration rate and tubular secretion reduced
Protein binding
Higher alpha acid glycoprotein
Reduced albumin levels in elderly with poor nutrition
Pharmacodynamics (altered sensitivity to drugs)
Receptor change(s)
Reduced $beta_1$-adrenergic responsiveness
Blunted reflex responses
Reduced baroreceptor response

The alterations in drug distribution related to changes in body composition and plasma proteins that occur with age have many implications for response to a wide variety of drugs. Age-associated changes include an increase in adipose tissue, a decrease in total body water, and a decrease in lean body mass. This may result in a more extensive distribution of lipid-soluble drugs resulting in a longer half-life, and a reduced volume of distribution of water-soluble drugs leading to a higher serum concentration (65,66). Alterations in binding to plasma proteins may be expected as well. A reduction in serum albumin has been observed with age; however, the effect of age on $alpha_1$-acid glycoprotein is less clear (65,66,69,70). Although alterations in protein binding may occur, these changes are not as clinically significant as the effects of pathophysiologic changes (reduced renal and hepatic function, reduced cardiac output) on drug disposition. Alterations in hepatic blood flow and metabolism (particularly the cytochrome P-450 enzyme system) and the well-known changes in renal function with aging are major considerations in selecting drug dosage and are important determinants of the half-life of drugs. Important age-related changes in drug clearance would be attributed to liver size, liver blood flow, liver uptake, and the activities of specific hepatic enzymes. That a reduction in the activity of hepatic enzymes would account for most of the reduction in hepatic clearance of drugs may seem likely, but information indicates that reduction in liver size and blood flow account for most changes in drug metabolism that occur with age (71,72,73 and 74).

Although studies are somewhat fragmentary, glomerular filtration rate at age 70 may be only 60% of that at age 20. Renal blood flow may be decreased by 40%, and maximum sodium and water conservation in older persons is impaired. Because of the reduced muscle mass, calculated creatinine clearance does not indicate the same glomerular filtration rate in the old as in the young. The true glomerular filtration rate, however, may remain within the normal range in the *healthy* elderly individual and could be underestimated by creatinine clearance values, especially creatinine clearance calculated by the Cockroft-Gault formula (73).

Age-related changes in the conduction system and altered baroreceptor responses make bradycardia, hypotension, and orthostatic responses more frequent when antihypertensive agents, calcium channel blockers, or nitroglycerin are used.

Pharmacologic age-related changes can be summarized. Drugs can improve function and make elderly patients more comfortable, but adverse reactions and drug interactions are so common that constant vigilance is essential. Overall, a propensity is seen for increased drug concentrations in the blood as a result of reduced metabolism, decreased tissue and protein binding, and slower elimination. This, coupled with alterations in end-organ response, reduced blood volume, and altered reflex responses, emphasizes the need to give lower dosages of drugs, monitor the patient critically, alert the patient to side effects and the possible need for dosage adjustment, and minimize the use of multiple drugs. Finally, confusing drug effects with manifestations of disease is problematic in the aged. Further clinical investigations specifically studying the elderly, especially those older than age 75, are urgently needed.

CARDIOVASCULAR RISK FACTORS IN THE ELDERLY

The role of conventional cardiovascular risk factors in the elderly is incompletely understood because only fragmentary and inadequate data are available in most instances. The hypothesis that conventional risk factors are not important in the aged, because age itself is such a powerful risk factor, is no longer tenable as more and better data concerning conventional risk factors, particularly smoking, hypertension, and lipid levels, are obtained.

Hypertension

Hypertension is the most important modifiable cardiovascular risk factor in the elderly (see Chapter 5). *Hypertension*, defined as systolic pressure greater than 140 mm Hg as an isolated finding or in association with a diastolic pressure of greater than 90 mm, occurs in more than one-half of the elderly (60 years or older) (75,76,77,78 and 79).

Isolated systolic hypertension (ISH) presents problems in definition related to what is normal, inevitable, and innocent aging. The morphologic changes in the aorta and the peripheral vessels make systolic hypertension inevitable and, at least partly, a consequence of aging per se (80,81), as discussed in an earlier section. In addition, the choice of drugs is an issue because the incidence of adverse effects is common and costs can be great.

Epidemiologic data, especially during the last decade, persuasively demonstrate the major risks for cardiovascular events in the elderly with ISH (79,82,83,84,85 and 86). Wide pulse pressure has been identified as a specific risk (86,87,88,89,90,91 and 92).

In several studies, wide pulse pressure is more strongly associated with risk than either systolic blood pressure or diastolic blood pressure (86,89,91). After adjusting for demographics, morbidity, and coronary heart disease (CHD) risk factors, 10–mm Hg increments in pulse pressure were associated with a 12% increase in CHD death. The risk of CHD rose 2% to 22% and the risk of CHF increased 14% with each 10–mm Hg increment. Although systolic blood pressure and mean arterial blood

pressure showed positive association with these end points, pulse pressure yielded the highest likelihood ratio. When pulse pressures were entered into a model in conjunction with other blood pressure parameters, the association remained positive for pulse pressure but became negative for the other blood pressure variables. These data strongly support the hypothesis that pulse pressure is a powerful independent predictor of cardiovascular end points in the elderly (86,87). Possibly the principal reason to measure diastolic blood pressure carefully in the elderly is to determine the pulse pressure to assess risk. Treatment trials have not used pulse pressure per se as an entry criterion, so pulse pressure should not be used in place of elevated systolic blood pressure as an indication to treat. Clearly a lower diastolic blood pressure should encourage rather than discourage the treatment of high systolic blood pressure (85).

Multiple studies have assessed the risks of elevated systolic blood pressure in the elderly. The Framingham study demonstrated that elevation of systolic or diastolic pressure or both was associated with major increased risk of CHD in both men and women. In the Framingham study, participants aged 65 to 94 years with a systolic pressure greater than 180 mm Hg had a three- to fourfold increased risk of CHD compared to patients with a systolic pressure less than 120 mm Hg (80,82). The risk curve in this population does appear to be J shaped, especially in patients older than age 85 (79,88). The postulation is that the lower diastolic perfusion pressure may be proischemic, although interpretation is complicated by possible comorbidity resulting in lower pressure and increased mortality and morbidity. Nonetheless, treatment of diastolic hypertension in older patients has been shown to reduce morbidity and mortality.

Nonpharmacologic Treatment

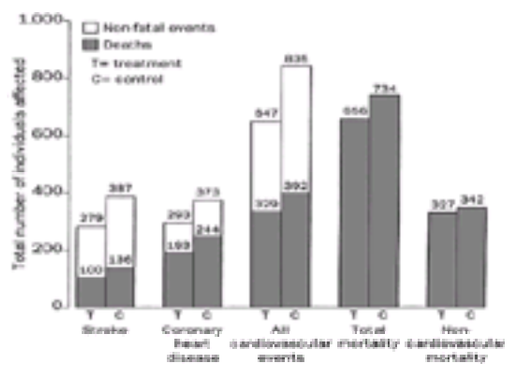
Nonpharmacologic treatment should be pursued in all patients and includes salt restriction, exercise, abstinence from alcohol, and weight reduction when appropriate. The Trial of Nonpharmacologic Interventions in the Elderly (TONE) enrolled 975 hypertensive patients between the ages of 60 and 80. Patients were randomly assigned to undergo a reduction in dietary sodium intake, weight reduction, both interventions, or neither. Each intervention individually reduced blood pressure significantly, but the combination reduced blood pressure the most (93).

Drug Therapy

The first randomized, controlled trial of the treatment of ISH was the Systolic Hypertension in the Elderly Program (SHEP) (94). Nearly 450,000 patients older than age 60 were screened, and 4,736 were randomly assigned to receive treatment or placebo and followed for approximately 5 years. An unequivocal benefit was seen for the primary end point (stroke) and the secondary end point (MI) with treatment. A strong trend toward improved overall and cardiovascular survival with treatment was also seen. Results of other studies indicate that blood pressure reduction affects occurrence of cerebrovascular events more than occurrence of cardiovascular events or total mortality. Adverse drug effects were not an important problem in these trials, likely related to the low dosages of drugs used (thiazide diuretic or beta-blocker or both in those showing inadequate response). This supports the points emphasized in the pharmacology discussion.

Additional random controlled trials confirm this favorable benefit with acceptable adverse drug effects (82,83). The principal drugs used in these trials, particularly the diuretics, are inexpensive; however, newer but more expensive drugs, such as angiotensin-converting enzyme (ACE) inhibitors and calcium channel blockers, are widely used. The Syst-Euro study used a calcium channel blocker (82). The health policy implications of using such drugs to treat all older patients with ISH needs careful study. Because of the favorable effects of ACE inhibitors on renal function, however, elderly hypertensive patients with renal disease should be treated with that class of drugs (79,80,81,82,83,84 and 85).

A metaanalysis of eight trials involving patients aged 60 years or older with ISH and enrolling a total of more than 16,000 patients in their sixties and seventies has been reported (84). The weighted average age was 70.3 years. The risk of death was directly correlated with systolic blood pressure and inversely related to diastolic pressure, which suggests that pulse pressure perhaps is a marker for arterial stiffness and is a new risk factor for cardiovascular complications. When results of all trials were combined, treatment was found to lower systolic blood pressure by 10 mm Hg and diastolic blood pressure by 4 mm Hg. Total mortality was decreased by 13% in the treatment group, with a 26% reduction in all fatal and nonfatal cardiovascular events, a 30% reduction in stroke, and a 23% reduction in coronary events. Active treatment was particularly effective in men, in patients 70 years or older, and in patients with cardiovascular complications. For seven clinical trials addressing treatment of hypertension, data from patients who were 80 years of age or older were selectively analyzed. A total of 1,640 patients were evaluated in the metaanalysis, ranging in age from 80 to 99 years (weighed mean age, 83 years). The analysis showed that treatment significantly reduced the risk of stroke by 34% and also significantly reduced the risk of cardiovascular events and heart failure (eFig. 33.0.2) (84).



***e*FIGURE 33.0.2** Metaanalysis-isolated systolic hypertension. Total number of individuals affected in this metaanalysis of more than 16,000 patients with mean age of 70.3 years. (From Staessen JA, Gasowski J, Wang JG, et al. Risks of untreated and treated isolated systolic hypertension in the elderly: meta-analysis of outcome trials. *Lancet* 2000;355:865–872, with permission.)

Although this analysis had limitations, a placebo-controlled trial, Hypertension in the Very Elderly Trial, provided more data indicating that treatment is useful in patients older than age 80 unless they have specific contraindications or conditions that would significantly limit their life expectancy (95,96).

In summary, studies over the past few years have focused on the importance of systolic hypertension and pulse pressure as risk factors for cardiovascular and cerebrovascular complications in the elderly. New clinical trials indicate that systolic hypertension can be treated safely and effectively by means of lifestyle changes. When drugs are used, the choices are as broad as for younger patients. Although some controversy remains regarding long-acting dihydropyridine, calcium channel blockers appear to be safe and effective in the elderly; however, they do not displace diuretics as the first-line therapy, nor ACE inhibitors or beta-blockers as appropriate treatment for CHD and heart failure. ACE inhibitors remain the first choice in patients with renal disease, especially those with diabetes (79,95).

Dyslipidemia

The importance of dyslipidemia (see Chapter 3) as a risk factor in the elderly, particularly those older than age 75, has been a subject of increasing interest and continuing controversy. Because CHD is the leading cause of death in older people, even a modest relative effect of lipid lowering would represent a substantial absolute mortality and morbidity benefit. Hence, although the relative risk benefit may be less in older people when lipids are favorably influenced, the absolute benefit and number of lives saved could be greater. A particularly contentious aspect has been the role of screening, which is exceedingly popular in younger persons. This relates, in part, to the fact that epidemiologic studies suggesting that hypercholesterolemia is a risk factor in the elderly are confounded by the inclusion of frail, ill, older people, who have low cholesterol levels because of poor health and wasting and whose survival is shortened by noncardiac diseases (97,98). Further, whether lipid-lowering treatment would benefit patients whose dyslipidemia is detected only by routine screening (primary prevention) is not clear (87,88). This emphasizes the issue repeatedly discussed in this chapter: that is, a highly individualized approach to treatment of cardiovascular disease in old age, including the decision to measure blood lipid levels and consider lipid-lowering therapy, is essential. Lipid levels should be evaluated in vigorous elderly patients who are biologically young, and if they meet conventional indications (in younger patients) for treatment, they should be treated; this is particularly true in reference to secondary prevention, which has been shown to have a highly favorable effect (99,100,101,102,103 and 104).

The Rotterdam study—a population-based cohort study of 6,006 individuals older than the age of 55 years—is instructive (105). In both men and women 70 years of age and older, total cholesterol level remained an important risk factor for MI. Relative risk for the top quartile compared to the bottom quartile was 3.2 for men (confidence interval, 1.3 to 7.7) and 2.9 for women (confidence interval, 1.3 to 6.6). For high-density lipoprotein (HDL), the relative risk in the highest quartile compared to that in the lowest quartile was 0.5 for men (confidence interval, 0.3 to 0.9) and 0.4 for women (confidence interval, 0.2 to 0.9). HDL cholesterol was a weaker predictor in men after the age of 70 with wide confidence intervals (quartile 4 vs. quartile 1, 0.8; confidence interval, 0.3 to 2.1). In women of 70 years and older, the relative risk also was not significant (quartile 4 vs. quartile 1, 0.6; confidence interval, 0.3 to 1.3), although the trend over the quartiles was significant. The convincing findings in this study tended to be confirmed by a variety of other studies that were less well designed or included few older people or both.

The information can be summarized as follows. Epidemiologic studies have been inconsistent and somewhat confusing, but the body of evidence now indicates that dyslipidemia remains a risk factor in elderly people, although data for those older than age 75 are sparse. Randomized controlled trials of treatment of dyslipidemia in the elderly, and particularly in patients older than the age of 75, are sparse. A metaanalysis of five trials (30,817 participants) of statin therapy (104) revealed an overall 31% reduction in major coronary events and 21% reduction in mortality of all causes in the treatment arm. Reduction in risk of major cardiac events was similar in persons older than 65 years (32% reduction) and in the younger cohort (31% reduction). Hence, this metaanalysis suggests a risk reduction that is similar for elderly and middle-aged persons. In vigorous elderly patients (biologically young), age should not be considered a contraindication for therapy. Secondary prevention should be instituted along the same lines as for younger patients. Comorbidity, particularly diabetes, which is common, must be taken into consideration. The choice of drugs is discussed in detail in Chapter 3, and the same considerations for drug selection are appropriate to the elderly. The easiest group for which to make decisions is the young old, those between 65 and 70 years of age, for whom the algorithms applied to the young, including screening, should pertain. In addition to obtaining more and better data on who should be screened in the elderly population and for whom treatment is effective, many more data on cost effectiveness must be obtained. Studies on cost effectiveness show an enormous variation with regard to cost-benefit analyses, depending on the subset of patients undergoing treatment (106).

Diabetes Mellitus

Studies of the epidemiology and pathophysiology of glucose intolerance in the elderly and the availability of new drugs has heightened awareness and interest in the importance of diabetes mellitus in the elderly (see Chapter 7). Diabetes mellitus is common in older persons, occurs in nearly 1% to 15% of people older than the age of 70, and is overwhelmingly type 2 diabetes (non–insulin-dependent diabetes mellitus) (107,108). Hereditary associations are found, and the condition may be aggravated by obesity and several commonly used drugs as well as dietary intake. Age-related deterioration in glucose tolerance enhances the propensity to develop type 2 diabetes because of the lack of multiple reserve mechanisms to control hyperglycemia. Late-onset diabetes has pathophysiologic mechanisms different from diabetes in the young, in whom autoimmune mechanisms are important and insulin lack is a key abnormality. Impairment in glucose-induced insulin release and resistance to insulin-mediated glucose disposition (particularly in the obese) are important mechanisms in the elderly (109,110). The diagnosis of non–insulin-dependent diabetes mellitus is assuming increasing importance at a time when establishing the diagnosis is more problematic (see Chapter 7).

Epidemiologic surveys of the elderly show that impaired glucose tolerance is underdiagnosed, but known diabetes correlates with risk factors for adverse cardiovascular events, including death (even in patients older than 75 years). The elderly, especially among ethnic minorities, also have more complications of diabetes (111). The elderly are particularly susceptible to drug-induced hypoglycemia because of reduced awareness of hypoglycemic warning. The frequent use of beta-blockers and the age-related reduction in the levels of regulatory hormones, particularly glucagon, and other hormones, including growth hormone, add to the need for careful monitoring (109).

Although data from randomized trials such as have been performed in younger cohorts (112,113) are lacking, abundant epidemiologic evidence suggests that good blood glucose control can reduce the risk of long-term cardiovascular complications in the elderly. The options for treatment have expanded in recent years and involve enhancement of glucose secretion, alteration of absorption, and gluconeogenesis. Lack of insulin is usually not the primary cause of hyperglycemia, as is the case for diabetes in the young, but insulin therapy is sometimes needed (114). Fastidious dietary regulation with emphasis on weight reduction for obese elderly patients, as well as exercise, are critical aspects of treatment (see Chapter 7).

Left Ventricular Hypertrophy

An important but poorly appreciated risk factor in the elderly is left ventricular hypertrophy (LVH). LVH often reflects arterial hypertension and (to a lesser extent) obesity but is an important independent risk factor for cardiac events. Echocardiographic studies have shown that increased left ventricular mass is independently associated with higher risk of cardiovascular events (115,116 and 117). Because hypertension and obesity increase with age, the prevalence of LVH may be 50% in people older than 65 years.

Initially, LVH is a compensatory response, but as it progresses, it is associated with serious morbidity and mortality. Some but not all antihypertensive agents can slow the progression of or reverse the course of LVH, and whether regression of LVH reduces cardiovascular morbidity and mortality is currently being evaluated in several large studies (118,119,120,121 and 122).

Smoking

Twenty percent to 30% of the elderly are smokers. Smoking is a much stronger predictor of cardiovascular events in the young than in the elderly, and studies of smoking as a risk in the elderly have yielded mixed results (123,124).

An observational study of the Coronary Artery Surgical Study Registry (125) encompassed 1,800 patients divided into two groups reasonably well matched except for smoking. All patients were older than 55 years but the mean age was only 60 years and few were older than the age of 75. A statistically significant reduction in the risk of MI or death occurred in patients with advanced CHD if they quit smoking. When the patients were divided into risk quartiles, the benefits of smoking cessation were demonstrated to be greatest in those with a moderate risk (of infarction or death) and barely discernible for the two quartiles with minimal and highest risk. More data are needed, but smoking cessation likely will benefit patients at risk in all age groups.

Psychosocial Risk Factors

Not only are social isolation and depression more common in elderly patients after MI, but emerging data indicate that they may represent independent risk factors for recurrent events and death (126,127). In the Cardiovascular Health Study, depression in the elderly was an independent risk factor for cardiac events (128). Emerging evidence indicates that the treatment of these risk factors results in improved outcomes. Clinical trials are very difficult to perform in the elderly, even more so in the psychosocial area, but data, including trial results, are accumulating (129).

Estrogen and Cardiovascular Risk (Postmenopausal State)

The very complicated, interesting, and important topic of estrogen levels and cardiovascular risk is reviewed extensively in Chapter 8. The estrogen deprivation that occurs with menopause results in an increase in low-density lipoprotein cholesterol, a small decrease in HDL, and possibly changes in lipid uptake in the vessel wall, as well as altered glucose and insulin levels. Regardless of the mechanisms, postmenopausal women have increased risk for CHD, so that by the time women reach their seventies, their risk is equal of that of men. Early menopause and bilateral oophorectomy increase risk at an earlier age. In addition to having the potential to reduce cardiovascular disease in postmenopausal women, hormone replacement therapy (HRT) also offers the advantage of reducing osteoporosis and hip fracture. Dosage levels and drug formulations have been sources of great debate and many studies. The benefits of HRT come at the cost of an increased risk of uterine cancer (which probably can be prevented by the concomitant use of progestins) and a possible small increase in breast cancer risk (130,131,132 and 133).

Many mechanistic studies of the effects of estrogen on hemostasis, carbohydrates, and lipoproteins, as well as vessel wall reactivity, support a cardioprotective role for estrogen. In addition, observational studies have found that estrogen replacement therapy, with or without progesterone, significantly reduces the risk of CHD. These mechanistic and observational studies can only establish association, however, not a cause-and-effect relationship; bias and patient selection may influence the risk estimates in observational trials.

The Heart and Estrogen/Progestin Replacement Study (134) was the first large randomized, controlled trial to evaluate the efficacy of estrogen/progesterone replacement therapy. This was a secondary prevention trial. Women with established CHD were selected for the trial and followed an average of 4.1 years. The average age was 66.7 years. Overall, the study found that HRT did not reduce cardiovascular risk, and an early increase in the risk of thromboembolic events was seen. Hence, this large randomized, controlled trial for secondary prevention (the only randomized, controlled trial available) failed to confirm the value of HRT despite the appealing underlying hypothesis and the results of observational trials. Additional analyses and follow-up will be forthcoming, but health-care providers must carefully consider whether to prescribe HRT solely for secondary prevention.

HRT to reduce cardiovascular risk and osteoporosis remains a very attractive hypothesis, and as an approach to primary prevention can still be strongly supported. Issues related to patients with established CHD and other cardiovascular syndromes require further study and clarification almost certainly requiring randomized, controlled trials.

Exercise

That exercise has value in reducing the risk of CHD mortality and morbidity is intuitively appealing but has been very difficult to investigate. The Honolulu Heart Program studied 2,678 physically capable elderly men, aged 71 to 93 (135). The study demonstrated a relationship between a reduction in the risk of CHD and an increase in the distance walked. Men who walked less than 0.25 miles a day had a twofold higher risk of CHD than those who walked more than 1.5 miles per day

(5.1% vs. 2.5%). Combined with the evidence indicating that an active lifestyle reduces the risk of CHD in younger and more diverse groups, these data suggest that walking has value for elderly men (and, by extrapolation, women). A realistic walking exercise program in the elderly can be assumed to have a beneficial effect and should be recommended.

Potential and Emerging Risk Factors

Ankle to Brachial Blood Pressure

Low ankle to brachial blood pressure index (ABI) is a marker of generalized atherosclerosis in the elderly. The Honolulu Heart Program evaluated ABI level as a risk factor in 2,863 Japanese American men (71 to 93 years of age) who were followed for 3 to 6 years (136). One hundred eighty-six coronary events occurred. Age-adjusted benefit related to ABI persisted even after adjustment for other risk factors. Men with an ABI of less than 0.8 had an event incidence of 15.3%, whereas those with an ABI of 1.0 or more had a 5.4% event incidence. This potentially significant risk factor needs further study to confirm and clarify its importance in the elderly.

Hyperhomocystinemia

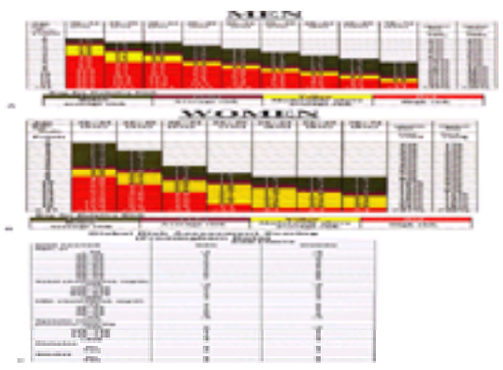
The data are persuasive that hyperhomocystinemia increases the risk of CHD. The prevalence of hyperhomocystinemia in the general population is between 5% and 15% and may be as high as 35% to 40% in the elderly population (137,138). Although evidence is insufficient to recommend routine screening in the elderly at the present time, consumption of the recommended daily allowance of folate, vitamin B_{12}, and vitamin B_6 from dietary sources should be strongly encouraged.

Infection and Inflammatory Markers

Additional emerging risk factors include levels of C-reactive protein (CRP) (which must be measured with special techniques) and fibrinogen, and *Chlamydia pneumoniae* antibody titers. These and other factors are under intense investigation as potential markers of disease activity and targets for therapeutic intervention (139,140). High-sensitivity CRP has the potential to predict events in the short term and to help define the unstable phase. *C. pneumoniae* may be involved in the development of atherosclerosis.

Assessment of Total Risk

In the elderly, as in the young, it is the total risk that is most important. Hypertension, smoking, dyslipidemia, diabetes mellitus, as well as extent of target organ damage (heart, cerebral, or peripheral vascular disease; retinopathy; nephropathy) must all be assessed to determine total risk. Grids developed from epidemiologic data are available to help estimate risks in specific patients (*e*Fig. 33.0.3) (141).



***e*FIGURE 33.0.3** Multiple risk factor estimates for men **(A)** and women **(B)**. Relative risk corresponds to color: green, below-average risk; violet, average risk; yellow, moderately above-average risk; red, high risk. Low absolute risk (*) level = 10-year risk for total coronary heart disease (CHD) end points for a person of the same age with blood pressure <120/<80 mm Hg, total cholesterol 160–199 mg/dL, high-density lipoprotein cholesterol ³45 mg/dL, no smoking, no diabetes. Percentages show 10-year absolute risk for total CHD end points. †Points can be calculated from table in **C**. ‡Includes all forms of CHD. ¶Hard CHD end points are death and myocardial infarction. **C:** Global risk score is the sum of the six variables and is used to estimate total risk from **A** and **B**. HDL, high-density lipoprotein. [From Grundy S, Pasternak R, Greenland P, et al. Assessment of cardiovascular risk by use of multiple risk factor assessment equations. *Circulation* 1999;100(13):1481–1492, with permission.]

CORONARY HEART DISEASE

General Principles

The precise relationship between coronary atherosclerosis and aging is difficult to define, but atherosclerosis is universally present and increasingly severe in the elderly, although not inevitable. At autopsy, more than 50% of people older than the age of 50 were found to have significant stenosis of at least one coronary artery, and the severity and number of stenoses increase with each age decile (142). The incidences of all cardiovascular disease, including stroke, peripheral arterial disease, and particularly CHF, increase markedly with age (see Chapter 1). In the case of CHD, the relationship to aging may reflect the cumulative effects of exposure to the risk factors discussed in the previous section.

The important gender-age relationship in CHD has been cited earlier. Event rates are much lower in women than in men at age 35 (ratio of 1:5); however, the frequency of events steadily increases in women, so that by age 75 the ratio is 1:1 (143).

Presentation

Textbooks have traditionally described CHD from the perspective of young white men (younger than 65 to 70 years of age). With the dramatic aging of the population, more than 60% of AMIs—and all other manifestations of CHD—occur in patient older than 65 years of age. Hence, although clinical presentations are often described as “atypical” for cardiovascular syndromes in the elderly, the fact is becoming increasingly apparent that the “atypical presentation” should be folded into a broader definition of the norm. For CHD, the diagnosis depends less on the presence of chest pain, because other symptoms, particularly dyspnea, and other vague complaints are often present as “ischemic equivalents.” Inactivity in the elderly may prevent effort-related symptoms from occurring, and comorbidity—especially pulmonary, renal, and musculoskeletal—can greatly modify symptoms. In addition, as the nation has become more diverse culturally, it has become apparent that the clinical presentation and course of CHD are different in minority populations than in young white males.

The electrocardiogram (ECG) of an elderly patient frequently shows nonspecific changes or consequences of aging, such as bundle branch block or other intraventricular conduction delays. ST-segment depression, rather than ST-segment elevation with typical Q-wave changes, is often the manifestation of AMI. Physical examination and basic laboratory screening can identify conditions that predispose to myocardial ischemia, such as thyroid dysfunction, anemia, and any cause for LVH (especially increased blood pressure and aortic stenosis), all common in the elderly. A variety of noncardiovascular comorbid conditions are regularly manifest on the physical examination, and their presence modifies the workup and clinical decision making.

Diagnostic Testing

Older patients often cannot increase the heart rate to the desired 85% of the predicted maximum on exercise, which makes nuclear and pharmacologic stress testing useful and popular. Exercise testing is preferred, however, because valuable data in addition to diagnosis, including prognosis, can be obtained. Echocardiographic findings with stress testing have been studied to a limited degree in elderly people, and a variety of abnormalities occurring in the elderly (including diastolic dysfunction) can confound interpretation of echocardiographically monitored stress testing. These issues are discussed in the sections on specific clinical syndromes.

When the diagnosis of CHD remains questionable and establishing the diagnosis is important to the patient, angiography should be considered. As with all other modes of evaluation in the elderly, however, interpretation of angiographic findings presents special complexities, because atherosclerosis is apt to be present and may be

severe with no manifestations of CHD. Hence, the coronary arteriogram can represent a false positive in reference to diagnosis, although the information may be useful. Important comorbidity, including renal disease, is often present, and complications are modestly increased with diagnostic arteriography.

Interventions

Randomized clinical trials of interventions have included few elderly patients. Analyses of retrospective studies and some prospectively collected data form the basis for much of the current knowledge, providing valuable descriptive information and some outcome data (144,145,146,147,148,149,150,151,152,153,154,155,156 and 157). Revascularization is an important strategy in the management of CHD in the elderly, and these procedures, especially catheter-based interventions, are becoming increasingly popular. The elderly may be more refractory to medical therapy, possibly because of the far-advanced atherosclerotic disease and ventricular dysfunction (particularly diastolic dysfunction). The elderly are less tolerant of drug therapy, as discussed in the section on pharmacology, which makes relief of symptoms by percutaneous catheter-based intervention attractive. Details regarding patient selection and discussion of outcomes in the stable angina pectoris and acute coronary syndromes are discussed in subsequent paragraphs.

The goals of revascularization in the elderly depend on the physiologic age of the patients. For patients who are “old-old” and have important comorbidities, the objective is relief of symptoms; percutaneous revascularization is the strategy of choice, but it may not be feasible due to diffuse disease.

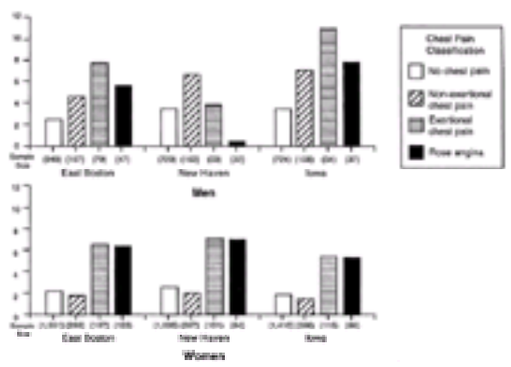
The heterogeneity of the aging process makes assessment of the total patient, not primarily the extent of cardiovascular disease, the key to successful clinical decision making and successful outcomes of treatment (pharmaceutical or otherwise) in the elderly patient. This assessment should be prospective and ongoing, because such assessment is not possible in the acute situation. Intentionally incomplete revascularization (targeting of the culprit lesion) has appeal (158). The “long-term” (3-to 5-year) outcome is primarily dependent on the overall status of the patient, not on the details or extent of CHD (32,32a,159). Competing risks are a major issue in clinical decision making (160). If the patients are “young-old” or have a good comorbidity profile, then the extent of disease, degree of left ventricular dysfunction, and patient preference should dictate the type of revascularization procedure.

Finally, the patients’ values and preferences should be a major consideration. Determination of these requires considerable physician time and is difficult under any circumstances, but it is particularly complicated when rapid management decisions are required, such as during acute MI or life-threatening arrhythmias. Psychosocial problems are also more prevalent and more challenging to deal with in elderly patients. Depression, dementia, noncompliance, isolation, inadequate social support, and dependency are all issues that can complicate care of the elderly and shorten survival independent of disease severity. These factors emphasize that one must consider the entire clinical and personal situation in the elderly and make highly individualized clinical decisions, particularly for patients older than age 75, and especially for patients older than age 80.

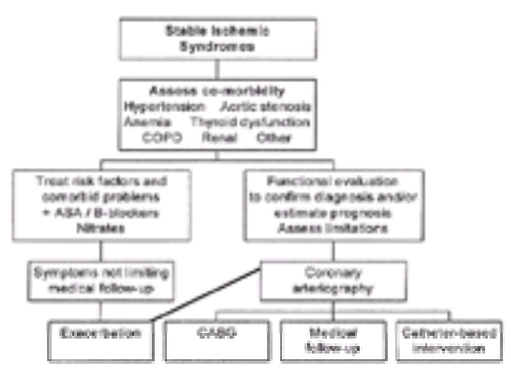
Stable Angina Pectoris

Clinical Recognition and Diagnosis

Stable angina pectoris (SAP) is a common presentation for CHD with a prevalence of 10% in people older than age 65. The diagnosis can be difficult because atypical, vague symptoms, dyspnea, weakness, and silent ischemia are common. In three large community cohort studies, individuals with typical and atypical complaints had a similar 3-year mortality (161) (eFig. 33.0.4). Comorbidity, which is frequently present, may produce complaints that mimic SAP. A particular problem in elderly patients with angina is the lack of vigorous physical activity, so that angina may rarely occur even though severe ischemia is present. Communication and memory problems make the recall of symptoms vague, incomplete, and inconsistent from one interview session to the next. All of these difficulties require additional time and careful attention to multiple lines of inquiry if a proper interpretation is to be made. Detailed information concerning functional capacity in reference to activities of daily living is of particular importance in deciding how to proceed. Symptoms are a critical element in the decision to pursue further investigation and represent the principal reason for interventions with increasing age (eFig. 33.0.5).



***e*FIGURE 33.0.4** Three-year mortality data for 8,359 people aged 65 and older in reference to chest pain evaluated by questionnaire. All members of three diverse communities were studied. All patients with a history of myocardial infarction (“heart attack”) were excluded from the sample. Atypical complaints (any exertional chest pain or nonexertional chest pain) were associated with a mortality rate similar to that for typical angina (Rose angina). (From LaCroix AZ, Guralnik JM, Curb JD, et al. Chest pain and coronary heart disease mortality among older men and women in three communities. *Circulation* 1990;81:437–446, with permission.)



***e*FIGURE 33.0.5** Stable ischemic syndromes. The algorithm illustrates the need for a broader but more individualized approach in the elderly (details discussed in the text). ASA, acetylsalicylic acid (aspirin); B-blockers, beta-blockers; CABG, coronary artery bypass grafting; COPD, chronic obstructive pulmonary disease.

Noninvasive Testing

In the elderly, noninvasive testing is rarely justified as a screening tool in the asymptomatic individual, particularly those older than age 75, although silent ischemia increases with age in asymptomatic individuals (162,163). Testing can be useful in symptomatic patients in whom the diagnosis is not established by clinical evaluation or when prognostic information is needed. Because the presence of associated cardiac diseases, inability to exercise, and resting ECG abnormalities complicates test performance and interpretation, noninvasive testing is less helpful and predictive in elderly patients than in younger cohorts. Systematic data from large numbers of older patients undergoing functional tests with meaningful long-term (3- to 5-year) follow-up do not exist. Small studies of highly selected patients fail to provide information about the incremental value of the tests (164,165,166 and 167).

Exercise ECG testing (see Chapter 48) remains the simplest, most widely available, and least expensive approach, and provides valuable information (168,169,170,171,172 and 173). Exercise protocols must often be modified with regard to speed and rate of incline of the treadmill. Exercise duration and workload can usually be safely increased to achieve a satisfactory heart rate pressure product. Heart rate may not reach 85% of the predicted value, but the marked increases in systolic blood pressure that frequently occur result in a major increase in myocardial oxygen consumption and a high heart rate pressure product. The high incidence of resting ECG abnormalities in this age group lowers the sensitivity and specificity of ST-segment depression. Multiple studies demonstrate that the ability to exercise and the duration of exercise are much more important in assessing prognosis than any single feature, such as ST-segment depression. Conversely, the inability of an

older patient to exercise, regardless of the reason, carries a poor prognosis (171,172 and 173).

Nuclear imaging and echocardiographic techniques (see Chapter 51 and Chapter 53) have become popular because of the desire to increase the diagnostic yield (sensitivity) and prognostic capability of noninvasive testing. Pharmacologic agents (dipyridamole, adenosine, and dobutamine hydrochloride) are frequently used to produce the stress, which further enhances the appeal of the test for the elderly, who are frequently unable to perform dynamic exercise because of underlying medical conditions, particularly orthopedic conditions. Data for elderly patients with stable ischemic syndromes are sparse and fragmentary, and include retrospective analyses of relatively small numbers of highly selected elderly patients. Studies are consistent in demonstrating that completely normal studies predict a very low incidence of MI and death. The data on long-term outcomes with positive test findings are sparse and give conflicting results with reference to prognosis (173,174,175,176 and 177).

Coronary Arteriography

The role of coronary arteriography in the diagnosis and management of stable ischemic syndromes in the elderly is an interesting, complex, and important issue. Coronary arteriography is the standard for establishing the presence and extent of coronary atherosclerosis during life. The belief is widespread that defining the atherosclerosis anatomically must be of value in any patient known or suspected of having CHD, but such is not true in the elderly. The decision to use coronary arteriography is complicated by the high prevalence of significant coronary atherosclerosis, which makes it problematic to attribute functional significance to the anatomic abnormalities defined. Hence, in elderly patients, coronary arteriography may be of little help in establishing the diagnosis of CHD or assessing prognosis in the absence of unequivocal clinical manifestations or functional studies demonstrating ischemia in stable patients.

In light of its limited usefulness as a diagnostic test in elderly patients, angiography should be undertaken primarily to assess the suitability of the coronary circulation for revascularization; that is, arteriography is usually performed as an aid in planning therapy. Despite the fact that older patients tend to have more severe symptoms of longer duration with a greater extent of left ventricular dysfunction, the complication rate for arteriography is not much increased, provided that the patient is stable and does not have major complicating comorbidity in the heart or elsewhere (177,178).

Revascularization

The frequency of revascularization procedures in the elderly is increasing dramatically. Morbidity and mortality from procedures is significantly higher in the elderly and highly dependent on case selection. Diabetes, prior MI, reduced ventricular function, renal insufficiency, and frailty substantially increase the risk. In a single-center study (768 patients older than 65 years of age seen at the Mayo Clinic) (179), 3.4% of patients undergoing revascularization experienced in-hospital MI or death. In a registry evaluation of 301 patients older than the age of 80 undergoing stenting procedures (157), death or MI occurred in 11%, but mortality was only 1.3% (compared to 0.1% mortality in patients younger than the age of 80). Most of the infarcts (9.3%) were non–Q-wave MIs. In a large database in New York State including 68,088 cases (Hannan EL, *personal communication*, December 15, 2000), in-hospital mortality for stent-placement procedures was 2.28% in patients older than age 75 compared to 0.46% for patients younger than age 65, with an intermediate 0.9% mortality rate for patients aged 65 to 74. For percutaneous transluminal coronary angioplasty (PTCA), mortality was 2.62%, 0.51%, and 1.04% for the respective age groups. In another portion of the database (180) comparing single-vessel stent placement (8,075 patients) with PTCA (33,077 patients), the mortality rates were minimally lower for stent procedures but the age gradients remained unchanged; for example, for those 75 years or older, mortality was 1.6% for stents and 2.6% for PTCA. In another large registry of nearly 110,000 patients (151), the 7,472 octogenarians had an in-hospital mortality of 3.8% compared to 1.1% in the younger patients in the cohort, and showed a slightly higher rate of Q-wave MI, stroke, renal failure, and vascular complications. In this study, the mortality for octogenarians varied tenfold depending on the presence of comorbidities (0.79% to 7.20%).

Coronary artery bypass grafting (CABG) in the elderly has a highly variable mortality and morbidity depending on the number of patients in the various reports and on case selection. In a study of the Medicare database (144), 24,461 octogenarians who underwent isolated CAGB had a 30-day mortality of 10.5% compared to 4.3% in the cohort 65 to 80 years old. A report of a voluntary registry (155) of 22 centers that enrolled 64,467 patients (4,306 of whom were older than 80 years) found that mortality was 8.1% among octogenarians and 3% among others for isolated CABG. Mortality for aortic valve replacement (10.1%) and mitral valve replacement (19.6%) with CABG was much higher in the octogenarians. In addition to having a greater frequency of far advanced coronary atherosclerosis, the octogenarians also more frequently had comorbid conditions, including peripheral vascular disease, pulmonary disease, and renal disease.

Although improved case selection and technical advances will undoubtedly alter mortality and morbidity, substantially higher risks seem certain to persist in the elderly. With a highly individualized approach to case selection, revascularization is the preferred approach in many stable patients. Further, as more experience is gained, the long-term (3-year) outcome will become increasingly important in selecting patients for revascularization procedures, because 3-year mortality in octogenarians, when reported, remain high—usually in excess of 30% regardless of the in-hospital mortality for CABG; this finding again emphasizes the phenomenon of competitive risk (160).

Acute Coronary Syndromes: Unstable Angina Pectoris and Acute Myocardial Infarction

More and better prospectively collected data are needed to understand acute coronary syndromes in the elderly (see Chapter 17, Chapter 18, Chapter 19, and Chapter 20). Data from randomized, controlled trials usually involve relatively small numbers of the elderly, and those participating tend to represent “healthy” older persons. Diagnostic problems arise, as alluded to in the earlier section, because clinical presentations are atypical, the ECG is much less likely to show an elevated ST segment in AMI (and a variety of ECG changes related to past coronary and other cardiovascular disease may be present), and only minimal enzyme elevations may occur. Hence, differentiating unstable angina pectoris (UAP) from AMI is difficult. Management is often similar in patients who present this diagnostic dilemma. Definite AMI carries a higher mortality and greater risk of complications, but with UAP, advanced age is an independent risk factor for complication and death. Elderly patients who present with acute coronary syndromes are more likely to be female and to have a history of hypertension, diabetes, previous MI, angina pectoris, or CHF than their younger counterparts. Delay in presenting to the hospital is a feature of acute coronary syndromes in the elderly. Forty percent of patients older than age 75 may die before arrival at the hospital, in part due to a delayed response to symptoms and psychosocial factors (181,182,183,184 and 185).

Clinical Presentation

Clinical presentation in AMI can be classified as typical, painless or atypical, or silent. Silent MI (absolutely no symptoms and detection exclusively by serial ECG changes or unmistakable evidence of myocardial scar or both) occurs in 40% of elderly patients (186,187,188 and 189). Complaints other than pain, particularly dyspnea (30% to 50% of patients) but also syncope, acute confusion, vague constitutional symptoms, or signs and symptoms of stroke or peripheral embolism, are as common as typical ischemic discomfort, particularly in the over-80 age group (190,191).

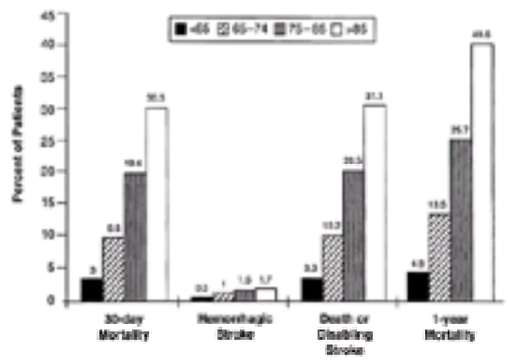
Dyspnea in the elderly MI patient may be more common due partly to age-related diastolic dysfunction, age-related lung changes, or associated independent pulmonary disease (145,192). Neurologic symptoms, syncope, stroke, and acute confusion are related to an acute reduction in cardiac output and age-related central nervous system (CNS) changes or independent cerebrovascular disease. Concurrent hypoxemia, changes in glucose tolerance, or delayed medication clearance may be contributors. Delirium may accompany any illness in the elderly and may be the presenting complaint in the very elderly with AMI.

When pain is the principal presenting complaint, it may be atypical in character and location, and sometimes appears as an upper abdomen pain rather than a crushing or squeezing substernal sensation. Elderly patients have changes in opiate receptor affinity and an altered pain threshold, but the explanation for frequent atypical and confusing pain syndromes is not known.

Diagnosis and Clinical Course

The elderly have a higher rate of non–Q-wave MI (184,192) and much higher mortality. Complications are more frequent among the elderly despite their having lower total creatine kinase levels. This paradox cannot be explained on the basis of past disease, because patients with their first MI (with or without ST-segment elevation) also show these phenomena (193,194). Their occurrence may be related to a different pathophysiology with less frequent total coronary artery obstruction.

Age is by far the single strongest predictor of 30-day mortality in many different models and for study sample sizes varying from a few hundred to 41,000 patients (146,193,194 and 195,242) (*e*Fig. 33.0.6). This extraordinarily high mortality with increasing age must be related in large part to changes of aging per se (which reduce the elderly patients’ physiologic reserve and ability to respond to the stress of AMI); these include diastolic dysfunction, altered baroreceptor and beta-receptor responses (diminishing heart rate and increasing blood pressure), and reduced lung compliance and renal function (which make these organs prone to complications due to reduced cardiac output and pressure changes). Electrocardiographically determined infarct location does not predict risk in the elderly as well as in the young. Inferior infarcts carry risks similar to anterior ones, which is probably related to a high incidence of right ventricular infarction or age-related changes or both.



***e*FIGURE 33.0.6** Profound effects of age on mortality and stroke in a very large sample of 41,021 patients from the GUSTO-I trial (95). Of the total, 24,708 were younger than 65; 11,201 were 65 to 74; 4,625 were 75 to 85; and 412 were older than 85 years. All patients had ST-segment elevation and were treated with thrombolytic agents. Postdischarge 1-year mortality remained high in the oldest group (6.1% and 10.3%) and continued to be low (1.5%) in the under-65 group. (From White HD, Barbash GI, Califf RM, et al. Age and outcome with contemporary thrombolytic therapy: results from the GUSTO-I trial. *Circulation* 1996;94:1826–1833, with permission.)

A single-institution study of 198 patients with inferior MI who were older than 75 years (195) found an overall mortality of 23%. In patients who had right ventricular MI (41% of the sample), mortality was 47%. A graded mortality from 5% to 30% was seen in patients without right ventricular MI related to the degree of reduction in left ventricular ejection fraction. No relationship was seen between left ventricular ejection fraction and mortality in patients with right ventricular MI. Death was primarily related to cardiogenic shock. A higher incidence of complete atrioventricular block (33% vs.9%) and interventricular septal rupture (9% vs.0%) was present in the patients with right ventricular MI. This was the first MI for all patients studied.

The nonspecific ECG changes that are often present with AMI and bundle branch block deserve special comment. Right or left bundle branch block occurs in 5% to 10% of AMI cases. In an extraordinary sample of 29,585 patients with AMI and left bundle branch block in the Second National Registry of Myocardial Infarction, the mean age was 76.4 years and mortality was 22% (145). Only 8.4% of this sample had any form of reperfusion therapy. This low use of a powerfully effective therapy in such a high-risk group of AMI patients must be related to the lack of typical symptoms (only 50% of this sample had chest pain) and “nonspecific” ECG (left bundle branch block) abnormalities.

The risk of cardiac rupture greatly increases in the elderly, reflecting age-related fundamental changes in cardiac anatomy (193). Thrombolytic therapy increases the risk of cardiac rupture (197), adding to the age-related hazard of rupture.

Management and Reperfusion Therapy

Management decisions during the first several hours have the greatest effect on survival in the elderly (147,196,197,198 and 199), as is true for all age groups. The pivotal decision is whether to proceed to reperfusion therapy (thrombolytic therapy or percutaneous catheter-based intervention). The overall care available and the expertise and experience of the hospital and its staff may be the most important factors determining outcome for the majority of elderly AMI patients (148,149). Therapeutic interventions carry added risks in the elderly, so the potential benefits must be carefully considered and judged to be clearly present. In younger patients, the prevailing philosophy in the United States is to undertake many therapies and interventions in AMI almost as a routine despite the lack of convincing evidence of benefit with regard to mortality and recurrence of MI in some subsets (200). This approach is clearly not justified in the elderly. An additional important factor in treating the elderly, particularly those older than 80 years of age or those who are frail, is the need to consider the patients’ values and wishes—a matter that is extremely difficult to address in view of the drama and urgency that surround AMI and often include transfer to physicians at facilities with no background information concerning the patient. For many elderly patients, life will not be prolonged (or quality of life improved) despite effective therapy for their acute coronary syndromes (160). Thoughtful, refined clinical judgment with a highly individualized approach to each patient is the key to optimal management with emphasis on the use of treatments that are known to be helpful and have a low propensity for major complications.

Thrombolytic Therapy

Elderly patients are underrepresented in all thrombolytic trials (147,196,197,198 and 199) because of concern about the risk of complications, particularly cerebral hemorrhage. Although most major hemorrhages occur at vascular puncture sites, intracranial hemorrhage rates are increased in the elderly. Spontaneous ischemic strokes related to AMI increase in frequency with age.

The increased risk of stroke in patients older than age 70 is thought to result from the reduced integrity of the cerebrovascular system, previous silent cerebral ischemic events, or cerebral amyloid angiopathy. Large randomized, controlled trials and case-control studies all demonstrate a higher risk of cerebral hemorrhage in the elderly with tissue-type plasminogen activator (t-PA) than with streptokinase treatment (201,202 and 203). An algorithm to estimate the probability of hemorrhagic stroke after thrombolysis indicated that age and the use of t-PA are two of the most important variables, along with female gender, low body weight, and hypertension (33,33a).

Heparin sodium use requires special attention in the elderly. In addition to age, small body size and female gender alter metabolism and dosing requirements. Lower dosages, a 3,000-U bolus (instead of 5,000) and 500 U per hour rather than 1,000 should be considered for 50-kg elderly patients, and partial thromboplastin time should be followed fastidiously. Low-molecular-weight heparin is increasingly popular and does not require monitoring. Comparative safety data for the elderly are not available.

Given the profound effect of age on mortality, the increased rate of hemorrhagic events must be weighed against the substantial mortality reduction that is felt possible with thrombolytic therapy. Efficacy was demonstrated in multiple randomized, controlled trials. In the Fibrinolytic Therapy Trialists’ overview, the greatest absolute benefit of thrombolytic therapy was seen in patients older than age 75 (147), but the number of elderly in randomized, controlled trials is relatively small. Studies of effectiveness now question this finding. The data compiled by the Health Care Financing Administration for its Cooperative Cardiovascular Project during the years 1994 to 1995 have been studied by two different groups of investigators in retrospective studies. Patient selection was different and methodologies were not identical. In the study by Berger et al., 15,940 patients older than the age of 65 had thrombolytic therapy or primary angioplasty (1,599) (204). They concluded that patients who underwent reperfusion had a lower mortality at 1 year than those who did not undergo reperfusion. Interestingly, only primary angioplasty was associated with a better survival at 30 days (see subsequent paragraph). Using the same database, Thiemann et al. evaluated 7,864 Medicare patients who had fee-for-service treatment (205). In evaluating thrombolytic therapy in this group, they concluded that a survival benefit was seen in patients 65 to 75 years old, but in the group aged 76 to 86 years, thrombolytic therapy was associated with survival disadvantage. Hence, data are conflicting, and a serious concern exists that patients older than the age of 75 may not benefit from thrombolytic therapy. If adverse outcomes in the over-75 group are confirmed, pharmacologic differences in the handling of drugs (and the interaction among drugs) as well as changes related to the aging process per se may explain the lack of benefit.

These confusing and inconsistent findings coupled with the atypical clinical presentations and ECG findings, as well as the delay in seeking care, make the use of thrombolytic therapy problematic in older patients, especially those older than the age of 75. In addition, a disappointingly small number of elderly patients meet conventional eligibility criteria for thrombolytic therapy: ST-segment elevation, arrival within 6 hours of the event, and no contraindication. In one study, only approximately 10% of patients older than age 75 met eligibility criteria because of the absence of ST-segment elevation, late arrival, and comorbidity (184).

Primary Percutaneous Catheter-Based Interventions

Issues related to logistics and the treatment of low-risk patients are still debated, but the extremely high mortality and features discussed earlier make PCI particularly appealing for the elderly because it can be used in patients without ST-segment elevation and the major CNS morbidity risks of thrombolytic therapy can be largely avoided.

Some of the issues related to the use of PCI have been discussed under “thrombolysis” (see also Chapter 18). Pooled analyses of the results of randomized, controlled trials of PTCA versus thrombolytic therapy (primarily in younger patients) found a mortality advantage and reduced in-hospital reinfarction rates in patients randomly assigned to undergo to angioplasty (206,207). These results were not confirmed in an important observational study of patients of all ages (more than 3,000 patients) performed in Seattle, Washington, and in a French study, which showed no benefit for angioplasty (208,209).

Another observational trial of the Second National Registry of Myocardial Infarction suggests that primary PTCA and fibrinolytic therapy result in similar outcomes (154). Patients with ST-segment elevation underwent primary PTCA (4,939) or were given t-PA (24,705). Fifteen percent of the patients in both groups were older than

75 years of age, and mortality among these patients was 16.5% in the group receiving t-PA and 14.4% in those undergoing PTCA. For total mortality and disabling strokes, the rates were 18.4% for those given t-PA and 14.6% for those undergoing PTCA.

Two registry studies add substantial observational data but do not resolve some of the major issues. Berger et al. (204) studied the Health Care Financing Administration's Cooperative Cardiovascular Project database, which contains information on 140 clinical variables collected prospectively. They studied the 20,683 patients who received reperfusion therapy out of 80,356 who were judged eligible for reperfusion. The total cohort contained 234,769 patients older than 65 years. The data analyses are extensive, complex, and sophisticated, and incorporated baseline patient cardiac risk factors, hospital characteristics, and (to a limited degree) qualitative general patient characteristics, including presence of chronic obstructive pulmonary disease or dementia, and degree of mobility limitation. The conclusion from this study is that primary PTCA is associated with a modest short-term and long-term mortality benefit compared to fibrinolytic therapy. Thirty-day mortality was 8.7% versus 11.9% and 1-year mortality was 14.4% versus 17.6%. In the smaller subgroup of patients who were classified as ideal for reperfusion therapy, the observed benefit of primary PTCA was not seen. The relatively low mortalities indicate considerable bias in case selection in favor of healthier old people.

In summary, the precise role of PCI in elderly patients with AMI remains to be defined. Additional registry data will be useful, but the decision to use PCI, fibrinolytic therapy, or neither—particularly in patients older than the age of 75—is likely to remain inherently a highly individualized clinical decision. In addition, the logistics and expertise required for timely catheter-based interventions provide major obstacles to the widespread and routine use of this approach. The presence of multivessel disease, which is regularly found in the elderly, makes it imperative to identify the infarct-related vessels in these patients, most of whom have ST-segment depression.

Adjunctive Therapy

Adjunctive therapy has not been evaluated as intensely in the elderly as in the young, but clearly several adjunctive agents are very effective in the elderly and tend to be underused.

Aspirin use was investigated in the Second International Study of Infarct Survival (198). Patients older than age 70 achieved particular benefit, with a 21% relative reduction in mortality (from 22.3% to 17.6%). As doses increased from 80 mg to 325 mg in this study, the rate of gastrointestinal complications increased twofold, particularly in the elderly. No data are available on gastrointestinal bleeding in the elderly with the use of cyclooxygenase-2 inhibitors. Aspirin is underused in treating acute MI in the elderly, with reported usage rates of 55% in patients older than age 75 versus 65% in those younger than age 75 (210,211,212 and 213).

Early studies of intravenous glycoprotein II_b/III_areceptor blockers have shown promise in treating acute coronary syndromes but primarily in patients undergoing PCI. Data specifically pertinent to older patients are fragmentary. If PCI is not performed, no mortality benefit has been seen in randomized, controlled trials. Trials combining II_b/III_a agents and thrombolytic agents for reperfusion are under way (see Chapter 17 and Chapter 18).

Beta-blocker therapy has a greater effect on survival after MI in the elderly than in younger patients (214,215), with a 34% reduction in mortality in patients between the ages of 60 and 69 but only a 19% reduction in patients aged 30 to 59 years who received propranolol 5 to 21 days after MI. Early intravenous administration has been studied in three randomized, controlled trials (216,217,218 and 219). In 8,513 patients older than 60 (the majority was older than 65), mortality was reduced from 8.9% to 6.9%, so that 20 lives were saved per 1,000 patients treated. In the 14,687 patients younger than age 65, the mortality reduction, from 2.6% to 2.5%, was insignificant. These studies were performed before the fibrinolysis era, but the use of early intravenous beta-blockade as an adjunct to thrombolysis suggests that the agent is useful in that setting.

The use of long-term beta-blocker therapy for secondary prevention after AMI is of value in elderly patients. Three large randomized, controlled trials using propranolol hydrochloride, atenolol, or metoprolol show convincing reduction in mortality in both young and old patients after MI (217,220,221). Mortality reduction was much greater in the 2,462 older patients (14.9% to 8.9%) than in the 4,654 younger patients (7.6% to 5.5%). For every 1,000 patients treated, 60 lives were saved among the older patients compared with 21 lives among the younger patients. Despite these clear benefits, clinicians underprescribe beta-blockers in elderly patients (212,213), perhaps because they fear the side effects that are more frequent in the elderly, including heart block, CHF, bronchospasm, depression, and impaired glucose metabolism. Beta-blocker therapy can benefit even those with mild CHF, diabetes, or both. The substantial benefit of these drugs makes it important that they be used liberally, with careful observation for adverse effects in patients who have relative contraindications, such as bradycardia, low systolic blood pressure, and propensity to heart block.

The survival benefit of treatment with ACE inhibitors after AMI is greater in the elderly than in younger groups. In one trial, the reduction in the risk of death was greatest (25%) in patients older than 65 years who received captopril, whereas it was lower in those younger than 55 years (8%); the reduction in recurrent, fatal, or nonfatal MI was also greater in those older than 65 years (213). Among patients older than 70 in the third Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardio study (GISSI-3), a 12% reduction was seen in the combined end point of mortality and severe ventricular dysfunction (222,223). Details concerning the timing of initiation of therapy and implications of left ventricular dysfunction are discussed in Chapter 18.

The role of intravenous antithrombin agents in the elderly is complicated. Intensive anticoagulation poses particular bleeding risks in the elderly. The use of low-molecular-weight heparin has not been compared with the use of fractionated heparin in the elderly. Combinations of fibrinolytic, antiplatelet (glycoprotein II_b/III_c), and antithrombin agents are being evaluated, which adds to the uncertainty. Heparin is required with t-PA therapy but offers no advantage with streptokinase treatment (224). The use of heparin is always associated with increased bleeding risks.

Calcium channel blockers are favored in many situations when beta-blockers are contraindicated, but multiple clinical studies have shown no benefit of this treatment for AMI (225,226). Although their use remains popular, the lack of efficacy of these agents appears to be a class effect, and independent of age, at least for the first-generation calcium channel blockers. Second-generation agents may have a role in certain subsets (see Chapter 18 and Chapter 20).

Glucose-Insulin Infusions

Diabetes is commonly present in elderly MI patients and is a predictor of adverse outcomes. The hypothesis that glucose-insulin-potassium infusions can alter the metabolic substrate and improve the outcome of AMI has been evaluated for 40 years (227,228). Swedish investigators (229,230) have used insulin-glucose infusions to treat diabetic patients. The short-term and long-term outcomes obtained in a well-designed randomized, controlled trial involving 600 patients (mean age, 68 years) demonstrated convincing benefit. After a 24-hour infusion, subcutaneous insulin was given four times daily for at least 3 months in the treatment group. Mortality was lower in the treatment group than in the control group (9.1% vs. 11.2%). By the end of 1 year, the reduction in mortality was 18.6% versus 26.1%. This mortality benefit was still present 3.5 years after infarction. Of particular importance is the fact that the mortality reduction was most evident in patients who had a low cardiovascular risk profile and who had received no insulin treatment before the AMI. Among this subset of patients, the 3-year mortality was 6.5% in the infusion group and 13.5% in the control group. Fastidious control of hyperglycemia during the course of AMI should be seriously considered in all elderly patients.

Complications and Cardiogenic Shock

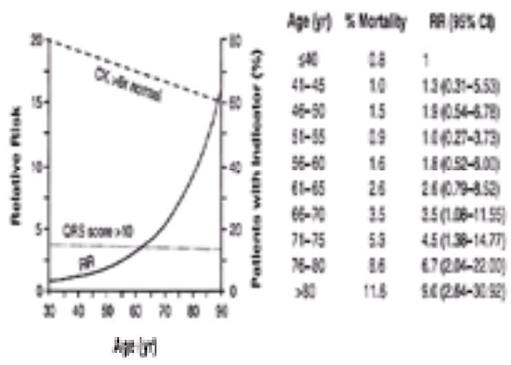
The complications of AMI are, overall, more frequent and the consequences of the complications more catastrophic in the elderly. Primary ventricular fibrillation is the probable exception to that rule because it is less frequent with increasing age. Complications are discussed in detail in Chapter 18, Chapter 19, and Chapter 20. The approach to complications is no different in the elderly than in younger cohorts, when allowances are made for comorbidity and the implications of competing risks.

Cardiogenic shock (see Chapter 19) deserves special comment because it is relatively common (7% to 10% of all AMI cases), is the leading cause of death in AMI, occurs overwhelmingly in the elderly, and continues to carry a high mortality. The studies of Hochman and her colleagues (231,232 and 233) have provided important insight into the issues involved, including the problems in establishing the diagnosis, that is, verifying that the shock is related to myocardial dysfunction. In addition to confirming that the patient's hypotension and hypoperfusion are not related to decreased left ventricular filling pressure or arrhythmias, one must look for mechanical complications (ruptured ventricular septum, ruptured papillary muscle with mitral regurgitation, and free wall ventricular rupture) (233,234,235 and 236). All of these complications are more frequent in the elderly and, of course, require a different management approach. Hochman and her colleagues have studied cardiogenic shock in a sample of 302 patients in a randomized, controlled trial and have extensive data on a registry of an additional 1,109 patients.

These studies provide an extraordinary body of data, but problems related to transfer bias and the fact that these studies were performed at highly experienced centers that can provide optimum care for complicated cases make it probable that their results cannot be directly transferred to the usual practice setting. The outcome for patients age 75 or older, however, is probably correct. In that subset of patients, revascularization had an adverse effect compared to optimum medical therapy. Of the many subsets analyzed, this was the only subset in which an adverse outcome occurred with revascularization. In multiple subsets, the benefit of revascularization was small and often statistically insignificant (see Chapter 19 for further information). The complexities of cardiogenic shock, including the use of intraaortic balloon pumping, revascularization therapies, and a variety of pharmacologic agents, require the ultimate in clinical judgment in treating the elderly and especially patients older than age 75 (237). A highly individualized, thoughtful approach will provide the optimum outcome and most humanistic alternative in treating this relatively common and extremely lethal complication, which probably carries a mortality of at least 50% despite optimum therapy (231,232,233,234,235,236 and 237).

Risk Stratification after Myocardial Infarction

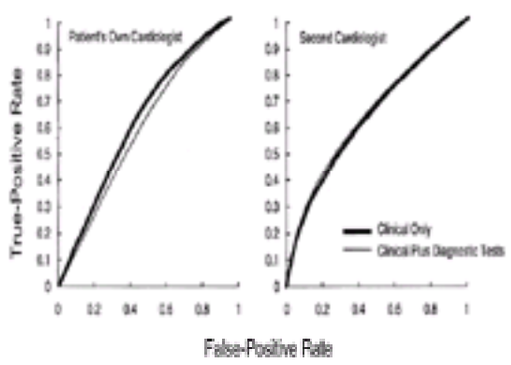
Elderly hospital survivors of AMI have an extremely high overall 1-year mortality, in the range of 30% to 40%, including hospital mortality. This rate is highly variable depending on a number of factors, particularly left ventricular dysfunction, residual myocardial ischemia, and major ventricular arrhythmias (*e*Fig. 33.0.7). Half of these deaths occur within the first 3 months (238,239). (See also Chapter 20.)



***e*FIGURE 33.0.7** Six-month mortality for 9,720 patients surviving their first myocardial infarction. All patients had ST-segment elevation on electrocardiogram, presented within 6 hours of the onset of chest pain, and were given thrombolytic agents. The creatinine kinase (CK) release and QRS scores with acute myocardial infarction were lower in older patients. The postdischarge 6-month mortality was quite low in patients younger than age 65 and increased markedly with age. CI, confidence interval; RR, relative risk. (From Maggioni AP, Maseri A, Fresco C, et al. Age-related increase in mortality among patients with first myocardial infarctions treated with thrombolysis. *N Engl J Med* 1993;329:1442–1448, with permission.)

A useful approach is to divide the survivors of AMI into high- and low-risk groups and use revascularization procedures in the high-risk groups (240,241). Intensive medical therapy for left ventricular dysfunction and prevention of progression of atherosclerosis is indicated in all survivors, as discussed in the section Cardiovascular Risk Factors in the Elderly. Very high 1-year mortality (up to 50%) is seen for some elderly AMI survivors who have significant ventricular dysfunction, major comorbidities, and limited ability to ambulate. The inability to perform an exercise test, regardless of the reason, is associated with a high short-term mortality (171,172). However, this group also has a high rate of mortality and complications after interventions. Again, a highly individualized approach must be taken through risk stratification after AMI in the elderly, with emphasis on noncardiac disease features—evidence of aging and comorbidity. Overall exercise tolerance is the single most predictive feature.

Clinical exercise test variables that correlate with adverse long-term outcome in the elderly include an inability to increase systolic blood pressure by more than 30 mm Hg, an exercise duration of less than 5 minutes, and poor increase in the rate pressure product. In one study, the prediction of 1-year outcome for older patients after MI on clinical grounds only (by experienced clinicians) was not improved by knowledge of the results of exercise testing, radionuclide angiography, or 24-hour Holter ECG recording (241) (*e*Fig. 33.0.8). All these studies emphasize the importance of the overall evaluation of the elderly patient after MI, not only the assessment of CHD severity.



***e*FIGURE 33.0.8** Attempt to determine the incremental value of post–myocardial infarction noninvasive testing in 147 older patients (mean age, 75 years). Clinical evaluation included history, physical examination, routine laboratory studies, electrocardiographic data, and chest radiograph. Noninvasive diagnostic tests included an exercise test, 24-hour ambulatory electrocardiographic monitoring, and radionuclide-based estimate of ejection fraction. The postdischarge 1-year mortality was 16% for the group. Using receiver operating characteristic (ROC) curves, clinical estimates by the patients' own cardiologists and by a second independent cardiologist were compared with estimates that also incorporated the noninvasive diagnostic testing. In this study, the addition of the noninvasive diagnostic test selected did not add incremental value to estimates of 1-year mortality, perhaps because ventricular function—the most powerful predictor of outcome—has been recently estimated by clinical data. Disappointingly, the ROC curve areas were in a relatively low range (0.60 to 0.65). (From Myers MG, Baigrie RS, Charlat ML, et al. Are routine non-invasive tests useful in prediction of outcome after myocardial infarction in elderly people? *Lancet* 1993;342:1069–1072, with permission.)

Because many elderly patients cannot exercise (40% in some studies), stress has been induced pharmacologically to assess perfusion and ventricular performance. Dipyridamole, adenosine or dobutamine in conjunction with thallium or echocardiography can be used; dobutamine is particularly useful in older patients with obstructive lung disease for whom dipyridamole and adenosine are relatively contraindicated. Although these approaches are appealing, reports ordinarily do not give information about the incremental value of these approaches. An urgent need exists to determine the incremental value of post-MI testing in the elderly.

The use of coronary arteriography is another debated issue. Valuable information can be obtained, including information on systolic and diastolic function, cardiac hemodynamics, and extent, severity, location, and characteristics of lesions (including residual thrombosis of coronary lesions). In addition, valvular disease, particularly calcific aortic stenosis, is frequently present and can be evaluated. For these reasons, some argue that angiography should be a routine part of risk stratification (240,241) in the elderly. Multivessel disease is present in a high percentage of elderly patients, however, and the incremental value of coronary arteriography for assessing prognosis (in contrast to planning treatment) is problematic. In a large observational study of post-MI angiography in the United States and Canada, the greater use of angiography in the United States (35% vs. 10%) was not associated with a reduction in 1-year mortality (35% in both cohorts) (150).

Video 33.1 A 76-year-old female patient with bicuspid aortic valve, aortic stenosis, and coarctation of aorta. Left anterior oblique aortogram revealed coarctation of the aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

In the absence of outcome data, highly individualized decisions are required with regard to the use of post-MI arteriography in the heterogeneous population of elderly post-MI patients.

Cardiac Rehabilitation

Normal aging is accompanied by reduced exercise capacity or alterations in lifestyle, or both, which reduce physiologic reserve. Hence, rehabilitation involving exercise is particularly important in the elderly (243,244,245,246 and 247). Healthy elderly patients can significantly increase their exercise capacity through exercise training,

which need not occur within a structured group program but is feasible at home (although fewer outcome data are available using this design). An important component of cardiac rehabilitation programs is individual and group counseling, including focused diet, risk-factor modification, and social adjustment interventions. A British study of 166 consecutively treated patients aged 70 to 97 years randomly assigned to attendance at a special outpatient counseling clinic or to the usual medical follow-up showed reduced hospital readmissions, less depression and anxiety, and increased mobility and physical function with outpatient counseling (244). Comprehensive cardiac rehabilitation in some form should be strongly considered after MI in elderly patients.

CONGESTIVE HEART FAILURE

Incidence, Risk Factors, and Implications

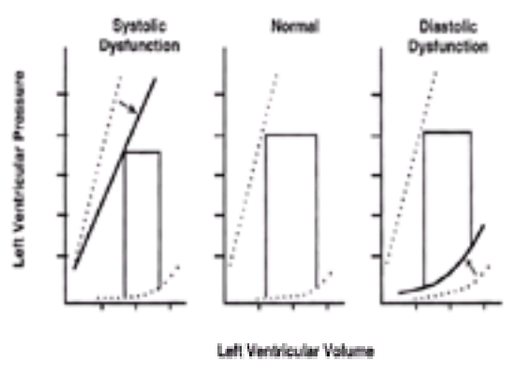
CHF (see Chapter 88, Chapter 89, Chapter 90, Chapter 91, and Chapter 92) is the most common reason for admission of Medicare recipients to an acute care hospital, and readmission rates are extremely high (30% to 50%) within 3 to 6 months of the initial discharge. CHF is one of the most important chronic conditions contributing to limitations in mobility and activities of daily living (248,249,250 and 251).

Age is a powerful risk factor for development of CHF. The risk of developing heart failure was nearly twice as high in persons 75 to 85 years of age than in those 65 to 74 years of age. The incidence of CHF further increased in both men and women from 13% and 8% per 1,000 person-years, respectively, at age 65 to 74 years to 29% and 18% per 1,000 person-years, respectively, at age 85 and older. Other strong risk factors are left ventricular hypertrophy, coronary artery disease, cardiomegaly, reduced vital capacity, valvular heart disease, elevated baseline body mass index, elevated pulse pressure, MI, and diabetes mellitus (250).

Randomized controlled trials have provided a huge volume of data that help characterize patients with CHF and define treatment (14,15,16,17,18,19 and 20). Unfortunately, such trials provide limited insight with regard to older patients. Older patients included in trials do not reflect the typical older patient with CHF. The Study of Left Ventricular Dysfunction (SOLVD) trials developed a registry of patients with CHF or left ventricular dysfunction to understand this issue better (252,253). The 6,273 patients in this registry demonstrated important differences from the 7,897 SOLVD trial patients; the most important was that the registry contained a much higher proportion of patients aged 71 years or older (23.8% vs. 11.0% of trial patients). The 1-year mortality and hospitalization rates were higher in the registry group. This emphasizes the problems in interpreting the results of many randomized controlled trials, in which relatively healthy and low-risk elderly patients are selected, and in which a relatively small number of elderly patients are included.

Pathophysiology

CHF is a syndrome of diverse causes and well-known signs and symptoms, which results in the inability of the heart to adequately supply the oxygen and metabolic needs of the body, sometimes at rest but especially with exercise, at normal intracardiac filling pressures (254,255 and 256) (*e*Fig. 33.0.9). The syndrome may be due to myocardial dysfunction of systolic or diastolic origin, but myocardial function may be normal and abnormal loading conditions (valvular disease and hypertension, common conditions in the elderly) may be responsible for the syndrome. Rarely, a restrictive process (such as pericarditis) is responsible. In any situation congestion may not be present, so the term *heart failure* is more appropriate than *congestive heart failure*.

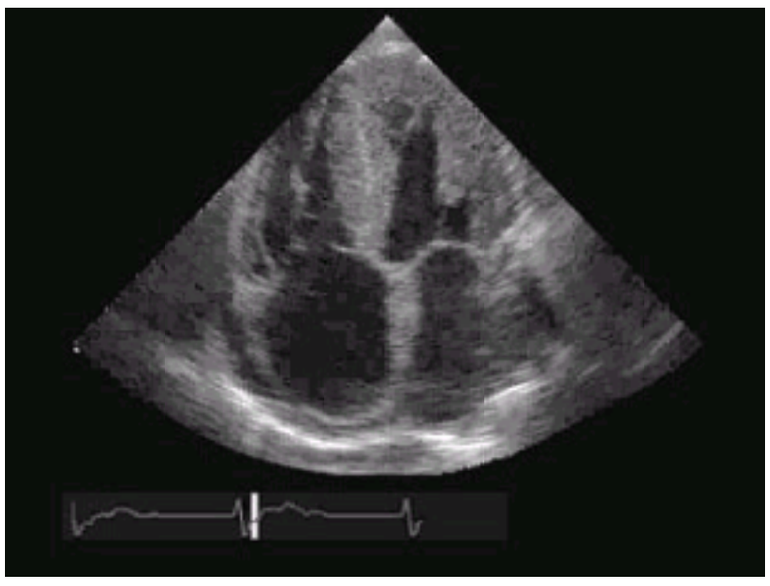


***e*FIGURE 33.0.9** Diagram of left ventricular pressure-volume loops illustrating systolic and diastolic dysfunction. In systolic dysfunction, the end systolic pressure-volume relationship (ESPVR, *dotted line*), an estimate of contractility, is displaced downward and to the right, and the stroke volume (SV) and ejection fraction (EF) are reduced. In diastolic dysfunction, which can occur as a consequence of aging, hypertrophy, or diabetes, the diastolic pressure-volume relationship is shifted upward and to the left, but the SV and EF are normal. Contractility is preserved (ESPVR is unchanged). In this setting, use of diuretics will reduce SV and EF if left ventricular filling pressure is lowered to a normal range. Inotropic agents are not useful (discussed in text). (From Gaasch WH. Diagnosis and treatment of heart failure based on left ventricular systolic or diastolic dysfunction. *JAMA* 1994;271:1276–1280, with permission.)

Regardless of the cause or pathophysiology of CHF, age-related changes in the cardiovascular system contribute to its development and complicate its diagnosis and treatment (257). This is particularly true for older patients with CHF and preserved systolic function (258,259,260,261,262,263 and 264). Many elderly patients with CHF, possibly a majority older than the age of 80, have preserved systolic function. Age-related diastolic dysfunction results from both the altered myocardial properties and left ventricular chamber characteristics described earlier in this chapter. In addition, in patients older than the age of 75, amyloid deposits may be sufficient to worsen diastolic dysfunction (discussed in subsequent paragraphs). Diastolic dysfunction coupled with CHD, so prevalent in the elderly, is particularly devastating because myocardial ischemia also produces diastolic dysfunction. Precipitation of myocardial ischemia can produce sudden, dramatic increases in left ventricular filling pressure and pulmonary venous pressure, which results in dyspnea and “flash pulmonary edema.” The etiology of CHF in the elderly is frequently multifactorial. Atrial fibrillation, common in the elderly, results in loss of “atrial kick”; this produces a substantial increase in left ventricular filling pressure, which may result in pulmonary congestion and heart failure (222). The contribution of atrial contraction in maintaining a relatively low left ventricular filling pressure is especially important when diastolic dysfunction is present (254,260,263).

Clinical Presentation and Diagnostic Assessment

Diagnosis of heart failure in elderly patients can be challenging, as is true for all cardiovascular syndromes in the elderly. The usual symptoms of dyspnea, cough, paroxysmal nocturnal dyspnea, and orthopnea may be present, but noncardiac symptoms often predominate or may be the only presenting complaint (255), in part because of patients’ sedentary lifestyle. Nonspecific complaints such as weakness, fatigue, and anorexia may be the primary features, or subtle deterioration in CNS function with resultant somnolence, confusion, and disorientation (on occasion related to azotemia secondary to reduced renal perfusion) may confuse the diagnosis. Objective data are particularly valuable because multiple causes are frequently present, and the pathophysiology of heart failure in the elderly is complex. Electrocardiogram and chest radiograph are always useful, but the echocardiogram is the most valuable imaging technique in the elderly. Determining left ventricular ejection fraction is essential. Doppler echocardiography is of particular value because of the high incidence of diastolic heart failure. Heart failure with preserved systolic function occurs in at least 30% to 40% of elderly patients, and at even higher rates in the oldest old (258). Establishing the pathophysiology of CHF with echocardiography is critical in selecting therapy. In addition, the echocardiogram can precisely define valvular abnormalities, which are common, and give clues to rare but important abnormalities that occur in the elderly, such as amyloid infiltration.



Apical four-chamber view of amyloid heart disease. Note the significant thickening of the left ventricle and right ventricle walls due to infiltration. There is also characteristic thickening of the valves and biatrial enlargement. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)

Video 33.2 Transthoracic apical four-chamber view of a patient with amyloidosis. Note the thickened “sparkling” walls of the right and left ventricles. Both the mitral and tricuspid valves are mildly thickened and there is biatrial enlargement and a trivial pericardial effusion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 33.3 Transthoracic subcostal view of a patient with amyloidosis showing markedly thickened right and left ventricular walls, showing the characteristic “sparkle.” The right ventricle is towards the top of the screen and the right ventricle free wall is 1.5 cm thick. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The difficulties in diagnosing heart failure in the elderly even with sophisticated and expert echocardiography have led to an interest in the use of neurohormonal markers to diagnose heart failure as well as to assess prognosis (see Chapter 88). One of the more widely studied markers is brain neuropeptide (266,267).

Prognosis

The prognosis for elderly patients with CHF varies extensively (1-year mortality rates from less than 10% to well over 50%), depending on the cause of CHF, the patient’s age, the presence of atrial fibrillation, and the presence of comorbidity (258,259,264,265,268,269). Patients with primarily diastolic dysfunction tend to fare better than those with principally systolic dysfunction or a combination of the two. Female gender and diabetes worsen prognosis (270). In randomized trials, the oldest patients tend to benefit most from therapy because their mortality rate is much higher (269), but mortality and morbidity remain at high levels despite this therapy benefit.

Management

Careful assessment of the pathophysiology is the key to appropriate management. Calcific aortic stenosis, CHD, hypertension, or diastolic dysfunction—or some combination of these entities—is often present in a single patient. This emphasizes the importance of echocardiographic evaluation and the complexity of treatment. Sodium restriction is as effective in the elderly as in the young and should be recommended.

Systolic Heart Failure

Systolic dysfunction is treated as in younger cohorts, with allowances made for the comorbidity and altered pharmacology in the elderly. Diuretics are the cornerstone of therapy for controlling congestive symptoms and preventing heart failure in hypertensive patients. Digoxin continues to be used to control heart failure symptoms but has no advantage with respect to survival and must be dosed carefully in the elderly (15). ACE inhibitor therapy is the cornerstone of treatment, although dosage remains controversial. In ACE-intolerant patients, angiotensin II receptor blockers have been used, and two studies (ELITE-1 and ELITE-2) have evaluated their use in the elderly with conflicting results (16,20). The more recently completed ELITE-2 study showed a trend for the angiotensin II receptor blocker losartan potassium to be inferior to captopril, results that reversed the earlier findings of the ELITE-1 study. The situation is complicated further by the view that a combination of ACE inhibitor and angiotensin II receptor blocker may be superior because the agents work by different mechanisms. Clinical trials of carvedilol and metoprolol have shown a morbidity and mortality advantage in treating systolic heart failure independent of age. Calcium channel blockers have not demonstrated effectiveness in treating patients with left ventricular systolic dysfunction, including the elderly population. The PRAISE-II study, in which the calcium blocker amlodipine besylate was used, did not confirm the early advantage seen in PRAISE-I (17,271). Control of hypertension is an important aspect of preventing heart failure in the elderly (272).

The role of anticoagulant therapy for CHF in the absence of specific complications or atrial fibrillation is uncertain (273,274). Trials are under way to answer these questions. In fragile people, the benefit from anticoagulation therapy must be weighed against the risks of falls, gastrointestinal bleeding, and drug interactions. Nonsteroidal antiinflammatory agents are frequently used in the elderly because of the high prevalence of musculoskeletal disorders. Nonsteroidal antiinflammatory agents not only can attenuate the benefits of diuretic therapy or ACE inhibitors but may actually contribute to worsening renal function, hyperkalemia, and other abnormalities (275,276).

Diastolic Heart Failure

When diastolic heart failure is the primary problem, pulmonary congestion can be relieved by diuresis, but the very steep diastolic pressure-volume relationship (eFig. 33.0.9) indicates that even a modest decrease in circulating blood volume can markedly reduce left ventricular filling pressure, which results in hypotension, fatigue, and reduced renal perfusion. Hence, the use of diuretics requires individualized decisions with regard to dosage and duration of treatment as well as careful monitoring (eFig. 33.0.9). Judicious use of nitrates may be helpful, but avoidance of undue reduction in preload is critical.

The paucity of well-done control studies involving elderly patients with heart failure and preserved systolic function makes the choice of drugs problematic. Diastolic dysfunction with impaired left ventricular filling may be improved, however, by the use of beta-blockers and calcium channel blockers, which may enhance compliance and also reduce atrioventricular node conduction and slow the ventricular response, prolonging filling. ACE inhibitors are probably valuable for most patients with diastolic dysfunction because the nonhemodynamic effects of these drugs may be useful in reducing the collagen deposition of diastolic heart disease and because most elderly patients have an element of systolic, as well as diastolic, dysfunction related to systolic hypertension.

Digitalis preparations are of limited value in both systolic and diastolic heart failure (15) (see Chapter 91, Chapter 92, Chapter 93, Chapter 94, and Chapter 95). No inotropic agent (and digitalis is a weak one) can be expected to provide any benefit to diastolic dysfunction. Although debate exists on this point, digitalis preparations may produce more toxicity in the elderly because of myocardial alterations and because of age-related myocardial and renal changes. Digitalis preparations may be useful in controlling the ventricular rate in patients with atrial fibrillation, but age-related atrioventricular nodal dysfunction often prevents a rapid ventricular response to

atrial fibrillation.

VALVULAR HEART DISEASE

Systolic murmurs are extremely common in elderly patients, with a prevalence of 60% or greater. Most murmurs do not carry important clinical implications and are the result of age-related aortic valve thickening and sclerosis or minor mitral regurgitation secondary to papillary muscle dysfunction caused by CHD, hypertensive or idiopathic cardiomyopathy, or age-related mitral valve changes (277).

Senile Calcific Aortic Stenosis

The most frequent cause of potentially serious valvular heart disease in older persons is calcific aortic stenosis. A Finnish epidemiologic study in a population older than the age of 55 demonstrated a steady increase in the degree of aortic valve calcification and stenosis (278). In the group aged 55 to 71 years, only 7% had severe calcification and 72% had no calcification, whereas in the group older than age 85 years, 19% had severe calcification and only 25% had no calcification. In the 75- to 79-year-old group, 4.1% had an aortic valve area of less than 1 cm^2; this number had risen to 13.7% in the over-85 age group, with 4% having a valve area of less than 0.6 cm^2 (eTable 33.0.5).

*e*TABLE 33.0.5 HELSINKI AGING STUDY: AORTIC VALVE AREA AND AGE

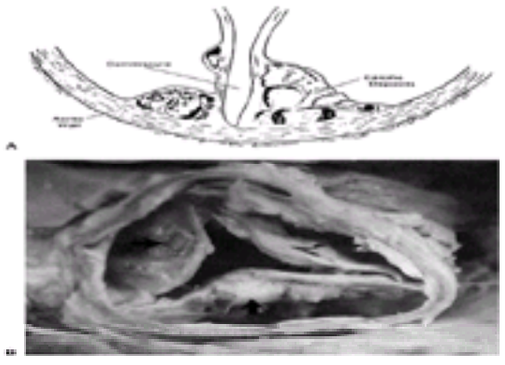
	Age group (yr)		
Aortic valve area (cm^2)	**75–76 (n = 197)**	**80–81 (n = 155)**	**85–86 (n = 124)**
£1.2	2.5%	3.9%	8.1%
<1.0	2.6%	2.6%	8.1%
<0.8	0.5%	2.6%	5.6%
<0.6	None	1.9%	3.2%
<0.4	None	None	0.8%

Note: Critical as +2.9; moderate as +4.8.
From Lindroos M, Kupari M, Heikkila J, et al. Prevalence of aortic valve abnormalities in the elderly: an echocardiographic study of a random population sample. *J Am Coll Cardiol* 1993;21:1220–1225.

Early changes are characterized by fibrosis followed by calcium deposition, first within the fibrosa at the base of the cusps, which results in cuspal stiffness (279). Calcium deposits do not extend beyond the linea alba and do not involve or compromise the commissures, which is distinctly different from the case with rheumatic or congenital lesions. Mild or even moderate calcific deposits may reduce cuspal mobility but impose minimal hemodynamic alterations; however, heavy deposits may immobilize all three cusps with resultant stenosis. Age-related changes in the aortic ring may produce a systolic murmur that must be differentiated from aortic valve stenosis. The loss of parallel orientation of collagen fibrils, development of fatty changes, and eventually calcification may result in annuloaortic ectasia and sometimes mild or moderate aortic regurgitation. The histopathology of these changes may be an inflammatory process with macrophage and T-cell infiltration, lipid deposition, and basement membrane disruption.

Aortic valve calcification. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

A congenitally bicuspid aortic valve with acquired calcification and stenosis is the most frequent cause of calcific aortic stenosis into the sixth decade (280); by age 70, however, age-related changes in the normal tricuspid aortic valve are usually responsible for stenosis (*e*Fig. 33.0.10). Rheumatic aortic stenosis (now extremely rare in the United States) does not occur as an isolated finding and mitral involvement is always present.



***e*FIGURE 33.0.10 A:** Schematic presentation of early calcific deposits at the junction of the cusps with the aortic wall. Note that the process does not induce commissural adhesions. **B:** Photograph of senile calcific aortic stenosis from above the valve. Heavy calcific deposits are seen at the depths of the sinuses (*arrows*), and no commissural fusion is present. (From Friesinger GC, Gravanis ME. Aging and the cardiovascular system. Clinical Evaluation

The murmur of significant senile calcific aortic stenosis may not be prominent and often is no greater than grade 2. The associated findings, including left ventricular hypertrophy, delayed carotid upstroke, narrow pulse pressure, and basal thrill, are often absent in older patients because of comorbid conditions such as hypertension or pulmonary disease. A diminished aortic second sound is virtually always present, however, because of the restricted valve movement with heavy calcification.

Doppler echocardiography is the ideal approach to assess the significance of basal systolic murmurs and follow the course of senile calcific aortic stenosis. Whenever the condition is suspected, this study provides the diagnosis and assesses its severity.

Compensatory hypertrophy may not be as great in elderly patients, especially in women; at least, hypertrophy has been shown to be age dependent in the rat model (281). The clinical diagnosis of senile calcific aortic stenosis can be difficult. A high level of suspicion and a careful search for physical findings is needed. It should be considered in all elderly patients with angina, dyspnea, or subtle CNS symptoms, and echocardiography should be performed if doubt exists.

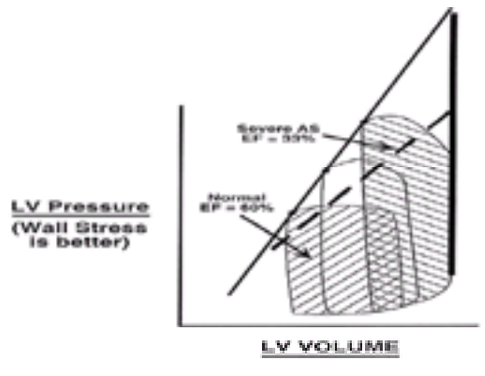
Management

Management of senile calcific aortic stenosis is similar to management of calcific aortic stenosis in younger patients (see Chapter 22) but is more complicated because of the frequent presence of associated important coronary atherosclerotic disease and other cardiac and noncardiac comorbidities. In addition, operative mortality and morbidity are considerably higher. Hence, the timing of aortic valve replacement must be highly individualized in older patients with severe obstruction.

As in younger patients, postponing valve replacement until the appearance of major symptoms of aortic stenosis—CHF, angina, and syncope (or equivalent symptoms)—is usually appropriate, but interpreting symptoms in elderly patients can be very difficult because of confounding factors. Angina can be related to CHD, CHF to past hypertensive disease or old infarction, and syncope (or CNS symptoms) to degenerative conduction-system disease, arrhythmias, and carotid or cerebral vascular disease. When convincing symptoms and a major mean gradient (50 mm Hg) are present, the decision to proceed with valve replacement is straightforward. Even if associated CHD and important comorbidity are present, the decision is justified *if the patient wishes to proceed*, with the understanding that mortality is high (up to 50% in the oldest patients) during the following 3 or 4 years (282).

Two clinical situations constitute special and relatively common problems in elderly patients with calcific aortic stenosis. First, patients with a reduced ejection fraction and a moderate gradient (mean of 25 to 30 mm Hg) whose symptoms are likely to be multifactorial in origin (dyspnea from pulmonary disease, angina because of major coronary arteriosclerosis, etc.) present a particularly difficult treatment problem even when the aortic valve area is markedly diminished (less than 1 cm^2). Highly individualized decisions are needed that consider the patients' desires and reflect the understanding that operative risk is high, complications frequent, convalescence often prolonged, and long-term benefit less likely than in patients in whom symptoms can be clearly attributable to severe aortic stenosis. A variety of provocative tests designed to assess the ability of these dysfunctional ventricles to "recruit contractility" and increase the gradient have been proposed. Most popular has been the use of dobutamine echocardiography (283,284). Although some studies report that this approach can be useful, no agreement has been reached on the issue, and the decision to replace the aortic valve remains inherently a clinical one.

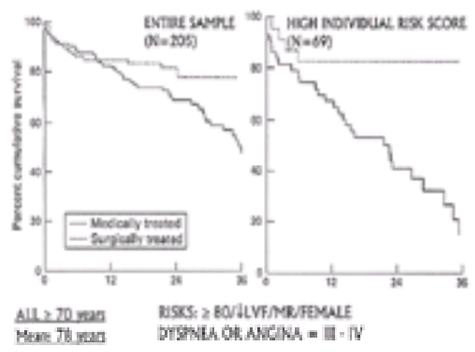
The end systolic pressure-volume relationship provides a powerful conceptual framework to assess the effect of afterload and contractility on reduced ejection fraction (285) (eFig. 33.0.11). If the left ventricular systolic peak pressure is no greater than 130 to 140 mm Hg, severe contractile dysfunction is usually present despite severe aortic stenosis and markedly reduced aortic valve area. In patients with low left ventricular systolic peak pressure, operative mortality is high and a very significant number of patients experience no benefit even if they survive surgery. Perhaps as many as one-third of the patients undergoing surgery experience substantial benefit. Preoperative selection of these patients remains problematic (286).



***e*FIGURE 33.0.11** End systolic pressure-volume relationship in aortic stenosis (AS). The solid line represents normal contractility for the end systolic pressure volume relationship. The dashed line represents reduced contractility. For the same degree of aortic stenosis and same reduction in ejection fraction (EF), the left ventricular (LV) systolic pressure is greatly reduced with diminished contractility (discussed further in the text).

The second difficult clinical situation involves patients with severe angina whose extensive coronary atherosclerosis requires CABG and who have associated mild to moderate calcific aortic stenosis; that is, aortic valve replacement would not be recommended in the absence of the need for CABG. The ability to predict the rate of progression of calcific aortic stenosis is needed to make the best judgment in this situation. Despite multiple reports studying the progression of aortic stenosis and reasonable agreement about progression in various groups of patients, variability in individual patients is very high. In a carefully done prospective study including patients with an average age of approximately 65 years, the increase in the mean left ventricular aortic gradient was approximately 7 mm per year and the decrease in the aortic valve area was approximately 0.1 cm^2 per year (287). Individual variability in such studies is too wide for the results to be useful in predicting progression in a specific patient. Other investigators have performed retrospective studies involving patients with mild to moderate aortic stenosis who underwent CABG without aortic valve replacement (288). In short-term follow-up of such patients (less than 5 years in most cases), the need for reoperation for aortic valve replacement was high (25%). Although whether or not to replace the aortic valve when mild to moderate stenosis is present at the time of CABG remains an inherent clinical problem, strong consideration should be given to replacement if surgical mortality can be kept low. Avoiding a second operation in the short term (less than 5 years) is highly desirable. Issues such as aortic valve area (range of 1 cm^2), gradient (20 to 25 mm Hg or more), velocity of the jet (3 to 4 m per second), and probably the extent of aortic valve calcification should enter into the decision.

Operative mortality ranges from under 5% to over 20% (289,290,291,292 and 293). Risk factors increasing operative mortality include low functional class, lack of sinus rhythm, preoperative left ventricular systolic dysfunction, aortic regurgitation, performance of concomitant surgical procedures, previous bypass surgery, need for emergency surgery, coronary artery disease, female gender, concurrent mitral valve surgery, hypertension, and left ventricular systolic dysfunction (*e*Fig. 33.0.12). Perioperative complications are common, and the incidence of stroke varies from under 2% to more than 10%. As has been emphasized, not only the extent of cardiovascular disease but also the overall preoperative status of the patient is of particular importance in assessing operative risk and especially long-term outcome. Assessment of biologic age rather than chronologic age is the important issue.



***e*FIGURE 33.0.12** Surgical versus medical treatment for aortic stenosis in the elderly with 36-month outcomes. ↓LVF, decreased left ventricular ejection fraction; MR, mitral regurgitation. [From Bouma BJ, van Den Brink RB, van Der Meulen JH, et al. To operate or not on elderly patients with aortic stenosis: the decision and its consequences. *Heart* 1999;82(2):143–148.]

Percutaneous balloon dilatation of the aortic valve has been explored as an alternative to valve replacement. Although the procedure may benefit a few highly selected patients, the risks of the procedure and lack of a long-term benefit in the overwhelming majority of patients has led to its abandonment (294,295) (see Chapter 91).

Aortic Regurgitation

Aortic regurgitation, much less common than aortic stenosis in the elderly, is usually trivial and results from hypertension, age-related valvular deformity, or changes in the aortic root including dissection. Occasionally it results from infectious endocarditis and a variety of rare causes, including Marfan syndrome, ankylosing spondylitis, and collagen vascular diseases (296). For aortic regurgitation in the elderly to be severe enough to justify surgery is unusual. Aortic regurgitation secondary to dissection and endocarditis are exceptions and are discussed in Chapter 25 and Chapter 107. Aortic regurgitation related to dissection or endocarditis usually has a sudden onset and is relatively easily diagnosed.

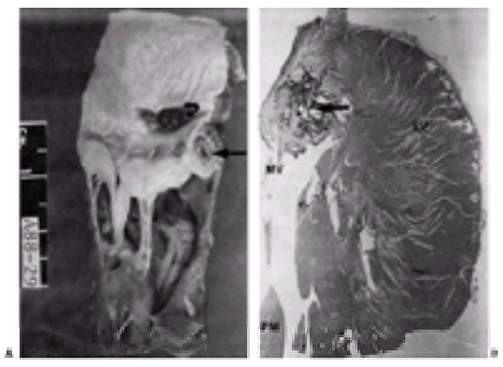
As with all valvular disease, echocardiography usually allows a precise determination of cause and evaluation of the severity of the lesion, as well as an estimate of left ventricular function, the latter of which is of critical importance in estimating prognosis and surgical outcomes. Patients with severe aortic regurgitation can usually be easily diagnosed by clinical examination using the pulse pressure, classic peripheral findings, evidence of left ventricular hypertrophy, and the diastolic murmur. These findings may be modified in the elderly because of associated peripheral atherosclerosis, which results in wide pulse pressure and modification of peripheral signs, and in particular produces systolic hypertension. In addition, only a short or difficult-to-hear regurgitant murmur may be present because of associated pulmonary disease or high left ventricular end diastolic pressure or both.

Because left ventricular dysfunction can occur in the absence of symptoms, the practice of operating to correct severe aortic regurgitation in younger patients before the development of symptoms has become understandably and appropriately popular. A variety of clinical prediction rules related to echocardiographic abnormalities have been developed to aid the decision to perform surgery. These include a variety of measurements but generally some estimate of left ventricular ejection fraction and end systolic dimension (297). The 55-55 rule is often cited: When the ejection fraction is under 55% or the left ventricular end systolic dimension is greater than 55 mm or both, aortic valve surgery should be undertaken, because waiting longer may result in increased operative mortality and a poorer outcome with regard to left ventricular function. Conceptually, this approach stems from application of the principle of the left ventricular end systolic pressure-volume relationship. In elderly patients, particularly those older than the age of 75, postponing surgery even in this situation seems reasonable, because the risk of surgery and long-term outcomes are not well characterized and medical therapy using afterload reduction is a reasonable alternative. In younger patients, nifedipine therapy has been shown to postpone and reduce the need for surgery in a randomized, controlled trial (298). Afterload reduction with ACE inhibitors is strongly suspected to be the treatment of choice in elderly patients.

Mitral Regurgitation

Mitral regurgitation is extremely common in the elderly and is usually mild. Minor mitral regurgitation from papillary muscle dysfunction is common. Mitral regurgitation often represents an incidental finding that is unlikely ever to require any medical or surgical therapy. However, in a substantial minority of the elderly with mitral regurgitation, the degree of regurgitation poses a major dilemma in assessing its importance in reference to the patient's syndrome. This problem is particularly important when coronary bypass surgery is under consideration. This matter is discussed in subsequent paragraphs.

Age-related changes in the mitral valve are more striking in the anterior leaflet, where they are characterized by fragmentation and disorganization of elastic and collagen fibers, and deposition of lipids and calcium. Similar degenerative changes in the fibrous ring of the mitral valve lead to calcification. Severe calcification abolishes the sphincteric function of the mitral ring, may immobilize the posterior mitral leaflet, and results in moderate mitral regurgitation. Extensive calcific deposits in the mitral ring may affect the conduction system and produce heart block, ulcerate and embolize, or become the site of infectious endocarditis (*e*Fig. 33.0.13).



***e*FIGURE 33.0.13** Age-related changes in the mitral valve (MV) apparatus. **A:** Photograph of a longitudinal section of the posterior wall of the left atrium, posterior mitral leaflet, and posterior left ventricular wall. Note massive calcification of the mitral annulus (*straight arrow*) and the ulceration through the atrial endocardium. The latter is covered by a thrombus (*curved arrow*). **B:** Microscopic longitudinal section of posterior left ventricular wall, posterior mitral leaflet, and posteromedial papillary muscle (PM). Massive calcification of the mitral annulus (*arrow*) is apparent, extending also into the adjacent myocardium. [From Kitzman DW, Scholz DG, Hagen PT, et al. Age-related changes in normal human hearts during the first 10 decades of life. Part II (maturity): a quantitative anatomic study of 765 specimens from subjects 20 to 99 years old. *Mayo Clin Proc* 1988;63:137–146.with permission.]

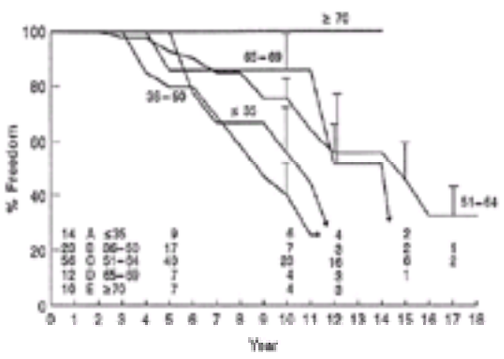
Mitral annular calcification, usually associated with only mild or moderate regurgitation, occurs almost exclusively among the elderly. (It may occur in young patients with specific diseases, such as Marfan syndrome.) It can be seen easily on chest radiography, is always diagnosed by echocardiography, and should be considered in a differential diagnosis of a systolic murmur in older persons, particularly women (299). Rarely, the regurgitation can be marked, and occasionally calcification is so extensive that mitral inflow is impeded and functional mitral stenosis is present.

The regurgitation that occurs with mitral valve prolapse (MVP), which is common in the young (more frequently in women) but seems less frequent in older persons, is of increasing interest and importance. A minority of patients with MVP have progressive regurgitation, and in older age a few experience spontaneous chordal rupture with marked mitral regurgitation and associated CHF (300,301). MVP with myxomatous degeneration of the mitral valve is an increasingly common indication for mitral valve replacement or repair in older patients (302). In a report of 266 patients undergoing mitral valve surgery for severe mitral regurgitation (mean age, 64 years), slightly over 60% had MVP. The underlying morphologic changes (expansion of the leaflets, stretching and thinning of the chordae tendineae, and increased mucopolysaccharides in the spongiosa layer of the leaflets) are similar to those observed in younger patients but are more extensive, which makes mitral valve repair less likely (302).

Management and Surgical Considerations

The threshold for the use of afterload-reducing agents, particularly ACE inhibitors, should be low in elderly patients with regurgitant lesions, particularly because of associated hypertension and CHD. In well-compensated moderate to severe mitral regurgitation, the left ventricular ejection fraction should be above normal, but a well-maintained left ventricular ejection fraction should not be considered a contraindication to the use of afterload-reducing agents, even though no convincing data exist to indicate that the progression of the disease is slowed. Watchful waiting, judicious use of vasodilator therapy, and careful serial echocardiography are key issues in decision making regarding surgical intervention.

The indications for mitral valve surgery in the elderly are similar to those in the young, with greater emphasis on relieving symptoms rather than on preserving ventricular function (in the absence of symptoms). Myocardial dysfunction can progress despite maintenance of overall pump function (absence of symptoms and a normal ejection fraction), and this has led to earlier surgery (in which valve repair is often possible) in younger cohorts. In mitral regurgitation, the increase in preload can obscure the fact that left ventricular dysfunction is occurring; that is, left ventricular ejection fraction can be maintained in the normal range (pump function is preserved) while contractility is being compromised (muscle function is deteriorating). The left ventricular end systolic pressure-volume relationship provides a conceptual framework to allow differentiation of muscle dysfunction and pump function. A variety of indices have been developed relating preoperative left ventricular end systolic volume (or echocardiographic dimension) with ejection fraction to allow prediction of postoperative ejection fraction, which is the most important determinant of long-term outcome. One popular algorithm calls for operating when the left ventricular end systolic dimension is less than 45 mm and the ejection fraction is in the normal range (285,302). Due to the shortened life expectancy, increased mortality, and increased complication rate after valve surgery, however, decisions must be must be highly individualized. An exception to this approach is older patients who are in general good health and who have developed acute or subacute symptoms due to rupture of major chordae tendineae, for whom prompt operation is desirable. Biologic valves, subject to degeneration and calcification in younger patients, are frequently the valves of choice in older individuals, in whom prosthesis longevity is increased (303) (*e*Fig. 33.0.14).



***e*FIGURE 33.0.14** Freedom from structural deterioration of Carpentier-Edwards porcine bioprosthesis, stratified by age group, for all valve positions. (From Jamieson WRE, Munro AI, Miyagishima RT, et al. Carpentier-Edward standard porcine bioprosthesis: clinical performance to seventeen years. *Ann Thorac Surg* 1995;60:999–1007, with permission.)

Mitral valve repair instead of replacement has become increasingly effective and popular, and is always desirable when feasible. Preserving the valve, and particularly the valvular apparatus including the papillary muscles, lessens postoperative complications and greatly improves long-term outcome, and should always be encouraged; however, it is not always possible in the elderly (303) (see Chapter 21).

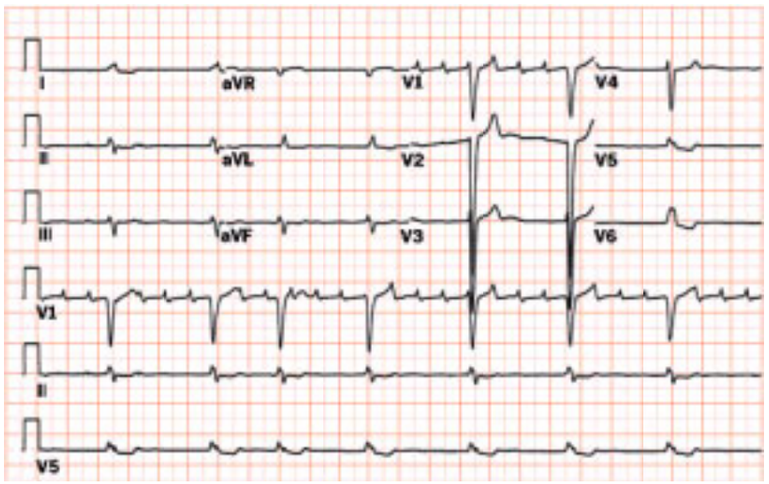
As with aortic stenosis, a large proportion of elderly patients with important mitral regurgitation have accompanying advanced coronary heart disease with past infarction or active myocardial ischemia or both. This constitutes a special problem in clinical decision making. Most of these elderly patients are in a situation in which the conventional measures predicting a good outcome have been exceeded, ejection fraction is substantially reduced (often 35% or less), and the end systolic dimension exceeds the desirable limit (304,305,306,307 and 308). In patients in whom CABG is clearly indicated because of important ischemia, the preferred approach usually is to perform the bypass and not to include mitral valve repair if the regurgitation is only mild or moderate and particularly if it is not associated with pulmonary hypertension. In many such patients the mitral regurgitation may improve postoperatively, which is probably related to ventricular remodeling due to the improved myocardial blood flow. In this setting, a highly individualized decision must be made and is guided not only by clinical judgment but by the experience of each center. In those patients in whom the clinical problem is primarily or exclusively CHF with severe mitral regurgitation related to CHD, anecdotal experience and reports of small series indicated that patients can undergo operation with a relatively low surgical mortality (range of 10% to 15%) and that in some instances the ejection fraction, surprisingly, is improved with mitral valve repair. Long-term follow-up information is limited, however, and postoperative mortality remains high. In all patients with valvular disease, fastidious attention to prophylaxis for subacute bacterial endocarditis is a very important part of management.

Arrhythmias

Arrhythmias are a major problem in the elderly but are discussed only briefly here. Chapter 58, Chapter 59, Chapter 60, Chapter 61, Chapter 62, Chapter 63, Chapter 64, Chapter 65, Chapter 66, Chapter 67, Chapter 68, Chapter 69, Chapter 70, Chapter 71, Chapter 72, Chapter 73, Chapter 74, Chapter 75, Chapter 76, and Chapter 77 comprehensively and extensively summarize the data on mechanisms, diagnosis, prognosis, and treatment. Age-related changes in the heart and autonomic

nervous system discussed in earlier sections of this chapter, especially those involving the conduction system, are important in arrhythmias.

Age-related electrocardiographic and electrophysiologic abnormalities are common in the elderly. Degenerative changes in the conduction system (309,310,311,312,313,314,315 and 316) produce important clinical manifestations. Sinus pauses, sinus bradycardia, atrial fibrillation, and other varieties of atrial ectopy and arrhythmias result. The number of sinus node cells decreases with age, and a greater irregularity is seen in their shape. An increase in fat, elastic fibers, and collagen within the nodal tissue is also seen with aging. Despite the significant cellular reduction, particularly after the age of 75, sinus node activity may be normal. Vascular disease in the sinus node artery is not considered to be the cause of the histologic changes in the sinus node (312).



High-grade atrioventricular block. Note marked discrepancy between atrial and ventricular heart rates.

Trifascicular block. Note right bundle branch block, left anterior hemiblock, and associated first-degree atrioventricular block.

An 83-year-old patient with complete heart block, junctional escape rhythm, left anterior hemiblock, and complete right bundle branch block.

“Sick sinus syndrome” is a misnomer because other manifestations of degenerative conduction system disease can usually be uncovered when specifically sought. In many instances, the ECG also shows additional infranodal conduction defects such as left anterior hemiblock and right or left bundle branch block. These changes in the His-Purkinje system are sometimes, but not always, predictors of progressive degeneration of the conduction system and the development of heart block, frequently with syncope. However, electrophysiologic studies undertaken to predict progressive changes and important clinical manifestations have been disappointing (310).

A 93-year-old male patient with trifascicular block.

A 75-year-old male patient with trifascicular block.

In cases of complete heart block, and in some cases of supraventricular tachycardia, the arrhythmia per se is responsible for symptoms and dictates the management approach. More frequently, the extent of associated cardiac disease, primarily CHD with ischemia or left ventricular dysfunction or both, are key features in producing symptoms. The total picture—not the presence of ECG abnormalities caused by degenerative conduction system disease and the arrhythmias (especially if atrial)—should dictate therapy.

Drugs commonly used in older patients, including beta-blockers, calcium channel blockers, digitalis, and antihypertensives (such as alpha-methyldopa), can produce some of the same ECG changes as degenerative conduction system disease. This further illustrates the need to carefully differentiate abnormalities and findings caused by adverse drug reactions from those related to disease in the elderly.

Atrial Fibrillation

Atrial fibrillation (see Chapter 64) is extremely common in the elderly. It is responsible for considerable morbidity and mortality, especially stroke and CHF (29,265,317,318,319 and 320), and is a marker for increased in-hospital mortality in Medicare patients. Often, it is asymptomatic. Its prevalence may be 10% in persons older than 70 and may increase to 15% by the mid-eighties. The median age for atrial fibrillation is 75 years. The range for 1-year mortality is extremely wide, from less than 1% to 15%. Patients at highest risk for stroke are those older than age 75 and those with impaired ventricular function and a history of thromboembolism and associated conditions, particularly hypertension and diabetes. Left atrial size as judged by echocardiography is another independent predictor but has not been well studied in the elderly population.

A careful general clinical evaluation searching for subtle hyperthyroidism, chronic pulmonary disease, the use of beta-agonists, hypokalemia (from drugs), and alcoholism is important. These and other diseases and conditions can precipitate atrial fibrillation and can be very subtle in their clinical manifestations in the elderly. Cold remedies, antihistaminics, and all varieties of stress (especially infections and surgery) may precipitate atrial fibrillation.

Management

Management of atrial fibrillation is complex in the elderly, but as in the young, the goals are prevention of thromboembolytic complications and treatment of arrhythmia-related symptoms, especially CHF. Transthoracic and, on occasion, transesophageal echocardiography have an important role in the evaluation and management of patients with atrial fibrillation. Details about ventricular function, size of the left atrium, and presence of valvular disease, and a search for intraatrial thrombi (usually requiring transesophageal echocardiography) are of great value in assessing the cause, potential for sustained sinus rhythm after cardioversion, and the risk of thromboembolism (321,322a). All patients should receive anticoagulation therapy unless specific and strong contraindications exist. Data are convincing that warfarin should be used. In patients presenting with acute symptoms, initial treatment aimed at slowing the rate is essential, and a variety of approaches are available (see Chapter 64). For treatment after the acute phase has been addressed, two strategies are debated: control of the ventricular rate and restoration of sinus rhythm.

The decision to convert atrial fibrillation to sinus rhythm in the elderly is complex and problematic. The frequency of side effects of commonly used antiarrhythmic medications and the relatively low rate of maintenance of sinus rhythm (30% to 60% revert to atrial fibrillation within a year) diminish the attractiveness of cardioversion unless the atrial transport function can be shown to be of major benefit in improving symptoms of CHF. Age-related diastolic dysfunction makes it desirable to restore normal sinus rhythm with the expectation that left ventricular filling pressure will be reduced and symptoms of pulmonary congestion alleviated. In many elderly patients, however, sinus bradycardia with ineffective atrial contraction follows restoration of sinus rhythm. Other approaches to maintain sinus rhythm, particularly the use of amiodarone hydrochloride and, more recently, nonpharmacologic approaches such as atrioventricular nodal modifications or ablation with use of rate-responsive pacemakers, implantable atrial defibrillators, or even surgical interventions (maze procedure), are increasingly used, but these are apt to be helpful in only a limited number of highly specialized situations in the elderly. In many patients, maintenance of an optimum antithrombotic regimen and control of ventricular response are the preferred approaches. The National Institutes of Health Atrial Fibrillation Following Investigation of Rhythm Management (AFFIRM) study is a large randomized, controlled trial that is investigating the feasibility, desirability, and implications of restoration of sinus rhythm versus control of ventricular rate. Results of a small randomized, controlled trial have been reported, and restoration of sinus rhythm has not been shown to be superior to rate control and anticoagulation therapy (352).

The use of pacemakers in atrial fibrillation due to sick sinus syndrome is very popular and is often invoked because of drug-induced bradycardia or the desire or need to use antiarrhythmic agents that may interfere with atrioventricular conduction in elderly patients who have age-related atrioventricular nodal dysfunction. Ambulatory electrocardiographic monitoring is frequently performed in these patients, and pauses of 2 to 4 seconds (sometimes longer), particularly during nighttime, are commonly found. Elderly patients tend to have cerebral symptoms, fatigue, and other symptoms that might be related to pauses, but unless the symptoms and pauses correlate, the use of a pacemaker is difficult to justify. This common practice has not been evaluated in any systematic way, although the belief that pacemakers should be used to abolish symptoms, possibly pause related, or prevent long pauses, even though asymptomatic, or both is intuitively appealing.

Ventricular Arrhythmias

The risk of ventricular arrhythmias is related to the structural heart disease and other comorbidities. CHD and ventricular dysfunction are the most important structural heart diseases that increase the risk of sudden cardiac death, but smoking, systolic hypertension, hypercholesterolemia, and left ventricular hypertrophy are additional risk factors.

Monitoring and electrophysiologic testing are key elements in evaluation of patients who have or are suspected of having ventricular arrhythmias. These matters are discussed in detail in Chapter 60, Chapter 62, and Chapter 67. Treatment for sustained ventricular arrhythmias has increasingly involved the use of implantable cardioverter-defibrillators (ICDs; see Chapter 67 and Chapter 75). The benefit of ICDs in patients older than the age of 70 is similar to that in younger patients (perhaps greater), but the number of elderly studied in controlled trials has been small, and such patients are undoubtedly highly selected (323,324 and 325). As has been repeatedly emphasized, the evaluation of the total patient—particularly with reference to comorbidity and competing risks—should dictate treatment when an ICD is being considered (326,327,328,329 and 330). In patients who are physiologically young and are judged to have the opportunity to benefit for a number of years, ICD placement should be considered according to criteria similar to those used for younger cohorts, as has been demonstrated to be useful in randomized, controlled trials. [Clearly, the indications for ICD placement in practice do not follow those adopted in randomized, controlled trials (326,328).] In many older patients, however, particularly those older than age 75 and especially those older than age 80, death from noncardiac disease or nonarrhythmic death becomes increasingly likely (160,327). In a single-center observational study, among 74 patients older than the age of 75 who underwent ICD implantation, mortality was 33% at 4 years. Appropriate shocks were infrequent (35%). No sudden deaths occurred. This high non–sudden cardiac death mortality in the elderly again emphasizes that caution is needed in extrapolating outcomes found in younger cohorts, because benefit in the elderly will most certainly be overestimated. Antiarrhythmic drug therapy, particularly the use of beta-blockers, has an important role in the treatment of sustained ventricular tachycardia in the elderly (331), although drug selection is always complicated and problematic (see Chapter 67).

The large group of patients with asymptomatic nonsustained ventricular arrhythmias represents a major clinical dilemma, because data for this group of the elderly are totally inadequate to direct clinical decision making. The principles discussed in Chapter 67 and Chapter 75 apply but must be used in a much more precise and highly individualized fashion. In particular, attention to comorbidity, frailty, and ventricular function is important. Although the range of available devices is becoming broader and devices are becoming more sophisticated, this only adds to the complexity in making clinical decisions for the elderly without greatly simplifying the issues.

Complete Heart Block

Complete heart block occurs overwhelmingly in the elderly population. Chapter 63, Chapter 71, and Chapter 74 discuss the issues involved, including indications for the use of pacemakers in heart block and the rationale for selection of a specific type of pacemaker. Assessing the cause of symptoms can be very difficult in the elderly because conduction system disease is frequently present in the absence of symptoms, and a variety of disease processes, particularly carotid and cerebrovascular disease, may be responsible for the patient's complaints of dizziness or syncope. Therefore, a fastidious workup is required. On occasion, an empiric clinical decision must be made in the absence of any supporting documentation regarding the cause of complaints (332). Debate is ongoing as to whether more sophisticated and expensive atrioventricular universal (DDD) pacemakers provide additional benefit over atrioventricular sequential pacing (DVI) pacemakers in the elderly (333,334 and 335).

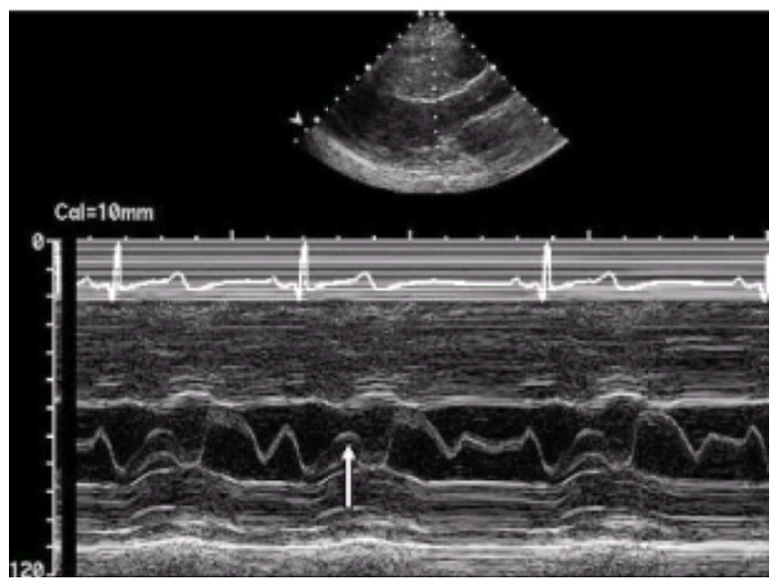
Electrophysiologic and Ablation Treatments

The indications for electrophysiologic testing are evolving and for some patient groups are controversial, so the fact that no consensus exists about the use of these approaches in elderly patients is not surprising. However, EPS clearly is feasible, can provide valuable information, and is specifically helpful in directing therapy in elderly patients. Patient selection remains the issue. Similarly, catheter ablation treatments at the atrioventricular node for selected cases of atrial fibrillation and for supraventricular tachycardia in elderly patients not responding to simple drug therapy is feasible, carries relatively low risk, and is effective.

Hypertrophic Cardiomyopathy and Hypertensive Hypertrophic Cardiomyopathy

That hypertrophic cardiomyopathy (see Chapter 29) has a different genetic basis and a different prognosis in the elderly than in young patients is increasingly evident. The condition is not rare in the elderly, and several studies have found that more than 50% of patients are older than the age of 50 and as many as 40% are older than the age of 60 (336). Morphology is also different.

Echocardiographic studies have shown similar asymmetric hypertrophy of the septum, systolic anterior motion of the mitral valve, and severity of an outflow tract gradient, in young and elderly patients, although younger patients have more severe hypertrophy (337,338). Ventricular cavity contours differ; the septum in the young is more hypertrophied, has reversed curvature, and thus creates a crescent-shaped left ventricular cavity, whereas elderly patients have normally shaped left and right ventricles and less severe hypertrophy overall.



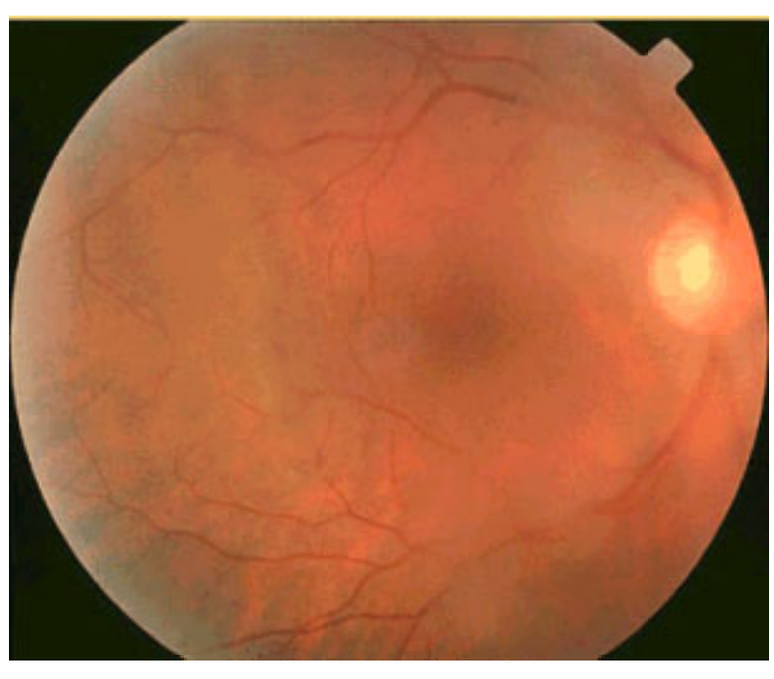
M-mode tracing of hypertrophic cardiomyopathy with severe septal hypertrophy seen at the top of the trace and systolic anterior motion (SAM) of the mitral valve in systole seen in the middle of the trace (designated by the arrow).

A subgroup of elderly patients with obstructive hypertrophic cardiomyopathy, 87% of whom were women, revealed an atypical systolic contact between the mitral valve and the intraventricular septum, which produced a dynamic subaortic obstruction (338). This contact can also result from a posterior excursion of the ventricular septum toward the mitral valve. Sizable calcium deposits in the mitral valve annulus in these patients probably contributed to the outflow tract narrowing. Another subset of patients, most of whom were African-American, showed severe concentric hypertrophy with a small left ventricular cavity, an increased ejection fraction (80%), and diastolic dysfunction (339). Most of these patients had hypertension; the increased blood pressure may somehow serve as the stimulus to unusual and severe hypertrophy. The association of hypertrophic cardiomyopathy with systemic hypertension in a subgroup of elderly patients has prompted some to suggest an etiologic link between these two entities. Others, although recognizing that hypertension may aggravate the underlying cardiomyopathy (leading to an increase in myocardial mass), have stressed that hypertension is not the primary cause of hypertrophic cardiomyopathy. These observations indicate the complexity of the spectrum of hypertrophic cardiomyopathic disease in the elderly.

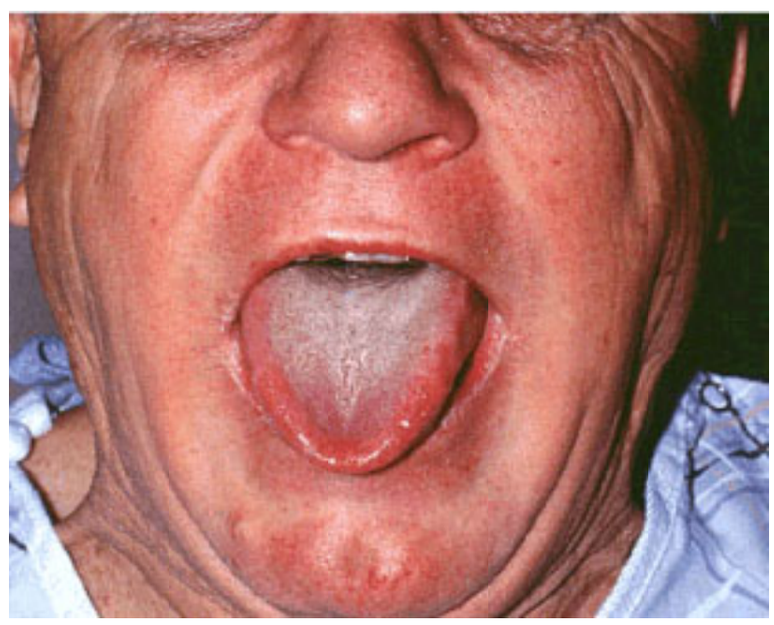
The long-term survival rate of elderly patients with hypertrophic cardiomyopathy is very similar to that of an age- and sex-matched control group (336,337,338,339 and 340). Although adequate studies on the genetic transmission of hypertrophic cardiomyopathy in the elderly are lacking, the genotypes are different from those that occur in the more malignant syndrome seen in younger patients (341,342), especially patients with a family history of disease (and, most important, when the family history involves sudden cardiac death) (341,342,343,344 and 345).

Senile Amyloidosis

Autopsy studies indicate that amyloid is commonly present in patients older than the age of 75, and up to two-thirds of patients older than age 85 may show evidence of amyloidosis (346). Among these patients, approximately one-third may show extensive ventricular involvement; CHF is present in approximately half the patients and may be attributable primarily to the amyloidosis (347). Amyloidosis was judged to be an important contributor to death (perhaps the primary cause) in one group of patients (348). Amyloid deposits were first described in elderly patients in 1876, but their potential importance with regard to pathophysiology in most patients is not clear. In addition, the biochemical properties of amyloid in old hearts and its relationship to the amyloid in familial amyloidosis and that associated with multiple myeloma need further clarification (336). Although it is rarely diagnosed clinically, definitive diagnosis has been made by biopsy (349).

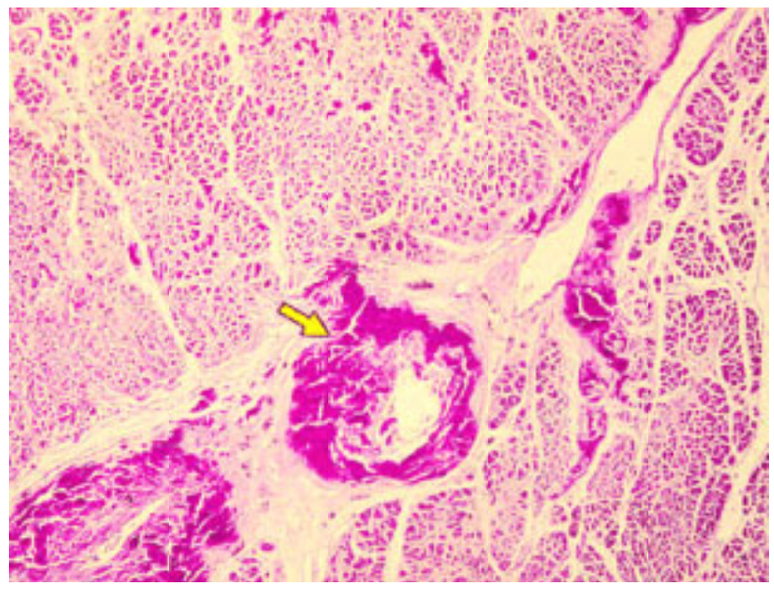


Vitreous opacities in association with amyloidosis.

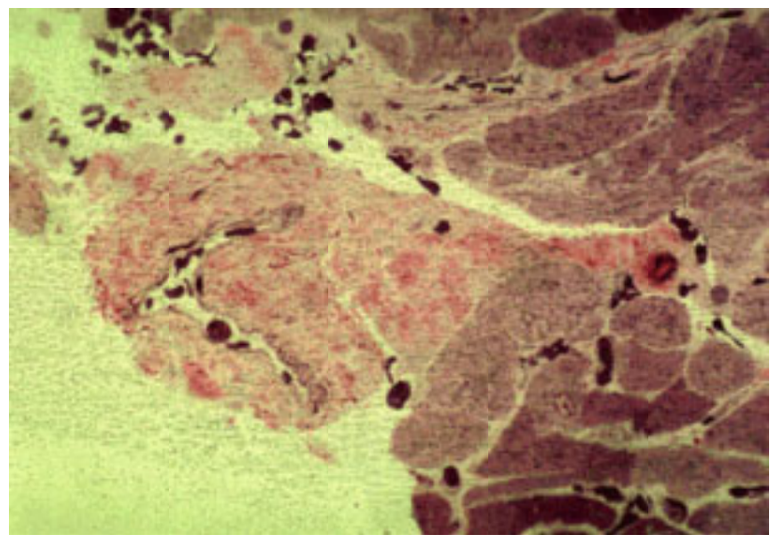


Amyloidosis. Infiltration of the tongue occasionally leads to macroglossia. Cardiac manifestations include cardiomegaly, congestive heart failure, and arrhythmias.

Amyloidosis. Infiltration of the skin results in raised waxy papules or plaques that are usually in clusters.



Amyloidosis of the heart. This is cresyl violet stain of the left ventricular myocardium. The yellow arrow indicates a metachromatic red-violet homogenous deposit around an intramyocardial arteriole with similar interstitial deposits.



Amyloid deposition. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

In recent years, immunohistochemical studies have recognized three distinct types of senile cardiovascular amyloidosis: isolated atrial amyloidosis, senile aortic amyloidosis, and senile systemic amyloidosis, in which organs such as lungs, liver, and kidneys are involved (in addition to the heart) (350). The latter, although rare, may cause significant cardiovascular morbidity. Distinguishing between nonsecretory, immunoglobulin-derived primary amyloidosis with cardiac involvement and senile systemic amyloidosis is possible only with immunohistochemical techniques.

Diastolic dysfunction increases as amyloid deposits increase, which results in pulmonary congestion and eventual right heart failure with edema. Conduction defects and atrial fibrillation, although common in older patients with amyloid deposits, do not seem related to amyloid infiltration into the conducting system. This must not be confused with the conduction system disease that occurs because of deposits in patients who have familial amyloidosis with polyneuropathy (351). Echocardiographic study can be useful and may be relatively specific in diagnosis (see Chapter 49).

Patients with senile amyloidosis may be more sensitive to the effects of digitalis and have more episodes of digitalis toxicity, but this is not well established (351,352). The outcome of patients with senile amyloidosis is grave, and such patients have a mortality of 50% by 6 months from the time of endomyocardial biopsy diagnosis. Not surprisingly, the CHF responds poorly to all interventions. Much remains to be learned about the characteristics, occurrence, and pathophysiologic effects of senile amyloidosis. Whether its occurrence is somehow genetically determined or is only related to the immunologic changes associated with aging is also unclear.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The amount and cost of cardiovascular care provided to the elderly will continue to increase because of the growing number of elderly patients, the larger number of services and procedures provided per patient, and the increased cost of the sophisticated care given. The pressure to control cost will continue (Medicare expenditures are now at $200 billion annually). Although the rate of rise will ameliorate, the absolute expenditures will continue to increase appreciably. This will be particularly true in the over-75 age group, because cardiovascular disease tends to have a more complicated course in this group and the physiologic changes, both in the cardiovascular system and throughout the rest of the body, make all management strategies different and more complicated than in the younger old (65 to 75 years).

Physicians will feel obligated to use the considerable fiscal resources available for elderly care most appropriately. They will require more and better outcome data for all major cardiovascular syndromes, which will lead to an understanding (or disappearance) of the widely disparate practice patterns, especially in the use of procedures in the elderly. Data on such outcomes must include “long-term” information, because these older patient subsets have a high 3- to 5-year mortality even with successful therapeutic interventions. These “long-term” outcome studies will highlight the need for a philosophical approach that emphasizes quality of life and the patient’s choice (incorporating the patient’s individual value system). These issues may be more important than short-term mortality data and longevity per se.

Randomized, controlled trials are unlikely to play a major role in resolution of management dilemmas in the elderly because of the extraordinary heterogeneity in this population. Registries (databases) involving carefully prospectively collected key variables are likely to be a more effective approach. Critical characterization of complications of procedures and adverse drug reactions, and collection of follow-up data on functional status are among the critical issues, and these can be addressed by registry studies. Algorithms and clinical rules developed for younger cohorts are not directly transferable to elderly cardiovascular patients, which further emphasizes the need for prospectively collected, syndrome-specific data.

The heterogeneity of aging will serve as a stimulus for physicians to characterize elderly patients more objectively in relation to their ability to withstand the stress of procedures and complications of disease, with emphasis on physiologic reserve and biologic age rather than chronologic age. With better characterization of biologic age and physiologic reserve, more precise estimates of outcomes of therapies and interventions can be made, patients can be given better information, and, with their families, they will have more realistic expectations. Better-informed decisions will result. Biologic age is multifactorial, involving cognitive, emotional, physical, and nutritional attributes as well as function of specific organs (lung, kidney, liver), because no single feature can characterize the total elderly patient. The concept of competing risks will evolve, since even the most successful therapy will have limited effect on longevity in the very old.

Although important research at the cellular and molecular level will characterize and provide better understanding of the aging process, this basic information is not likely to be immediately useful in the management of the large number of elderly patients with major cardiovascular disease. Preventive measures, including physical exercise, mental stimulation, avoidance of depression, good nutrition, and abstinence from tobacco use, are helpful approaches to postpone or ameliorate the consequences of aging and allow patients to tolerate cardiovascular diseases better when these become manifest.

THE FUTURE

Advances in medicine will result in a larger elderly population. These patients will require a more philosophical approach with emphasis on quality of life and the patient's choice, as well as cost considerations. Data from "long-term" outcome studies will guide the physician in making appropriate choices and providing realistic expectations for the elderly patient. Prevention and postponement of cardiovascular disease will be emphasized as the most effective approaches.

OVERVIEW

Life in the coronary care unit (CCU) is changing. Once a comfortable “laboratory” for conducting studies of physiology and pharmacology, as well as a bastion of medical education, the modern CCU has become a vastly different place over the course of the last 15 to 20 years. This is particularly true in large, tertiary teaching hospitals. The patients are older and sicker, and they have more multiorgan dysfunction than before. They frequently require multiple-team, interdisciplinary management. Patients who have routine, uncomplicated myocardial infarction continue to be admitted, but many such patients are now well cared for in large suburban hospitals by highly qualified cardiologists. Tertiary teaching hospitals more often receive elderly patients with highly complex conditions who are transferred on day 2 or 3 of acute myocardial infarction complicated by acute pulmonary edema, stroke, refractory ventricular tachycardia, cardiogenic shock, severe mitral regurgitation, ruptured interventricular septum, critical aortic stenosis, acute renal failure, sepsis, or some combination of the above. Such patients can usually be stabilized and their conditions managed, but they not uncommonly languish for days in the CCU, obtunded, unable to be easily weaned from the ventilator. Anxious families understandably become frustrated, and uncertainty about prognosis only serves to further fracture the bond between physicians and family members.

The dilemma is made worse by the inability of many patients to participate in the decision-making process. Families may be absent. Occasionally, competing interests and desires may emerge among family members. Decisions about the end of life are seemingly more complex in today’s world. Resources are often constrained, and economic pressures exist to reduce the length of stay in the CCU. The overall daily charges for the CCU range from $2,000 to $10,000 per day. To put the economic burden into perspective, it is estimated that critical care costs in the United States are more than $80 billion per year, or approximately 1% of the gross domestic product (1). Of course, the high cost of care is a global problem, certainly not unique to the United States.

The aging CCU patient population, complexity of disease, high prevalence of multiorgan dysfunction, unrealistic expectations of patients and families, and persistence of taboos regarding discussions of the end of life in most cultures mean that physicians who work in the CCU must be familiar with certain guiding principles regarding the withholding and withdrawal of life-support systems. The decision to withhold or withdraw life-sustaining support from a critically ill patient is an increasingly difficult but necessary part of providing care in the CCU. The preciousness of human life is embedded in nearly every religion and culture. The natural tendency of every physician is to nurture the patient back to health, and therefore to preserve life without regard to age, cost, or other culturally imposed boundaries. It is clear that in a small number of cases, death is inescapable. In such cases, the wise physician turns attention to the family, while ensuring that the patient is made comfortable. But mostly there are gray zones, in which outcomes are uncertain and decisions about continued aggressive treatments are extremely difficult. Uncertainty becomes champion.

How are these decisions made? Who makes these decisions? What are the ethical principles that underlie these decisions? How does a physician actually withdraw life support? The goal of this chapter is to provide CCU physicians with practical advice that will help guide them through this difficult process.

HISTORICAL PERSPECTIVE

For many years, the ethical and legal consensus in the United States has been that patients and their surrogates have the right to refuse life-prolonging therapy. This stems from the common-law right of self-determination (the principles of autonomy), which was upheld by the U.S. Supreme Court in 1891 (2). Despite agreement on this general principle, dying patients in the United States frequently receive unwanted interventions (3,4). The patient’s right to autonomy, though sacred and carefully guarded, sometimes competes with the staff member’s skill in providing aggressive life-extending treatment. Physicians and nurses are often poorly trained in withholding or withdrawing intensive life support. It is sometimes easier for them to continue aggressive care than to struggle with the difficult decision to withdraw life support. This issue came to a head in the landmark case of Karen Ann Quinlan (1976), and the courts ultimately forged a legal consensus based on the principle of patient autonomy. This principle establishes the right of patients (or their surrogates) to determine which medical interventions to accept or refuse, even when the absence of treatment results in death. It was affirmed by the U.S. Supreme Court in the case of Nancy Cruzan in 1990. The court acknowledged that patients who die after life support is withheld or withdrawn die of the underlying disease process. Such deaths are not assisted suicides or euthanasia. The courts have also reasoned that the spouse and children are the most appropriate surrogates because they are best positioned to know the patient’s feelings and desires about treatment.

In fact, next of kin are no better than physicians in estimating what the patient would want with regard to end-of-life care (5). Therefore, the physician, acting on behalf of the patient, must assess the validity of the surrogates’ preferences and the commonality of belief structure. Friends or family members may hold power of attorney to make decisions for the patient, as directed by a living will or advanced directive. However, living wills have not had a major impact on decision-making or costs associated with end-of-life care, because they are so nonspecific. Patients frequently express different beliefs when they are healthy than when they face decisions about withdrawal of life-support measures (6). The U.S. Supreme Court has unanimously ruled that there is no constitutional right to physician-assisted suicide but has also effectively required all states to ensure that their laws do not obstruct the provision of palliative care—including the administration of drugs as needed to avoid pain at the end of life (7). The provision of morphine or other medications at the end of life to control pain and suffering has the full force of the judiciary behind it.

From a historical context, these rulings have come at a time when modern technology can sustain organ function for prolonged periods, and thus they are of great importance to physicians working in the CCU. Lay people, through the print media and television, have come to expect full recovery after illness. Families and patients often seem mystified when informed of the details of an illness and become alarmed when they realize that meaningful recovery may not be possible. The gap between family expectations and medical reality can only be closed by frequent empathetic and effective communication between the medical team, the family, and, when appropriate, the patient.

ETHICAL PRINCIPLES

Some fundamental principles of medical ethics have evolved over centuries and are generally accepted (Table 34.1).

Autonomy
Preservation of life
Alleviation of suffering
First do no harm
Justice: ensure that medical resources are allocated fairly
Telling the truth
The rule of double effect

TABLE 34.1 FUNDAMENTAL PRINCIPLES OF MEDICAL ETHICS

Autonomy

The term *autonomy* is derived from the Greek words *auto* (self) and *nomos* (rule or law). The principle is the source of the common-law right of self-determination and lies behind the constitutional right of privacy. No right is held more sacred, and the U.S. Supreme Court has used this principle in asserting the right of patients to refuse life-saving treatment. If an adult patient is heavily sedated or unconscious, a surrogate decision-maker (usually a spouse or family member) should authorize decisions about care. Health care providers need to realize that decisions about care are in the hands of the patient, not the medical team. The attending physician and other members of the medical team determine treatment strategy on the basis of scientific principles and then decide on the best course of action based on discussion with the patient or the families. The patient (or the surrogate decision-maker) almost always accepts the team's advice, but the relationship is one of partnership, not paternalism. The ethical principle of autonomy states that the patient has a right to self-determination that supersedes the desires of the medical team—even if it means that death of the patient will result. In the United States, minors do not have autonomy under the law, and parents become the decision-makers.

The CCU environment doesn't always allow for the luxury of time, and lengthy discussions with multiple family members are sometimes not possible. Management of cardiogenic shock, recurrent ventricular fibrillation, acute pulmonary edema, or acute aortic dissection requires quick, reasoned actions. In such emergencies, the principle of preservation of life guides the physician, provided there are no antecedent instructions from the patient or family to withhold life support.

Although end-of-life issues are best discussed in the privacy of the outpatient clinic when the patient is medically stable, many patients misunderstand the process of advanced life support or are apprehensive about discussing death. This may be related to the nearly universal taboo against discussing death, which is particularly common among the older generation. A significant number of people prefer a less dominant autonomous role in end-of-life decisions and put their trust in their doctors and the health care system (8). To approach a critically ill patient in the CCU with heartless questions about cardiopulmonary resuscitation and intubation is a grotesque distortion of what should be a very private, reasoned dialogue. Trying to berate a sick patient into being autonomous near end of life is a tragic mistake. My practice is always to discuss end of life in the outpatient setting when possible. When this is not possible, which is often the case, it is helpful to talk to the patient alone at the bedside and attempt to have them understand and make distinctions between short-term aggressive care and prolonged life support.

In the end, the informed patient can usually make an autonomous decision. Physicians must guard against imposing their own values and should not slant the discussion in such a way as to mirror their own feelings about the end of life. It must be recognized that some cultures object to informing patients of a terminal diagnosis. It may be believed that the family, not the patient, should make life-support decisions. Violating a patient's cultural values should be avoided. This is a serious problem that defies a simple solution. It is often useful to have serious dialogue with the family and then the patient as soon as possible—usually within 48 hours of admission to the CCU.

Preservation of Life

All physicians are aware of this ethical principle, and it requires no explanation. Problems may arise when preservation of life competes with beneficence or alleviation of suffering. For a dying patient, alleviation of suffering may be more important than prolonging the end of life. However, the sanctity of life is of great importance and has its roots in most religions of the world. Many believe that every second of life is sacred and must be preserved at all cost.

Alleviation of Suffering (Beneficence)

To restore health and relieve suffering is one of the most time-honored goals of physicians. It is the fundamental duty of all doctors. Beneficence supersedes the perceived beliefs of society or the personal values of the physician. Relief of suffering may supersede preservation of life (see the section Rule of Double Effect), particularly when death is inescapable.

First Do No Harm (Nonmaleficence)

Primum non nocere is an ancient principle of medicine and is embedded in the Hippocratic oath: "I will use treatment to help the sick according to my ability and judgment, but I will never use it to injure or wrong them." This principle underlies the physician's decision to recognize that death is inescapable and to proceed with comfort care. However, the Hippocratic oath's injunction to "do no harm" seldom applies in today's environment. It is unethical to continue aggressive care for patients who have no hope for recovery; the physician's goal is to provide comfort, not to prolong dying. Likewise, inappropriate drug use and the ordering of diagnostic tests that are potentially risky but not likely to help the patient are unethical under certain circumstances. On the other hand, there may be pressure from families to "keep going." Such a dilemma requires frequent and careful dialogue with the family. It may take days for some family members to realize that death is imminent. In the CCU, it isn't always possible to know when death is inescapable, and it is important for the physician to convey a sense of hope, when appropriate. Families and patients sometimes have unrealistic expectations and will request that "everything be done," even though the patient has little or no hope for meaningful recovery. Some families will put a highly spiritual spin on the problem and insist that the medical team should hold out for a "miracle." Often, the patient wants more aggressive care than the family (9). Physicians may be inaccurately overly pessimistic, whereas patients tend to be inaccurately overly optimistic (8). Frequent, careful assessment of the patient and the prognosis coupled with frequent communication with family becomes even more important.

An experienced CCU physician can often sense when multiorgan failure is beginning to emerge and is keenly aware of this when each day brings a new struggle to keep the patient alive. Such patients are often intubated, sedated, and unable to carry on meaningful dialogue. It is the physician who has specialized knowledge of the natural history of disease, not the family, and it is the physician who must use this powerful knowledge to help guide families when making decisions about withdrawal of life support. Families often want certainty, but there is no certainty in most instances, only judgments. Physicians should clearly describe what will likely happen if aggressive treatments are continued and contrast this information with what will likely happen if comfort care only is begun. A combination of objective quantitative information and the physician's judgment about outcome is better than either alone (8).

Justice: Ensure That Medical Resources Are Allocated Fairly

It is clear that some economically deprived populations are underserved and as a consequence may have higher morbidity and mortality rates. Decisions regarding care should be blind to economic circumstances, ethnicity, perceived societal views, political persuasion, gender, and age. As care becomes more rationed in our society, the principle of justice takes on more practical importance. Heart transplantation, for example, is a highly rationed form of treatment with generally accepted medical indications and contraindications. If a heart is transplanted into a patient who does not comply with treatment and who dies quickly of rejection, two people die: the noncompliant patient, and the anonymous patient on the transplant list who dies while waiting for a heart transplant. In our society, end-stage heart failure and the need for heart transplants occurs in cocaine dealers, prisoners, pedophiles, and wealthy elderly people who are beyond the usual age limit for heart transplantation. The principle of justice would assume that only medical need determines care. However, outcomes for heart transplantation are affected by social issues, medical compliance, age, family support, and underlying general health. If there were a surplus of donor hearts, decisions about who should receive a heart transplant would be less difficult. As all therapy becomes more rationed in an era of harsh cost-containment, the principle of justice becomes more applicable in the CCU. The principle of justice will become more difficult to apply as competition for scarce resources intensifies. Some evidence exists that justice has been ignored and that racial bias has entered the decision-making process (9).

Telling the Truth

Honest communication between physician and patient is very important and is a major principle of ethics in Western society (10). In some Asian societies, it is

considered inappropriate to tell a patient that he or she has cancer; the stigma and fear associated with knowing one has cancer outweigh the active withholding of information about diagnosis and prognosis. In the United States, it is assumed that patients and families want to understand the diagnosis, prognosis, and risks and benefits of various diagnostic and therapeutic procedures, but the level of understanding desired by patients and families is highly variable (5). This principle is particularly important to uphold in the CCU, where the presence of many different teams and fellows can greatly fragment the care of the patient. It is important to try to personally explain to the patient the risks and benefits of cardiac catheterization, percutaneous coronary interventions, and cardiac surgery, fully understanding that someone else will obtain direct informed consent and will further expound on the risks and benefits of these procedures. Patients tend to view the CCU team and the attending physician as “their” doctors. This is who they see on rounds daily and know and trust most explicitly, and this is who should explain to the patient and family what diagnostic and therapeutic plans are evolving—what the strategy will be for the next 24 to 72 hours. Consultants may be asked to discuss the case with families on occasion. For example, when complex noncardiac complications occur, such as intracerebral hemorrhage or severe hypoxic encephalopathy, it is reasonable for the neurology team to have a discussion with the family. If an internist or family doctor has a long-standing relationship with the patient, that person should be consulted and engaged with the decision when possible.

Rule of Double Effect

The rule of double effect may be the ethical principle least understood by medical personnel and lay people. Many are not even aware of the principle. According to the rule of double effect, outcomes that would be morally wrong if intentionally provoked are permissible if foreseen but unintended (11,12 and 13). Specifically, administering opioids to treat a terminally ill patient’s dyspnea or pain may be acceptable even if the medication contributes to or causes the patient’s death. A harmful effect of treatment, even death, is permissible if death is not intended but occurs only as a side effect of a beneficial action. It is not uncommon for dying or terminally ill patients in the CCU to receive morphine as part of comfort care. It is usually given in small doses (an initial drip of 1 to 2 mg per hour or repeated boluses ranging from 10 to 30 mg per hour) to alleviate air hunger or dyspnea, supplemented by benzodiazepines to treat anxiety or agitation. Appropriate use of opioids for symptom control does not usually shorten life, and there is generally little or no need to invoke the rule of double effect (14).

The rule of double effect was developed by moral theologians of the Roman Catholic Church in the Middle Ages (15,16). The underlying logic is that it is impossible for a person to avoid all harmful actions. Failure to intervene to comfort a dying patient harms the patient by allowing treatable discomfort to continue. If the intent of treatment is to relieve suffering, the foreseen but unintended risk of earlier death is permissible. The U.S. Supreme Court has demonstrated support for this principle by requiring all states to ensure that their laws do not obstruct the provision of adequate palliative care, especially for alleviation of the physical discomfort of patients who are facing death (17,18). The physician’s goal under these circumstances is to relieve the patient’s discomfort (in this case, air hunger or dyspnea). Neither the physician nor the patient intends for the patient to die. If death occurs from the opioids (rare), it is foreseen but unintended. The rule of double effect and subsequent legal rulings supporting the principle have served to reassure physicians that prescribing morphine drips for terminally ill patients is morally and legally permissible and is the proper thing to do (19).

FAMILY CONFLICTS

The decision to withdraw advanced life-support measures is one of the most difficult decisions that clinicians and families must make. Often the prognosis is not absolutely certain. The patient’s judgment should be involved when possible, although most patients who are on advanced life support are not mentally competent. Only a small minority are able to participate in the initial decision to limit treatment [4% in a surgical intensive care unit (ICU) vs. 27% in an oncology service] (20). It is important to provide hope to families, but hope is a double-edged sword. Hard questions need to be asked of families: What has been the family’s experience with other dying patients? What do they consider “suffering”? What is their concept of “meaningful recovery”? The medical team should avoid offering guarantees and certainties regarding death or recovery. The worst thing a physician can do is give mixed messages or abdicate responsibility. Families need time to deal with the devastating thought of withdrawal of life-support systems and death. A useful tactic is to get the family together in a quiet, private room and discuss the issue at length. Give them room to vent. Allow the family to verbalize their grief. Make sure their spiritual needs are attended to by a hospital chaplain. Warring siblings with polarized desires for aggressive care versus comfort care are a particularly difficult problem, and an ethics consultation is usually in order. When our CCU team is first contemplating withdrawal of advanced life support, we take the following steps:

1. Determine the prognosis as carefully as possible. Unfortunately, Acute Physiologic Assessment and Chronic Health Evaluation (APACHE) scores do not apply to CCU patients. One must be able to deal with the uncertainty of dying.
2. Assess the patient’s competence; engage them when possible. Patients receiving advanced life support are generally not mentally competent.
3. Discuss the case with the whole team and reach consensus about a decision. Nurses often have a more expansive knowledge of the family and the patient’s needs and wants.
4. Do not rush the families! A useful strategy is to tell them that if things do not improve over the next 48 to 72 hours, withdrawal of life support may be appropriate. It should be stressed that repeated procedures and diagnostic tests can be uncomfortable and can be a form of suffering. Emphasize that comfort care may allow the patient to have a more peaceful and dignified death. The time-limited goal often allows the family time to contemplate a most difficult decision.
5. Families need assurances that comfort care will be maintained and that the CCU team will not abandon them. However, in some cases, transferring the patient out of the CCU after withdrawal of life support is appropriate, and this should be explained to the family in anticipation of such a move.

When family members or legal surrogates want “everything done,” the medical team should comply with this request. A direct challenge by the medical team usually fails to convince the family of the futility of further treatment, but repeated, compassionate discussions can result in ethical decisions that will benefit the patient.

FUTILITY

The concept of medical futility has been controversial and remains vague. It attempts to establish the principle that physicians may use their judgment and skills to determine when treatment is futile. Once such a determination has been made, the physician can unilaterally withhold or withdraw treatment, even if the patient or family objects. The principle of autonomy is thus essentially expunged. Futility is not an objective entity but embraces many judgment-based values (21). There is no clear definition of medical futility (22). Such decisions, other than about physiologic futility (e.g., treating hypertension with an antibiotic) or an absolute inability to prevent death, always involve judging value. Whose value counts?

In reality, physicians can only frame choices for the patient; they cannot make unilateral decisions. Moreover, the courts have not recognized the right of physicians to act unilaterally in cases in which they believe further care would be futile (23). This is not to say that physicians do not recognize clinical situations in which care is futile. It simply means they cannot act unilaterally. Their obligation is to speak with the patient or the family, frame the issue, and have the patient or the family participate fully in the decision regarding further care. Judgments about anything other than physiologic futility are vague; imposed value judgments, imprecise definitions, a lack of concrete data, and great uncertainty about the definition of “futility” intervene. Communication of information to the family such as the success rate of resuscitation, long-term meaningful recovery, and likelihood of discharge from the hospital must be clear and consistent.

WITHHOLDING OR WITHDRAWAL OF LIFE-SUSTAINING THERAPY

Once the medical team and the patient or family has decided that the patient is dying and that further aggressive care is unwarranted, there is precious little guidance about how the process should be implemented. Physicians seem poorly trained in managing the transition from aggressive care to comfort care. The following steps should be considered:

- A final decision should be made after careful discussion with the patient (if appropriate), the family, and the nursing staff.
- Such patients are frequently intubated, and therefore a do-not-resuscitate order should also be written. If the patient is not intubated, a do-not-intubate order should be written.
- A morphine drip should be started. Patients in the CCU often suffer dyspnea as the primary discomfort, and morphine, 1 mg per hour, will usually alleviate this symptom. Presumed respiratory distress can be treated with a 5- to 10-mg bolus of morphine, followed by an increase in the infusion to 2 to 5 mg per hour.
- Conscious patients who manifest anxiety should be treated with intravenous lorazepam (1 to 4 mg every 30 minutes), and patients with delirium should be treated with intravenous haloperidol if necessary. If tolerance to these medications has developed, the hypnotic drug propofol may be used.
- Ventilation: in most cases, I prefer to leave the endotracheal tube in place while gradually decreasing the ventilator rate, positive end-expiratory pressure, oxygen therapy, and tidal volume until the patient is spontaneously breathing room air through the endotracheal tube. This way, secretions can be suctioned to prevent rattling, which may be perceived as suffering by the family. The gradual turning off of the ventilator (30 minutes to 3 hours) allows the family to spend time at the bedside if desired, but there is no merit in prolonging the dying process by very slow weaning over the course of many hours. Patients who are receiving neuromuscular blocking drugs should cease receiving such treatment before the ventilator is withdrawn. Such agents should not be introduced when the ventilator is being withdrawn, and neuromuscular function should be restored before life support is withdrawn (24). It is believed that withdrawal of life support can ethically occur in the presence of pharmacologic neuromuscular blockade when death is expected to be rapid, but it is usually safest to stop neuromuscular blockade before withdrawing the ventilator, because assessment of comfort is impossible. When discontinuation of neuromuscular blockade is not possible because the burden on the family of waiting for neuromuscular blockade to wane exceeds the benefits of allowing better assessment of the patient’s comfort level, sedatives and analgesics can be skillfully administered.
- Some patients or families will specifically request that the endotracheal tube be removed. This can be done after appropriate suctioning. Humidified air can be

given to prevent drying of the airway.
- Pressors should be stopped.
- Intraaortic balloon pumps should be turned off.
- Antibiotic therapy should be stopped.
- Artificial nutrition should be stopped.
- Blood draws should be stopped.
- Intravenous fluids should be reduced and used to facilitate analgesics and sedation.
- Restraints should be removed, monitors discontinued, and alarms silenced.
- Excess secretions should be suctioned.

The median time between withdrawal of life support and death was 3.5 hours in one study but varied from 5 minutes to 5.5 days (25). Families should be told that death may not be instantaneous, and that patients are sometimes transferred to a palliative care ward where they will be kept comfortable. Rarely, patients may even spontaneously recover.

Withdrawal of artificial nutrition and hydration is often very difficult for health care workers and families to accept (26). However, both ethical guidelines and court decisions support the practice (27,28). Recent information supports the conclusion that tube feeding seldom achieves the intended medical aims and that it may cause, rather than prevent, suffering (29). Continued nutrition and hydration may lead to considerable volume overload and pulmonary edema in a patient who is not otherwise being monitored carefully (30). Emerging consensus now suggests that dying patients experience little or no discomfort on withdrawal of tube feedings, parenteral nutrition, and intravenous hydration (31).

There is a growing recognition that nephrologists should maintain a low threshold for initiating dialysis on a trial basis, and a similarly low threshold for discontinuing dialysis that fails to appreciably improve the quality of life. Death occurs, on average, 9.6 days after discontinuation of chronic dialysis treatment (32).

Lastly, it must be emphasized that forgoing life-sustaining treatment is usually not a single-point decision but one that evolves over the course of several days (20). In two large academic surgical ICUs (Moffitt-Long Hospital, San Francisco, and San Francisco General Hospital), the median time from ICU admission to death in patients undergoing withholding or withdrawal of life support varied from 4 to 8 days (median time period at Moffitt-Long Hospital and San Francisco General Hospital, respectively) (33). This suggests that it takes time for the decision to evolve and for the patient to die after the decision is made. However, surgical ICUs are quite different from CCUs. No such data are yet available from CCUs. At the Cleveland Clinic Foundation, the CCU mortality rate is 7.5%. Approximately one-half of the deaths result from withholding or withdrawing of life support, and one-half result from “natural” causes. Current prognostic models have limitations (Table 34.2) but should be used as an adjunct to the process of shared decision-making.

Prognostic models give probabilities of survival or death rather than a "yes" or "no" answer; because of 95% confidence intervals, no model can statistically exclude survival even in the most severely ill patients.
Individual accuracy of these predictions depends on whether a specific patient's medical condition was reasonably well represented in the population from which the model was derived.
Most models derive their predictions from factors present at or shortly after admission to the intensive care unit and do not provide updated mortality estimates as the patient's condition changes.
Some patients have inherently unpredictable courses.
Conventional models of patients in the intensive care unit predict only hospital survival, not long-term survival, functional status, or quality of life after hospital discharge.

Modified from Faber-Langendoen K, Lanken PN. Dying patients in the intensive care unit: foregoing treatment, maintaining care. *Ann Intern Med* 2000;133:886–893, with permission.

TABLE 34.2 LIMITATIONS OF PROGNOSTIC MODELS FOR END-OF-LIFE DECISION-MAKING IN THE CORONARY CARE UNIT

The withholding or withdrawal of life support is a difficult, often agonizing process. It requires careful scrutiny and rests on important ethical and legal principles that are continually evolving (34). There are no absolute guidelines for deciding when to withdraw advanced life support. Each patient and clinical situation must be considered in their own contexts. Frequent communication with patients, families, or legal surrogates; open sharing of data; and careful assessment of the changing prognosis are critical to the process.

EUTHANASIA

Euthanasia is the act of putting to death without pain a person suffering from an incurable and painful condition. It is a vague and emotionally provocative term and best describes an act such as giving a lethal injection. It is not to be confused with withholding or withdrawing life support in a dying patient. The U.S. Supreme Court has unanimously ruled that there is no constitutional right to physician-assisted suicide (euthanasia) (17,18). There is no constitutional right to suicide, and there is no legal or historical support for such a right. The right to abortion or the right to refuse treatment is different from the right to assisted suicide. Limiting physician-assisted suicide to terminally ill patients also has no basis in constitutional principles. Only 6% of medical students, house staff, or faculty physicians surveyed in one study were willing to terminate the life of a patient deliberately by administering medication to cause respiratory arrest, and only 1.1% of those surveyed were willing to do so if it causes a cardiac arrest (35). Of course, it is possible that these numbers might increase if legal restraints were removed. However, there is a long and impressive list, starting with Hippocrates and including leading physicians, philosophers, and biomedical ethicists, of professionals who are opposed to euthanasia. One humane alternative is to simulate a home environment for dying patients in the ICU (Table 34.3).

Transportable aspects of a patient's home	Ways to provide these aspects in the intensive care unit
Privacy	Provide a private room Close doors and curtains
Ready access to family	Suspend restrictive visiting hours Provide comfortable chairs, recliners, and cots for family members in the patient's room
Access to patient's own possessions and amenities	Allow family to bring in favorite music, clothes, religious icons, food, and pets
Family serving as personal caregivers	When appropriate, allow family to assist with patient care
Access to religious rituals and spiritual support	Provide religious and spiritual resources Encourage religious and other family rituals at the bedside before and after death

TABLE 34.3 WAYS IN WHICH INTENSIVE CARE UNITS CAN SIMULATE A HOME ENVIRONMENT FOR DYING PATIENTS

Strong popular support for euthanasia exists in Holland, which legalized euthanasia in 2000 (36). It is estimated that 5,000 to 10,000 Dutch citizens die each year after administration of a barbiturate followed by a lethal injection of a paralytic agent. In 1994, Oregon voters passed the Death with Dignity Act. This act does not permit euthanasia, but it allows state residents to receive prescriptions for self-administered lethal medications from their physicians. A 1-year follow-up indicated that only 23 patients received such prescriptions, 15 patients died after taking them, six died from underlying illness, and two patients who received such prescriptions were still alive (37). Some good has come out of the euthanasia movement—it has forced physicians to deal with death and dying.

SUMMARY

People in the United States are uncomfortable discussing death. They do not know how to start the conversation and in some cases do not want to discuss it at all. People remain confused about what constitutes a “good death” (Table 34.4). A good death includes management of pain and symptoms, clear decision-making, preparation for death, and completion. The language is not always precise—a feeding tube is not the same as food and water. Only frequent, clear, and open dialogue will overcome this hurdle. Eventually, society needs to understand end-of-life issues in a more realistic light and to realize that what they see on the television series *ER* does not mimic the real world. Patients will die despite our best efforts. Our job as physicians is to help patients and their families through the dying process, just as

we help them achieve meaningful recovery.

To know when death is coming, and to understand what can be expected
To be able to retain control of what happens
To be afforded dignity and privacy
To have control over pain relief and other symptom control
To have a choice and control over where death occurs (at home or elsewhere)
To have access to information and expertise as necessary
To have access to any spiritual or emotional support required
To have access to hospice care in any location, not only in the hospital
To have control over who is present and who shares the end
To be able to issue advance directives that ensure wishes are respected
To have time to say goodbye and control over other aspects of timing
To be able to leave when it is time to go, and not to have life prolonged pointlessly

TABLE 34.4 PRINCIPLES OF A GOOD DEATH

CONTROVERSIES AND PERSONAL PERSPECTIVES

The concept of futility is controversial (21). It is supported by neither scientific principle nor the justice system. When continued aggressive life-support seems futile, it is best to discuss the likely outcome of continued support versus comfort care with the family. The final outcome—death—may be the same, but how the patient dies may be quite different. It is best that the family not perceive that the team is giving up, but rather that passive comfort care may be preferable to the potential suffering associated with continued life support. It must be stressed that such a decision is based on experience and judgment, not on the certainty of death. The family needs to understand and agree that the patient's best interests are served by such a strategy. Medical futility cannot be easily defined and is value-laden.

It has also been my personal experience that partial withdrawal of life support or "slow codes" confuse the issue and can prolong suffering. Decisions to withdraw or withhold life support should be complete. Only those measures that offer comfort should be continued.

THE FUTURE

We do a poor job of training our residents and fellows in end-of-life issues. Dying is part of living, and to ignore the management of dying is as grievous an error as ignoring methods of managing a major illness. We need to do a better job of educating our trainees and ourselves about these uncomfortable issues. At our institution, we have end-of-life small-group seminars as part of our didactic curriculum in the CCU. Bioethicists, pharmacists, and cardiologists assigned to the CCU participate in these lectures, which are often centered around a specific case history. We need to educate the public about death and dying. Expectations for individual patients must be framed carefully and repeatedly. Above all, families must be drawn into these important dialogues. Hope for meaningful recovery must in some cases be replaced with hope for comfort and caring.

THE HEART AND OTHER ORGAN SYSTEMS

ROBERT M. CALIFF

Introduction

INTRODUCTION

Cardiovascular specialists are often consulted to evaluate patients with diseases that emanate from organ systems remote from the heart, but with substantial cardiac manifestations. At some point the cardiovascular system becomes a factor in most major systemic diseases. In this section, commonly encountered problems involving an interaction of the heart and other organ systems are reviewed. The goal is to focus on the cardiovascular manifestations of these problems without providing a comprehensive review of the illnesses per se.

Increasing attention is being focused on the interaction between the cardiovascular system and the central nervous system. Ranging from genetic diseases associated with neuromuscular degeneration to atherosclerotic disease of the cerebrovascular circulation, considerable knowledge about cardiovascular manifestations is required to understand the manifestations of neurologic disorders.

Myocarditis, endocarditis, and pericarditis are covered in detail in other portions of the book, but the enormous number of infectious causes of these problems, each with specific implications for treatment, requires discussion here. In addition, the rapidly growing knowledge base concerning the effects of the human immunodeficiency virus on the cardiovascular system will increasingly require the attention of cardiovascular specialists.

Although cardiovascular manifestations of rheumatic diseases are not common compared with atherosclerosis, some of the most striking cardiovascular problems arise from rheumatic diseases. The management of vasculitis, pericarditis, or aortic valve difficulties associated with rheumatic diseases requires a thorough understanding of both areas.

As with cerebrovascular disease, the basic approaches to atherosclerosis (medical management, percutaneous intervention, and surgical intervention) create a close tie between the most common type of renal disease and the cardiovascular system. In addition, the rapid growth of angiography with its associated problem of contrast nephropathy creates an iatrogenic condition requiring careful evaluation and treatment by the angiographer.

Finally, in many respects, cardiovascular disease is an endocrine disease in the sense that a major contributor to disease progression and outcome in cardiovascular diseases is the neuroendocrine status. In particular, diabetes has become the focus of activity in understanding factors associated with increased risk.

We hope that these sections in combination with specific disease-oriented chapters throughout the book will provide the reader with a comprehensive view of the interaction of the cardiovascular system with other organ systems in the development and progression of human disease.

INTRODUCTION

Cardiovascular involvement is frequent in endocrine disturbances. Clinical suspicion remains the most important step in diagnosing endocrine disorders—in particular, their cardiovascular manifestations, as they can be subtle and nonspecific. The purpose of this chapter is to summarize relevant interactions between endocrinologic diseases and the cardiovascular system to facilitate diagnostic recognition and to highlight management options.

THE THYROID

A relation between the thyroid and the heart has long been recognized (1). In the late 1700s, a patient with clinical features of thyrotoxicosis including palpitations, irregular pulse, and dyspnea was described (2). In the early 1900s, a patient with "myxedema heart" was reported: The critical findings were enlarged cardiac silhouette, low electrocardiographic voltage, and bradycardia (3).

Thyroxine (T_4), a relatively inactive hormone, is the major secretory product of the thyroid gland. Triiodothyronine (T_3), the biologically active compound, is in large part derived from peripheral conversion of T_4 by the 5'-monodeiodinase enzyme. Therefore, alteration in T_3 plasma level may occur independently from thyroid function. Cardiovascular manifestations are frequent in thyroid dysfunction and may be the result of direct hormone effects at the cellular level, interactions with the sympathetic nervous system, or alterations of peripheral circulation and metabolism (4). At the cellular level, thyroid hormones act mainly through binding to specific nuclear receptors and activation of gene transcription (5). Additionally, they activate extranuclear sites as mitochondrial and membrane-bound enzymes (6). Women are more likely to develop thyroid dysfunction, with an estimated 2.7% prevalence of hyperthyroidism and 1.9% prevalence of hypothyroidism in an unselected population (7).

Thyrotoxicosis

The terms *hyperthyroidism* and *thyrotoxicosis* can be differentiated but are frequently used interchangeably. Hyperthyroidism is defined as increased formation and release of thyroid hormones from the thyroid gland, whereas thyrotoxicosis describes the clinical syndrome that results from the thyroid hormone excess. The most frequent cause of thyrotoxicosis is Graves' disease, which accounts for 60% to 90% of cases and occurs among women ten times more frequently than men. This disorder is characterized by autoantibodies activating the thyroid-stimulating hormone (TSH) receptor. Other causes of thyrotoxicosis include toxic adenoma (Plummer's disease), toxic multinodular goiter, thyroiditis, and thyroid autonomy. Common symptoms of thyrotoxicosis are nervousness, emotional lability, sleep disturbances, tremor, diarrhea, heat intolerance, and weight loss. Clinical findings include goiter, exophthalmos, proximal muscle weakness, hyperreflexia, and occasionally pretibial myxedema. Thyrotoxicosis in the elderly might be particularly subtle and present with nonspecific symptoms such as weakness, weight loss, and apathy.

Amyloidosis. Infiltration of the skin results in raised waxy papules or plaques that are usually in clusters (*arrow*).

In subjects with preexisting thyroid autonomy, iodine administration (i.e., in the form of amiodarone or contrast agents) can result in iodine-induced thyrotoxicosis. Iodine deficiency, the presence of a goiter, and baseline low TSH levels have been considered risk factors for iodine-induced thyrotoxicosis. Accordingly, this disease is more frequently observed in areas with low iodine intake. An investigation in almost 800 patients from an iodine-deficient area undergoing coronary angiography showed that the risk of developing thyrotoxicosis was low (<0.3%) despite significant prevalence of low TSH levels (4%) and goiter (23%) (8). In contrast, amiodarone may induce thyrotoxicosis in up to 10% of iodine-deficient patients (9).

Cardiovascular Involvement

Thyrotoxic patients have increased mortality, primarily because of cardiovascular complications (10). Cardiovascular symptoms in this setting are frequently nonspecific. Palpitations are usually caused by sinus tachycardia and, occasionally, by atrial fibrillation. Exercise intolerance and dyspnea on exertion may be caused by a combination of inability to raise cardiac output and skeletal and respiratory muscle weakness. Cardiovascular involvement in the elderly may be limited to arrhythmias such as sinus tachycardia or atrial fibrillation, which occasionally trigger heart failure, angina, or both. The hemodynamic changes occurring in thyrotoxicosis are summarized in Table 35A.1 and include tachycardia, increased cardiac output and stroke volume, and decreased systemic vascular resistance (11,12). In contrast to hypothyroidism, which is characterized by diastolic hypertension, hyperthyroidism is associated with systolic hypertension in the presence of normal or low diastolic blood pressure. It is speculated that isolated systolic hypertension is secondary to the inability of the vasculature to accommodate increased cardiac output and stroke volume (1).

	Thyrotoxicosis	Hypothyroidism
Systemic vascular resistance	↓	↑
Cardiac output	↑	↓
Systolic blood pressure	↑	↓ or →
Diastolic blood pressure	↓	↑ or →
Heart rate	↑	↓
Systolic function	↑	↓
Diastolic function	↑	↓
Blood volume	↑	↓

↑, increased; ↓, decreased; →, unchanged.

TABLE 35A.1 CARDIOVASCULAR HEMODYNAMICS IN THYROID DYSFUNCTION

Sympathetic Nervous System

Many of the cardiovascular signs and symptoms of thyrotoxicosis mimic those occurring in states of increased beta-adrenergic activity and respond to beta-blockade (13), suggesting an underlying dysfunction of the catecholamine metabolism or, alternatively, an increased sensitivity to catecholamines. However, patients with thyrotoxicosis have low or normal plasma catecholamine levels and normal urinary catecholamine excretion (14). Moreover, these patients have normal responses to catecholamine infusion (13). Finally, there is no conclusive evidence of increased beta-adrenergic receptor density in the myocardium, increased catecholamine turnover at neural synapses, or increased affinity of adrenergic receptor for catecholamines (15).

Ventricular Function

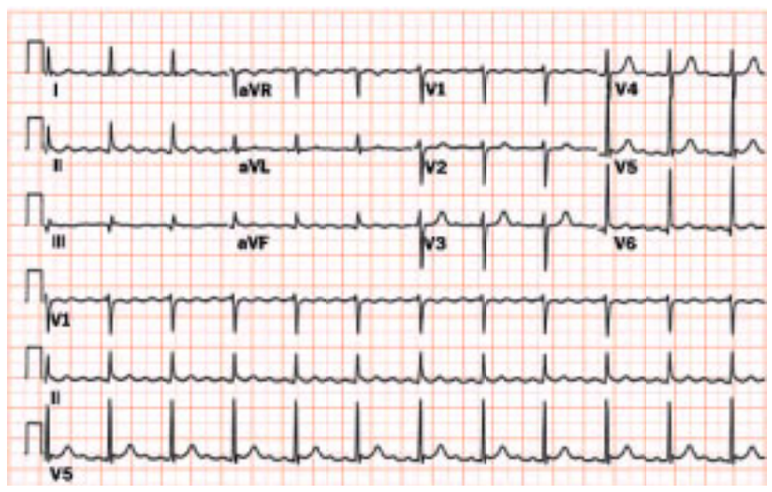
Short-term hyperthyroidism is associated with increased cardiac contractility and improved diastolic function (16,17) (Table 35A.1), which may be caused, at least in part, by augmented activity of the sarcoplasmic reticulum calcium ATPase pump (18). Both in humans (19) and animals (20), chronic thyrotoxicosis causes variable degrees of left ventricular hypertrophy (LVH). Thyroid hormones have been shown to induce cardiac protein synthesis, leading to the hypothesis that this is the trigger of LVH (21). However, beta-adrenergic blockade has been shown to block or reverse hypertrophy, suggesting that increased cardiac workload is the mediator of hypertrophy (22,23 and 24). In addition to the effects on the myocardium, thyroid hormones, specifically T_3, show vasodilator properties by acting directly on vascular smooth muscle cells, potentially explaining the decreased systemic vascular resistance observed in hyperthyroidism (25,26).

It remains a source of debate whether thyrotoxicosis per se may lead to heart failure. In the vast majority of cases, heart failure can be explained by the combination of underlying heart disease, arrhythmias, and/or chronically increased cardiac output. However, myocardial dysfunction has been described also in absence of underlying cardiac disease (27), even in children (28), and improvement in myocardial contractility after restoration of euthyroidism has been reported (29,30). Several factors may potentially contribute to heart failure in thyrotoxicosis. Diastolic function deteriorates in the course of the disease because of LVH and progressive LV stiffness, leading to filling impairment, particularly in the setting of tachycardia or atrial fibrillation (4). Additionally, thyrotoxicosis is associated with increased total blood volume and plasma volume (31). Occasionally, the decreased systemic resistance may overwhelm the cardiac capacity and cause high output failure. More frequently, however, the high-output state may unmask coronary artery disease, and heart failure is precipitated by ischemia. Myocardial ischemia in thyrotoxic patients has been described even in the absence of significant coronary artery disease, secondary to coronary vasospasms (32,33 and 34).

Arrhythmias

Sinus tachycardia at rest, during sleep, and during exercise is the most common arrhythmia in thyrotoxicosis (35,36). It is speculated that thyroid hormones have direct effects on the conduction system, possibly via cellular changes in cation transport, including a decrease of atrial excitation threshold, an increase of sinoatrial node firing, and a shortening of conduction tissue refractory time (11,37). Other common arrhythmias include atrial premature contractions and atrial fibrillation. Less frequently, patients present with paroxysmal atrial tachycardia and atrial flutter. Ventricular premature contractions and ventricular arrhythmias are rare.

Acute inferior myocardial infarction complicated by atrial fibrillation. Note ST-segment elevation in the inferior leads with reciprocal changes laterally. Atrial fibrillation has complicated this acute infarct.



Atrial flutter. Atrial rate of 300 beats/min with upright P waves inferiorly. This is consistent with atypical atrial flutter.

Although thyrotoxicosis accounts for less than 5% of all cases of atrial fibrillation, this arrhythmia occurs in up to 15% of hyperthyroid patients (15). The ventricular rate response is frequently rapid because of increased atrioventricular node conduction. Atrial fibrillation related to thyrotoxicosis is more frequent in the elderly and in male subjects, probably reflecting their increased prevalence of intrinsic heart disease (38). Because this arrhythmia, particularly in the elderly, may be the only manifestation of thyrotoxicosis, thyroid hormone excess should always be excluded in patients with atrial fibrillation. Accordingly, one report showed subtle hyperthyroidism in 12.5% of elderly patients with atrial fibrillation previously considered idiopathic (39). One study, performed in patients 60 years of age or older, demonstrated that even patients with subclinical hyperthyroidism (i.e., asymptomatic but with low TSH) had a threefold higher risk of developing atrial fibrillation in the subsequent decade (40) (Fig. 35A.1). Major complications of thyrotoxic atrial fibrillation include heart failure and embolic events. In the absence of chronic atrial fibrillation or underlying heart disease, most patients convert spontaneously to sinus rhythm within 8 to 12 weeks of antithyroid treatment (41). Conversely, reversion into atrial fibrillation is likely in persistently thyrotoxic patients. Anticoagulation is indicated and cardioversion should be deferred until euthyroidism is restored.

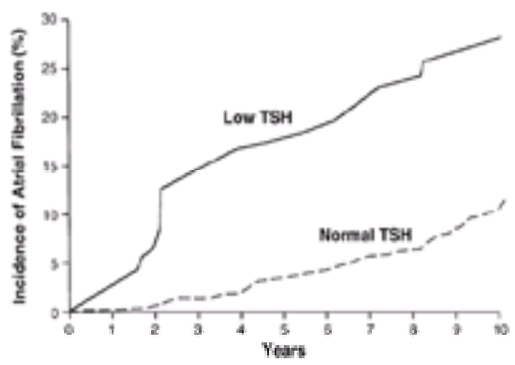


FIGURE 35A.1 Cumulative incidence of atrial fibrillation among subjects 60 years of age or older, according to serum thyroid-stimulating hormone (TSH) levels at baseline. Low TSH defined as £0.1 mU per L; normal TSH defined as >0.4 to 5.0 mU per L. (Adapted from Sawin CT, Geller A, Wolf PA, et al. Low serum thyrotropin concentrations as a risk factor for atrial fibrillation in older persons. *N Engl J Med* 1994;331:1249–1252.)

Diagnosis and Therapy

Measurement of serum TSH is the most sensitive screening test for hyperthyroidism. An undetectable value is the hallmark of this thyroid dysfunction, whereas normal TSH levels virtually exclude the disease (42). Confirmation is usually sought measuring elevated serum free T_4 and free T_3. Beta-adrenergic blockers provide relief of symptoms such as tachycardia, tremor, anxiety, and heat intolerance. The nonselective agent propranolol has been traditionally used for this purpose but selective $beta_1$-adrenergic antagonists such as atenolol appear equally effective. If beta-blockers are contraindicated, calcium channel blockers such as verapamil or diltiazem can be administered as negative chronotropic agents (43). However, caution is warranted, as these agents may lead to hemodynamic instability by further reducing systemic vascular resistance and contractility. The thionamide derivatives propylthiouracil and methimazole are effective in decreasing thyroid hormone synthesis. Radioactive iodine is a valid alternative, particularly for older patients with moderate hyperthyroidism and goiter, for patients with prior allergic or toxic reaction to the antithyroid medication, and when frequent medication intake cannot be guaranteed. The disadvantages of radioactive iodine include a long latency of action and the fact that this therapy is ineffective in iodine-induced hyperthyroidism. Surgery is indicated in patients with large goiters causing airway obstruction or with malignant or equivocal nodules on fine-needle aspiration. Occasionally, surgery is necessary in severely hyperthyroid patients not responding to conservative treatment.

Hypothyroidism

Hypothyroidism is the clinical syndrome associated with decreased secretion of thyroid hormones. This condition reflects in over 90% of cases a disease of the gland itself (primary hypothyroidism). Rarely, hypothyroidism can be caused by pituitary disease (secondary hypothyroidism) or hypothalamic disease (tertiary hypothyroidism). The most frequent cause of hypothyroidism in adults is autoimmune thyroiditis, or Hashimoto's disease. Accordingly, women are more frequently affected. The slow and progressive nature of hypothyroidism often makes the diagnosis difficult. This is particularly true in elderly patients whose clinical manifestations may be limited to dry skin, weight gain, fatigue, and forgetfulness—all of which are easily explained by the aging process. Other complaints of hypothyroid patients include increased tiredness and sleep requirement, depressed mood, cold intolerance, constipation, and decreased exercise tolerance. Pleural effusions and pitting edema may occur in absence of heart failure.

Cardiovascular Involvement

Most hypothyroid patients present with nonspecific symptoms caused by psychological or skeletal muscle dysfunction. However, long-standing hypothyroidism may affect the cardiovascular system in several ways (Table 35A.1). Bradycardia is common, and pericardial effusion may occur in up to one-half of patients but rarely causes hemodynamic compromise (44). Both diastolic and systolic LV performance may be decreased (45), presumably because of alterations in calcium uptake and release by cardiac myocytes (18). Additionally, an increase in systemic vascular resistance is observed, possibly as the result of the lack of direct vasodilatory effect of thyroid hormones (25,26). Despite the fact that hypothyroid patients have symptoms suggesting a decreased sympathetic tone, plasma catecholamines are increased (46). The resulting hemodynamic changes are opposite but less marked than with thyrotoxicosis. Characteristic features include low cardiac output; decreased stroke volume, diastolic function, intravascular volume, and peripheral oxygen consumption; and increased systemic vascular resistance (47,48 and 49). Heart failure may occur when the metabolic demand cannot be matched by adequate cardiac output. As in patients with thyrotoxicosis, overt heart failure in hypothyroidism generally represents exacerbation of intrinsic cardiac disease. Rarely, however, hypothyroidism alone may cause cardiomyopathy (50). Therefore, unexplained heart failure should prompt determination of thyroid hormones. In the absence of underlying heart disease, the decreased myocardial contractility observed in hypothyroidism is generally reversible after hormone replacement (45,47), probably as a result of improved calcium handling in cardiac myocytes (18) and decreased systemic vascular resistance (47).

Risk Factors

Total cholesterol, low-density lipoprotein (LDL) cholesterol, very-low-density lipoprotein (VLDL) cholesterol, lipoprotein(a), and apolipoprotein B concentrations are often elevated in hypothyroidism; some patients have high serum triglyceride levels (1). It has been demonstrated that patients with hypothyroidism have an intrinsic LDL catabolism dysfunction, which is reversible after hormone replacement (51). Therefore, screening for this condition is mandatory when assessing patients with hyperlipidemia. The powerful interaction between thyroid hormones and lipid metabolism is highlighted by the fact that thyroid hormones have been used in the past as lipid-lowering agents. However, this strategy was associated with increased morbidity and mortality in patients after myocardial infarction (52).

Hypothyroidism is associated with increased prevalence of hypertension. In a review of 12 studies, the overall prevalence of hypertension was 21% (1). In large series of hypertensive patients, hypothyroidism accounted for 3% to 5% of the cases (53,54). Hypothyroid patients have a low-renin form of hypertension, and the mechanism remains unknown (54). The causal link between thyroid hormone deficiency and hypertension is confirmed by the fact that hormone replacement may lead to improvement of hypertension (54).

Coronary Artery Disease

Patients with hypothyroidism frequently have risk factors for coronary artery disease, but data to support the direct association between hypothyroidism and coronary artery disease are lacking (55). The suggestion that hypothyroidism may indeed represent an independent risk factor for coronary disease comes from a population-based cross-sectional study. In this analysis, women with subclinical hypothyroidism—defined as asymptomatic, with normal serum free T_4 and elevated TSH—had a higher prevalence of aortic atherosclerosis and myocardial infarction than euthyroid women (56). These observations are in agreement with previous case-control studies showing an association between subclinical hypothyroidism and coronary heart disease in elderly women (57,58). In contrast, a Finnish study addressing latent thyroid failure in both men and women found no association with coronary disease (59).

Diagnosis and Therapy

An elevated TSH combined with a low free T_4 is diagnostic of primary hypothyroidism. Antimicrosomal and antithyroglobulin antibodies are characteristic of Hashimoto's disease. Hypothyroidism is preferentially treated with thyroxine because of its long half-life. In the elderly, as well as in patients with known or suspected coronary disease, it is prudent to start hormone substitution at a lower dosage. However, exacerbation of angina because of hormone replacement is rare (60) and responds well to beta-adrenergic blockade.

Amiodarone and Thyroid Dysfunction

Amiodarone is an iodine-rich benzofuran derivative with similar molecular structure to thyroid hormones. Organic iodine represents almost 40% of the molecular weight of amiodarone. A daily dose of 200 mg of amiodarone corresponds to an intake of 75 mg of organic iodide and generates approximately 7 mg of free iodine (61). Given the fact that the normal dietary requirement of iodine is 100 to 200 µg per day, amiodarone therapy is associated with an enormous iodide load, reflected in a 40-fold increase in plasma and urinary iodide levels (61). Because iodine is a necessary substrate for thyroid hormone synthesis but, at the same time, directly influences intrathyroidal processes, it is not surprising that over 50% of the patients on amiodarone have abnormal thyroid function test results, although most of them remain euthyroid (62). The predominant peripheral action of amiodarone on thyroid hormones is the inhibition of the deiodination of T_4 to T_3. As a result, the serum levels of T_4 increase and the levels of T_3 decrease (61,63) (Table 35A.2). In addition, high iodide availability initially inhibits thyroid hormone synthesis (the Wolff-Chaikoff effect) (64). During the first 3 months of therapy, TSH levels are commonly slightly elevated because of lack of feedback inhibition, due to the lowered T_3 levels, but they tend to normalize during long-term administration. Amiodarone-induced thyrotoxicosis (AIT) prevails in areas with low iodine intake, and hypothyroidism is more frequent in areas with high iodine intake. Whereas thyrotoxicosis can occur throughout the treatment period and even several months after treatment, hypothyroidism rarely develops beyond 18 months of initiation of therapy (65). Monitoring of thyroid function in this setting relies on TSH. If TSH is abnormal, free T_4 and free T_3 levels should be assessed to detect underlying gland dysfunction that may predispose to amiodarone-induced hyperthyroidism or hypothyroidism. Additional assessments are recommended at approximately 3 months and yearly thereafter.

Test	Treatment <3 mo	Treatment >3 mo
Thyroxine	Increased	Remains increased by up to 40% above baseline; may be in high reference range or modestly raised
Triiodothyronine	Decreased, usually to low reference range	Remains in low reference range or slightly low
Thyroid-stimulating hormone	Transient increase (up to 20 mU/L)	Normal, but may fluctuate with periods of high and low values

TABLE 35A.2 EFFECTS OF AMIODARONE ON THYROID FUNCTION IN PATIENTS REMAINING EUTHYROID

A noniodinated analog of amiodarone, dronedarone, has been synthesized. Preliminary animal data show that this compound has similar electrophysiologic effects to amiodarone (66). The development of dronedarone or a similar compound will be followed with interest, because iodine deletion is expected to overcome endocrine side effects of amiodarone. However, extensive safety and efficacy data in animals are required before human testing.

Amiodarone-Induced Hypothyroidism

Hypothyroidism is a frequent sequela of amiodarone therapy, with a reported incidence ranging from 13% in iodine-replete countries to 6% in countries with low or intermediate iodine intake (63). Its occurrence is not related to the daily or cumulative dose of the drug. The risk of developing hypothyroidism is increased in the elderly and women, particularly in the setting of autoimmune thyroiditis. Accordingly, women on amiodarone with microsomal, thyroglobulin, or both autoantibodies have been shown to have more than a tenfold higher risk for subsequent hypothyroidism (65). Possible mechanisms leading to hypothyroidism in this setting include failure to escape the Wolff-Chaikoff effect and iodine-mediated exacerbation of preexisting autoimmune thyroid disease. TSH levels above 10 to 15 mU per L in patients on chronic amiodarone usually represent hypothyroidism. The diagnosis is confirmed by low T_4 or free T_4. The assessment of T_3 or free T_3 adds little information, because these parameters may be diminished in euthyroid patients on amiodarone. Once the diagnosis of hypothyroidism is established, the drug can be safely continued, if needed, and thyroxine replacement added in increasing doses at 4- to 6-week intervals until TSH returns within normal limits and symptoms resolve (63). If amiodarone is discontinued, recovery of thyroid function is influenced by the presence of thyroid antibodies. In fact, the absence of antibodies is associated with frequent recovery, mostly within a few months, whereas patients with thyroid antibodies usually do not recover normal thyroid function (63).

Amiodarone-Induced Thyrotoxicosis

In countries with high iodine intake, AIT is less frequent than hypothyroidism, with an estimated incidence of approximately 2%. In contrast, in the presence of iodine deficiency, AIT may occur in up to 10% (9). Antiadrenergic effects of amiodarone may partially conceal thyrotoxic symptoms. AIT should be suspected in the presence of new or recurrent atrial arrhythmias or unexplained weight loss. Three pathophysiologic mechanisms have been associated with thyrotoxicosis in the setting of chronic amiodarone therapy (61). First, iodine may affect thyroid autoregulatory mechanisms and may lead, particularly in patients with underlying thyroid disease, to excessive hormone synthesis. Second, inflammatory destructive histologic changes and increased cytokines (e.g., interleukin-6) and thyroglobulin levels have been demonstrated in this setting, suggesting a direct cytotoxic effect of amiodarone (67). Third, it has been postulated that amiodarone may trigger an autoimmune response to the thyroid gland. Amiodarone should be discontinued whenever possible. The choice of treatment can be guided by distinction of two forms of AIT (68). In type I AIT patients have a goiter, positive thyroid antibodies, and abnormal (i.e., measurable or even high) 24-hour radioiodine uptake. Treatment consists of a combination of thionamides, propylthiouracil or methimazole, which inhibit hormone biosynthesis, and potassium perchlorate, which blocks thyroid iodide uptake (69,70). Patients with type II AIT have a normal thyroid and low radioiodine uptake. The efficacy of corticosteroids, alone or in combination with thionamides, has been convincingly demonstrated in this setting (68,71,72). However, because a mixed form of AIT is frequent, patients can be approached pragmatically with an initial combination of thionamides and potassium perchlorate, with corticosteroids being added after 2 weeks if no improvement occurs (Fig. 35A.2). In patients not responding to this therapy, lithium may be a valid alternative (73).

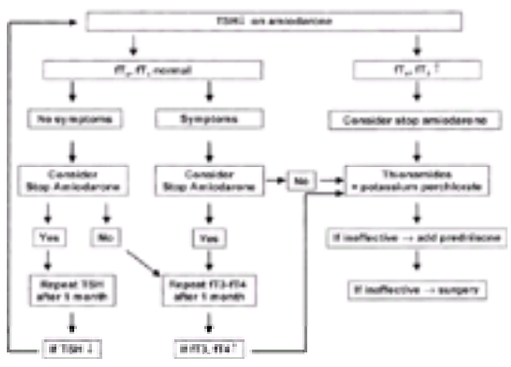

FIGURE 35A.2 Management algorithm for amiodarone-induced thyrotoxicosis. fT_3, free triiodothyronine; fT_4, free thyroxine; TSH, thyroid-stimulating hormone. (Courtesy of F. Cattaneo, MD, Lugano, Switzerland.)

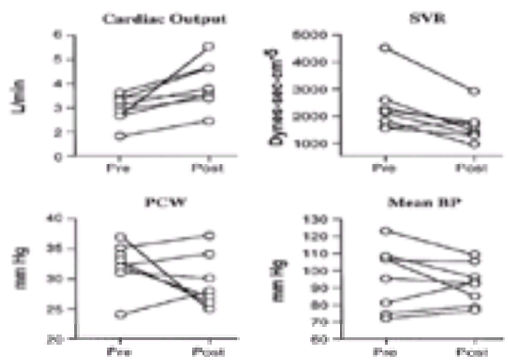
The cardiovascular risk associated with continuing amiodarone therapy is unknown, but the rate of remission following antithyroid drugs is decreased. However, discontinuation of the drug can be hazardous, particularly if the indications were ventricular arrhythmias, and thyrotoxicosis may take up to 8 months to subside (74). In addition, because of the extremely long terminal half-life of amiodarone, the use of beta-adrenergic antagonists is limited by the additive chronotropic and dromotropic effects, potentially leading to severe bradycardia, conduction abnormalities, or both. Because the high iodide plasma concentrations typically suppress iodine uptake in

the thyroid, radioactive iodine treatment is not effective in this particular form of thyrotoxicosis. Subtotal thyroidectomy is the treatment of choice if pharmacologic regimens are ineffective (75,76). Surgery has been associated with low perioperative morbidity and mortality, even in the presence of thyroid storm, heart failure, and therapy-refractory arrhythmias (63,75,76).

Investigational Thyroid Hormone Therapies

Heart Failure

Because low thyroid hormone levels have been associated with poor prognosis in heart failure (77), hormone supplementation has been attempted in this setting. Bolus and infusion of T_3 in a small group of euthyroid patients with advanced heart failure have been shown to increase cardiac output and lower systemic vascular resistance, with no change in LV ejection fraction or filling pressures (78) (*e*Fig. 35A.2.1). A small randomized study showed improved exercise capacity with 100 µg per day of thyroxine for 1 week in 20 patients with idiopathic dilated cardiomyopathy (79). Benefits in terms of LV ejection fraction, LV diastolic dimension, and functional capacity were observed in another small placebo-controlled trial after administration of the same dose for 3 months (80). Although these initial reports are intriguing, there are currently no data to support routine thyroid hormone supplementation in euthyroid patients with heart failure.



***e*FIGURE 35A.2.1** Hemodynamic parameters at baseline (Pre) and 2 hours after (Post) 0.7 µg per kg triiodothyronine (T_3) bolus and 0.17 µg per kg per hour infusion in seven patients with severe heart failure. BP, arterial blood pressure; PCW, pulmonary capillary wedge pressure; SVR, systemic vascular resistance. (From Hamilton MA, Stevenson LW, Fonarow GC, et al. Safety and hemodynamic effects of intravenous triiodothyronine in advanced congestive heart failure. *Am J Cardiol* 1998;81:443–447, with permission.)

Bypass Surgery

Patients undergoing cardiac surgery frequently have low thyroid hormone levels in the postoperative phase (81). Based on this observation and on initial encouraging data (82), two trials have randomized patients undergoing cardiopulmonary bypass surgery to perioperative administration of large doses of T_3 or placebo (83,84). Thyroid hormone therapy was not associated with improved outcome or diminished inotropic requirement.

Organ Donors

Brain death is associated with rapid loss of pituitary functions and low levels of cortisol and TSH. Preliminary data suggest that administration of T_3 to brain-dead organ donors may be beneficial in maintaining organ viability by increasing hemodynamic stability, reducing inotropic agent requirement, decreasing filling pressures, and improving metabolic status (85). Further studies are needed to validate this interesting observation.

THE ADRENAL GLAND

The cortex of the adrenal gland produces corticosteroid hormones, and the medulla—functionally a sympathetic ganglion—produces catecholamines. Clinical syndromes associated with adrenal hypersecretion and cardiovascular involvement include Cushing's syndrome and primary aldosteronism (Conn's syndrome) and result from excessive secretion of cortisol and mineralocorticoid, respectively. Cardiovascular involvement in adrenal insufficiency is mainly limited to its acute form (Addison's crisis) and is characterized by volume depletion, refractory hypotension, arrhythmias, and conduction abnormalities secondary to electrolyte disturbances.

Cushing's Syndrome

Cortisol, a central modulator of carbohydrate and protein metabolism, is synthesized in the adrenal cortex in response to pituitary adrenocorticotropic hormone (ACTH). The term *Cushing's syndrome* denotes glucocorticoid excess, which can be either endogenous or exogenous. ACTH-secreting pituitary tumor (Cushing's disease) accounts for approximately 80% of the cases of endogenous hypercorticism. In 10% of cases, an ectopic ACTH-producing tumor is identified (ectopic ACTH syndrome). Glucocorticoid excess is caused in another 10% of cases by adrenal pathologies such as adenoma, carcinoma, or bilateral hyperplasia.

Clinical Findings and Cardiovascular Risk

The characteristic findings in Cushing's syndrome include truncal obesity, abdominal striae, hypertension, osteoporosis, proximal muscle weakness, fatigue, and hyperglycemia. Concomitant androgen excess may lead to hirsutism and amenorrhea, and mineralocorticoid effect may cause hypokalemia. Early studies performed when no treatment was available showed that glucocorticoid excess is associated with premature atherosclerosis and increased cardiovascular morbidity and mortality (86). The risk profile of this population is characterized by a high prevalence of glucose intolerance or overt diabetes mellitus and hypertension (87). Additional cardiovascular risk factors include truncal obesity and hyperlipidemia. Hypertension has been related to volume expansion, increased production of vasoactive substances, and increased reactivity of vascular smooth muscle cells (88,89 and 90). LVH may be more frequent, more severe, or both in patients with Cushing's syndrome when compared with patients with essential hypertension (91). Despite surgical treatment, cardiovascular morbidity and mortality remain higher than in the general population (92), possibly because of residual obesity, insulin resistance, or both (93).

Cushing's syndrome. Deposition of adipose tissue in the face and in the interscapular area causes "moon facies" and "buffalo hump." This is seen in hypercortisolism.

Diagnosis and Therapy

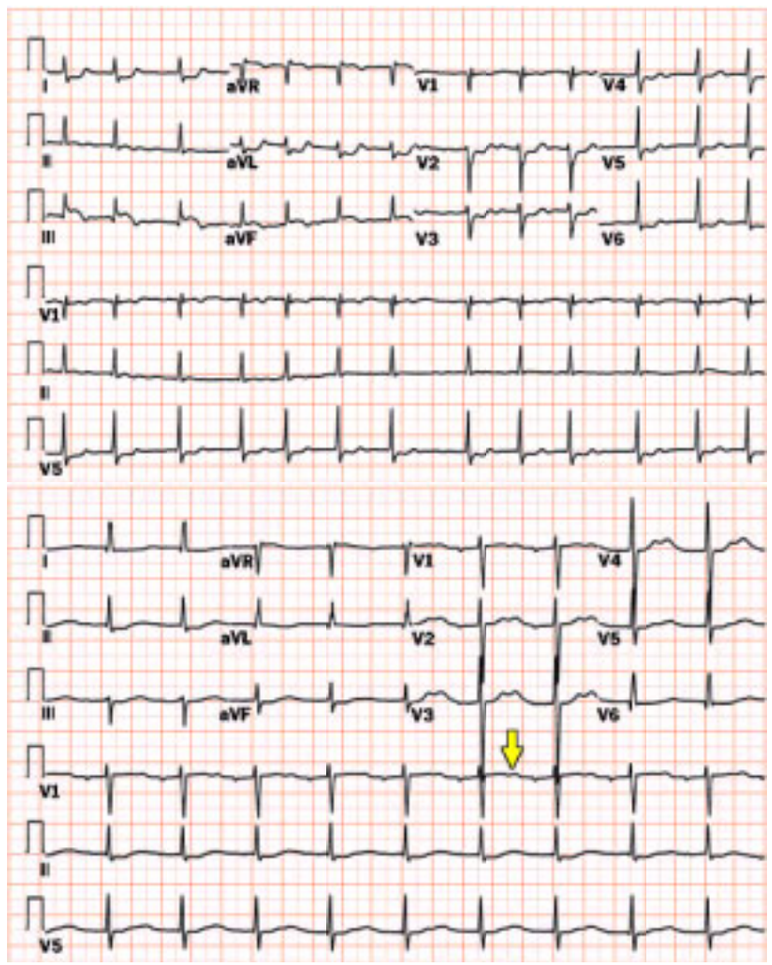
Diagnosis and treatment of Cushing's syndrome are complex and go beyond the scope of this textbook. In patients with clinical features suggestive of hypercorticism, screening can be performed with, among others, a 24-hour urine collection for free cortisol. Confirmatory tests include, among others, the dexamethasone suppression test or a second elevated free cortisol in a 24-hour urine sample (94). Specific treatment, which may include surgical removal or pharmacologic or radiation therapy, is chosen depending on the underlying process.

Primary Aldosteronism

Primary aldosteronism was first described in 1955 by Conn in a patient with an aldosterone-producing adrenal adenoma (95). This benign tumor is the most common cause of primary aldosteronism, accounting for approximately 65% of cases, whereas bilateral adrenal hyperplasia, also called *idiopathic hyperaldosteronism*, accounts for another 30% of cases. Primary aldosteronism has been considered the cause of hypertension in a minority of unselected hypertensive patients, with an incidence ranging between 0.05% and 2.20% (96). However, recent data suggest a higher prevalence of primary aldosteronism in the hypertensive population (97,98). Symptoms of primary aldosteronism are nonspecific and mainly result from potassium depletion. Neuromuscular involvement includes weakness, paralysis, cramps, tetany, and paresthesias.

Cardiovascular Manifestations

Primary aldosteronism is associated with moderate to severe hypertension (99). Acute mineralocorticoid administration induces renal sodium retention and potassium and hydrogen excretion, resulting in vascular volume expansion, hypokalemia, and metabolic alkalosis. Although hypertension is presumably related to sodium retention and volume expansion, chronic mineralocorticoid excess is associated with only mild hypervolemia due to escape mechanisms (99). Accordingly, peripheral edema is rare. Primary aldosteronism is associated with cardiac and vascular remodeling. Characteristic features include perivascular fibrosis, excessive LVH, and myocardial fibrosis (100,101).



Hypokalemia. Prominent U waves are seen.

Diagnosis and Therapy

Because mineralocorticoid excess does not produce specific symptoms, primary aldosteronism is a biochemical diagnosis. Diagnostic tests of choice include plasma renin activity, plasma aldosterone levels, aldosterone-to-renin ratio, and dexamethasone suppression test (102). The association of hypertension and hypokalemia, if not diuretic induced, is characteristic of primary aldosteronism and should prompt appropriate analyses. However, mineralocorticoid excess may be present also in normokalemic subjects (97,98). Surgery is the treatment of choice in aldosterone-producing adenomas, but hypertension resolves only in approximately 35% to 50% of cases (96). As the rate of hypertension regression following bilateral adrenalectomy in idiopathic hyperplasia is even lower, therapy in this setting relies on the aldosterone antagonist spironolactone and a sodium-restricted diet.

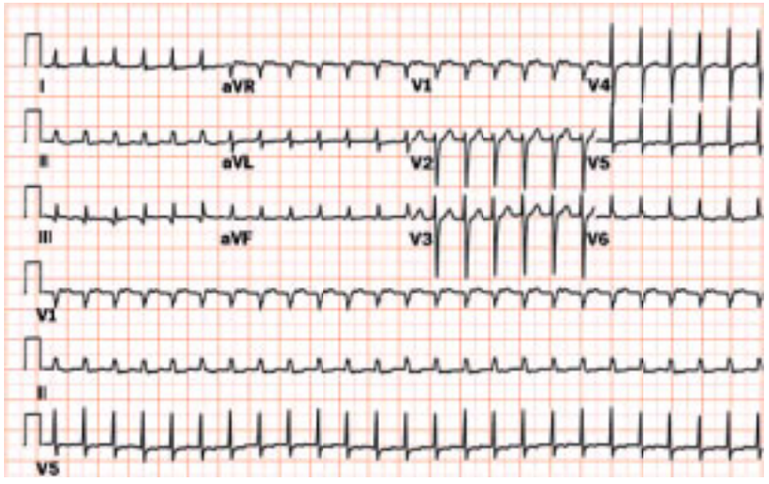
Pheochromocytoma

The clinical presentation of pheochromocytoma is characterized by episodic catecholamine release. In approximately 90% of cases, pheochromocytomas are located in the adrenal glands (in less than 10% the process is bilateral), whereas extraadrenal tumors, originating from chromaffin tissue of any sympathetic paraganglion (paragangliomas), account for the remaining 10% of cases. Over 90% of pheochromocytomas are benign and cured by surgery with low operative mortality (103). After surgical resection, up to 25% of patients may remain hypertensive. Life-long follow-up is mandatory because the disease may show late recurrence (104). Familial forms are rare and associated with bilateral or extraadrenal involvement and occasionally with multiple endocrine neoplasia type II.

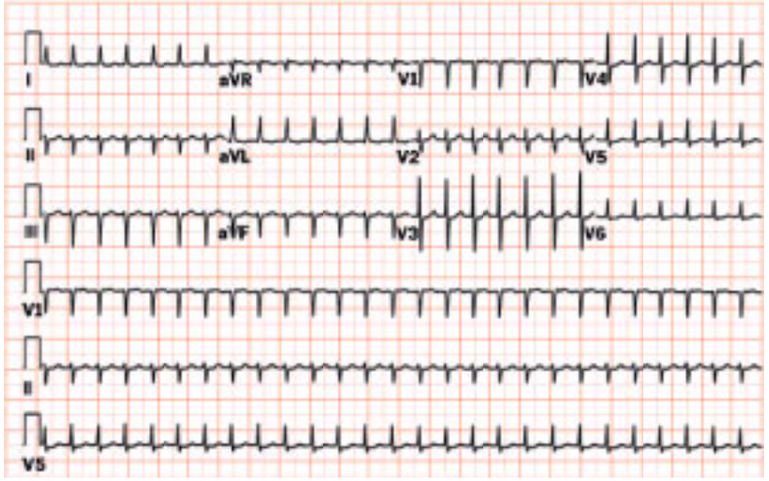
The classic presentation of pheochromocytoma consists of a paroxysm of the triad of palpitations, diaphoresis, and headache. These episodes begin abruptly, may last for minutes to hours, and subside gradually. Less common symptoms include orthostatic hypotension, anxiety, tremor, chest pain or abdominal pain, weakness, and weight loss. Because only a minority of patients presents with characteristic paroxysmal symptoms, the diagnosis is easily missed.

Cardiovascular Manifestations

Hypertension, one of the hallmarks of pheochromocytoma, is paroxysmal only in approximately one-half of the cases (105). Heart rate is frequently elevated during hypertensive episodes but may decrease because of reflex bradycardia, and usually no factors precipitating hypertensive episodes can be elicited. Prolonged exposure to high levels of catecholamines results in arterial and venous vasoconstriction and plasma volume contraction. Orthostatic hypotension may occur; possible mechanisms include plasma volume contraction and autonomous nervous system dysfunction (106). Electrocardiographic abnormalities are frequent but nonspecific and include T-wave abnormalities, signs of LVH, sinus tachycardia, and occasionally supraventricular ectopy and paroxysmal supraventricular tachycardia. In addition, particularly during hypertensive episodes, patients may show ischemic electrocardiographic changes. It has been postulated that pheochromocytoma affects the myocardium in the form of catecholamine-induced myocarditis, cardiomyopathy, or both (107,108). Tumor removal has been associated with regression of both LV dilatation and LVH (109,110 and 111).



Supraventricular tachycardia. Note narrow QRS complex with short RP interval.



Supraventricular tachycardia. P wave is not visible in this example, suggesting atrioventricular nodal reentry tachycardia.

Diagnosis

Because pheochromocytoma is the cause of hypertension in only approximately 0.1% of unselected patients (96), routine screening is not warranted. There is no gold standard to diagnose pheochromocytoma. Assessments of 24-hour urinary metanephrines and plasma metanephrines have shown comparable diagnostic sensitivity and specificity (112). Alternatively, plasma and urine metanephrines can be obtained during hypertensive paroxysm. Because only extreme elevations of plasma catecholamines affect blood pressure, normal levels in the setting of a hypertensive episode make pheochromocytoma highly unlikely. The great majority of pheochromocytomas are located in the abdomen and can be imaged by computed tomography or magnetic resonance imaging. Metaiodobenzylguanidine or octreotide scintigraphy may be useful for localization of metastatic, recurrent, or extraadrenal tumors.

Therapy

Surgery frequently represents the cure for pheochromocytoma. Adrenergic blockade for a few weeks is indicated before tumor resection, although on rare occasions urgent surgery may be necessary (Fig. 35A.3). The goal of preoperative treatment is adequate blood pressure control without inducing intolerable orthostatic hypotension. The alpha-blocker phenoxybenzamine, an irreversible noncompetitive antagonist predominantly of the $alpha_1$-receptors, has been the mainstay of preoperative and perioperative antihypertensive therapy (103,113). In patients intolerant to phenoxybenzamine, the $alpha_1$-selective antagonists prazosin, terazosin, or doxazosin have been used (103,113). To achieve optimal control of hypertension, tachyarrhythmias, and sinus tachycardia, beta-blockers can be added. However, beta-blockade should not be started if the patients are not pretreated with alpha-blockers. In fact, in the setting of high catecholamine levels, blockade of $beta_2$-mediated vasodilation can potentially lead to unopposed $alpha_1$-mediated vasoconstriction and exacerbation of hypertension. Frequently used drugs include the nonselective antagonist propranolol, $beta_1$-selective antagonists such as metoprolol or atenolol, and the mixed alpha/beta-blocker labetalol. However, because labetalol has a predominantly beta effect, additional alpha-blockade is usually required. In subjects with contraindications to beta-blockade, amiodarone can be used for tachyarrhythmia control. Severe hypertensive crisis may be acutely managed with intravenous nitroprusside or the $alpha_1$/$alpha_2$-blocker phentolamine. Several drugs can potentially trigger hypertension in pheochromocytoma and should, therefore, be avoided, including opiates, cocaine, tricyclic antidepressants, and metoclopramide (114).

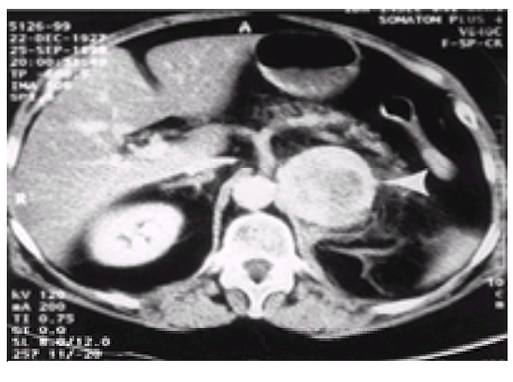


FIGURE 35A.3 Abdominal computed tomographic scan with contrast showing hemorrhagic transformation of a pheochromocytoma (*arrowhead*). The patient presented with lower back pain and extreme hemodynamic instability requiring emergency surgery. (Courtesy of E. Lipp, MD, Swiss Cardiovascular Center, Bern, Switzerland.)

Perioperative and Postoperative Management

Hypertensive episodes are more likely to occur during anesthetic induction, intubation, tumor palpation, and ligation of tumor veins (103). Intraoperative or postoperative hypotension is first approached with aggressive intravascular volume expansion. Only after euvolemia is restored, norepinephrine infusion may be indicated. Hypertensive responses are frequently controlled with intravenous nitroprusside, or alternatively, with phentolamine (113). Persistent hypotension is the main complication following surgery, possibly caused by tumor-induced suppression of catecholamine secretion of the contralateral adrenal gland and/or downregulation of adrenergic receptors (103). Less frequently, patients may be hypertensive postoperatively, because plasma catecholamines may remain elevated for several days after tumor removal. If hypertension persists several weeks after surgery, 24-hour urinary metanephrines should be assessed in order to exclude residual unresected tumor. In addition, hypoglycemia may be encountered in the perioperative or postoperative period.

ACROMEGALY AND GROWTH HORMONE DEFICIENCY

Growth hormone (GH) is produced and stored in large amounts in the pituitary gland. Direct GH effects include stimulation of lipolysis and gluconeogenesis. Indirect GH actions are mediated by insulin-like growth factor (IGF)-1. IGF-1, synthesized in hepatocytes and fibroblasts following GH stimulation, inhibits GH secretion in a classic feedback loop mechanism and acts as mediator of GH effects at the tissue level (i.e., it promotes chondrocytes proliferation and stimulates protein synthesis and glucose uptake in muscle cells). Stress, exercise, and a variety of neurogenic stimuli increase GH secretion. GH secretion persists throughout life, reaching the

maximum during puberty and then gradually declining in adulthood. In this book, the focus is exclusively on pituitary gland dysfunctions in the adult.

Acromegaly

Acromegaly is a rare disorder caused by a GH-secreting pituitary tumor, with an estimated incidence of approximately three per million (115). Excess GH secretion occurring during childhood leads to gigantismus. GH-producing tumors account for 10% to 15% of all pituitary neoplasms. Signs and symptoms are either caused by tumor mass effect (e.g., headaches, visual field defects, and hypopituitarism) or by GH excess (e.g., acral overgrowth, excessive sweating, and soft tissue swelling). Changes in facial appearance include enlargement of the lower jaw (prognathism), leading to malocclusion and increased spacing between the teeth and enlargement of the lips, tongue, nose, and sinuses. Progressive increase in shoe size and inability to wear rings are typical. Other features include sleep apnea, arthropathy, neuropathy, and cancer. Specifically, acromegalic patients have a three- to eightfold excess risk of colon cancer or premalignant polyps (116). Therefore, in these patients, screening with colonoscopy is recommended over the age of 50 years.

Acromegaly. The soft tissue and bone enlargement caused by growth hormone excess result in increased hand size as shown here. This condition may be associated with hypertension, cardiomegaly, and left ventricular hypertrophy.

Cardiovascular Involvement

Despite the fact that cardiovascular symptoms are the leading feature at presentation in less than 5% of the patients, overt cardiac disease may occurs in as many as 20% of acromegalic patients (117). GH excess is associated with a two- to threefold increase in mortality, mainly due to cardiovascular disease (118,119 and 120). Other causes include neoplastic and respiratory disorders. Hypertension is present in 25% to 35% of acromegalic patients, a three- to fourfold increase over the general population (117,121). The pathophysiology remains unknown, but its salt-sensitive nature suggests that, at least in part, it may be caused by a direct GH effect on the renal sodium pump leading to sodium retention (117,121). Glucose intolerance is present in up to 50% of the patients and overt diabetes mellitus in 10% to 25% (117). Diabetes resolves in two-thirds of patients after successful surgery (122). The lipid metabolism in acromegaly is characterized by hypertriglyceridemia (123), whereas no consistent findings on cholesterol abnormalities have been reported.

Electrocardiographic abnormalities are frequent and include ST-segment and T-wave depression, other signs of LVH, and, occasionally, conduction defects. Echocardiographic abnormalities, found in up to 80% of patients, include LVH and decreased systolic function (124,125). It has long been postulated that GH has trophic properties on the myocardium, but to date it remains a source of debate whether acromegalic cardiomyopathy exists. The assessment is complicated by frequent concomitant hypertension and/or coronary artery disease. However, echocardiographic studies in patients with acromegaly of recent onset and no associated cardiovascular abnormalities have demonstrated LVH, with or without associated diastolic dysfunction (126,127). These observations are in accordance with previous reports showing that less than 10% of patients with LVH and impaired LV function may have no evidence of hypertension or coronary artery disease (122,128). Additional arguments in favor of an acromegalic cardiomyopathy include the observation that LVH, LV dysfunction, or both may improve with treatment of GH excess (129,130). Moreover, both *in vitro* and *in vivo* animal models of GH excess have consistently demonstrated LV hypertrophic response and enhanced cardiac function (131,132). Finally, one autopsy series of acromegalic patients showed frequent myocardial interstitial fibrosis and inflammatory infiltrates (133). These observations suggest that, although most cardiac disease in acromegaly is explained by coexisting hypertension and/or coronary artery disease, a small proportion of patients may have a cardiomyopathy. It is speculated that elevated GH and/or IGF-1 levels may initially lead to LVH, followed by fibrosis, diastolic dysfunction, and later in the process, systolic dysfunction and overt heart failure (134).

A 71-year-old patient with left ventricular hypertrophy and negative U waves.

Diagnosis and Therapy

Because GH is secreted in a pulsatile manner, random GH plasma levels are not useful in diagnosing acromegaly. IGF-1 levels correlate with GH production and disease activity and represent the screening test of choice. Definitive diagnosis is made with the glucose tolerance test, showing no decrease of serum GH level following oral glucose load.

The goals of therapy are to reverse or prevent tumor mass effects and to reduce the long-term morbidity and mortality without incurring hypopituitarism. The current treatments for acromegaly include surgery, radiation therapy, and pharmacologic management. Among patients treated surgically, only 60% overall and less than one-half of those with large tumors can be cured (135,136). These low rates are explained by the fact that frequently, because of its extension and infiltrative nature, the tumor cannot be completely resected. Radiation therapy is characterized by delayed effect, poor efficacy, and a high incidence of panhypopituitarism (137). Preliminary data on stereotactic radiotherapy (gamma knife) appear promising, but its role in the treatment of acromegaly has yet to be demonstrated. Dopamine agonists, such as bromocriptine, cabergoline, or quinagolide (not available in the United States), adequately lower GH levels in only a minority of patients, and their adverse effects limit compliance (138). The somatostatin analogs octreotide and lanreotide inhibit the secretion of GH and are regarded by many authors as the first-line treatment of acromegaly. However, this drug class also leads to normalization of GH and IGF-1 levels only in approximately one-half of patients (139,140).

Pegvisomant is a recently developed, genetically engineered GH receptor antagonist. In the short run, this compound has been shown to be effective and well tolerated in over 100 patients with acromegaly (141). Should these promising results be confirmed in a large patient population with longer follow-up, GH receptor antagonism may become a useful tool for the medical management of acromegaly.

Growth Hormone Deficiency

GH deficiency (GHD) in the adult is primarily caused by hypothalamic or pituitary disorders, often leading to multiple pituitary hormone deficiencies (hypopituitarism). Neoplastic lesions, particularly pituitary adenomas, are the most common cause of acquired hypopituitarism. Other causes include radiation, trauma, pregnancy

(pituitary apoplexy, Sheehan's syndrome), anticoagulation-related pituitary hemorrhage, sickle cell anemia, and sarcoidosis.

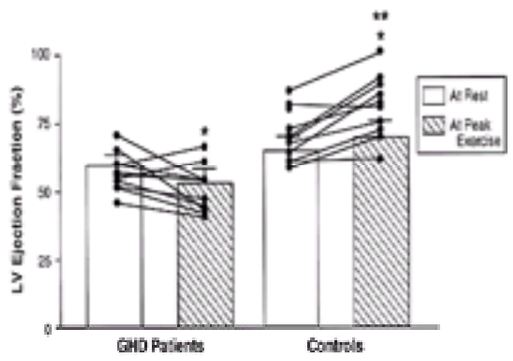
Clinical Presentation and Cardiovascular Risk Factors

GHD is a common finding in adults with hypothalamic or pituitary diseases. The deficiency is clinically characterized by changes in body composition including increase in adipose tissue mass and reduction in lean body mass, bone density, muscular strength, and exercise capacity (142,143). The psychosocial constellation of adult-onset hypopituitarism includes fatigue, emotional lability, sex life disturbances, and social isolation (144).

Several studies have shown that life expectancy in hypopituitary patients is decreased, mainly because of excess cardiovascular mortality, even after correct replacement of thyroid, adrenal, and sexual hormones (145,146). Serum total and LDL cholesterol, apolipoprotein B, and triglycerides are elevated in GH-deficient adults, whereas high-density lipoprotein (HDL) cholesterol is decreased (147,148). GH is believed to play a role in the regulation of hepatic LDL receptor activity, a major pathway of plasma LDL cholesterol removal (149). Hypertension is not a major feature of hypopituitarism, and the increased prevalence found in some studies compared with the normal population may be the result of more intense medical care (150).

Cardiovascular Involvement

There have been conflicting reports on LV wall thickness, LV mass, and systolic function in hypopituitary patients. On the contrary, diastolic dysfunction has been a consistent finding (150). Diminished exercise capacity compared with control subjects has been shown in a limited number of studies (151). In addition, abnormal LV systolic function during peak exercise has been reported (152,153) (eFig. 35A.3.1). One single study has so far addressed carotid artery morphology in patients with adult-onset hypopituitarism, showing a greater intima-media thickness ultrasound compared with controls (154). Studies on coronary arteries are lacking.



***e*FIGURE 35A.3.1** Left ventricular (LV) ejection fraction at rest and at peak exercise in growth hormone–deficient (GHD) patients and controls measured by radionuclide angiography. The bars represents the mean ± standard error of the mean. *, p <.05 compared with LV ejection fraction at rest; **, p <.001 with LV ejection fraction in GHD patients. (From Colao A, Cuocolo A, Di Somma C, et al. Impaired cardiac performance in elderly patients with growth hormone deficiency. *J Clin Endocrinol Metab* 1999;84:3950–3955, with permission.)

Diagnosis and Therapy

Insulin tolerance test, which assesses GH response to hypoglycemic stress following intravenous administration of insulin, is the diagnostic tool of choice for GHD (155). Alternatively, GH secretion can be assessed following stimulation with arginine or arginine and GH-releasing hormone. Despite being expensive, the administration of recombinant human GH has been approved in several countries for treatments of adults with GHD. Short-term studies show that GH replacement increases lean body mass, decreases adipose tissue mass, and improves the sense of well-being in adults with documented GHD, but long-term safety and efficacy data are limited. Benefits of long-term administration of GH in 12 patients was confined to body composition, with no effects on lipid levels or exercise tolerance (156). In particular, it remains unknown whether GH treatment affects mortality, and specifically cardiovascular mortality, associated with the disease.

In conclusion, although increased cardiovascular mortality has been attributed to GHD, the exact mechanisms have not been established. Chronic under- or overreplacement of other hormones may potentially contribute to the cardiovascular risk of hypopituitary patients.

Growth Hormone Abuse

The role of GH as performance enhancer in athletes has been reviewed (157). Over the last 10 years, GH abuse by athletes and body builders has been increasingly reported, facilitated by the fact that it remains undetected. Although the number of controlled trials is small, there is no scientific evidence that GH, even in supraphysiologic doses, enhances exercise performance or strength (157). In athletes undergoing regular training, the administration of supraphysiologic doses of GH for up to 3 months was not beneficial in terms of muscle strength or body composition (158,159). However, dose and duration of GH administration were different from those taken by athletes or body builders.

Chronic abuse of GH is likely to be associated with significant side effects, and potentially with the increased morbidity and mortality observed in acromegaly. In addition, it has been reported that, because of the high costs of recombinant GH, athletes may be purchasing cheaper cadaveric GH extracted from human pituitary glands (157). This product has been associated with Creutzfeldt-Jakob disease, and despite being banned in most western countries, it remains available (160).

Growth Hormone Therapy in Heart Failure

Several animal studies have indicated that GH and IGF-1 induce favorable early postinfarction remodeling, characterized by additional hypertrophy of the noninfarcted myocardium, reduction of LV dilatation, and decrease in systemic vascular resistance (161,162). Interestingly, GH-induced hypertrophy appears to be physiologic, as indicated by lack of fibrosis and by improved diastolic function (162,163). GH axis stimulation has been reported in patients with myocardial infarction (164), although the significance of this observation remains uncertain. GH has received attention as a potential adjunctive treatment for heart failure. In this setting, chronic administration of GH has been shown to induce concentric LVH (165,166). Initial small and uncontrolled trials have shown beneficial effects of GH therapy in heart failure (165,167). However, these results could not be reproduced in a larger placebo-controlled trial (166).

HYPERPARATHYROIDISM

In primary hyperparathyroidism (PHPT), inappropriate secretion of parathormone (PTH) causes excessive renal calcium reabsorption, phosphaturia, $1,25(OH)_2D$ synthesis, and increased bone reabsorption. Hypercalcemia, hypercalciuria, hypophosphatemia, and loss of cortical bone are typical associated findings. Based on surveys, a prevalence of PHPT between 0.1% and 0.5% has been estimated (168). Women are affected approximately twice as much as men, and after the age of 40 years the incidence of the disease sharply increases (168). The underlying pathology is in over 80% of cases parathyroid adenoma, in 10% to 20% hyperplasia of all parathyroid glands, and in fewer than 2% parathyroid carcinoma (169). Hyperplasia of parathyroid glands is most often familial and found in the context of inherited diseases, such as multiple endocrine neoplasia types I and II and familial hypocalciuric hypercalcemia.

PHPT is most frequently diagnosed following incidental plasma calcium measurements. Therefore, nowadays, most patients with PHPT are either asymptomatic or have vague, nonspecific symptoms such as fatigue, weakness, and mental disturbances. Other manifestations include proximal muscle weakness and pseudogout. Subperiosteal bone reabsorption and kidney stones are rare.

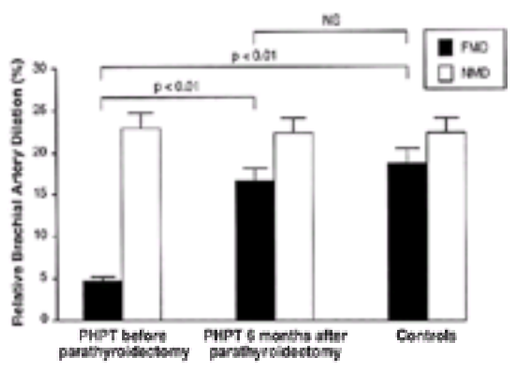
Cardiovascular Involvement

The relationship between PHPT and cardiovascular disease has not been conclusively defined. Previous epidemiologic studies (170,171) linking PHPT with increased mortality, and specifically, increased cardiovascular mortality, have been questioned by other large-scale observations (172,173). This discrepancy may be at least in part explained by different patient selection. Older studies frequently enrolled symptomatic patients with markedly elevated plasma calcium levels, whereas patients in

more recent studies were more likely to be asymptomatic and have mild hypercalcemia.

Approximately 30% to 40% of PHPT patients are hypertensive, which represents an approximately twofold increased incidence compared with the general population of the same age and sex (168). In an unselected population of hypertensive patients, approximately 1% may have PHPT (96). Because no direct correlation between hypertension and elevated PTH or calcium levels has been found, the pathophysiology of hypertension in this setting remains unclear. It is controversial whether PHPT in the absence of hypertension causes LVH. Mild LVH was documented in one small echocardiographic series (174), but this observation could not be reproduced (175). More convincing data on a link between high PTH levels and LVH are derived from patients with end-stage renal disease. End-stage renal disease is characterized by, among others, secondary hyperparathyroidism—a condition that produces much higher PTH levels than PHPT. The incidence of LVH is higher in this patient population if compared with controls matched for age, sex, and blood pressure (176,177). Additionally, a regression of LVH after parathyroidectomy in hemodialysis patients has been described (178,179).

Endothelial dysfunction in otherwise healthy patients with PHPT has been reported (180). Interestingly, the same authors found that endothelial dysfunction was reversible after parathyroidectomy (181) (eFig. 35A.3.2). Similar findings were documented in another small series (182). In addition, initial data show that mild PHPT might be associated with decreased vascular compliance (183).



***e*FIGURE 35A.3.2** Relative flow-mediated (endothelium-dependent) vasodilation (FMD) and nitroglycerine-induced (endothelium-independent) vasodilation (NMD) of the brachial artery of patients with primary hyperparathyroidism (PHPT, n = 19) before and after parathyroidectomy and of control subjects (n = 20). There was no significant difference in NMD with time or between groups. FMD was significantly reduced in PHPT compared with controls at baseline and improved significantly after parathyroidectomy with time. (From Kosch M, Hausberg M, Vormbrock K, et al. Impaired flow-mediated vasodilation of the brachial artery in patients with primary hyperparathyroidism improves after parathyroidectomy. *Cardiovasc Res* 2000;47:813–818, with permission.)

Diagnosis and Therapy

The finding of hypercalcemia in the presence of an elevated or nonsuppressed intact PTH level is the key to diagnosis. Parathyroidectomy remains the therapy of choice for patients with severe hypercalcemia, recurrent kidney stones, nephrocalcinosis, renal failure thought to be related with the disease, reduced bone mass, and probably for asymptomatic patients younger than 50 years (184). Patients older than 50 years with mild PHPT may not need surgery (184). This approach is supported by long-term studies showing a remarkable stability of the disease over the years, but prospective randomized trials are lacking. Because hypertension remission after surgery is variable, hypertension is considered a minor criterion for recommending parathyroidectomy (185). Cure rates, extremely operator-dependent, range between 90% and 95% (186,187).

A 54-year-old male patient with hypercalcemia.

ANDROGENS AND THE CARDIOVASCULAR SYSTEM

Androgens in general, and testosterone in particular, are widely believed to be associated with a higher cardiovascular risk in men, probably because male gender itself is an established independent risk factor for cardiovascular disease. Additionally, the abuse of synthetic androgens in high doses by athletes and body builders has been associated with hypertension, cardiomyopathy, myocardial ischemia, and sudden death (188). However, a number of more recent reports challenge the assumption that androgen is detrimental for the cardiovascular system. Animal studies *in vitro* have shown that testosterone is a coronary vasodilator (189). This observation was reproduced in humans in a study showing that intracoronary administration of physiologic doses of testosterone increased coronary blood flow in men with ischemic heart disease (190). Accordingly, significant improvements in angina threshold have been demonstrated in patients given supplemental intramuscular, oral, or intravenous testosterone (191,192). However, the doses used in these trials were supraphysiologic, raising concerns about potential side effects. The daily administration of small doses of testosterone to men with chronic stable angina was shown to prolong time to myocardial ischemia compared with placebo, and the magnitude of the benefit was comparable with the previous studies using higher testosterone doses (193). Additionally, castration resulted in a significant increase in aortic atherosclerosis in cholesterol-fed rabbits—a process that was markedly inhibited by testosterone replacement (194). In men without prior myocardial infarction referred for coronary angiography, a significant inverse correlation was found between plasma testosterone levels and extent of coronary disease, suggesting that low testosterone may represent a risk factor for coronary atherosclerosis (195). However, a number of prospective epidemiologic studies have failed to show a relationship between baseline testosterone levels and the subsequent development of coronary disease (196,197 and 198). The influence of androgens on serum lipids and glucose metabolism in men remains controversial (195,199,200). Currently no data exist on the effects of testosterone therapy on cardiovascular morbidity and mortality and on potential side effects such as growth in prostatic hyperplasia or prostatic cancer.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Cardiovascular involvement is frequent in endocrine disease. However, it is often controversial whether hormonal imbalance has direct deleterious effects on the cardiovascular system or if cardiovascular involvement is caused by the increased prevalence of associated cardiovascular risk factors. Little is known about how hormones directly interact with the cardiovascular tissue and how they influence risk factors such as hypertension or hyperlipidemia.

In addition, it remains unproven whether therapy reduces cardiovascular morbidity and mortality in endocrine diseases other than diabetes mellitus. The fact that many endocrine disturbances are uncommon makes clinical research in this field difficult.

The potential for thyroid hormone and GH supplements in heart failure has been recognized. Data are limited; therefore, these therapies should be considered investigational. Equally controversial is the interaction between androgens, and specifically testosterone, and the cardiovascular system in men.

Notwithstanding the interest of these topics, we have to realize that frequently the most challenging step in endocrine disorders remains the diagnosis. Clinical suspicion is essential, as endocrine diseases and, in particular, their cardiovascular manifestations may present in a subtle and nonspecific way.

THE FUTURE

Amiodarone remains a cornerstone of antiarrhythmic therapy. However, its use is limited by side effects and, in particular, by frequent thyroid dysfunction. Preliminary animal data on a noniodinated analog of amiodarone have been encouraging. An iodine-free “amiodarone-like” compound without the disturbing endocrinologic side effects would be a major advance in cardiovascular medicine.

In the near future, newer innovative therapeutic modalities, including applications of pharmacogenomics, may modulate endocrinologic diseases before cardiovascular involvement. In addition, targeted therapy based on a patient’s individual genetic profile may allow more selective and specific treatment of cardiovascular manifestations of endocrine diseases.

ANEMIA

Pathophysiology

Severe anemia (hemoglobin less than 7.0) results in profound hemodynamic and neurohormonal changes aimed at maintaining adequate oxygen delivery to vital organs (eTable 35B.0.1 and eFig. 35B.0.1). Hemodynamic changes observed in patients with severe anemia include increased cardiac output, heart rate, and stroke volume and decreased systemic vascular resistance, mean arterial pressure, and circulatory transit time (1). Neurohormonal changes include activation of the renin-angiotensin-aldosterone system and increases in vasopressin and norepinephrine release. Elevated levels of 2,3-diphosphoglycerate result in lower oxygen affinity for hemoglobin and hence greater tissue extraction of oxygen (2). All these adaptations correct with reversal of the anemia. Although healthy adults can sustain hemoglobin concentrations as low as 5 mg per dL without detrimental effects on tissue oxygenation (1), symptoms of fatigue may occur in anemia and resolve with transfusion (3). Although clinically significant myocardial ischemia is rare in otherwise healthy people, cardiac reserve is impaired (4).

Hemorrhage

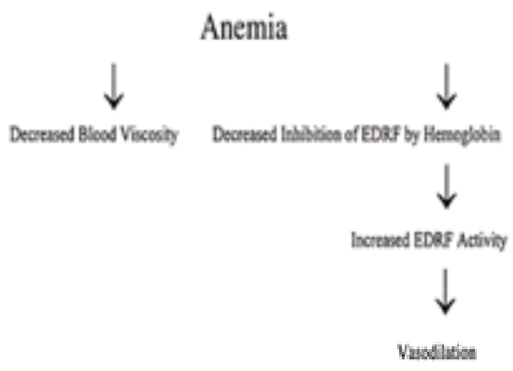
***e*FIGURE 35B.0.1** Compensatory physiologic changes associated with anemia. ADH, antidiuretic hormone; CO, cardiac output.

The high cardiac output found in anemia results from decreased systemic vascular resistance and increased heart rate. Heart rate is increased as a result of lower basal parasympathetic tone (5). The mechanisms by which systemic vascular resistance is decreased in anemia include both decreased blood viscosity and vasodilation (eFig. 35B.0.2). Experiments in anemic dogs, in which hematocrit is held constant but blood viscosity is varied using dextrans of varying molecular weights, have shown that decreased blood viscosity contributes to, but does not fully explain, the decreased resistance and increased cardiac output found in anemia.



***e*FIGURE 35B.0.2** Mechanisms by which anemia reduces vascular resistance. EDRF, endothelium-derived relaxing factor.

One hypothesis for the mechanism by which the vasodilation component of decreased systemic vascular resistance is produced is that endothelium-derived relaxing factor (EDRF) activity is enhanced by anemia. Anand and colleagues studied forearm blood flow in eight patients with chronic severe anemia and found that N^G-monomethyl-L-arginine, a specific inhibitor of EDRF, decreased forearm blood flow three times more than for controls or anemic patients after treatment, suggesting that EDRF is indeed a major contributor to the vasodilatation found in anemia (6). Hemoglobin, a known potent inhibitor of EDRF, may enhance EDRF activity in anemia because of reduced inhibitory effect.

In the most severe cases of anemia, congestive heart failure may develop and can resolve by simply correcting the anemia. *Congestive heart failure* is actually something of a misnomer in this case because most patients usually have normal or increased myocardial contractility. However, in some cases of protracted anemia, left ventricular systolic dysfunction can develop, and this, too, is reversed by correcting the anemia (7). When ventricular function remains preserved, the fluid retention in severe anemia appears to be caused by the neurohormonal activity (induction of the renin-angiotensin-aldosterone system and increased vasopressin release) that is caused by the decreased renal blood flow that occurs when low systemic arterial pressures result in a reflexive increase in renal vascular resistance.

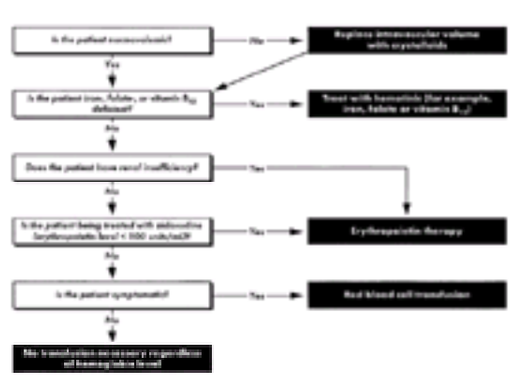
Treatment

All of the hemodynamic and neurohormonal changes described previously readily correct with reversal of the anemia. The risks of blood transfusion, although low, are not zero. The risks of transmission of the potentially deadly viruses hepatitis C, hepatitis B, and human immunodeficiency virus have been estimated at 1:300 to 1:900, 1:200 to 1:300, and 1:40,000 to 1:1,000,000, respectively, with current screening practices (2). The risks of the noninfectious complications of minor immunologic reaction (fever, chills, urticaria), hemolytic transfusion reaction, and fatal hemolytic transfusion reaction have been estimated at 1:50 to 1:100, 1:6,000, and 1:100,000, respectively. Transfusion-related graft-versus-host disease has also been reported in immunocompetent recipients, but the quantitative risk is unknown (2). Because of these potential complications, red cell transfusions should be performed only when the benefit is judged to outweigh these risks.

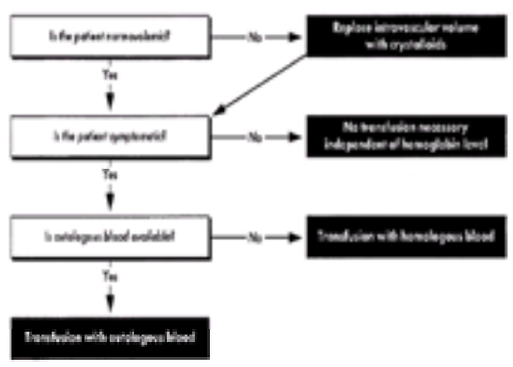
Guidelines have increasingly advised that routine transfusion using the *10/30 rule*(hemoglobin of 10 mg per dL or hematocrit of 30%) as a trigger should be avoided. Both to reduce the risk to transfusion recipients and to conserve blood products, the overall status of the patient should be considered in addition to the specific measurements of hemoglobin or hematocrit. The primary reasons usually given for transfusion are to increase myocardial oxygen supply and to diminish the increased demand caused by the physiologic adaptations described previously. However, most evidence supports the concept that myocardial oxygen supply is maintained above a hemoglobin of 6 to 7 mg per dL (2) and that, at least in otherwise healthy individuals, administration of stored blood in mild anemia does not improve hemodynamics or tissue oxygenation. In a randomized clinical trial of critical care patients, those kept at a hemoglobin level of 7 to 9 mg per dL had a lower in-hospital mortality (p = .05) and a nonsignificantly (statistically) lower 30-day mortality compared with those kept at a hemoglobin of 10 to 12 mg per dL (8).

In anemia from acute blood loss, blood volume should be replaced first with crystalloid before determining if red cell transfusion is necessary, based on signs or symptoms. If blood loss can be anticipated, such as in elective surgery, arrangements should be made, if possible, for autologous blood donation. Finally, in chronic anemia, homologous blood transfusion should be the treatment of last resort: All other avenues, such as iron replacement or erythropoietin, should be tried before consideration of homologous transfusion, and then transfusion should only be performed for symptoms or signs attributable to the anemia. These symptoms include syncope, dyspnea, orthostatic hypotension, tachycardia, angina, or transient ischemic attacks (2).

The absence of definitive evidence concerning the point at which the increased myocardial oxygen demand creates a problem for patients with coronary artery disease makes practical criteria for cardiac patients difficult. No evidence exists that anemia in these patients predisposes to adverse cardiovascular events. Deleterious consequences of sending patients home after cardiopulmonary bypass or percutaneous intervention with hematocrit values between 21% and 30% have not been documented. One study suggests that, among patients with angina and anemia, low exercise capacity is caused more by anemia than by coronary disease when the hematocrit is below 25% (9). Therefore, the general guidelines of the American College of Physicians are recommended (eFig. 35B.0.3 and Fig. 35B.0.4); only severe symptomatic anemia should be corrected with red cell transfusions, and only after nontransfusion therapy has been exhausted (2). In the setting of persistent refractory ischemia, packed red blood cells should be given to correct the anemia until the acute situation is stabilized.



***e*FIGURE 35B.0.3** Elective red blood cell transfusion in patients with persistent anemia: management strategy. (From Welch HG, Mechan KR, Goodnough LT. Prudent strategies for elective red blood cell transfusion. *Ann Intern Med* 1992;116:393–402, with permission.)



***e*FIGURE 35B.0.4** Elective red blood cell transfusion in patients with transient anemia from acute blood loss: management strategy. (From Welch HG, Mechan KR, Goodnough LT. Prudent strategies for elective red blood cell transfusion. *Ann Intern Med* 1992;116:393–402, with permission.)

Among patients with chronic heart failure, anemia is common and increases in frequency with severity of heart disease, such that nearly 80% of patients with New York Heart Association class IV symptoms were anemic in one study (10). This prospective study found that raising the hemoglobin from a mean of 10 mg per dL to 12 mg per dL with iron and erythropoietin in a group of heart failure patients was associated with improved ejection fraction (EF) and functional class and reduction in hospitalization and diuretic dose (10). Another study found that patients with ischemic cardiomyopathy had a lower cardiac index when anemic, and that correcting the anemia increased the cardiac index (11).

Patients with end-stage renal disease represent a separate entity. The link between anemia and heart failure in these patients is strong, and anemia in this population is also associated with cardiac mortality (12). Heart failure in these patients can develop as a result of the stress of long-standing anemia on the heart leading to myocyte hypertrophy. These hypertrophic changes have been shown to regress after reversal of anemia (13). Improvement in myocardial ischemia has not been shown (14).

A few specific causes of anemia merit special consideration from the cardiologist because of their relationship to cardiac disease. These include the hemoglobinopathies, including the thalassemias and sickle cell anemia, and hemolytic anemia related to heart disease.

Thalassemia

The thalassemias are diseases of the red blood cell resulting from decreased amounts of either the a (a-thalassemia) or b (b-thalassemia) chain components of hemoglobin, because of either absent or defective genes. The relative excess of the normal globin component leads to hemolysis and ineffective erythropoiesis. The thalassemic syndromes range from subclinical to life-threatening depending on the number and severity of the genetic defects. b-Thalassemia major, characterized by defects in both copies of the beta-globin gene, has been the best studied with regard to cardiac problems.

Cardiac disease, the most common cause of death in b-thalassemia major, develops because of multiple blood transfusions (which become necessary beginning at 4 to 6 months of age when beta-chain production supplants g-chain production) rather than the disease itself. These blood transfusions, plus increased gastrointestinal absorption of iron, result in an iron-overload state, which leads to myocardial iron deposition, causing a restrictive cardiomyopathy, cardiac enlargement, ventricular dysfunction, and congestive heart failure. Both systolic and diastolic left ventricular dysfunction can occur (15). Arrhythmias (atrial and ventricular tachyarrhythmias and bradyarrhythmias, particularly involving atrioventricular block) may result from this cardiomyopathy or from hemosiderosis-related damage to the conduction system. Pericarditis is also commonly seen (16).

The advent of the iron-chelating agent deferoxamine in the mid-1970s resulted in an overall reduction in cardiac complications (17) and improvement in survival (18). Thus, deferoxamine, generally administered by continuous subcutaneous injection by a pump device, is a mainstay of medical treatment of b-thalassemia major. Allogeneic bone marrow transplant has been used as an alternative to long-term transfusion and iron chelation therapy (19).

Sickle Cell Disease

Sickle cell anemia is caused by a point mutation in the beta-globin gene, resulting in the substitution of valine for glutamate in the sixth amino acid of the protein. This change, in homozygous form, results in deoxygenated HbS polymerizing, distorting the shape of the red blood cell (sickling) and leading to occlusion of capillaries and end-organ damage. In addition, the abnormal hemoglobin results in a shortened life span of the erythrocyte, resulting in an anemia with reticulocytosis.

Sickle cell ulcer. Chronic skin ulcer in the leg commonly occurs in sickle cell disease. The chronic severe anemia and hypoxemia impose a burden on the heart that may elicit a hyperdynamic response.

In contrast to b-thalassemia, cardiac complications of sickle cell anemia are not among the major causes of morbidity or mortality, although the heart is affected. Several studies using noninvasive imaging techniques have demonstrated abnormalities in sickle cell patients. Diastolic dysfunction, increased left ventricular mass and wall thickness, and enlargement of the cardiac chambers and aortic root are all common by echocardiography (20). Although resting EF is almost always normal (21,22), subtle abnormalities in load-independent parameters suggest underlying systolic dysfunction (21), and impaired EF response to exercise has been described (23). Right ventricular abnormalities and significant pulmonary hypertension are uncommon (21,24). Primary valvular disease is uncommon as well (24). Treatment involves addressing the underlying disease, including supportive therapy consisting of hydration, analgesics, oxygen, and transfusions when indicated. Newer therapies include hydroxyurea and allogeneic bone marrow transplant.

Changes associated with anemia in general, as described previously, are present in sickle cell disease, especially when the hemoglobin falls below 7 mg per dL. Most of the physical examination findings relate to compensatory adjustments to the anemia, rather than intrinsic cardiac abnormalities. Thus, a widened pulse pressure, prominent precordial impulse, and systolic and diastolic flow murmurs may be present, all reflecting a hyperdynamic state. The electrocardiographic (ECG) results are frequently abnormal, although there is no specific finding indicative of sickle cell disease. One study by Uzsoy found ECG abnormalities in 78% of 148 patients, including left ventricular hypertrophy, first-degree atrioventricular block, right ventricular hypertrophy, and nonspecific ST changes (25). Increased voltage, even when meeting the Sokolow-Lyon criteria, is not specific for left ventricular wall thickening, but instead represents ventricular dilatation and eccentric remodeling. Abnormal septal Q waves are reflective of septal hypertrophy and correlate with anemia. Chest radiography generally reveals an enlarged cardiac silhouette (25) and enlarged pulmonary artery segments.

Evidence is sparse for a specific cardiomyopathy directly related to the sickle cell anemia. Most autopsy studies reveal no myocardial infarction or narrowing of

epicardial vessels (26). However, one study did find pathologic evidence of myocardial necrosis in 7 of 72 patients, and microthrombi in two of these, with clinical correlates of chest pain, typical ECG abnormalities, and one sudden death (27). Among 531 patients with acute chest syndrome in a multicenter study, the most common specific causes were pulmonary fat embolism and infection. Serious in-hospital complications involved pulmonary emboli, pneumonia, and neurologic catastrophe and rarely related to cardiac events. None of the 18 deaths was cardiac in nature (28). Echocardiographic findings remain constant during a sickle crisis (26), and many of the chronic echocardiographic abnormalities described previously correlate with the degree of anemia. Thus, acute cardiac events are rare, and chronic abnormalities are most often caused by the stress of chronic anemia.

Hemolysis and Heart Disease

Hemolysis following valve replacement occurs mainly because of turbulence of blood flow and, in patients with mechanical valves, direct trauma to erythrocytes (29) (see Chapter 24). It is common, occurring in up to 50% of patients, although severe hemolysis is rare (30). Significant hemolysis is strongly indicative of valve dysfunction or a paravalvular leak (30) and may even be the presenting sign (31). The degree of hemolysis is directly related to severity of regurgitation. However, severe hemolysis necessitating repeat surgery in the absence of paravalvular leak or valve dysfunction has been reported (32). Risk factors for hemolysis include smaller prosthesis, mechanical valve versus bioprosthesis (29), double- versus single-valve replacement (30), suture type (33), and annular calcification (33). In addition to prosthetic valve disease, hemolysis has been reported following mitral valve repair, with native valve disease, and in patients following repair of ventricular septal defect (34). Diagnosis of hemolysis requires elevated lactate dehydrogenase, which is the most sensitive test and correlates well with severity (35). Other laboratory evidence includes elevated reticulocytes, low haptoglobin, hemosiderinuria, anemia, and schistocytes seen on peripheral smear (30). Treatment is usually conservative, consisting of observation and iron and folate supplementation as needed. Beta-blockers may help by ameliorating shear stress (34). Transfusions may be required. Severe refractory anemia may necessitate repeat surgery.

DISORDERS WITH INCREASED BLOOD VISCOSITY

Polycythemia

Polycythemia is characterized by an increased concentration of circulating red blood cells. Absolute polycythemia represents an increase in red cell mass, whereas relative polycythemia denotes increased red cell concentration with normal red cell mass, due to reduced plasma volume. Absolute polycythemias may be characterized as primary (polycythemia vera) or secondary, caused by an increase in erythropoietin.

Polycythemia vera, caused by a neoplastic, clonal proliferation of hematopoietic stem cells, results in excess bleeding as well as thromboembolic complications in up to 60% of patients (36). These events include stroke, myocardial infarction, deep venous thrombosis, pulmonary embolism, and arterial embolism (36,37). Neurologic symptoms such as headache, dizziness, vision changes, and confusion may result from chronic decreased cerebral perfusion caused by elevated blood viscosity, rather than an acute event. Although thromboembolism tends to occur mainly in small vessels, aortic and cardiac intraventricular thrombi have been reported (38). Valvular lesions by echocardiography, usually thickening but occasionally distinct vegetations, occur commonly and are associated with thromboembolic events (39). Acute events are treated with phlebotomy and aspirin at a dose of approximately 300 mg per day (40). Chronic therapy includes phlebotomy (41), hydroxyurea (42), and interferon-a (43). Prophylaxis against thromboembolism with low-dose aspirin (75 mg per day) could be considered, although no randomized prospective trials of this have yet been conducted, and a higher risk for bleeding is incurred (40).

Secondary polycythemias may be caused by either an appropriate increase in erythropoietin secondary to hypoxia (such as in chronic obstructive pulmonary disease or congenital heart disease with right-to-left shunt; see Chapter 31) or an inappropriate increase in erythropoietin production due to an erythropoietin-producing tumor such as a renal cell carcinoma. Hematocrits tend to vary inversely with arterial oxygen saturation and in congenital heart disease have been reported to be as high as 85%. Clinical manifestations of secondary polycythemia are similar to those of polycythemia vera and can include thrombotic episodes and bleeding.

Polycythemia associated with smoking and chronic obstructive pulmonary disease is associated with a lower frequency of thromboembolic events compared with polycythemia vera, but events may occur in up to 40% of patients (36). The benefit of phlebotomy to reduce such events has not been conclusively proven (44). Exercise tolerance, however, has been shown to improve with phlebotomy to achieve a hematocrit in the range of 50%, but no further benefit seems to accrue by keeping hematocrit in the normal range (45). The mechanism may be caused by improved right ventricular performance due to decreased preload. Patients in clinical congestive heart failure receive more benefit than mildly symptomatic patients. To avoid significant hypovolemia, simultaneous volume expansion with normal saline may be required (41).

Relative, or spurious, polycythemia is defined by increased hematocrit with normal red cell mass, generally caused by either reduced plasma volume or the combination of high normal red cell volume and low normal plasma volume. Morbidity is not directly related to this condition; thus, phlebotomy is not warranted.

Essential Thrombocythemia

Essential thrombocythemia is a myeloproliferative disorder similar to polycythemia vera with clonal overexpression of a multipotent stem cell, but resulting predominantly in thrombocytosis rather than erythrocytosis (46). As in polycythemia, this condition results in both bleeding and thromboembolic complications, with 9% to 40% of patients experiencing one or more thrombotic events (47,48). Large vessel thrombosis is most common, but myocardial thrombosis has been reported (48). Because a history of a thrombotic event is a risk factor for future recurrence, patients suffering such events are usually started on cytoreductive therapy, which may include radiophosphorus, hydroxyurea, busulfan, or interferon-a (46,47). Platelet count does not correlate with thrombosis in most studies, and even young patients may have serious or even fatal thrombotic events (48). The benefit of prophylactic therapy, however, currently remains controversial (46,49).

HEMATOLOGIC EFFECTS OF CARDIAC DRUGS

Occasionally, drugs used to treat cardiovascular disorders may cause hematologic abnormalities such as anemia, neutropenia, and thrombocytopenia (*e*Table 35B.0.2). Antihypertensive drugs associated with rare untoward hematologic effects include captopril, which has been associated with leukopenia, neutropenia, and fatal pancytopenia (50). Thiazides have been associated with thrombocytopenia (51). Hemolytic anemia (51) and thrombocytopenia (52) have been seen with use of alpha-methyldopa. Agranulocytosis has been reported after propranolol administration (53). Antiarrhythmic drugs have also been associated with hematologic abnormalities. Thrombocytopenia has been seen with digoxin use (52). Quinidine has been associated with hemolytic anemia and thrombocytopenia (52), and neutropenia and agranulocytosis have been reported with use of procainamide and tocainide (54). Use of the antiplatelet agent ticlopidine after coronary stent procedures has been associated with neutropenia, aplastic anemia, thrombocytopenia, and an incidence of thrombotic thrombocytopenic purpura of 1 in 1,600 to 5,000, resulting in over 250 deaths (55) and prompting recommendation of screening hematologic profiles while the patient remains on the drug (56). Clopidogrel is an alternative that has a safer hematologic profile, but nonetheless has been associated with thrombotic thrombocytopenic purpura (57). Hematologic abnormalities generally reverse with discontinuation of the offending agent.

Heparin-Induced Thrombocytopenia

Frequency

Perhaps one of the most commonly seen hematologic abnormalities caused by a cardiac drug in clinical practice is heparin-induced thrombocytopenia (HIT). Two types of HIT have been observed. Type I HIT is the more common, milder form, rarely resulting in platelet counts below 100,000. It occurs with a frequency of 10% to 25%, usually during the first 4 days of therapy, and resolves without serious sequelae despite continuation of heparin (58). A proaggregatory effect on platelets by heparin has been proposed as the mechanism for type I HIT. In contrast, type II HIT, a much more serious complication that is the subject of the remainder of this section, occurs with a frequency of approximately 1% to 5% of patients receiving heparin, usually 4 to 8 days after the start of heparin therapy (58). If there has been previous exposure to heparin, however, especially within the previous 3 months, onset may be much sooner, and therefore timing of thrombocytopenia alone cannot distinguish between HIT types I and II. The frequency with low-molecular-weight heparin is less than 1% (58).

Pathophysiology

The prevailing mechanistic theory is that binding of platelet factor 4 to heparin causes expression of an epitope that induces production of an immunoglobulin (Ig) G antibody, which then binds to platelets via the Fc receptor, in turn causing platelet activation and aggregation (59,60). Thrombosis is caused by aggregation and activation of platelets, including platelet production of microparticles inducing procoagulant activity, leading to induction of the coagulation cascade and thrombin generation (61). The platelets coated with antibody are removed from circulation by the reticuloendothelial system, thereby producing thrombocytopenia. Other negatively charged, polysulfated saccharides such as dextran sulfate may also induce an antibody response. The tendency to induce this response is likely related to a molecule's molecular weight and degree of sulfation (58). In some cases the antibody may recognize chemokines such as interleukin-8 and neutrophil-activating peptide-2, both of which are similar in structure to platelet factor 4. Moreover, in some patients type II HIT has been documented with induction of antibodies of the IgM and IgA, but not IgG, subtype, implying that the Fc receptor is not always involved in pathogenesis.

Genetic predisposition to HIT may occur. Specifically, the Fc-RIIA subclass may commonly exhibit a mutation at position 131, substituting histidine for arginine. The mutated protein binds strongly to HIT antibodies of the IgG_1 subclass. Accordingly, patients with HIT have a disproportionately high frequency of this genetic polymorphism (62).

Clinical Presentation

Thrombocytopenia occurs 4 to 8 days after the start of heparin and almost always drops to below 100,000, usually to a nadir of 30,000 to 50,000 (58,63). The platelet count decreases to less than 15,000 in only 5% of patients, in contrast to other drug-induced thrombocytopenias, in which nadirs are typically around 15,000 (64). Timing of thrombocytopenia has been documented to start as early as 2 days after initiation of therapy if recent previous exposure has occurred.

Thrombosis occurs with a high frequency, anywhere from 25% to 80%, depending on the patient population and treatment initiated (58,65). Importantly, up to 50% of thrombotic events occur before HIT can be recognized by low platelet counts, and patients remain at increased risk for events up to 30 days after the syndrome has been identified, despite cessation of heparin (58,65) (Fig. 35B.1).

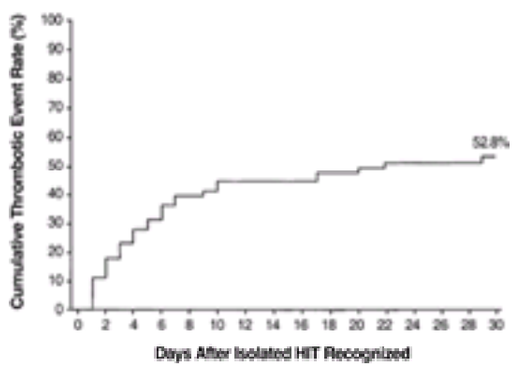

FIGURE 35B.1 Cumulative frequency of thrombotic events in patients with heparin-induced thrombocytopenia (HIT) presenting with isolated thrombocytopenia. (From Warkentin TE, Kelton JG. A 14-year study of heparin-induced thrombocytopenia. *Am J Med* 1996;101:502–507, with permission.)

The types of thrombotic events that occur are almost always severe. Pulmonary embolism accounts for up to one-fourth of the events (65), followed by proximal deep venous thromboses, stroke, myocardial infarction, and otherwise rare events such as bilateral adrenal vein thrombosis, cavernous sinus thrombosis, and extremity or visceral arterial thrombosis (64,65). Death occurs in up to 10% to 20% of patients, despite cessation of heparin and initiation of appropriate treatment (63,66). Despite sometimes severe thrombocytopenia, hemorrhage is relatively rare in HIT, occurring in under 10% of patients (58,63).

Attempts at predicting thrombotic events have not met with success. Although lower platelet count nadir and an earlier decrease in platelets are strongly associated with new thrombotic events, thromboses have been documented in patients with platelet counts above 150,000 (58), although in all these patients the counts had dropped by at least 30%. Although therapeutic doses result in HIT more often than prophylactic doses, even small amounts of heparin associated with flush solutions can cause the syndrome. Heparin resistance, likely caused by release of platelet-factor 4 into the circulation binding to and inhibiting heparin (60), tends to occur before thromboses, but not reliably so.

Diagnosis

Because the HIT antibody may be found in the absence of any clinical sequelae (58), HIT remains a clinical diagnosis, requiring the following conditions: (1) occurrence of thrombocytopenia during heparin administration, (2) resolution of thrombocytopenia after heparin is discontinued, and (3) exclusion of other causes. Heparin resistance, a new thrombotic event, and laboratory evidence all help support the diagnosis.

Among the laboratory assays, the ^{14}C-serotonin release assay is the most sensitive and remains the current standard for laboratory diagnosis, although it is difficult to perform and time-consuming. It relies on detection of ^{14}C-serotonin when radiolabeled donor platelets are incubated with serum from a patient with HIT and heparin and has a sensitivity of approximately 94%, with a specificity of 90% to 100% (67). The platelet aggregation test uses platelet-rich plasma from both normal donors and patients incubated together. The test result is positive when platelet aggregation occurs when heparin but not buffer is added. This test is the easiest to perform, but usually has a sensitivity of only 50% (60). The sensitivity may approach that of the ^{14}C-serotonin release assay, however, when washed platelets from multiple donors are used, and different concentrations of heparin are used as well (60). The enzyme-linked immunosorbent assay test to detect IgG antibody is sensitive but not very specific because weak antibodies may be detected (60).

Functional laboratory assay results become negative an average of 3 months after resolution of the clinical syndrome, but may remain positive for as long as 14 months (63,68). Platelet counts return to normal after a mean of 4 to 6 days, but this may take as long as 2 weeks (63,64).

Treatment

Cessation of heparin is critical when the diagnosis of HIT is reasonably suspect. Because thrombotic complications may occur even after stopping heparin (58), additional anticoagulation should be strongly considered. Lepirudin, a recombinant derivative of hirudin, an anticoagulant originating from leeches, is currently the only drug approved by the U.S. Food and Drug Administration for treatment of HIT. It directly inhibits thrombin and is renally excreted. Two clinical trials have shown improvement compared with historical controls with respect to death (9% vs. 22%) and new thromboembolism (18% vs. 32%) (66,69). During the trials, new events were reduced from 5.1% per patient-day before treatment to 1.5% per patient-day during treatment. Bleeding was higher (44% vs. 27%), but there was no statistically significant increase in the requirement for transfusion (13% vs. 9%). Other agents that have been used include danaparoid, argatroban, and anacrod (59). Of note, argatroban is excreted normally in patients with renal failure. Low-molecular-weight heparin should not be used to treat HIT because of a high rate (up to 85%) of cross-reactivity with the antibody.

ONCOLOGIC DISORDERS AND THE HEART

Metastatic Disease Involving the Heart

Metastatic disease involving the heart is uncommon, but not rare. In contrast, primary tumors of the heart are exceedingly rare, with an incidence of less than 0.002% of all autopsies (70). Of 58,600 autopsies done between 1936 and 1960 as described in ten reports, the incidence of metastases to the heart was 1.1% of all cases (range, 0.2% to 6.0%) and 6.4% of all patients with malignancy (range, 2% to 21%) (71). In a study of 3,314 consecutive autopsies over a 14-year period at a single center, Abraham and colleagues reported a 2.9% incidence of metastatic malignancy involving the heart (70). Of the 3,314 cases, 24.3% revealed evidence of cancer, and of these cancer cases, 11.8% revealed evidence of metastatic cardiac involvement. The most common area of involvement was the myocardium (53.9%), followed by pericardium (28.4%), epicardium plus pericardium (13.7%), and endocardium (3.9%). However, other autopsy studies have indicated that the pericardium and epicardium are more common sites of metastasis than the myocardium (72).

The primary tumors resulting in cardiac metastases, in order of decreasing frequency, were lung (31.6%), lymphoma (15.8%), breast (13.7%), leukemia (13.7%), stomach (5.3%), melanoma (3.2%), liver (3.2%), colon (3.2%), and other tumors (10.5%) (70). These rates were dependent on the varying incidences of the primary tumors. To determine the propensity of a given tumor to metastasize to the heart, one large series examined the rate of cardiac metastases in autopsies showing evidence of each tumor. Malignancies with a high propensity for metastasis included leukemia (46% of all autopsies with leukemia showed cardiac involvement), melanoma (37%), thyroid (30%), lung (28%), sarcoma (26%), esophagus (23%), kidney (22%), lymphoma (22%), and breast (21%) (72).

Direct Effects of Tumors

Noncardiac tumors may either affect the heart directly, by actual infiltration of cardiac structures, or indirectly by thrombotic effects or secretion of mediators with cardiovascular effects (eTable 35B.0.3). Malignancy can involve the heart (including the pericardium) by a retrograde lymphatic route (carcinomas), hematogenously (carcinomas, sarcomas, lymphoma, leukemia, or melanoma), or by direct extension from contiguous structures (lung, breast, or esophageal carcinoma). Cardiac complications from direct effects of the tumor may occur by myocardial infiltration of tumor, pericardial infiltration causing effusion and tamponade, obstruction of the superior or inferior vena cava or right atrium, and pulmonary tumor emboli leading to elevated right-sided pressures and consequently right-sided heart failure (73). Cardiac complications are rarely the first signs of the malignancy; usually, the diagnosis of the primary tumor is well established before manifestation of cardiac involvement. It is also rare for cardiac metastases to occur without evidence of other metastases.

Video 35B.3 Transgastric 90-degree long-axis transesophageal echo view of a patient with a sarcoma metastatic to his left ventricular anterior wall. Note the invasion of the myocardium by this large mass. Additionally, there is severe hypokinesis of the anterior wall. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Myocardial Infiltration

Myocardial infiltration by metastases may be diagnosed by two-dimensional echocardiography or endomyocardial biopsy (74) (Fig. 35B.2), although most often it is discovered incidentally at autopsy. ECG findings are usually nonspecific. Multiple reports exist, however, of persistent ST-segment elevation changes resembling those

of myocardial infarction without other clinical evidence of myocardial infarction in patients with malignant myocardial infiltration, particularly if the epicardium is involved (75).

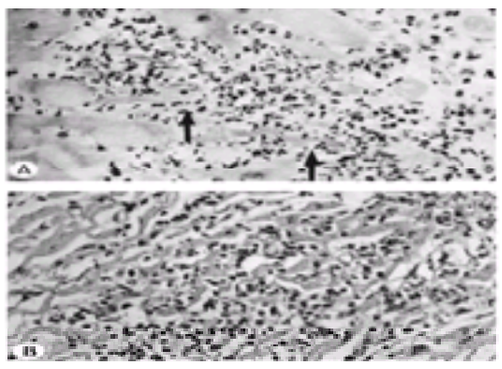

FIGURE 35B.2 A: Endomyocardial biopsy specimen in acute myelogenous leukemia showing myocardial infiltration by atypical hematopoietic cells and myocyte necrosis (*arrows*) (hematoxylin-eosin; ×400). **B:** Presence of immature myelogenous precursor cells is ascertained by chloroacetate esterase stain (×400). (From Flipse TR, Tazelaar HD, Holmes DR Jr. Diagnosis of malignant cardiac disease by endomyocardial biopsy. *Mayo Clin Proc* 1990;65:1415–1422, with permission.)

Myocardial infiltration by tumor is often clinically silent even when large amounts of myocardium are replaced by tumor, as in *charcoal heart* caused by metastatic malignant melanoma. However, clinical manifestations can include congestive heart failure (76), myocardial infarction (caused by tumor emboli, extrinsic compression, or ostial obstruction of coronary arteries) (77), and conduction disturbances (77,78). The pericardium is frequently also involved, and in these cases the clinical manifestations of pericardial disease predominate.

Treatment consists of addressing the underlying tumor; however, myocardial infiltration often represents an advanced state of the disease, in which treatment is ineffective. In cases of solitary cardiac metastases, surgical resection may be curative if the primary tumor has been controlled (79).

Pericardial Infiltration

Metastatic pericardial involvement, like myocardial involvement, is often asymptomatic and discovered as an incidental finding at autopsy. When clinically evident, pericardial disease is most often manifested by symptomatic pericardial effusion including tamponade. In rare cases pericardial tumor may encase the heart, leading to constriction. Initial diagnosis of pericardial disease is generally made by echocardiography, although occasionally computed tomographic scan may show disease when the echocardiography result was negative or may be necessary because of technically inadequate echocardiography (80).

When pericardial disease is discovered antemortem in cancer patients, malignant disease must be differentiated from idiopathic pericarditis and radiation-induced pericardial disease, both common in cancer patients. Clinical features helping to differentiate them include facial swelling in malignant pericardial disease; fever, pericardial friction rub, and improvement with nonsteroidal antiinflammatory drugs in idiopathic pericarditis; and constrictive pericarditis in radiation-induced disease. Cytologic examination of fluid is positive for malignant cells in 50% to 85% of cases (81). Bloody pericardial fluid with specific gravity greater than 1.016 and total protein greater than 3 mg per dL is also suggestive of malignant effusion.

Treatment of malignant pericardial effusions is only indicated in symptomatic patients. One retrospective, observational study of 93 consecutive patients revealed no difference in survival, duration of hospital stay, or hospital charges in less symptomatic patients managed conservatively initially compared with more symptomatic patients managed invasively. Furthermore, only 20% of the conservatively treated patients eventually required pericardiocentesis (82). Median survival after treatment is on the order of 3 to 4 months (81).

Treatment methods for malignant pericardial effusion include pericardiocentesis, pericardial sclerosis, systemic chemotherapy, radiotherapy, and surgery. Pericardiocentesis should be performed to relieve symptoms. Extended catheter drainage is associated with reduced recurrences compared with simple pericardiocentesis (81). Although pericardiocentesis alone can provide prolonged relief, symptomatic recurrence is frequent, up to 20% in one large series (81). Pericardial sclerosis may be performed using tetracycline.

Case series of patients undergoing pericardial sclerosis suggest that it is generally successful, with low recurrence rates (0% to 5%) and only minor complications such as fever or transient atrial arrhythmia, although an average of three instillations of tetracycline are required (83,84). Tetracycline sclerotherapy is an option for patients whose tumors are neither chemotherapy nor radiation sensitive, and who are poor surgical candidates. However, because of the potential complications and frequent discomfort, and since simple drainage is safe and effective, sclerotherapy may deserve second-line status after repeated failure of pericardiocentesis (81).

As reported in small case series, systemic chemotherapy has been effective in treating malignant pericardial effusions in conjunction with pericardiocentesis for tumors highly sensitive to chemotherapy, such as lymphoma, leukemia, and breast cancer. Other studies in patients with breast cancer, however, have shown a high rate of progression of pericardial disease in nonsurgically treated patients (85).

External radiation has also been used to treat malignant pericardial effusion and appears to be most effective in treating effusions from tumors known to be radiosensitive, such as Hodgkin's and non-Hodgkin's lymphoma, leukemia, and breast carcinoma. It can be used in patients who are refractory to chemotherapy, have radiosensitive tumors, and are poor candidates for surgical therapy.

Surgical therapy is commonly used to treat malignant pericardial effusion, usually by formation of a pericardial window. Multiple case series of patients undergoing pericardial window procedures have been reported. All show a high percentage of patients experiencing improvement in symptoms (range, 72% to 100%). Recurrence rates range from 0% to 33%, and death within 30 days due to the underlying malignancy is not uncommon (range, 0% to 67%), illustrating the importance of taking into account the prognosis of the underlying illness in patient selection for the procedure.

Conventional surgical approaches include the subxyphoid, left anterior thoracotomy, or median sternotomy. The advantage of the subxyphoid approach is that it can be done under local anesthesia, appears to be effective, and generally results in low morbidity and mortality. The theoretical advantages of the thoracotomy or median sternotomy approaches are that they allow greater exposure of the pericardium and hence larger amounts of pericardium to be removed. However, they have not clearly been shown to be more effective than the subxyphoid approach. One retrospective, nonrandomized comparison study of the subxyphoid approach with the anterior thoracotomy technique in 28 consecutive patients showed that although there was no difference in survival between the two groups, there was a much higher incidence of postoperative morbidity in the thoracotomy group (67% vs. 10%), including major complications in 50% of patients treated with thoracotomy, and none in those treated with the subxyphoid approach (86). However, for constrictive disease, a simple pericardial window is inadequate and extensive pericardial resection is required, generally through a median sternotomy approach (87).

Newer techniques for treatment of pericardial disease include video thoracoscopic surgical techniques and percutaneous approaches with balloon catheters. A report on 22 patients with pericardial effusion (9 malignant, 13 benign) who underwent video thoracoscopic pericardiectomy was promising, with no recurrences and no significant morbidity (88), but since the technique still requires general anesthesia, direct comparison studies with the subxyphoid approach would be required to demonstrate its equivalent or superior efficacy and safety. Results from percutaneous balloon catheter techniques for creation of pericardial windows have been reported and appear promising (89), but also require direct comparison studies with surgical approaches to determine their efficacy and safety.

Obstruction of Venous Inflow

Tumors may obstruct venous inflow into the heart, either by extrinsic compression or by direct invasion. Obstruction of the superior vena cava may result in the superior vena cava syndrome, which is caused in approximately 85% of cases by bronchogenic carcinoma, 10% by lymphomas, and the rest miscellaneous causes including benign etiologies (90). Extrinsic compression of the vein causes approximately 60% of cases and thrombosis the remainder.

In a retrospective review of 84 patients at a single center with superior vena cava syndrome, Perez and colleagues found that the most common presenting symptoms were shortness of breath (greater than 50%), facial swelling (43%), and swelling of the trunk or arms (40%). Chest pain, cough, and difficulty swallowing were also

common and each occurred in approximately 20% of patients. Physical findings in decreasing order of frequency were trunk vein distention (67%), jugular vein distention (59%), facial edema (56%), tachypnea (40%), facial plethora (19%), cyanosis (15%), arm edema (9.5%), vocal cord paralysis (3.5%), and Horner's syndrome (2.3%) (90).

Treatment generally involves chemotherapy or radiation therapy or both. In this series, chemotherapy, radiation therapy, or both resulted in excellent or good symptomatic improvement in 70% of patients with bronchogenic carcinoma and 95% of patients with lymphoma. Percutaneous stenting has also been used to relieve symptoms of superior vena cava syndrome (91).

Other conduits of venous inflow to the heart may also be obstructed. The inferior vena cava is most often obstructed by liver or renal tumors. Renal cell carcinoma may grow into the renal vein, and then continue on into the inferior vena cava and even the right atrium. Surgery to remove the tumor may be beneficial. Bronchogenic carcinoma may similarly invade the pulmonary veins and extend into the left atrium, impeding left-sided filling or potentially embolizing and causing myocardial infarction and cerebral infarction (73).

A final means of direct effects of malignancy on the heart is through pulmonary tumor emboli. In a review of 1,085 autopsies with evidence of malignancy, 2.4% had evidence of pulmonary tumor emboli, often with associated pulmonary thromboemboli. Of the patients with pulmonary tumor emboli, 31% had unexplained dyspnea and cor pulmonale and 15% had right ventricular hypertrophy. The tumors responsible included gastrointestinal carcinomas, breast carcinoma, and hepatoma (92).

Indirect Effects of Tumors

Nonbacterial Thrombotic (Marantic) Endocarditis

Nonbacterial thrombotic endocarditis (NBTE) is a condition in which sterile vegetations, consisting of mostly fibrin and platelets but not inflammatory cells, develop on valve leaflets. In contrast to infectious endocarditis, there is no disruption of the underlying valve architecture. This condition is frequently, but not exclusively, associated with malignancy and may be seen in other debilitating conditions (73). One case report of NBTE of the mitral valve documents resolution of the vegetation 4 weeks after resection of a hepatic tumor (Fig. 35B.3).

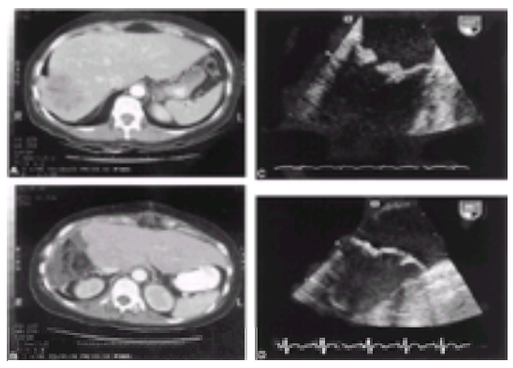

FIGURE 35B.3 Computed tomography scans of a hepatic tumor before **(A)** and after **(B)** resection. Transesophageal echocardiography demonstrating echodensities on the mitral valve consistent with vegetations **(C)**, and resolution of the abnormality 4 weeks after surgery **(D)**. (From Cockburn M, Swafford J, Mazur W, et al. Resolution of nonbacterial endocarditis after surgical resection of a malignant liver tumor. *Circulation* 2000;102:2671–2672, with permission.)

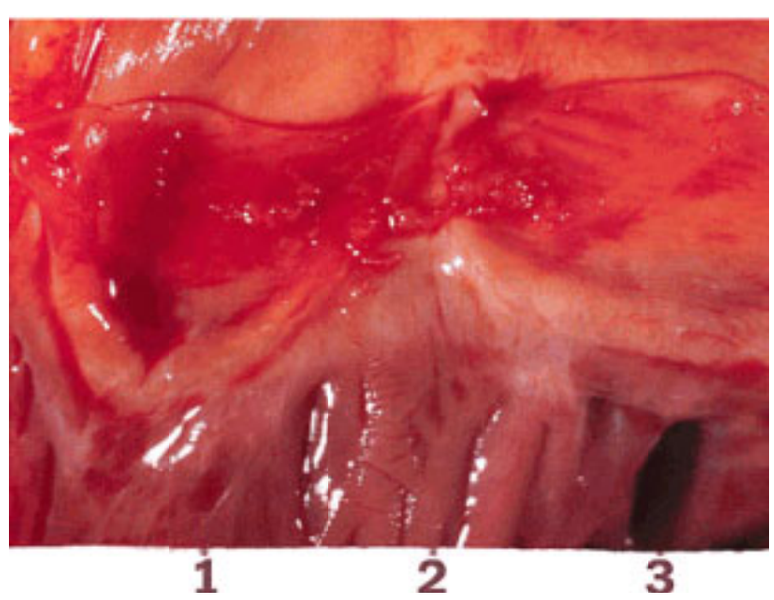

Marantic (nonbacterial) endocarditis of the pulmonic valve. Multiple vegetations are seen on the pulmonic valve in this patient with no bacterial growth from multiple blood cultures.

In one autopsy study of 3,404 patients reported by Chino and colleagues, 2.4% were found to have nonbacterial thrombotic endocarditis (93). Of these patients, 62% had associated malignancy, and 38% did not. Vegetations were present exclusively on the aortic or mitral valves or both. Other studies have shown that the right-sided valves may rarely be affected, although the presence of indwelling right-sided catheters may increase the likelihood of their involvement (94). In Chino and colleagues' study, NBTE was seen most frequently in patients with carcinoma of the colon, rectum, and female genital organs (93). Some other studies have found a greater degree of association between pancreatic and stomach cancer and NBTE, whereas others have shown higher rates in bronchiolar and adenocarcinoma of the lung (95). Although NBTE may not be clearly associated with one particular type of tumor, it does seem to be predominately associated with adenocarcinoma, probably because of a hypercoagulable state associated with these tumors. Although the exact underlying etiology of NBTE is unknown, immune complexes due to the underlying malignancy may play a role, as may a hypercoagulable state (73).

NBTE is usually clinically silent and can be diagnosed by transthoracic echocardiography, although transesophageal echocardiography is more sensitive (96). However, embolism of vegetations can occur and have been shown to cause infarctions in the brain, myocardium, kidney, spleen, and thyroid gland (93,95).

Pheochromocytoma

Pheochromocytomas are neoplasms that arise from the adrenal medulla or preganglion cells and secrete norepinephrine and epinephrine. Clinical manifestations include hypertension (present in most, but not all, patients), which may be sustained (approximately 60% of cases) or episodic (approximately 40% of cases) (97).

Paroxysms or crises occur in more than 50% of patients and are characterized by headache, diaphoresis, palpitations, pallor or flushing, and elevated blood pressure, at times to severe levels. Effects on the heart can include arrhythmias, angina, and even myocardial infarction. In addition, focal areas of myocardial necrosis with contraction bands may occur, probably because of the toxic effects of catecholamines on myocytes, and may with time lead to cardiomyopathy and congestive heart failure (98). Reduced myocardial ^{123}I-metaiodobenzylguanidine uptake has been noted with pheochromocytoma, suggesting that the high circulating catecholamines may damage cardiac sympathetic nerve function (99).

The disorder may be suspected when hypertension is present in conjunction with symptoms or signs of a hyperadrenergic state, such as tachycardia, palpitations, sweating, paroxysmal anxiety attacks, or headache (100). However, because these signs are nonspecific and the disease is rare, many patients who are evaluated for the disease end up not having it. Diagnosis is by determination of urinary levels of vanillylmandelic acid, metanephrines, and unconjugated catecholamines. Treatment involves surgery if possible to remove the tumor. Before surgery, cardiovascular effects can be managed with alpha-adrenergic receptor blockers such as phenoxybenzamine or prazosin and beta-adrenergic blockers. Alpha-receptor blockade should be fully established before beta-blockade, because beta-blockade alone

could lead to alpha-receptor–mediated vasoconstriction unopposed by beta$_2$-receptor–mediated vasodilation.

Carcinoid

Carcinoid tumors originate from amine precursor uptake and decarboxylase cells, and most commonly arise from the gastrointestinal tract. The tumors may secrete circulating chemical mediators such as serotonin and bradykinin, causing the carcinoid syndrome, which is characterized by flushing, diarrhea, wheezing, and episodic hypotension. Because these mediators are inactivated by the liver, carcinoid syndrome generally only develops if liver metastases are present or if the tumor is extraintestinal.

Cardiac abnormalities occur in approximately one-half of carcinoid syndrome cases. The cardiac lesion consists of a fibrous plaque made up of smooth muscle cells and collagen fibers in an acid mucopolysaccharide matrix (101). The lesions usually affect the right side of the heart only and may cause tricuspid valve and pulmonic valve dysfunction, typically tricuspid insufficiency and pulmonic stenosis. Although tricuspid valve surgery seems to result in symptomatic improvement in survivors of surgery, perioperative mortality is high (35% and 63% in two series) (102,103).

Although the etiology of the plaque is uncertain, it is probably caused by healing from multiple episodes of endothelial damage brought on by circulating mediators secreted by the tumor (73). Studies have shown that cardiac involvement with carcinoid correlates with higher levels of serotonin (104) and progression of cardiac disease (detected echocardiographically) correlates with posttreatment urinary 5-hydroxyindoleacetic acid levels (105), supporting the hypothesis that mediators released by the tumor cause the cardiac damage.

Cardiac Amyloidosis Secondary to Multiple Myeloma

Systemic amyloidosis occurs in approximately 10% of patients with multiple myeloma. When present, there is a high rate of cardiac involvement. One series reported amyloid-related cardiac failure in 40% of patients with systemic amyloidosis associated with myeloma (106). Clinical manifestations include congestive heart failure, arrhythmia, and restrictive cardiomyopathy. Definitive diagnosis must be made by endomyocardial biopsy, although the myeloma-involved heart has a characteristic, hyperrefractile appearance on echocardiography, which may assist in diagnosis. Other echocardiographic features include thickened ventricular walls, pericardial effusion, and thickening of multiple valves with regurgitation. Magnetic resonance imaging has also demonstrated promise in establishing the diagnosis noninvasively (107). Treatment is aimed at the underlying disease, in addition to using diuretics. There is anecdotal evidence that digoxin may be harmful because of heightened binding by amyloid fibrils in the heart, but systematic studies have failed to confirm this hypothesis (108). Coumadin may be beneficial, because intracardiac thrombi are frequently noted (108).

Cardiac Effects of Radiation Therapy for Cancer

Radiation therapy is used to treat many thoracic cancers and may cause injury to the heart and surrounding tissues (eTable 35B.0.4). The majority of patients with such radiation-induced heart disease (RIHD) have had Hodgkin’s disease. Because they tend to be young at the time of treatment and are curable, they live long enough to develop the clinical sequelae of RIHD, many of which are delayed (109,110). However, patients irradiated for non-Hodgkin’s lymphoma, esophageal

carcinoma, thymoma, lung, and breast cancer have also developed RIHD.

***e*TABLE 35B.0.4** RADIATION-INDUCED HEART DISEASE
Pericardial disease
Acute
Pericarditis
Chronic
Delayed onset “acute” pericarditis
Chronic effusion
Constriction
Myocardial disease
Fibrosis and restrictive cardiomyopathy
Left ventricular and right ventricular dysfunction
Valvular heart disease
Aortic > mitral > right-sided
Coronary artery disease
Ostial right coronary artery and left main disease
Conduction system disease
Bundle branch block
Atrioventricular block
Pacemaker malfunction

The likelihood of RIHD depends on the dose and method of administration of the radiation. The larger the total dose of radiation, the shorter the time period over which it is given, and the greater the volume of heart exposed, the higher the probability of RIHD (110,111). Using anterior and posterior fields instead of anterior fields alone decreases the dose of radiation to the heart and thereby lowers the incidence of RIHD. Cardiac exposure can be further reduced by subcarinal blocking with lead shields. Carmel and Kaplan found that the incidence of RIHD decreased from 20.0% to 2.5% when such blocking was used in patients with Hodgkin’s disease.

The most common form of RIHD is pericardial disease. Radiation-induced pericardial disease may be either of acute, or more commonly, delayed onset. The clinical presentation of acute radiation-induced pericarditis is similar to that of acute pericarditis of other etiologies. It is characterized by pleuritic chest pain, fever, friction rub, and ST-segment and T-wave abnormalities (111). It occurs most frequently in patients with a large mediastinal tumor burden next to the heart, probably resulting from inflammation related to tumor destruction rather than a toxic effect on the pericardium, and does not increase the likelihood of late cardiac complications (112). The incidence is uncommon, with one series of 635 patients showing an incidence of 1.2% for acute pericarditis, compared with 6.9% for delayed pericardial complications (113).

Delayed onset pericardial disease is the most common form of RIHD. It may occur months to years after treatment, but often occurs within 12 months of therapy (114). One manifestation of disease may be a delayed acute pericarditis, with symptoms and findings typical of pericarditis including pleuritic chest pain, fever, pericardial rub, and ST-segment and T-wave abnormalities. Pericardial effusion is common and may result in tamponade (112). Case reports have suggested that corticosteroids may be helpful, although withdrawal of the corticosteroids may lead to recurrence (112). However, randomized controlled trials of corticosteroids in RIHD have not been performed to confirm this benefit.

Acute pericarditis. Note diffuse, marked ST-segment elevation with PR-segment elevation in lead aVR.

The other form of delayed onset pericardial disease is chronic, consisting of either chronic effusion or constrictive pericarditis. Risk of constrictive pericarditis ranges from 4% to 20% in different series and depends on the amount of radiation given and the method of administration (112,113). The risk of constriction appears to be increased in patients in whom delayed acute pericarditis develops, especially if an effusion is present, with as many as 20% of such patients eventually developing constriction (112). Furthermore, a majority of patients with constriction previously had pericardial effusions. Treatment is pericardiectomy, although patients with constrictive disease caused by radiation therapy tend to do worse after pericardiectomy than those with constriction from other causes, with one series reporting a 12% 30-day mortality for patients undergoing pericardiectomy for any reason, but a 21% mortality in those who had the procedure for radiation-induced constriction (115).

VIDEO

Video 35B.7 Transesophageal echo (four-chamber view) demonstrating constrictive pericarditis. Note the abnormal septal bounce and the tethering of the right atrium and right ventricle by the thickened pericardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Radiation therapy only rarely causes injury to the myocardium itself, which is of clinical importance. Pathologically, myocardial fibrosis may occur (116). Clinical sequelae are usually mild or absent (109). However, subtle impairment of left ventricular function at rest and especially with exercise may be seen with radionuclide techniques or echocardiography (117). The right ventricle may also be abnormally dilated or have wall motion abnormalities (118). Most patients do not have overt congestive heart failure; however, a restrictive cardiomyopathy may be present and in the worst cases lead to actual heart failure (112). Restrictive cardiomyopathy and

constrictive pericarditis may both be present and may result in less than expected improvement after pericardiectomy, and may account for the poorer prognosis of radiation-treated patients after pericardiectomy (119). Chemotherapeutic agents, particularly anthracyclines, may potentiate the myocardial damage caused by radiation therapy (120).

Valvular heart disease may occur secondary to radiation therapy, probably secondary to endocardial fibrosis, causing valvular thickening and deformity (116,121). In a series of 129 patients treated with radiation for Hodgkin's disease, examined 5 to 13 years after treatment, Lund and colleagues found that 24% had valvular regurgitation, with the aortic valve involved most often, the mitral valve less often, and no cases of right-sided valvular abnormalities (122). Right-sided valvular disease, however, has been reported after radiation therapy (117,123). Although echocardiographic abnormalities are relatively common, clinically significant valvular heart disease is rare, with only three deaths occurring from valvular disease out of 635 patients in one series (113).

The risk of coronary artery disease is increased after radiation therapy to the chest, as shown by an autopsy study (116) and several case reports of coronary artery disease in irradiated patients who were young and without other risk factors (124,125). Angiographic assessment of the coronary arteries in such patients reveals frequent high-degree ostial stenosis of the right coronary artery and left main involvement (126). Boivin and colleagues reported a relative risk of death from myocardial infarction after mediastinal irradiation but not after chemotherapy, based on analysis of 4,665 patients treated for Hodgkin's disease with a mean of 7 years of follow-up (127). Coronary artery disease tends to appear late after radiation therapy and can be treated with coronary artery bypass surgery if necessary. However, because the left internal mammary artery is exposed to radiation, it may be difficult to dissect and may have a tendency to occlude prematurely (128).

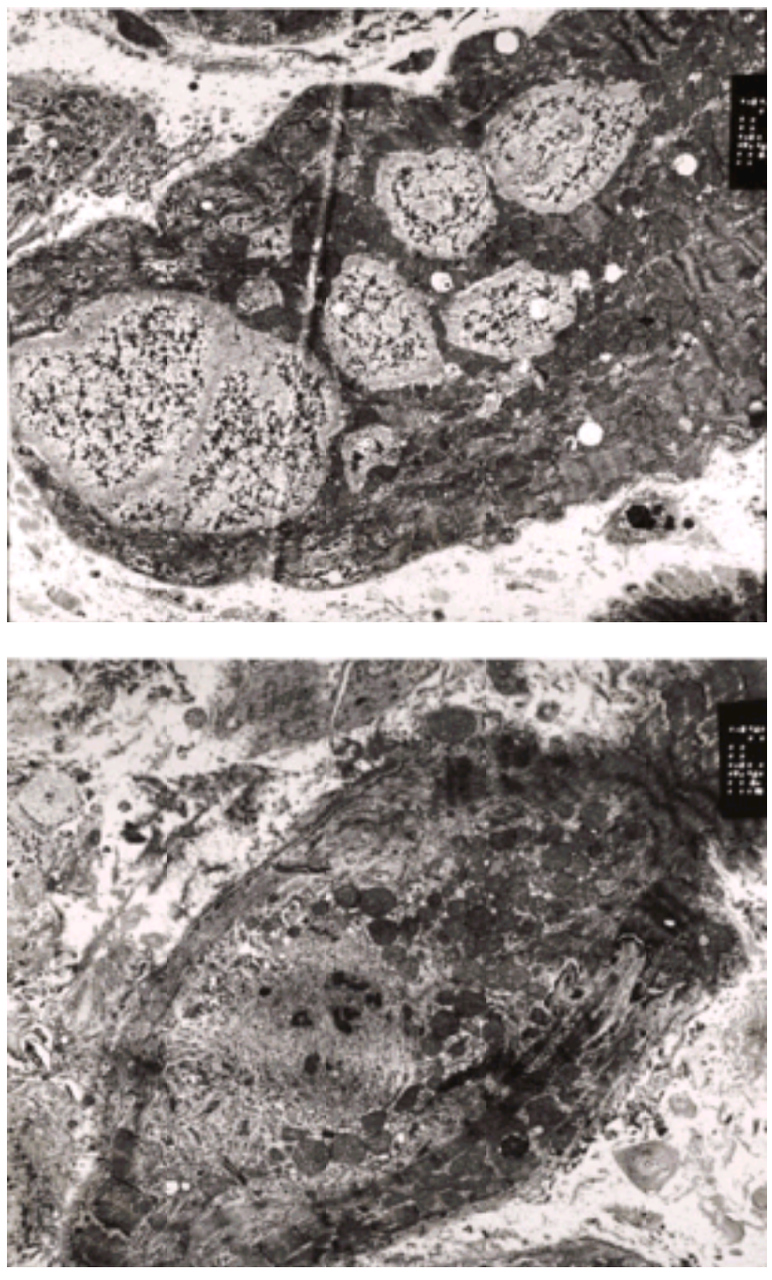
Pathogenesis of the ischemic heart disease associated with radiation appears to occur via damage to the microcirculation and epicardial arteries. Light and electron microscopy of irradiated rabbits has revealed cytoplasmic endothelial cell swelling followed by loss of capillaries and a decrease in capillary-to-myocyte ratio with the end result of progressive fibrosis (109). With regard to epicardial coronary artery disease, autopsy studies of humans have shown lesions that are largely fibrotic with a relative lack of lipids. Studies of irradiated animals have also shown adventitial fibrosis (109). In addition, studies of irradiated animals fed a high cholesterol diet have noted more large vessel changes than with the high cholesterol diet alone, suggesting that radiation damage may act synergistically with other factors to promote atherosclerosis (111).

Finally, radiation therapy to the chest may lead to conduction system abnormalities, including bundle branch block, and varying degrees of atrioventricular block, including complete heart block (111,129). Radiation may also affect pacemaker function, and therefore patients with pacemakers undergoing therapy should be closely monitored (130,131).

Effects of Chemotherapy on the Heart

Multiple chemotherapeutic agents cause cardiac toxicity (Table 35B.1), but the most widely recognized are the anthracyclines (e.g., doxorubicin and daunorubicin) used in treating leukemias, lymphomas, and solid tumors, because their main dose-limiting side effect is cardiac toxicity. Clinical manifestations of anthracycline-induced cardiac toxicity may be acute or chronic (132). Acute toxicity (occurring during or just after a single dose) is rare. Transient nonspecific ECG abnormalities are the most common manifestation, but arrhythmias such as supraventricular tachyarrhythmia or increased ventricular ectopy may be seen (133). These rarely are of clinical importance. Rare cases of acute left ventricular failure, pericarditis, fatal myocarditis, and sudden death have been reported (134,135). Chronic anthracycline-induced cardiac toxicity is more common and usually appears within 1 year of exposure (120). However, it may also become apparent after a prolonged, sometimes several-year, asymptomatic latent period. This has been particularly apparent in childhood survivors of cancer who are cured of their malignancy and live for long periods of time after treatment (136).

TABLE 35B.1 CHEMOTHERAPEUTIC AGENTS AFFECTING THE HEART



Electron microgram of 3+ doxorubicin (Adriamycin) toxicity (A,B). (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic

Foundation.)

The exact mechanisms by which anthracyclines cause myocardial damage are not fully established, but evidence points to free radical–induced myocyte damage as being an important factor. Effects on intracellular calcium homeostasis, adrenergic function, and damage caused by vasoactive amines and release of inflammatory cytokines such as interleukin-2 and tumor necrosis factor-a have also been proposed as mechanisms for anthracycline-induced myocardial injury (137,138). The most important predictor of cardiac toxicity is total cumulative dose, with probability of congestive heart failure increasing for doses above 400 mg per m^2 body surface area, and particularly above 500 mg per m^2 (120). However, toxic thresholds are variable, with doses above 1,000 mg per m^2 being tolerated by some patients, and doses less than 200 mg per m^2 causing cardiac damage in others. As described previously, concomitant or previous mediastinal irradiation also increases the likelihood of cardiac damage. Other proposed risk factors for cardiac toxicity include age greater than 70, combination chemotherapy, previous cardiac disease, hypertension, liver disease, and hyperthermia (139).

Clinically, cardiotoxicity can result in deterioration of systolic and diastolic left ventricular function as determined either by radionuclide techniques or echocardiography, which progresses to overt congestive heart failure in some patients (132,140). When overt congestive heart failure occurs, risk of mortality may be substantial, with reported mortality in patients with congestive heart failure ranging from 2.2% (141) to 43.0% (120). Clinical recovery with conventional heart failure therapy may occur in those who survive (141), including rare cases of complete reversal of left ventricular dysfunction (142). Prolonged infusions of drug (143), or more frequent dosing (144), may decrease toxicity for a given dose.

Prevention of anthracycline-induced cardiac toxicity is accomplished by monitoring for signs of myocardial damage using radionuclide angiocardiography, echocardiography, or both (*e*Table 35B.1.1). Schwartz and colleagues proposed guidelines for monitoring the EF of patients receiving doxorubicin, which were retrospectively validated by showing a lower incidence of clinical congestive heart failure in patients whose management was consistent with the guidelines (141). According to these guidelines, EF is determined by radionuclide angiocardiography at baseline. If the baseline EF is normal, then the second study should be at a cumulative dose level of 250 to 300 mg per m^2. If risk factors are present, the study is repeated at 400 mg per m^2, otherwise at 450 mg per m^2, and before all subsequent doses thereafter. If EF declines more than 10% during treatment to an absolute value less than 50%, then treatment is stopped. If baseline EF is greater than 30% but less than 50%, studies should be obtained before each dose, and treatment should be discontinued for a decrease in EF greater than 10% or an absolute EF less than 30%. If the baseline EF is less than 30%, anthracycline therapy should not be used (141).

***e*TABLE 35B.1.1** GUIDELINES FOR MONITORING PATIENTS RECEIVING DOXORUBICIN

Perform baseline radionuclide angiocardiography at rest for calculation of LVEF before administration of 100 mg/m^2 doxorubicin. Subsequent studies are performed at least 3 weeks after the indicated total cumulative doses have been given, before consideration of the next dose

Patients with normal baseline LVEF (³50%)

Perform the second study after 250–300 mg/m^2

Repeat study after 400 mg/m^2 in patients with known heart disease, radiation exposure, abnormal electrocardiographic results, or cyclophosphamide therapy; or after 450 mg/m^2 in the absence of any of these risk factors

Perform sequential studies thereafter before each dose

Discontinue doxorubicin therapy once functional criteria for cardiotoxicity develop [i.e., absolute decrease in LVEF ³10% (EF units) associated with a decline to a level £50% (EF units)]

Patients with abnormal baseline LVEF (<50%)

Doxorubicin therapy should not be initiated with baseline LVEF £30%

In patients with LVEF >30% and <50%, sequential studies should be obtained before each dose

Discontinue doxorubicin with cardiotoxicity; absolute decrease in LVEF ³10% (EF units), final LVEF £30%, or both

LVEF, left ventricular ejection fraction.

From Schwartz RG, McKenzie WB, Alexander J, et al. Congestive heart failure and left ventricular dysfunction complicating doxorubicin therapy. Seven-year experience using serial radionuclide angiocardiography. *Am J Med* 1987;82:1109–1118, with permission.

Additional measures to prevent anthracycline-induced cardiotoxicity include incorporating measurement of the peak filling rate (a measure of diastolic function) by radionuclide angiography into such guidelines for earlier detection of anthracycline toxicity. Systolic and diastolic function can also be assessed by echocardiography as a guide to development of cardiotoxicity (132). Echocardiographic parameters showing deleterious effects of anthracyclines on diastolic function have included automatic border detection calculation of peak filling rate (145) and Doppler measures of mitral valve inflow (146). In addition, the degree of uptake of indium-111–labeled antimyosin monoclonal antibodies has been shown to correlate with the degree of depression of the EF during anthracycline therapy. Both increased indium-111 antimyosin uptake and decreased iodine-123-metaiodobenzylguanidine uptake (indicating denervation of the heart) have also been shown to occur before deterioration of systolic dysfunction (147). Although these methods are highly sensitive, their relative lack of specificity for predicting clinical events may limit their usefulness. Elevation of troponin I after high-dose chemotherapy has been shown to predict more profound and prolonged decreases in left ventricular EF (148). At this point, however, the mainstay of monitoring for cardiac toxicity remains the radionuclide angiographically determined EF.

Pharmacologic agents have been investigated for use as cardioprotectants during anthracycline therapy. Currently, only dexrazoxane (ICRF-187), an iron-chelating agent that reduces free radicals produced by anthracyclines, has been approved in the United States for use during doxorubicin therapy (132,149). It is approved for use in metastatic breast cancer in patients who have received more than 300 mg per m^2 of doxorubicin. Probucol, calcium antagonists, and beta-blockers have also been proposed as cardioprotective agents, but more work must be done in human prospective studies to determine if they are truly efficacious (132,150).

Several other anticancer drugs have been associated with cardiac toxicity. There appears to be an increased risk of cardiomyopathy with doxorubicin when given in combination with paclitaxel (for metastatic breast cancer). Such adverse synergy does not appear to occur with doxorubicin and docetaxel. One possible explanation is that paclitaxel may interfere with the elimination of doxorubicin (151). Rhythm disturbances such as sinus bradycardia and atrioventricular block have also been seen with paclitaxel administration; however, ischemic manifestations seen during treatment largely occurred in patients with preexisting cardiac disease (152). Trastuzumab, a monoclonal antibody against the HER2 receptor, also used to treat metastatic breast cancer, has led to a high incidence of congestive heart failure (up to 28%) when used in combination with anthracyclines (153). The mechanism of cardiac toxicity with trastuzumab is uncertain, but it has been demonstrated that the HER2 receptor is involved in myocyte survival pathways. Cardiac complications with 5-fluorouracil have been reported with an incidence of 1.6% to 3.0% (154). Adverse effects have included angina, myocardial infarction, arrhythmia, and reversible left ventricular dysfunction (154). Cyclophosphamide, when given in high doses such as those used for pre–bone marrow transplant regimens, may cause a hemorrhagic myopericarditis characterized by left ventricular dysfunction, congestive heart failure, and pericardial effusion that is often fatal (155). In those who survive, left ventricular function appears to recover (155). The closely related drug ifosfamide has also been shown, in high doses, to cause severe, reversible myocardial dysfunction (156). Myocardial ischemia and myocardial infarction have been attributed to cisplatinum and etoposide (157). Amsacrine has been associated with cardiac abnormalities such as nonspecific ECG changes, atrial and ventricular arrhythmias, and congestive heart failure in approximately 1.2% of patients administered the drug (158). Finally, pre–bone marrow transplant regimens involving high doses of combination chemotherapy, including cyclophosphamide and cytosine arabinoside, plus total body irradiation, have been associated with a high incidence of cardiac complications including arrhythmia, congestive heart failure, and pericarditis (159).

Biologic anticancer agents such as the interferons and interleukin-2 have also been associated with cardiac toxicity. A review of 44 known cases of

interferon-associated cardiotoxicity (interferon-a or interferon-a_2 used in 36, interferon-g in 8) revealed arrhythmia as the most common manifestation, followed by myocardial infarction or ischemia, cardiomyopathy, sudden death, atrioventricular block, and congestive heart failure. Although some of the patients experiencing arrhythmia or myocardial ischemia had preexisting heart disease, this was not true for any of the five patients who developed cardiomyopathy (160). Interleukin-2 has been approved for use in renal cell carcinoma. It may cause a capillary leak syndrome resulting in hypotension, tachycardia, increased cardiac output, and decreased systemic vascular resistance. Arrhythmias, myocardial ischemia and infarction, left ventricular dysfunction, and a reversible lymphocytic and eosinophilic myocarditis have been reported with interleukin-2 administration (161).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Anemia

Whether patients with heart disease and mild anemia derive significant benefit from treating the anemia deserves further study. We believe that nontransfusion therapy, such as iron and folate, should be given to increase cardiac reserve, both for patients with obstructive coronary artery disease and particularly for patients with heart failure, because such a strategy in these patients is supported by prospective intervention data (161). The use of erythropoietin is likely to be cost effective only in patients with at least moderate anemia and severe heart failure requiring frequent hospitalization.

Heparin-Induced Thrombocytopenia

Laboratory testing for HIT remains controversial, because none of the tests is perfectly accurate. We recommend that the platelet aggregation test be performed first, because it is available in most laboratories and can be performed quickly and easily. When HIT is suspected, all heparin should be stopped even if the test result is pending or negative, given the potential devastating consequences of continuing heparin in the face of ongoing HIT. For patients with a negative platelet aggregation test result and a clinically high likelihood of the disease, the ^{14}C-serotonin release assay or enzyme-linked immunosorbent assay test should be performed to confirm the diagnosis.

Whether alternative anticoagulation should be given to patients with HIT in the absence of thromboembolic complications is considered by some an issue of controversy. We believe that these patients should receive a direct thrombin inhibitor in addition to discontinuation of heparin, because of ongoing thrombin generation imparting risk of developing serious events. This therapy may be discontinued once platelet count returns to baseline. Further therapy with warfarin should be strongly considered, because some patients may develop thrombotic complications even after the platelet count returns to normal. In the presence of an established thrombotic event, warfarin should be given in the absence of contraindications. Warfarin therapy should always initially overlap with direct thrombin inhibition by several days to avoid paradoxical limb gangrene. Clinicians should be aware that lepirudin increases the prothrombin time. Direct factor X assays could be used to monitor warfarin therapy while the patient remains on lepirudin.

Malignant Pericardial Effusion

The optimal invasive treatment for malignant pericardial effusion is not well defined. We recommend initial treatment in symptomatic patients with a percutaneous approach, including use of extended catheter drainage. Sclerotherapy should be tried next if pericardiocentesis fails or becomes frequently required. Surgery should be offered after failure of the first two approaches, depending on the overall status of the patient, and if the patient is willing to accept the perioperative risk.

Chemotherapy and Cardiac Toxicity

Areas for continuing investigation include optimizing methods for early detection and prevention of cardiac toxicity, such as cardioprotective agents or particular dosing strategies. Although use of the cardioprotective agent dexrazoxane has been controversial because of concerns that it may reduce antitumor activity, this has not been a consistent finding in trials of this agent. Therefore, we think it is reasonable to use dexrazoxane in patients receiving high doses of doxorubicin or with borderline left ventricular function before therapy.

THE FUTURE

Future studies will better delineate the potential benefits of treating anemia in patients with heart disease. The prevalence of HIT may decline with increasing use of low-molecular-weight heparins in lieu of unfractionated heparin. Genetic advances will allow clinicians to better define an individual patient's susceptibility to HIT and to cardiac damage from radiation therapy and chemotherapy. Additional agents that protect the heart from damage by chemotherapeutic agents will be developed.

OVERVIEW

Patients with renal impairment experience a disproportionate burden of cardiovascular morbidity and mortality, largely the result of accelerated atherogenesis, a hallmark characteristic of significant renal dysfunction (1,2 and 3). The increased risk associated with renal impairment has a pervasive influence on outcomes across all aspects of cardiac disease including acute coronary syndromes, cardiac failure, coronary revascularization, and valvular heart disease. Furthermore, renal insufficiency is associated with adverse outcomes, with the magnitude of risk positively correlated with the degree of renal impairment (1,4). Consequently, among patients with end-stage renal disease (ESRD), cardiac mortality accounts for approximately one-half of all deaths, and of these, more than 50% occur as a result of acute myocardial infarction, with an incidence three to five times higher than the general population (5,6). Salient data from the 34,189 patient U.S. registry of long-term dialysis demonstrate that myocardial infarction was associated with a 59% 1-year, 73% 2-year, and 90% 5-year mortality (7). Further contributing to symptomatic myocardial ischemia is small vessel disease, reduced capillary density, volume overload, and altered myocyte bioenergetics. Hence, up to 27% of patients have myocardial ischemia without obstructive coronary artery disease. A greater prevalence and consequence of traditional coronary risk factors such as diabetes, lipid abnormalities, and hypertension underlie this increased risk (8,9,10,11 and 12). These risk factors are often coexistent and therefore synergistic in their potentiation of atherosclerosis in addition to their effect on renal dysfunction (2). Whether dialytic therapy directly contributes to the increased risk of coronary artery disease remains contentious (13).

Renal dysfunction contributes to perturbation in all components of vascular integrity, culminating in both an elevated bleeding risk and a thromboinflammatory state (14,15). Uremia is associated with chronic endothelial injury with increased tissue plasminogen activator and von Willebrand's factor release (16,17); elevated plasma levels of F1+2, thrombin–antithrombin complex, fibrinopeptide A, and D-dimer, implicating increased thrombin generation (18); and heightened factor VII coagulant activity that correlates with the increased cholesterol levels, triglyceride levels, and thrombin generation (17). Finally, chronic renal failure (CRF) is associated with a proinflammatory state, evidenced by elevated interleukin-1, tumor necrosis factor, and fibrinogen levels; monocyte activation; and increased tissue factor and metalloprotease expression (19,20). As a clinical marker of this inflammatory process, elevated C-reactive protein among end-stage renal patients is associated with up to a 5.5-fold risk of coronary artery disease and 4.5-fold risk of cardiovascular death (21).

Left ventricular (LV) hypertrophy and cardiac failure are also more prevalent among patients with significant renal impairment and are observed in approximately 35% to 40% of the renal dialysis population (9,22,23). Reports observe an increasing prevalence of cardiac failure among hemodialysis patients, corresponding to a similar increase in the prevalence of coronary artery disease (24). High-output states associated with arteriovenous fistulas, salt and water overload, and anemia further contribute to ventricular overload and LV hypertrophy, whereas chronic ischemia and increased myocardial oxygen demand, hyperparathyroidism, uremia, and malnutrition augment cardiomyocyte loss, fibrosis, and systolic dysfunction (25,26,27,28 and 29).

This chapter focuses on the effect of the numerous metabolic derangements associated with chronic renal insufficiency and ESRD including secondary hyperparathyroidism; vitamin D deficiency; and phosphorus, calcium, and lipid abnormalities. These disturbances may be causal in changes of cardiac structure and function responsible for the high cardiovascular morbidity and mortality within this population. Given the biochemical uniqueness of these patients, the diagnosis and treatment of cardiac disease among patients with renal insufficiency present issues of interpretation and management. These issues, along with a description of the cardiovascular effects of renal replacement therapies, are also discussed.

METABOLIC CHANGES ASSOCIATED WITH CHRONIC RENAL FAILURE

Hyperparathyroidism

Secondary hyperparathyroidism is a multifaceted process and is highly prevalent among CRF patients. Decreased renal mass lowers 1,25-$(OH)_2D_3$ production, leading to hypocalcemia, while phosphorus retention also occurs. Other factors involved include impaired calcemic response to parathyroid hormone (PTH), altered degradation of PTH by the kidney, abnormal regulation of calcium-controlled PTH release, abnormalities in the calcium-sensor receptor, autonomous proliferation of the parathyroid gland, and increased levels of calcitonin, acidosis, sex steroids, cytokines, and growth factors (30,31 and 32). Experimental models have associated PTH with several changes in cardiovascular structure and function among patients with renal insufficiency. These include increased cardiomyocyte contractile force and frequency, increased blood pressure by increasing intravascular smooth muscle cell calcium, increased intracellular cardiomyocyte calcium concentration, increased LV mass via cardiomyocyte hypertrophy and interstitial fibrosis, increased atherosclerosis via increases in insulin resistance, calcium and phosphorus deposition in vessel walls, disturbed lipoprotein metabolism, hypertension, and increased intravascular smooth muscle cell calcium concentration (33,34,35 and 36). Treatment with

calcium channel blocker has been shown to block PTH-induced calcium entry and to restore normal cytosolic calcium levels, thus suggesting that these changes may be reversible (37,38).

Among patients with CRF, the presence of secondary hyperparathyroidism, or its markers, has been associated with increased myocardial calcium content and impaired ventricular systolic and diastolic function (39). LV function is inversely related to plasma PTH concentration; this is not universally reversed with parathyroidectomy, suggesting that either the PTH-induced changes became irreversible over time or that other factors are more important than PTH excess (33). Current treatment guidelines set a goal PTH level of 100 to 200 pg per mL in order to balance bone disease and cardiovascular effects.

Vitamin D

Vitamin D deficiency is also common among ESRD patients. With advanced CRF the increased serum phosphorus complexes with serum calcium, producing hypocalcemia, and also downregulates the a_1-hydroxylase that is responsible for the renal conversion of 25-(OH)D_3 to 1,25-$(OH)_2D_3$. The resultant deficiency of active vitamin D leads to deranged calcium and phosphate metabolism and accompanying increases in PTH levels.

The effects of vitamin D on cardiovascular structure and function seem to be related to opposing the effects of PTH. These include regression of LV hypertrophy (40) and decreased coronary artery calcification (41). Moreover, 26% of patients with congestive heart failure, New York Heart Association class III or IV, were found to have low serum concentrations of 1,25-$(OH)_2D_3$ (42), and the administration of vitamin D to patients with CRF has improved cardiac function either indirectly by suppression of PTH synthesis and secretion or directly via a vitamin D–dependent process in cardiac muscle (43). Intravenous calcitriol is commonly used to help control secondary hyperparathyroidism among ESRD patients. Subsequently, they are at risk of excess vitamin D that can lead to hypercalcemia, hyperphosphatemia, systemic calcinosis (including calcium-phosphorus deposits in vessel walls and heart valves), and hypertension (33). Vitamin D therapy among ESRD patients is limited by the calcium-phosphorus product with the risk of metastatic calcification increased when the product exceeds 60 to 70 $(mg/dL)^2$. The use of phosphate binders (either calcium- or non–calcium-containing) is mandatory. Vitamin D analogs and calcimimetic agents, which purportedly have a lower incidence of hypercalcemia and hyperphosphatemia, are currently being studied.

Calcium and Phosphorus

Hypocalcemia occurs commonly among ESRD patients and has been strongly associated with ischemic heart disease (26). It has also been shown to be independently associated with mortality in a large cross-section of dialysis patients (44). Treatment is with supplemental calcium and vitamin D and, if necessary, use of a dialysis solution containing at least 3.5 mEq per L calcium. Hypercalcemia also occurs and is most often associated with calcium administration, vitamin D therapy, or both. Hypercalcemia increases myocardial contractility and shortens ventricular systole. It can also cause characteristic electrocardiographic (ECG) changes, including a shortened QTc interval, T-wave broadening, and first-degree heart block. Treatment is directed toward correcting the underlying cause, i.e., decreasing calcium or vitamin D supplementation, dialysate calcium, and so forth.

A 54-year-old male patient with hypercalcemia.

Hypophosphatemia is associated with serious cardiac arrhythmias or respiratory arrest due to respiratory muscle weakness. Predisposing factors include poor nutritional intake, excessive phosphate-binding therapy, or overaggressive dialysis. Treatment is supplements and supportive therapy. Hyperphosphatemia results from decreased urinary elimination of phosphorus and is a consequence of vitamin D administration, limited clearance of conventional dialysis, limitations of phosphate binders (hypercalcemia, gastrointestinal side effects, improper dosing, and so forth), tissue breakdown, and dietary and medication noncompliance. Hyperphosphatemia and high calcium-phosphorus ion product has been associated with an approximately 30% increase in mortality among patients with ESRD (45) and is independent of PTH levels (46). Hyperphosphatemia has also been associated with progression of secondary hyperparathyroidism, elevated calcium-phosphorus product, coronary artery calcification, conduction defects, hypertriglyceridemia, hypercholesterolemia, myocardial fibrosis, and systemic calcification (including mitral and aortic valves, peripheral vessels, pulmonary, and periarticular). Importantly, an increased incidence of progression of coronary artery calcification is detectable by electron beam computed tomography among young patients (20 to 30 years old) with ESRD, correlating with serum phosphate levels, the calcium-phosphorus product, and the duration of dialysis. The relationship between this finding and clinically significant coronary lesions remains to be defined (47). Two different modalities have been used in an attempt to reverse hyperphosphatemia: restricting dietary phosphate intake and prevention of gastrointestinal absorption with the use of phosphate binders. Longer dialysis sessions and daily nocturnal dialysis can also improve clearance of phosphate (48).

Lipid Abnormalities

Abnormal lipid metabolism is common among patients with CRF (49) and contributes to the increase in cardiovascular events. These abnormalities are most prominent in the nephrotic syndrome in which marked elevations in the plasma levels of cholesterol, triglycerides, and lipoprotein(a) are common.

The two most common lipid abnormalities in the nephrotic syndrome are hypercholesterolemia and hypertriglyceridemia (50), possibly the result of increased hepatic synthesis of lipoproteins containing apolipoprotein B and cholesterol in response to the reduced plasma oncotic pressure (50,51). The severity of the hyperlipidemia is inversely related to the decrease in oncotic pressure (51), and albumin or dextran administration produces a rapid reduction in lipid levels (52). Alternate evidence suggests that reduced catabolism is primarily responsible for hypercholesterolemia among patients with the nephrotic syndrome (53) and is also a cause of the elevated triglyceride levels (49,50). The delipidation cascade in which very-low-density lipoproteins are converted to intermediate-density lipoproteins and then to low-density lipoproteins (LDL) by lipoprotein lipases is slowed in the nephrotic syndrome and with a trend toward reduced LDL receptor–mediated clearance of LDL and intermediate-density lipoproteins (54).

In concert with renal impairment, hyperlipidemia is a potent risk factor for cardiovascular disease (49,55). Compared with age-matched controls, a relative risk of 5.5 for death from coronary artery disease, 5.2 for myocardial infarction, and 2.8 for coronary death has been reported for nondiabetic nephrotic patients (56). The lipid abnormalities induced by the nephrotic syndrome reverse with resolution of the disease. The optimal treatment of patients with long-standing persistent nephrotic syndrome is uncertain because randomized trials have not been performed (49,50). The most successful lipid-lowering agents have been the 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors and the bile acid sequestrants (49,50,57). Treatment with these agents should also extend to renal insufficiency patients with hyperlipidemia in the absence of nephrotic syndrome. Angiotensin-converting enzyme (ACE) inhibitors are another potential adjunctive therapy for hyperlipidemia since they lower 24-hour urine protein excretion (58,59) and are associated with a 10% to 20% decline in the plasma levels of total and LDL cholesterol and lipoprotein(a) (60). Similar findings have been shown with losartan, an angiotensin II receptor antagonist (61).

Hyperhomocystinemia

Homocysteine levels have been shown to be elevated two- to fourfold among patients with CRF (62,63,64 and 65). Moderate hyperhomocystinemia is a recognized independent risk factor for coronary artery disease and is a strong predictor of mortality among patients with established coronary artery disease (66,67,68,69 and 70). From prospective observational data, hyperhomocystinemia remains an independent risk factor for cardiovascular morbidity and mortality among the ESRD population, conferring a relative risk of 1% per µmol per L increase in total homocysteine concentration or a relative risk ratio of 1.5 for levels greater than 5 µmol per L (2,71).

Homocysteine metabolism is dependent on vitamin B_6, vitamin B_{12}, and folic acid. In renal failure, poor nutrition coupled with removal of water-soluble vitamins by dialysis may partially explain a tendency to deficiencies of these vitamins and the high prevalence of hyperhomocystinemia. In non-ESRD populations, treatment with folic acid alone or in combination with vitamins B_{12} and B_6 has been shown to lower homocysteine levels. Low doses of folic acid have been shown to lower homocysteine levels in non-ESRD patients; however, the effects have not been as pronounced in ESRD patients (72,73). To date, no prospective studies have

reported the effect of lowering homocysteine levels on cardiovascular events, and this question requires further investigation.

Uremic Cardiomyopathy

Uremic syndrome is a multisystem deterioration including the cardiovascular, neurologic, hematologic, and immunologic systems. The pathophysiology of uremic syndrome is not completely understood but results from the retention of substances that are ordinarily removed by the kidneys, intake of dietary precursors, and derangements of hormonal and enzymatic homeostasis. The putative substance(s) or uremic toxins have not been clearly identified; however, several substances have been studied, including urea, PTH, beta$_2$-microglobulin, and middle molecules. Several factors may predispose or contribute to myocardial dysfunction in uremia, including hypertension, anemia, electrolyte disturbances, acidosis, hyperlipidemia, accelerated atherosclerosis, glucose intolerance, and malnutrition.

Abnormalities of LV structure and function are common among patients starting renal replacement therapy. Concentric LV hypertrophy is present in approximately 40% of ESRD patients starting dialysis (22,25,74). Twenty-seven percent of patients had LV dilatation and 18% had systolic dysfunction. These abnormalities occur early in CRF and progress rapidly as renal function deteriorates (75). Twenty-seven percent of patients with creatinine clearance greater than 50 mL per minute had LV hypertrophy and this increased to 31% and 45% for clearances between 25 and 50 mL per minute and less than 25 mL per minute, respectively.

VIDEO

Video 35C.1 Apical long-axis view of a patient with severe left ventricular dysfunction and annular dilatation causing 4+, centrally directed mitral regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Clinical cardiac failure is also common in ESRD patients with almost 50% having a history of cardiac failure before initiating dialysis (74). Congestive heart failure at the beginning of dialysis is an important predictor of cardiovascular and overall mortality in the ESRD population (median survival rate of 32 vs. 62 months) (74). Among ESRD patients, the incidence of valvular dysfunction is also elevated. Some studies note mitral or aortic valvular abnormalities in almost one-half of all patients with CRF. The most common reported abnormalities are mild to moderate mitral regurgitation secondary to LV dilatation and calcification. However, the prevalence of hemodynamically important valvular dysfunction is not well described in the literature thus far.

Uremic Pericarditis

Pericarditis associated with CRF was first described by Bright in 1836. It accounts for 3% to 4% of all deaths in dialysis patients, as a result of tamponade, cardiac arrhythmias, or heart failure. Initially, it was believed that uremic pericarditis would disappear with adequate dialysis because the presumed cause of pericarditis was the retention of nitrogenous waste products (76). The majority of nondialyzed patients with uremic pericarditis did improve rapidly after the initiation of dialysis; however, pericarditis occurred in up to 20% of patients on maintenance dialysis (77,78). Moreover, the pericarditis among patients on maintenance dialysis failed to resolve despite intensified dialysis treatments (79), thereby suggesting a different etiology. Pericarditis associated with CRF has been divided into two categories: uremic- and dialysis-associated pericarditis.

Uremic pericarditis is observed in 6% to 10% of patients with advanced renal failure (acute or chronic) before or shortly after dialysis is initiated (80). It results from inflammation of the visceral and parietal membranes of the pericardial sac. The pathogenesis is poorly understood, but among others, fluid overload, the hemorrhagic tendency of uremia, serositis, decreased fibrinolytic activity, and hyperparathyroidism have been implicated.

Dialysis-associated pericarditis occurs in approximately 13% of patients on maintenance hemodialysis (81) and may occasionally be seen with chronic peritoneal dialysis. Among patients undergoing dialysis, pericarditis may be the result of several factors, including inadequate dialysis, volume overload, accumulation of middle molecules, malnutrition, hyperparathyroidism, heparin therapy, viral infection, and, possibly, immune mechanisms (82).

Clinically, these two entities are similar. There is one relatively characteristic feature of uremic pericarditis: The ECG does not usually show the typical diffuse ST- and T-wave elevations, presumably because epicardial injury is uncommon (83).

The development of uremic pericarditis is an indication to institute dialysis, providing there is no circulatory compromise or evidence of impending tamponade. The majority of these patients responds quickly to dialysis with resolution of signs and symptoms. Either hemodialysis or peritoneal dialysis can be used; however, each has corresponding advantages and disadvantages. Heparin can increase hemorrhage into the pericardial space and therefore heparin-free hemodialysis should be used. Acute fluid removal with hemodialysis can lead to cardiovascular collapse among patients with tamponade or pretamponade. Alternatively, peritoneal dialysis can compromise respiratory function because of intraperitoneal fluid accumulation.

Dialysis-associated pericarditis requires more complicated management. The dialysis schedule is usually intensified by increasing the frequency of dialysis treatments in hemodynamically stable patients with no or small to medium-sized effusions. However, increased dialysis may result in intravascular volume depletion and electrolyte disturbances such as hypokalemia or hypophosphatemia (84). Intensified dialysis therapy usually leads to resolution of the pericarditis within 1 to 2 weeks. Surgical drainage, however, may be necessary before the initiation of dialysis if the effusion is significantly large (estimated to exceed 250 mL by echocardiography) or mandatory when overt tamponade appears (85). Antiinflammatory medications and systemic corticosteroids are associated with limited success in refractory pericarditis. Therefore, drainage is the treatment of choice if the effusion enlarges or fails to resolve after a trial of intensified dialysis (86).

Surgical drainage can be accomplished by any of four ways: pericardiocentesis, pericardial window, subxyphoid pericardiostomy, or anterior pericardiectomy. Pericardiocentesis using a blindly inserted needle is dangerous and never indicated except as emergency therapy. Hemorrhagic effusions are poorly drained using this technique, and the risk of coronary artery or cardiac puncture and arrhythmia are substantial. Subxyphoid pericardiostomy is the procedure of choice. The tube is left in place to closed drainage for several days until drainage ceases. Anterior pericardiectomy requires general anesthesia and thoracotomy and carries a significantly greater associated morbidity. Therefore, it is usually recommended only when pericardiotomy cannot be performed or has been unsuccessful.

RENAL INSUFFICIENCY AND END-STAGE RENAL DISEASE

Diagnosis

Clinical history remains the cornerstone of diagnosis in stable and unstable coronary artery disease among patients with renal insufficiency. However, the prevalence of reduced physical capacity and significant comorbidities among these patients may somewhat obscure clinical manifestations of coronary artery disease. Similarly,

specific interpretation of ECG changes is often limited by changes related to the presence of long-standing hypertension, LV hypertrophy, and electrolyte abnormalities. These factors may either falsely suggest or conceal the diagnosis of myocardial ischemia. These issues limit the diagnostic utility of the resting or exercise ECG in excluding significant myocardial ischemia among renal failure patients. The value of ambulatory ECG monitoring among patients on long-term dialysis also remains in question (87).

Cardiac Markers

Among patients with significant renal insufficiency, transient elevations in cardiac enzymes are commonly observed in the absence of clinical myocardial ischemia and are reported in up 72% of patients over long-term follow-up. The source of these enzyme elevations remains uncertain, but appears unrelated to the type of dialysis (peritoneal vs. hemodialysis) or the level of uremia. Elevations of these enzymes may be persistent, although often at low concentrations, with creatine kinase-MB (CKMB) fractions rarely exceeding 8%. Isolated elevation of the CKMB subfraction in the absence of demonstrable myocardial necrosis has also been observed. Nonspecific elevations of CK and CKMB contribute to a reduced diagnostic utility of these assays for confirming clinically significant ischemia (88). Similarly, serum myoglobin levels have limited diagnostic utility within this population because of the presence of these enzymes in skeletal muscle and its reduced renal clearance.

Cardiac troponin elevation is frequently observed among dialysis-dependent patients (30% to 50%), and less commonly, among patients with chronic renal impairment not requiring renal replacement (10% to 20%) (89). Troponin levels may also be directly influenced by hemodialysis. Consequently, reduced specificity and possibly sensitivity for myocardial ischemia has been reported within this population (90,91,92 and 93). Mild elevations in troponin T appear more common than in troponin I, suggesting that this assay may have greater specificity. Cross-reactivity with skeletal muscle enzymes may explain the high prevalence of troponin T elevation (89,93,94 and 95), although this is less of an issue with more recent assays (96). Nevertheless, troponin I or T among patients with symptomatic myocardial ischemia remains predictive of in-hospital mortality, whereas patients without troponin elevation appear to be at low risk (97,98). Increased troponin T on routine serial measurements of asymptomatic dialysis patients may also predict long-term adverse events, but this has not been consistently demonstrated (89,99,100 and 101). Among stable hemodialysis patients with and without known atherosclerosis, troponin T greater than 0.1 ng per mL has been associated with a sevenfold increase in long-term mortality (102). These studies demonstrate an acceptable sensitivity and improved specificity by adopting a higher threshold level. Conversely, among asymptomatic patients with renal insufficiency not requiring dialysis, the predictive utility of either troponin I or T remains low (89). Therefore, among patients with renal impairment, troponin elevation should be interpreted within the context of the clinical presentation, treatment with dialysis and the assay used, although adopting a higher threshold level may improve diagnostic specificity (Table 35C.1).

		Troponin I >0.5 ng/mL	Troponin T >0.04 ng/mL	Troponin T >0.1 ng/mL	Troponin T >0.2 ng/mL
Roppolo	Sensitivity (%)	50	–	100	83

TABLE 35C.1 TROPONIN: IMPROVED SENSITIVITY FOR PREDICTING LONG-TERM ISCHEMIC EVENTS AMONG PATIENTS UNDERGOING RENAL DIALYSIS WITH HIGHER THRESHOLD TROPONIN LEVELS

Exercise Electrocardiography

Among patients with CRF, exercise ECG testing for the diagnosis of coronary artery disease has demonstrated a sensitivity 50% to 60% of the diagnosis of single-vessel coronary artery disease and over 85% for triple-vessel disease (103). However, baseline ECG abnormalities and reduced exercise capacity are frequent in this patient population, limiting the diagnostic utility of this study. The sensitivity of exercise testing is dependent on adequate heart rate responses (85% of the age-predicted maximum heart rate), with this level being achieved in only 8% to 20% of patients undergoing treadmill testing (104,105).

Thallium Scintigraphy

The uses of diagnostic imaging studies overcome the issues of LV hypertrophy and repolarization abnormalities that confound the diagnosis of ischemia by ECG alone. However, the diagnostic utility of these noninvasive studies for coronary artery disease remains dependent on the cardiac work induced by either exercise or pharmacologic means. Consequently, among patients with renal failure, earlier studies have documented reduced utility of thallium scans for the diagnosis of coronary artery disease with a sensitivity and specificity as low as 37% and 75%, respectively (106). Furthermore, a low clinical value of thallium scans in predicting coronary artery disease and perioperative events in diabetic patients undergoing renal transplantation was initially observed. These results were attributable to a high prevalence of inadequate tests resulting from reduced exercise tolerance, inadequate heart rate response, concurrent beta-blockade, and the presence of LV hypertrophy (107,108

and 109).

Thallium-201 single-photon emission computed tomography stress and equilibrium images. Transverse, sagittal, and coronal plane images demonstrating inferior and posterior wall ischemia in a patient with a severe proximal stenosis in a dominant right coronary artery.

More recent reports document substantially improved sensitivity and specificity of thallium-201 scans for the diagnosis of coronary artery disease and prediction of subsequent cardiac events. This improved diagnostic utility has been associated with the use of dipyridamole or combined dipyridamole and exercise testing in some studies, overcoming the issue of limited exercise capacity of these patients (110,111 and 112). Of note, Dahan et al. demonstrated a 92% sensitivity, 89% specificity, and 71% positive predictive value with dipyridamole and exercise thallium scanning in patients undergoing hemodialysis. Within this study, the negative predictive value of a normal scan was 91% during 2.8 years of follow-up (113).

Dobutamine Stress Echocardiography

Stress echocardiography may also be a useful means of diagnosing coronary artery disease among patients with end-stage renal failure and stratifying risk for candidates for renal transplantation (114,115). The use of dobutamine serves to overcome the limited exercise capacity frequently encountered within this population. Initial studies have documented sensitivity and specificity in the range of 75% to 95% and 70% to 90%, respectively, for the detection of coronary artery disease among renal transplant candidates, with a normal study predicting a 97% 12-month event-free survival (116). The cost-effectiveness of dobutamine stress echocardiography in pretransplant risk stratification has also been demonstrated (117,118). Utility for predicting late cardiac events has also been documented among patients with ESRF. Compared with an 84% event-free survival observed among patients without ischemia, a 66% event-free survival over a mean of 38 months' follow-up was documented in ischemia on dobutamine stress echocardiography. Importantly, this study observed a prominent increase in events after 2 years in those without initial ischemia, potentially highlighting the duration of prognostic information provided by diagnostic testing in these patients with aggressive coronary artery disease (119).

Angiography and Contrast-Induced Nephropathy

The indications for coronary angiography within this population remain similar to the general population. However, in the patient with significant renal impairment not managed with renal replacement therapy, the additional risk of contrast-induced nephropathy bears careful consideration and preparation. Moreover, renal impairment is associated with a 3.3-fold increase in the overall complication rate during coronary angiography (120). Therefore, coronary angiography should be undertaken only when the anatomic information provided is essential to the planning of future management. Furthermore, technical considerations, such as the site of vascular access, bear careful consideration.

Contrast-induced nephropathy is a leading cause of in-hospital acute renal failure, occurring in less than 0.5% of patients undergoing coronary angiography. However, among patients with renal insufficiency, deterioration in renal function is reported to be between 10% and 40% of patients, depending on associated comorbidities (121,122,123,124 and 125). Of these patients, 75% experience complete recovery, whereas 10% require permanent dialysis. Factors clearly associated with worsening renal function are elevated baseline creatinine, volume depletion, diabetes, cardiac failure associated with a low output state, functioning renal allografts, the dose of contrast agent, and repeat contrast studies within 72 hours (126,127 and 128). Other potential contributing factors include hyperuricemia, anemia hypertension, and proteinuria (129). Age alone does not appear to increase the risk of contrast nephropathy (122).

Diabetes mellitus is a potent risk factor for the development of contrast-induced nephropathy, although most of this risk relates to the presence of associated diabetic nephropathy (130). In the diabetic patients with concurrent renal dysfunction, the risk is approximately fourfold that of diabetics without documented renal dysfunction, with an incidence of approximately 30%. In addition, the risk in diabetic patients appears greater for those with insulin-requiring diabetes than in those managed with oral therapy, although this may simply reflect the increased prevalence of diabetic nephropathy in the latter group. A strong correlation between dose and repeat administration of contrast and renal deterioration has been observed (123), although an independent relationship has not been universally demonstrated (122). Nevertheless, limiting the dose of contrast in these patients remains an important clinical practice. Low-osmolar agents are associated with less nephrotoxicity in animal models and fewer side effects clinically. However, a substantial difference between the low- and high-osmolality agents among relatively low-risk patients has not been consistently observed (131,132 and 133). Conversely, among high-risk patients, low-osmolar agents are associated with significantly lower rates of contrast-induced nephropathy (131). As with osmolarity, ionicity also appears to affect the development of contrast-induced nephropathy, again predominantly among patients with renal insufficiency (130). Therefore, the use of low-osmolar nonionic agents is advocated among those at substantial risk of contrast-induced nephropathy.

The precise mechanism of contrast-induced nephropathy has not been clearly defined. Direct toxic effects on proximal renal tubular epithelium and mitochondrial function have been observed (131). Intraluminal precipitation of protein has also been suggested (134). Glomerular hyperfiltration with mismatch between perfusion and filtration, particularly in the renal medulla observed with diabetes, may increase the susceptibility of these patients to contrast-induced nephropathy (135,136 and 137). Contrast agents may also induce a shift in the oxygen-dissociation curve, therefore reducing the availability of oxygen to the renal medulla (138). Heightened endothelial release of endothelin-1 may have a role in this response, with endothelin release increased with ionic compared with nonionic contrast media (139). Other potential contributing mechanisms include increased red cell rigidity and white cell margination, potentially affecting blood viscosity and rheology within the renal vasculature (140).

Clinically, contrast nephropathy manifests as an increase in serum creatinine, occurring 24 to 48 hours after angiography, peaking over 3 to 5 days, with slow resolution over 7 to 10 days. Oliguria is common among patients with reduced baseline renal function, with up to 50% of these patients requiring permanent dialysis. In addition, urinary sodium excretion is low, as is the fractional excretion of sodium (less than 1%). A persistent nephrogram on abdominal radiography and renal cortical attenuation on computed tomography are also frequently observed for more than 24 hours.

Maintenance of adequate intravascular volume status remains central in the prevention and management of contrast-induced nephropathy. Enhanced diuresis with either furosemide or mannitol has been shown to be of no greater efficacy compared with saline administration alone among patients with significant renal impairment (mean creatinine, 2.1 mg per dL) (141). Administration of 0.45% saline (1 mL per kg per hour) begun 12 hours before coronary angiography was associated with the lowest risk of renal insufficiency (11%) compared with either saline plus mannitol, 25 g (28%), or saline plus furosemide, 80 mg (40%) (141). Reports suggest that use of isotonic saline may be more efficacious (138). While improving urine output, the addition of diuretic agents may induce relative volume depletion and exacerbate nephrotoxicity (136,142). Forced diuresis with intravenous crystalloid infusion, furosemide, or mannitol, with or without dopamine, may also reduce the risk of contrast-induced nephropathy if a high level of urinary volume can be achieved (143). However, caution must be exercised in those with reduced cardiac function. Routine use of dopamine is not associated with a lower risk of contrast-induced nephropathy in high-risk populations (144). Vasodilation with endothelin-receptor antagonists appears to exacerbate contrast-induced nephropathy (139). By preventing renal vasoconstriction, calcium antagonists are a logical approach and have been shown to protect against reductions in glomerular filtration rate (GFR) and proteinuria. Similarly, the efficacy of alternate vasodilatory agents, such as atrial natriuretic peptide, adenosine, and theophylline, has been suggested in experimental models and some small human studies. A reduced rate of contrast-induced nephropathy has also been observed with ACE inhibition, but confirmation with larger studies is required for all of these agents (145). Interestingly, the preventive efficacy of acetylcysteine, an antioxidant administered together with intravenous saline, has been demonstrated. Among 83 patients with a mean creatine of 2.4 mg per dL, acetylcysteine, 600 mg twice daily administered for 1 day before and on the day of investigation, was associated with a small improvement in serum creatinine (0.4 mg per dL) compared with a small deterioration in renal function among controls (0.2 mg per dL; p <.001) (146).

Pharmacotherapy of Ischemic Heart Disease and Cardiac Failure

Reflecting general recommendations, risk-factor modification including smoking cessation, tight glucose control among diabetics, a goal blood pressure of less than 120/80 in predialysis patients and less than 140/90 in dialysis patients, total serum cholesterol less than 200 mg per dL, and LDL cholesterol less than 140 mg per dL remain important among patients with both renal insufficiency and cardiac disease. Other empiric recommendations unique to ESRD patients include hemoglobin 10 ± 0.5 g per dL, Kt/V greater than 1.2 in hemodialysis patients, weekly Kt/V greater than 2 in peritoneal dialysis patients, serum albumin greater than 3.8 g per dL, serum calcium greater than 2.2 mmol per L, and PTH less than 200 ng per L. Importantly, anemia decreases oxygen delivery, increases cardiac work by volume overload, and reduces coronary filling times and vasodilator reserve. Correction of uremic anemia with erythropoietin improves cardiac performance (147) and reduces angina, although no reduction in fatal or nonfatal cardiac events has been documented (148). Although hyperparathyroidism also results in increased cardiomyocyte calcium content, affecting myocardial oxidative metabolism and increasing the susceptibility of myocytes to injury (149), the value of rigorous control of calcium metabolism on cardiac end points requires prospective study.

When considering the choice of pharmacotherapy for patients with renal insufficiency, several issues bear consideration. These include the relative efficacy of the specific agent within this population and the implications of reduced renal function on dosing regimens. Dose modifications for most therapies among patients with renal insufficiency have been described. Furthermore, among preuremic patients the effect of therapy on renal function in those not yet requiring renal replacement therapy and the prevention of deterioration in renal function should also be considered. However, most randomized trials assessing the long-term efficacy of therapies used in the management of cardiac conditions have excluded patients with moderate to severe renal insufficiency (creatinine greater than 2.5 mg per dL). Thus, in the absence of specific data, recommendations for the management of cardiac indications among patients with renal insufficiency follow the guidelines set forth for the general

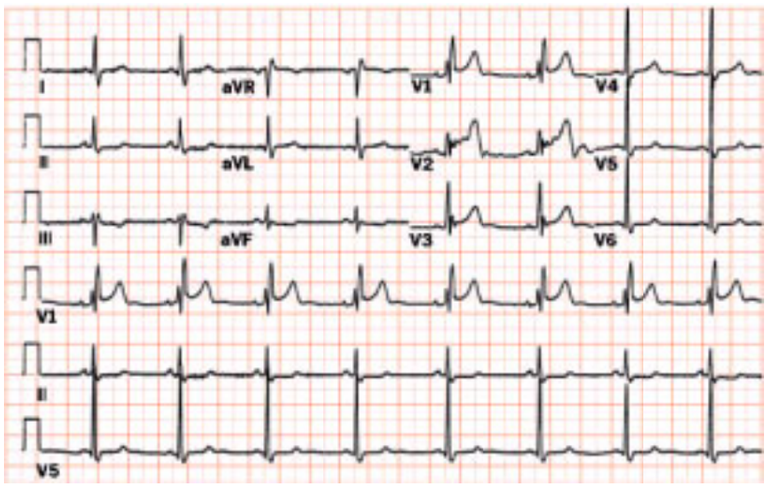
population. Nevertheless, the presence of renal impairment defines the high-risk nature of these patients, often warranting aggressive optimization of therapy.

Management of Hypertension

Control of hypertension is an important therapeutic goal for the prevention of LV failure and impeding the deterioration of function. Few data are available for guiding the choice of therapies among patients with renal insufficiency. Coexistent clinical indications may help guide therapy (e.g., beta-blockers among patients with ischemic heart disease). ACE inhibitors are of proven efficacy in the control of hypertension, may improve vascular distensibility (150), and also slow the progression of renal disease. Independent of their effects on blood pressure, these agents improve glomerular hemodynamics, reduce proteinuria, and antagonize the development of glomerular hypertrophy in patients with and without diabetes mellitus (151,152,153,154,155,156 and 157). Whether ACE inhibitors provide superior protection from renal deterioration in comparison with other agents is uncertain, but has also been suggested (158). Although calcium antagonists are also effective in the treatment of hypertension, the amlodipine arm of the African American Study of Kidney Disease and Hypertension Pilot Study (159) has been stopped. In this study, the use of this drug compared with ramipril and metoprolol was found to be relatively ineffective in preventing progression to dialysis and death among patients with severe proteinuria (L. Agodoa, *personal communication*, October 2000). Furthermore, renal-protective effects have also been documented among diabetic patients, mediated by improved renal blood flow, reduced glomerular hypertrophy, reduced proteinuria, and altered calcium metabolism with the kidney (160,161,162 and 163). Diuretic therapy is effective among patients with hypertension and fluid overload. Use of potassium-sparing diuretics in combination with ACE inhibitors should be avoided because of the risk of hyperkalemia. Thiazides may be ineffective among patients with a GFR less than 30 mL per minute.

Management of Acute Coronary Syndromes

In the absence of specific data within this high-risk patient subset, the management of acute coronary syndromes follows the guidelines developed for the general population. Mortality among patients presenting with acute coronary syndromes remains high, and underuse of therapies may account for some of this excess risk. Importantly, renal insufficiency is not a contraindication to the use of fibrinolytic therapy among patients presenting with ST-elevation myocardial infarction, but remains underused (164). No dose adjustment of any of the thrombolytic agents is required, and a marked increase in bleeding has not been observed in clinical trials. Nevertheless, attention to the established predictors of hemorrhagic risk should be maintained. Aspirin therapy is also indicated among patients presenting with acute coronary syndromes.



Anterior myocardial infarction in setting of right bundle branch block. ST-segment elevation in the anterior precordial leads and primary T-wave changes support acute anteroseptal myocardial infarction.

Because renal failure is considered a prothrombotic state, treatment with antithrombin therapy seems logical in the absence of specific data. With unfractionated heparin, titration of infusion doses to target activated partial thromboplastin time levels as defined within the general population is recommended. In contrast, despite the equivalent and possibly superior efficacy of low-molecular-weight heparins compared with unfractionated heparin within acute coronary syndrome patients, these trials have excluded those with significant renal impairment. Therefore, specific benefit among these patients has not been defined. The half-life of elimination for the low-molecular-weight heparins is significantly prolonged in the presence of renal impairment. Consequently, decreased frequency of dosing and monitoring of antifactor Xa levels are advocated, although specific dose-attenuation scales have not been defined. Although currently available direct thrombin inhibitors (bivalirudin) provide a useful alternative in those with heparin sensitivity, these agents also undergo renal elimination, and experience among patients with renal impairment is limited.

Trials evaluating glycoprotein IIb/IIIa inhibitors have excluded patients with significant renal impairment (creatinine greater than 2.0 to 2.5 mg per dL). Given the lack of randomized data in patients with significant renal impairment coupled with known underlying platelet dysfunction, use of these agents should be undertaken with caution and weighed carefully in the setting of acute coronary syndromes. Close attention to bleeding risk should be maintained. Both currently available small molecule antagonists (eptifibatide and tirofiban) undergo significant renal excretion and appear to be removed by dialysis. The adenosine diphosphate receptor antagonists are a useful alternative to aspirin, or in combination with aspirin among those receiving coronary stents. The degree of platelet inhibition provided by these agents among dialysis patients appears to be similar to that of the general population (165). Elimination of the adenosine diphosphate receptor antagonists clopidogrel and ticlopidine are by hepatic excretion, and dose attenuation is not required.

Management of Stable Coronary Artery Disease

Few randomized data are available to guide the choice of antianginal therapy among patients with renal insufficiency. Aspirin appears to increase skin bleeding time and reduce platelet aggregation by a greater degree in dialysis patients compared with healthy patients. Because of the known platelet defect associated with renal disease, the intermittent need for anticoagulation, and the high prevalence of clinical conditions known to be associated with adverse events following aspirin therapy, patients with renal disease receiving aspirin therapy as primary prevention should be monitored closely. In contrast, despite the lack of specific data, aspirin therapy is advocated as secondary prevention in all patients with coronary artery disease, based on compelling data within the general population. Among patients with renal impairment, beta-blockers are both safe and effective. As long-term therapy following myocardial infarction, treatment with beta-blockers is associated with mortality reductions among patients with renal insufficiency comparable with the general population. Chronic beta-blockade is associated with reduced renal blood flow and GFR, although these alterations in renal hemodynamics are usually minor and subclinical. Calcium antagonists are also effective in ischemic heart disease and can generally be administered without dose adjustment. Advantages with respect to the preservation of renal function have been suggested but require prospective validation. Nitrate preparations are also useful among patients with angina and renal insufficiency. However, given the prevalence of LV hypertrophy, these patients may be sensitive to preload reduction, which may be further exacerbated by dialysis. Ample evidence supports the aggressive treatment of hyperlipidemia, especially with 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, among patients with coronary artery disease within the general population. These recommendations have been extended to patients with renal insufficiency.

Management of Cardiac Failure

Within the general population, the benefit of ACE inhibition for the treatment of cardiac failure is well established. These agents are also advocated among patients with renal insufficiency. Specifically within the renal failure patient, ACE inhibitors have been shown to reduce LV hypertrophy and may improve vascular distensibility (150). Furthermore, among patients with a diverse array of cardiovascular indications treated with ACE inhibition, mild to moderate renal impairment (creatinine 1.4 to 2.3 mg per dL) is associated with a greater mortality reduction compared with patients with normal renal function. Nevertheless, among patients at risk of acute renal insufficiency such as the elderly; patients who are substantially volume depleted; and those with bilateral renal artery stenosis, diabetes mellitus, hypertensive nephrosclerosis, and cardiac failure associated with renal impairment, ACE inhibitor therapy should be instituted with caution. In these conditions, GFR is often maintained in the face of reduced renal perfusion by afferent arteriolar vasodilation and efferent arteriolar vasoconstriction mediated by angiotensin II. By reducing systemic pressure and limiting this compensatory response, these agents may induce a marked decline in GFR. Deterioration in renal function is usually reversible, with dose reduction or cessation of therapy. Effects on renal hemodynamics and proteinuria are also similar to those observed with ACE inhibitors, suggesting the effect on the kidney is mediated by antagonizing the effect of angiotensin II rather than potentiation of bradykinin (166,167,168,169 and 170). However, specific evidence of renoprotective and cardioprotective effects remains to be demonstrated.

Beta-blockers are also indicated among patients with cardiac failure, although data specific to patients with renal insufficiency are limited. Extending beta-blockers to patients with end-stage cardiac failure awaiting cardiac transplantation does not appear to be associated with a significant deterioration in renal function (170). Caution should be exercised with the use of digoxin among patients undergoing hemodialysis because rapid reductions in plasma potassium, magnesium, and hydrogen ions lead to elevated ionized calcium concentrations potentially exposing patients to digoxin-induced arrhythmias. Although digoxin Fab fragments are useful in the treatment of digoxin-induced arrhythmias, renal elimination of the digoxin Fab fragment remains prolonged, requiring extended monitoring in these patients. Both digoxin and the Fab immune fragment are removed by continuous arteriovenous hemodialysis. Among the inotropic agents, specific benefits of dopamine with respect

to renal function have been suggested but not substantiated by randomized studies.

Coronary Revascularization

The principles of revascularization among patients with renal impairment are similar to nonrenal patients, though the effect of renal disease on both short- and long-term outcomes bears careful consideration (Table 35C.2). Frequently, mechanical revascularization is essential for the management of acute coronary syndromes and to control angina resistant to medical therapy and should follow guidelines set forth within the general population in the absence of specific data. In particular, patients with cardiac failure or hemodynamic compromise as manifestations of myocardial ischemia warrant more aggressive investigation and management.

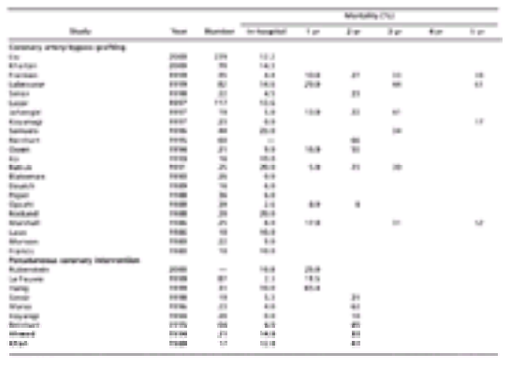


TABLE 35C.2 IN-HOSPITAL AND LATE MORTALITY AFTER CORONARY REVASCULARIZATION

Although the choice between revascularization strategies remains contentious within the general population, the poor long-term results associated with percutaneous coronary intervention has led many to recommend coronary artery bypass grafting as the preferred strategy for patients with significant renal impairment (171,172 and 173). However, with the continued evolution in mechanical revascularization strategies, of particular note coronary stenting, comparison of the relative benefits of each strategy among patients with ESRD requires prospective evaluation.

RENAL TRANSPLANTATION

Among patients undergoing renal transplantation, the incidence of coronary artery disease is increased and associated with a greater mortality, especially in high-risk groups (174,175). Risk stratification (176) and subsequent revascularization appear to reduce long-term cardiac events (174). Therefore, a diagnostic strategy among these patients is warranted. Coronary angiography has commonly been advocated for the screening of coronary artery disease given its prevalence within this population. However, strategies among asymptomatic patients identifying intermediate- and low-risk groups may allow some patients to proceed to transplantation without invasive testing. Patients considered at intermediate risk include those older than 50 years or with diabetes in the absence of clinical cardiac disease and may warrant initial noninvasive investigations. Patients younger than 45 years, with no history of smoking, without diabetes for more than 25 years, and no ST-T–wave changes on ECG, again without clinical cardiac disease, appear to be at low risk of coronary artery disease, and transplantation without prior cardiac investigation may be safe (177). These recommendations have been set forth in the American Society of Transplant Physicians Guidelines for risk stratification before renal transplantation (Fig. 35C.1).

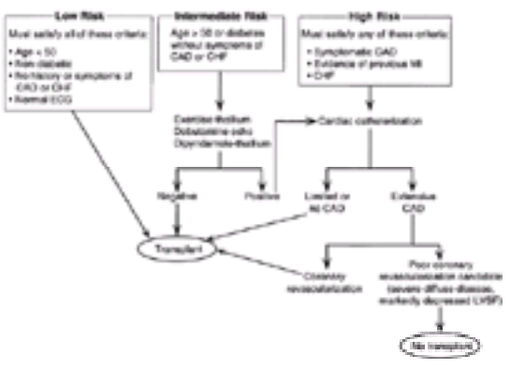

FIGURE 35C.1 American Society of Transplant Physicians Guidelines for risk stratification before renal transplant. CAD, coronary artery disease; CHF, congestive heart failure; ECG, electrocardiography; LVSF, left ventricular shortening fraction; MI, myocardial infarction.

Similarly, parameters of LV function also correlate with long-term mortality after renal transplantation. In a study of 141 patients undergoing echocardiography before transplantation, ejection fraction, end systolic and diastolic diameter, LV mass index, fractional shortening, and age were independent predictors of mortality. Not surprisingly, age and end systolic diameter were the strongest predictors of mortality (end systolic diameter risk ratio, 2.16; 95% confidence interval, 1.27 to 3.66, p <.01), whereas an association between LV mass index and mortality was also observed (178). However, whether targeting echocardiographic abnormalities provides improved survival in these cases requires validation.

Percutaneous Coronary Intervention

In comparison with the general population, earlier studies of coronary angioplasty among end-stage renal failure patients have reported reduced procedural and clinical success rates because of a substantial increase in ascular complications, long-term recurrent angina, myocardial infarction, restenosis, as well as in-hospital and long-term mortality (179,180 and 181). This excess in late adverse outcome extends to patients with chronic renal insufficiency, not requiring renal replacement therapy.

Developments in interventional practice, namely coronary stenting and novel adjunctive therapies, have led to some attenuation in the excess risk associated with renal impairment (182). Within a series of 362 patients, newer interventional techniques (coronary stenting in most patients) appear to be associated with an improved

procedural success rate and reduced long-term death, myocardial infarction, or revascularization rates compared with balloon angioplasty, among patients with baseline creatinine greater than 1.5 mg per dL. However, coronary stenting has also been associated with an increased rate of in-hospital cardiac events compared with balloon angioplasty (stents 11% vs. percutaneous transluminal coronary angioplasty 5%) among dialysis patients. Within this study, target vessel revascularization at 1 year was required in 22% of dialysis-dependent patients receiving stents, a rate that was comparable with a contemporaneous non–renal failure population. Nevertheless, late mortality and disease progression resulted in a poor late event-free survival (183), whereas angiographic restenosis after coronary stenting remains elevated even among patients with mild to moderate renal impairment (184). Evidence supporting alternate interventional techniques such as rotational atherectomy is promising but limited to small observational studies.

Data supporting the use of glycoprotein IIb/IIIa inhibition specifically in the renal insufficiency patient are limited. Given the substantial benefit within the context of percutaneous coronary intervention, extrapolation of the results seen within the general population to those with significant renal impairment appears reasonable, although an increased risk of bleeding has been observed (185). Bedside tests of platelet aggregation may also prove useful in guiding therapy with these agents, although appropriate therapeutic targets for platelet inhibition within this population have yet to be defined.

With the continued evolution of interventional strategies, more recent evidence indicates an improvement in acute procedural results (186,187), although still inferior to the general population, and an increased rate of in-hospital major adverse events (10.8% rate of death, Q-wave myocardial infarction, and urgent coronary artery bypass grafting) persists. Long-term recurrent angina, myocardial infarction, and target vessel revascularization remain a problem with target vessel revascularization rates and mortality remaining in the range of 50% and 30%, respectively. Factors contributing to these adverse events include a higher degree of calcification, greater residual stenosis, and smaller vessel size, reflecting the diffuse atheromatous disease process (188,189). An increased intensity of prothrombotic and proinflammatory mechanisms as evidenced by increased fibrinogen levels has also been linked to the restenotic process and late events (189). Thus, whether contemporary catheter-based revascularization offers results comparable with coronary artery bypass grafting remains to be examined prospectively (190).

Coronary Artery Bypass Grafting

The adverse prognostic effect of renal insufficiency on the outcomes after coronary artery bypass grafting is well established and extends to include those with moderate renal dysfunction (creatinine greater than 2.5 mg per dL). In addition to an increased prevalence of risk factors such as extensive coronary artery disease, LV dysfunction, diabetes, and prior myocardial infarction, elevated blood urea nitrogen appears to impart increased risk of perioperative mortality and a low cardiac output postoperative state. The mortality risk associated with blood urea nitrogen may be partly attributable to the presence of associated comorbid conditions, such as uremia-induced platelet dysfunction and fluid, electrolyte, and acid–base disturbances contributing to perioperative cardiac failure and arrhythmias. Depressed immune function also increases the rate of infection. Therefore, patients with renal insufficiency experience an increased incidence of prolonged ventilation, mediastinitis, and stroke, contributing to increased intensive care and in-hospital stays as well as an in-hospital mortality ranging from 4% to 14% or approximately three times the rate observed among the general population. Furthermore, combined coronary artery bypass grafting and valvular surgery appears to be associated with an even greater risk of in-hospital mortality (191).

Even within the general population, the incidence of renal failure after cardiac surgery ranges between 1% and 8% but is associated with a striking increase in operative mortality (63.7% vs. 4.3%, p <.001) (192). Similarly, myocardial infarction, mediastinitis, and reoperation for bleeding are also increased. Preexisting renal impairment, age, diabetes, and cardiac failure are important predictors of deterioration in renal function with approximately 25% of patients with preexisting mild or moderate renal insufficiency requiring permanent dialysis after cardiopulmonary bypass (192,193 and 194). Among renal transplant patients, a relatively small deterioration in renal function is also observed (195).

The use of peritoneal dialysis or hemodialysis on the day before surgery and after the operation is practiced in some centers. Minimizing fluid shifts and electrolyte disturbance during the procedure with intraoperative dialysis has also been suggested. Similarly, developments in operative technique and increased use of arterial conduits (196) may benefit these high-risk patients, while the minimally invasive surgery may prove a particular advance in renal failure patients, but this remains to be documented.

Although randomized comparisons are lacking, coronary artery bypass grafting appears to be associated with lower long-term mortality compared with patients receiving coronary stents or balloon angioplasty as observed in the United States Renal Data System database (61.2%, 70.6%, and 71.4%, respectively) (190). Nevertheless, the 22% mortality per year reported in more recent studies remains high (190,197,198,199 and 200). More recent reports of long-term survival do not differ substantially from earlier series. Furthermore, the presence of cardiac failure before coronary artery bypass grafting is associated with a three- to fourfold risk of increased late mortality (191,201). Thus, long-term survival after coronary artery bypass grafting is similar to the overall survival rates observed among dialysis patients regardless of revascularization (191,201,202 and 203). Whether revascularization provides a mortality benefit is uncertain and appears to depend not only on the extent of coronary artery disease, but also on the coexistent medical conditions within the individual patient.

OUTCOMES

Long-term morbidity and mortality from cardiac disease among patients with significant renal impairment remain high. Mortality is observed at a rate of approximately 1% per year among patients with renal insufficiency not treated with dialysis. After renal transplantation, annual mortality of 0.54% or approximately twofold greater than the general population is evident. Among patients receiving renal replacement therapy, cardiac mortality accounts for greater than 40% of all deaths, with an annual cardiovascular mortality 10- to 30-fold higher than the general population. This increased mortality extends across gender, race, and the presence of diabetes. An annual incidence of myocardial infarction among hemodialysis patients is reported to be approximately 8%, with a similar annual incidence of developing pulmonary edema or requirement for extra hemofiltration. Within this population, myocardial infarction is associated with a mortality of 59% and 90% at 1 year and 5 years, respectively (7). LV function remains an important determinant of survival. Among patients starting dialysis therapy, systolic dysfunction portends a median survival of approximately 3 years, whereas outcomes in those with LV dilation or concentric LV hypertrophy are slightly better (23). Patients with clinical cardiac failure commencing dialysis experience a near doubling of mortality compared with their counterparts without cardiac failure, whereas the development of new onset cardiac failure when on hemodialysis therapy is associated with a median survival of 18 months (23).

RENAL REPLACEMENT THERAPY IN A PATIENT WITH CARDIAC DISEASE

Hemodialysis

The term *hemodialysis* is applied to all renal replacement modalities that involve clearance of water and solutes across a synthetic semipermeable membrane. Clearance of solutes and water occurs by two processes, diffusion and convection, and although conceptually different, both processes occur contemporaneously. In chronic ESRD, hemodialysis is usually performed on a thrice-weekly basis for 3 to 4 hours. In critically ill, hemodynamically unstable patients, a more continuous dialysis or continuous renal replacement therapy can be used. Although conceptually identical to hemodialysis, continuous renal replacement therapy allows a wider variation in diffusive and convective clearance.

The acute hemodynamic consequences of renal replacement therapy and the long-term effects of renal replacement therapy both have an effect on cardiovascular disease. This discussion focuses primarily on the intradialytic element of the interaction between renal replacement therapy and cardiovascular disease, highlighting the special considerations of renal replacement therapy to patients with cardiovascular disease.

Hemodynamic Concerns

Hemodialysis alters both intracellular and extracellular composition and volume. These alterations may have the hemodynamic effects of hypotension, dysrhythmias, and ischemia that are particularly important among patients with cardiovascular disease. Hypotension is the most common complication of hemodialytic therapy. Cardiac output and systemic vascular resistance are the major components of blood pressure. Cardiac output is a function of heart rate and stroke volume, and stroke volume is affected by plasma volume. Ultrafiltration of intravascular fluid during hemodialysis reduces plasma volume subsequently, resulting in a decline in cardiac output and blood pressure. Hypotension, however, is not merely a reflection of ultrafiltration and its rate of removal. There are a number of other factors and processes relevant to dialysis-associated hypotension including plasma refill rate, dialysate-related factors, dialysis membrane factors, and autonomic and cardiac function.

Plasma refill rate is defined as the rate at which plasma volume removed by ultrafiltration is restored from intracellular and interstitial fluid compartments. Although there is wide patient variation, the size of the interstitial component has a direct relationship with refill rates (204). One mechanism driving plasma refill rate is the increase in intravascular oncotic pressure secondary to hypotonic fluid removal by ultrafiltration (205). Patients with low plasma protein levels are predisposed to intradialytic hypotension (206) related perhaps to reduced plasma oncotic pressure and consequently reduced plasma refill rate. As an elevated ultrafiltration rate can quickly overcome plasma refill rate, greater weight gain between dialysis treatments requires a faster ultrafiltration rate to achieve prescribed dry weights and therefore predisposes to hypotension. Removal of a high solute load from the intravascular space may cause an intracellular fluid shift and contribute to hypotension.

Dialysate may also play a role in dialysis hypotension. The inclusion of acetate as a buffer in dialysate lowers plasma refill rate and may have a negative inotropic effect (207,208 and 209). The widespread replacement of acetate with bicarbonate, however, has largely obviated this concern. Other electrolytes including sodium and calcium in the dialysate may also contribute to blood pressure modulation. As low sodium concentration in dialysate is associated with hypotension (210,211), elevated dialysate sodium is used therapeutically for intradialytic hypotension (212). Modeling of sodium concentration in the dialysate, usually programmed as a progressive decline from somewhat elevated to more physiologic concentrations over the course of a dialysis treatment, has been used to intervene or prevent hypotension. The long-term benefits of such interventions are not clear (212,213), as most studies report positive sodium balance, temporary decreases in intradialytic hypotension, less blood volume reduction, and a subsequent increase in thirst and body weight.

The use of an increased calcium concentration in the dialysate generally results in an increased serum ionized calcium concentration and improved LV contractility (214). This may contribute to the higher blood pressures seen with the use of low bicarbonate dialysate with higher ionized calcium concentration (215). Serum magnesium levels are frequently elevated among patients with ESRD; therefore, dialysate magnesium is kept at a low concentration. Intradialytic hypotension is less common with low dialysate magnesium (216). The variations in dialysate potassium concentrations have not been shown to significantly alter blood pressure during dialysis, although hypokalemia does have a theoretical inotropic effect.

Other factors that influence blood pressure include anemia, membrane interactions, and dialysate temperature. Intradialytic hypotensive episodes are significantly reduced in anemic patients after transfusion (217). Although the issue of biocompatibility and hypotension is controversial, it arose from the observation that hemofiltration is associated with a greater hemodynamic stability than hemodialysis (218). Although data suggest that the use of dialysis membranes that are considered biocompatible may be associated with less hypotension (219), this finding is not consistent across all studies (220). Dialysate temperature influences hemodynamic response by allowing dissipation of body heat without cutaneous vasodilatation. Maintenance of core temperature during isolated ultrafiltration and hemodialysis optimizes hemodynamic stability during dialysis (221).

The autonomic nervous system should provide an increase in systemic vascular resistance during ultrafiltration (222). Patients with cardiovascular disease may be more prone to hypotension if their sympathetic compensatory mechanisms are already maximized or if the use of certain medications, such as beta-blockers or ACE inhibitors, further compromises compensatory mechanisms.

Hypotension among patients with ESRD may also be an early sign of pericarditis or pericardial effusions. These disorders heighten the sensitivity of blood pressure to ultrafiltration and volume shifts. The treatment for pericarditis usually involves increasing dialysis dose; however, patients with large effusions may benefit from drainage or surgical therapy (223). Dialysis should be performed without heparin to minimize the risk of bleeding into the pericardial space. Aggressive ultrafiltration may reduce intradialytic right ventricular volume and may further predispose these patients to hypotension and cardiovascular collapse.

Seventy percent of incident hemodialysis patients have LV hypertrophy (22). V hypertrophy is associated with reduced LV compliance. Small increases in intraventricular volume may, therefore, result in disproportionate increases in diastolic pressure. Conversely, rapid lowering of preload impairs systolic function. Among patients who have narrow volume ranges because of these factors, modalities using longer durations such as continuous renal replacement therapy or peritoneal dialysis have been suggested (224).

Dysrhythmias

Dysrhythmias are seen frequently among patients during hemodialysis (225). The etiology of intradialytic dysrhythmias may be related to fluid, acid–base, or electrolyte shifts. Patients with ESRD and LV hypertrophy have significantly increased risks of sudden death (226), with up to 75% of such deaths attributable to ventricular fibrillation (227). Bicarbonate dialysate is associated with less frequent dysrhythmia than acetate dialysate (228). Hypokalemia precipitates dysrhythmias, and patients taking digoxin are more susceptible (229). Prevention of hypomagnesemia may also reduce intradialytic ventricular ectopy.

Ischemia and High Output Cardiac Failure

Fluctuations in blood pressure and heart rate during dialysis may lead to alterations in coronary perfusion. Hypoxemia is a common intradialytic problem compounding ischemia (230). The presence of LV hypertrophy and coronary artery disease among patients undergoing hemodialysis may further undermine coronary reserve. Intradialytic ischemia can be complicated by the sudden release of adenosine, which further compounds hypotension (231). Chest pain on dialysis should be treated with supplemental oxygen and by minimizing ultrafiltration rate. Patients with recurrent ischemia should be prescribed a tight fluid restriction to minimize ultrafiltration requirements. Intradialytic ST depression on ECG is predictive of future cardiac morbidity (232), and continuous blood volume monitoring has theoretic benefits in minimizing ischemia by reducing the amplitude of fluid shifts (233). Increasing the length of dialysis sessions to achieve adequate volume removal at a slower rate may minimize these clinical problems.

Arteriovenous fistulas are associated with cardiac enlargement and hypertrophy among patients with ESRD (234). The extent to which they contribute to high output failure is unclear as the occurrence of failure is unusual (235).

Peritoneal Dialysis

Peritoneal dialysis involves the same principles of ultrafiltration and diffusion. Ultrafiltration is achieved through the instillation of hypertonic fluid containing high concentrations of dextrose into the peritoneal cavity. Diffusion subsequently occurs across the semipermeable peritoneal membrane. The removal of solutes depends on a concentration gradient between blood and intraperitoneal fluid. The gradient is greatest at the beginning of dialysis and diminishes as dialysis progresses. Among patients susceptible to volume shifts, lower osmolarity PD fluid and longer dwell times can attenuate the rate of ultrafiltration.

Among patients with advanced LV systolic failure, peritoneal dialysis has been advocated as the therapy of choice. Because fluid shifts occur gradually, a more constant volume status is maintained. In addition, the need for an arteriovenous fistula with its consequent high output state is obviated (234). Whereas the intermittent nature of hemodialysis may contribute to an increased rate of sudden and cardiac deaths early in the week, sudden cardiac deaths are more evenly distributed among patients on peritoneal dialysis, suggesting a more benign effect of therapy (236). Peritoneal dialysis may lead to regression of LV hypertrophy (237), and although it has been associated with greater long-term mortality, this increase in mortality is not attributable to an increase in clinical and echocardiographic cardiac disease (13).

Peritoneal dialysis is associated with a large absorption of glucose across the peritoneal membrane, which may contribute to a number of metabolic abnormalities, including abnormal glucose and insulin metabolism, glucose intolerance, hyperinsulinemia, reduced peripheral sensitivity to insulin (238), and hyperlipidemia (239). Both hyperinsulinemia and hyperlipidemia are of concern for patients with ESRD, as they may constitute increased risk for development and progression of atherogenesis. Hyperinsulinemia and hyperlipidemia are thus important factors to consider among patients with preexisting atherosclerotic disease on peritoneal dialysis and should play at least some role in modality selection (240).

Nonenzymatic glycation of proteins in the peritoneal cavity with the resultant formation of advanced glycation end products may play a role in the genesis and progression of cardiovascular disease (241). Such concerns with glucose have contributed to the advent of alternative peritoneal dialysis solutions such as amino acid–containing solutions.

Transplantation

Although transplantation is considered the treatment of choice for management of ESRD and has been associated with regression of cardiovascular disease and particularly LV hypertrophy (242), atherosclerotic disease is the major cause of morbidity and mortality in transplant recipients (243,244). Two-year mortality after myocardial infarction for transplant recipients has been reported at 33.6% (245). The increasing prevalence of atherosclerotic disease in the transplant population may be related to the increase in age and increasing proportion of diabetics currently undergoing transplantation. There are, however, a number of factors specifically related to immunosuppressive therapies that predispose toward development and progression of atherosclerotic heart disease.

Therapy with calcineurin inhibitors is associated with the development of hypertension (246) and has been linked to accelerated atherosclerotic disease through mechanisms including the induction of heat shock proteins (247), enhancing endothelial sensitivity (248), and alteration of cardiac vascular remodeling (249). These drugs have been shown to potentiate the atherosclerotic effects of hyperlipidemia in mice (250) and to increase LDL oxidation in humans (251). Calcineurin inhibitors cause hypertension through a decrease in renal blood flow and an increase in systemic vascular resistance (252). Through these mechanisms, these drugs may predispose toward development of LV hypertrophy and uremic cardiomyopathy.

Electrolyte abnormalities are also associated with immunosuppressive agents. The use of cyclosporin is associated with hypomagnesemia (253), whereas both cyclosporin (254,255) and tacrolimus (256) can cause hyperkalemia. The development of diabetes mellitus posttransplant is associated with the use of corticosteroids,

cyclosporin, and tacrolimus (257) and may contribute significantly to increased cardiovascular risk. Tacrolimus suppresses insulin production in the pancreatic beta cells (258), and the introduction of tacrolimus has been associated with a significantly higher incidence of this problem (259).

THE FUTURE

Patients with both cardiac disease and renal insufficiency are increasing in prevalence, associated with an increase in the incidence of diabetes coupled with an aging population. Consequently, randomized trials of current and novel therapies addressing this high-risk population will provide specific clinical data to guide the management of these patients. Recognition of the heightened inflammatory, thrombotic, and metabolic processes contributing to cardiovascular disease within patients with renal insufficiency promises to provide important pathophysiologic information. Further, an understanding of the role of these mechanisms in the increased prevalence of cardiovascular disease among the population of patients with renal disease will provide insight into differential benefit from therapies such as revascularization procedures and pharmacologic management.

It has long been established that patients with ESRD have a tremendous burden of coronary artery and other cardiovascular disease. Increasing focus, however, is now being placed on the period in a patient's clinical course before the development of ESRD. The epidemiology of cardiovascular disease among patients with early renal insufficiency has not been fully explored. This population of patients has greater comorbidity and a unique pathobiology of disease that will require dedicated and focused study. A better understanding of the distribution and determinants of disease as well as the development of therapeutic strategies targeting the unique mechanisms is essential toward affecting the burden of cardiovascular disease in this population.

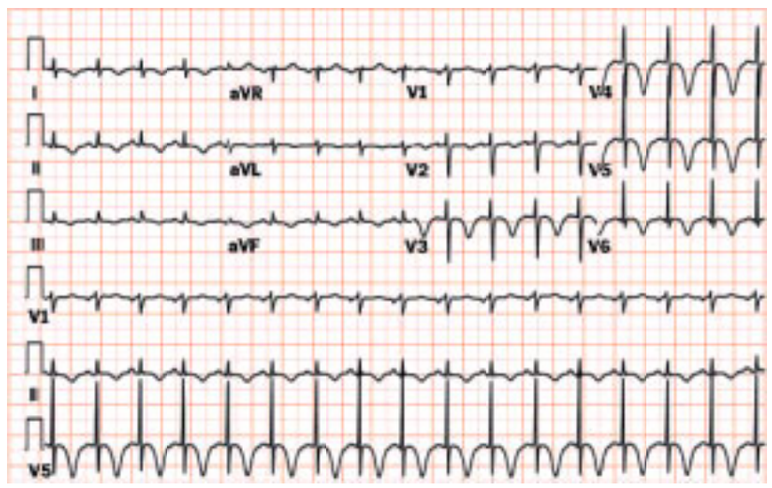
OVERVIEW

Cardiac manifestations of neurologic disorders are common and diverse. Understanding the pathophysiology of cardiac and neurologic disorders is critical for physicians caring for patients with cardiovascular and neurologic disease states and investigators attempting to develop therapies and management strategies for disorders that have both central nervous system (CNS) and cardiovascular components. The importance of interactions between cardiology and neurology is exemplified by ongoing collaborative efforts between cardiologists and neurologists in several key clinical areas, including stroke prevention in atrial fibrillation, percutaneous intervention in cerebrovascular occlusive disease, and the use of thrombolytic and antiplatelet therapies in nonhemorrhagic stroke. Many of these specific issues are discussed in other chapters. In this chapter, the focus is on cardiac manifestations of specific CNS events and the cardiac anomalies associated with hereditary and acquired neuromuscular disorders.

CARDIAC MANIFESTATIONS OF CENTRAL NERVOUS SYSTEM EVENTS

It was more than 60 years ago that Beattie and colleagues recognized that the CNS had neurogenic input in cardiac arrhythmias (1). Soon after, Aschenbrenner and Bodechtel reported electrocardiographic (ECG) abnormalities in young patients with brain lesions and presumed normal cardiac structure (2). It is now commonly known that ECG abnormalities can occur in the setting of CNS abnormalities such as ischemic stroke, intracranial hemorrhage, seizure, headache, meningitis, encephalitis, and cranial trauma. Generally, these ECG features can be interpreted correctly in the setting of known or suspected neurologic disease. However, the erroneous diagnosis of primary cardiac disease can occur and, more importantly, result in inappropriate therapy or delay in proper treatment. Substantial work has been done to attempt to understand the pathophysiology of these cardiac manifestations.



Neurogenic T waves. These deep, symmetric T-wave inversions developed after intracranial hemorrhage.

Acute Ischemic Stroke

Cardiovascular complications are extremely common following stroke and represent a major form of morbidity. These complications may be caused by focal cerebral injury or may be a manifestation of preexisting cardiac disease, which is common in this patient population.

Several studies have documented a high prevalence of ECG changes and arrhythmias in patients presenting with acute ischemic stroke. Common ECG changes include QT prolongation, T-wave abnormalities, prominent U waves, and ST-segment abnormalities (eTable 35D.0.1) (3,4,5,6 and 7). Although ECG changes are common with ischemic stroke, interpretation of these studies is difficult, as the prevalence of asymptomatic coronary artery disease in patients with symptomatic cerebrovascular disease has been reported to be as high as 28% to 65% (8,9). Thus, cerebrovascular disease may be a marker for coronary artery disease that becomes clinically apparent during the physiologic stress of acute ischemic stroke. Few studies have systematically examined old tracings to establish if the ECG changes were new (10). There has been no definitive correlation between the presence of ECG changes and cerebral infarct location.

***e*TABLE 35D.0.1** REPORTED ELECTROCARDIOGRAPHIC CHANGES AND ARRHYTHMIAS IN PATIENTS WITH INTRACRANIAL HEMORRHAGE OR ISCHEMIC STROKE

Electrocardiographic changes
QT prolongation
T-wave inversion
Increased T-wave amplitude
Prominent U waves
ST-segment elevation
ST-segment depression
Premature atrial complexes
Premature ventricular complexes
Atrioventricular block (first-, second-, and third-degree)
Fascicular block
Bundle branch blocks
Arrhythmias
Sinus tachycardia

Sinus bradycardia
Sinus arrest
Asystole
Supraventricular tachycardia
Wandering atrial pacemaker
Atrial fibrillation
Atrial flutter
Ventricular tachycardia
Ventricular flutter
Ventricular fibrillation
Idioventricular rhythm
Torsades de pointes

Arrhythmias are also common after acute ischemic stroke (*e*Table 35D.0.1). Atrial fibrillation has been most frequently described, although it is often unclear whether the atrial fibrillation was the cause of a cardioembolic event or secondary to cerebral infarction (3,10,11). Ventricular ectopy has also been frequently reported, although episodes of sustained ventricular tachycardia are distinctly uncommon. Atrioventricular (AV) block has been reported and has been attributed to excessive vagal stimulation (12). Intensive monitoring of patients presenting with acute stroke has increased the recognition of these arrhythmias, but this practice has not been shown to reduce morbidity or mortality. Because life-threatening arrhythmias in these patients are uncommon, it may be difficult to show a clear benefit. Prolonged cardiac monitoring, however, may be a useful diagnostic tool to help define the stroke etiology.

As many as 15% of patients with acute ischemic stroke may suffer a myocardial infarction (13,14). With the high coexistence between coronary artery and cerebrovascular disease, it is difficult to imply causality, although it is clear that there is a significantly increased morbidity in ischemic stroke patients who have a concurrent myocardial infarction.

Intracranial Hemorrhage

Byer et al. in 1947 first reported large T waves and QT prolongation in a patient with subarachnoid hemorrhage (15). The first systematic review of ECGs in patients with intracerebral or subarachnoid hemorrhage was done in 1954 and reported that QT prolongation, increased T-wave amplitude, and abnormal U waves were the most common abnormalities (16). Others have reported similar changes in small groups (*e*Table 35D.0.1) (17,18).

The precise incidence of specific ECG abnormalities is not known because reports have included patients with diverse baseline clinical characteristics and lesion types. The level of sophistication of ECG analysis has also varied. Reported rates for abnormalities on the ECG in patients with intracranial hemorrhage vary from 50% to 98% (3,10,17,19). Several larger series provide the best estimate of the frequency of ECG abnormalities. In 100 consecutive patients with acute stroke, 91% of patients with intracerebral or subarachnoid hemorrhage had abnormal ECG results (3). QT prolongation, increased T-wave amplitude, or prominent U waves were seen in 50% of patients. In another series of 45 patients with intracranial hemorrhage, ECG tracings from this group were compared with ECGs from a group of patients with ischemic stroke and a third group of age- and sex-matched general surgery patients who did not have a history of cerebrovascular or cardiovascular disease (19). Only 18% of the patients with intracranial hemorrhage had a normal ECG result compared with 46% in the ischemic stroke group and 75% in the control group. QTc prolongation occurred in 62% of the patients with hemorrhagic stroke, 18% of patients with ischemic stroke, and 11% of controls. Quantitative analysis of the QTc revealed that prolongation was particularly more frequent in the patients with intracerebral or intraventricular hemorrhage. Although there has been no definitive correlation between hemorrhage location and the ECG changes, several studies have noted an association between frontal lobe hemorrhage and QT prolongation (5,20).

The largest comparative series documenting specific ECG abnormalities in stroke patients included 150 stroke patients and 150 age- and sex-matched controls: 92% of stroke patients and 65% of controls had abnormal ECG results. Abnormal ECGs were found in 43 (98%) patients with intracranial hemorrhage. The most common ECG changes were QT prolongation, T-wave inversion, and prominent U waves. Few ECG findings characterized a particular stroke type. Atrial fibrillation was significantly more common in patients with cerebral embolus (47% vs. 9% for other stroke type), and QT prolongation was most common in patients with subarachnoid hemorrhage (71% vs. 39% for other stroke types). U waves were more common in patients with intracranial hemorrhage than in patients with other stroke types (25% vs. 8%). Prior ECG abnormalities were seen in 91% of stroke patients and 71% of controls. New ECG abnormalities at the time of stroke were identified in 74% of stroke patients and 14% of controls.

Supraventricular and ventricular arrhythmias as well as conduction abnormalities have been well documented in patients with intracranial hemorrhage (*e*Table 35D.0.1). Several observational series have reported arrhythmias in 47% to 90% of patients (10,11,21,22) and serious or life-threatening arrhythmias in 20% to 50% of patients with intracranial hemorrhage (21,23,24 and 25). However, because of diverse patient populations, the level of cardiac monitoring, and the severity of the disease state, the true incidence of specific arrhythmias is unknown.

The best data for the incidence of arrhythmias in stroke patients are from a large series reported by Di Pasquale and colleagues (21). Twenty-four-hour Holter monitor recordings were performed on 120 patients with subarachnoid hemorrhage: 96 of 107 patients (90%) with adequate recordings had arrhythmias. The most common arrhythmias were premature ventricular contractions (46%), sinus bradycardia (39%), sinus tachycardia (30%), sinus arrhythmia (30%), supraventricular premature complexes (27%), and sinoatrial block (21%) (*e*Table 35D.0.2).

***e*TABLE 35D.0.2** CARDIAC ARRHYTHMIAS AND TRANSIENT ST-SEGMENT CHANGES IN 107 PATIENTS WITH SUBARACHNOID HEMORRHAGE AND TECHNICALLY ADEQUATE HOLTER RECORDING

Holter findings	**Early stage (n = 62)**	**Late stage (n = 45)**	***p* value**
Ventricular premature complex	34	15	<.05
Nonsustained ventricular tachycardia	5	0	NS
Supraventricular premature complex	14	15	NS

From Di Pasquale G, Pinelli G, Andreoli A, et al. Holter detection of cardiac arrhythmias in intracranial subarachnoid hemorrhage. *Am J Cardiol* 1987;59:596–600, with permission.

Arrhythmias tended to be more frequent and severe in patients with recordings in the first 48 hours after onset of bleeding. The QTc interval was significantly prolonged in patients with malignant ventricular arrhythmias. Nearly one-half of the patients had hypokalemia on admission, and potassium levels were significantly lower in patients with ventricular arrhythmias in the first 48 hours. The site or extent of intracranial hemorrhage did not correlate with the presence or type of arrhythmia.

Severe life-threatening arrhythmias in patients with subarachnoid hemorrhage including torsades de pointes in the setting of marked QT prolongation have been reported (26,27,28,29,30 and 31).

The implications of arrhythmias are important because they can cause hemodynamic compromise that may have adverse effects on cerebral perfusion or may increase

the risk of further cerebral insult such as with atrial fibrillation. The presence of malignant ventricular arrhythmias or asystole has been reported as a univariable predictor of mortality after intracranial hemorrhage (10).

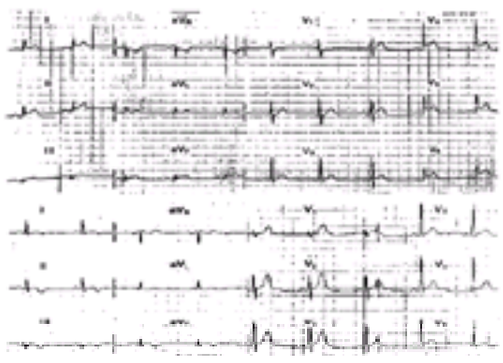
Management of Arrhythmias in Patients with Intracranial Hemorrhage or Ischemic Stroke

Management of patients with arrhythmias in the setting of intracranial hemorrhage has not been studied rigorously. Because of the high incidence of arrhythmias, continuous ECG monitoring is recommended, but there is no consensus about its required duration. Patients with QT prolongation should be monitored closely, and possible causative factors such as medications or electrolyte abnormalities should be identified and corrected. Patients with torsades de pointes have been treated with atrial or ventricular overdrive pacing or isoproterenol. Left stellate ganglion block has also been proposed in patients with recurrent arrhythmias (32).

Intracranial Hemorrhage and Electrocardiographic Changes Consistent with Acute Myocardial Infarction

Multiple cases of patients with intracranial hemorrhage and ECG changes consistent with acute myocardial infarction and normal coronary anatomy by cardiac catheterization or at autopsy have been reported (33,34,35,36,37 and 38). Although a rare clinical entity, physicians need to be aware that ECG changes and symptoms consistent with myocardial ischemia or acute infarction coexist with intracranial hemorrhage.

*e*Figure 35D.0.1 shows an ECG consistent with an acute myocardial infarction from a 30-year-old man with a several-day history of recurrent headache associated with nausea, vomiting, and chest pain. The patient was treated with streptokinase. The following day the headache recurred and computed tomography of the head revealed a large, left cerebellar hemorrhage. Coronary angiography revealed normal coronary arteries. An ECG 13 days later showed resolution of the ST-segment elevation (*e*Fig. 35D.0.1).



***e*FIGURE 35D.0.1** Electrocardiogram of a 30-year-old man with cranial trauma at admission and 13 days after admission. (From Kitching AD, Bernstein M, O'Kelly BF. Primary intracranial hemorrhage simulating acute myocardial infarction: a contraindication to thrombolytic therapy. *CMAJ* 1994;150:519–522, with permission.)

Intracranial hemorrhage associated with ECG evidence of acute myocardial infarction is uncommon. However, patients should undergo a thorough history and physical examination to avoid the catastrophic consequences of administering thrombolytic, anticoagulant, or antiplatelet therapy. Physicians should consider beta-blocker therapy in these patients, although there are no definitive supporting data.

Mechanisms of Electrocardiographic Changes and Arrhythmias in Patients with Intracranial Hemorrhage or Ischemic Stroke

Substantial work in experimental models and humans has been done to try to understand the pathogenesis of the ECG changes seen in patients with cerebrovascular events. The first comprehensive report of CNS control of cardiovascular function was proposed more than a century ago by Jackson (39). The most widely accepted mechanism by which lesions in the CNS result in changes in the ECG is a direct result of alterations in the autonomic nervous system control on cardiac electrophysiology. Several other processes are considered contributory, including a direct effect on the myocardium, consequences of the associated hemodynamic derangements, electrolyte abnormalities, alterations in circulating catecholamine levels, or concurrent coronary artery disease.

Experimental animal studies have strongly supported the belief that ECG changes associated with neurologic lesions are caused, at least in part, by altered sympathetic tone. Stimulation of various brain structures has resulted in specific ECG changes similar to those seen in patients with ischemic stroke and intracranial hemorrhage. Stimulation of the cortical surface of the frontal lobe (area 13) and the cingulate gyrus (area 24) caused increases or decreases in the blood pressure and changes in the heart rate (40). In cats, stimulation of the basal ganglia produced premature ventricular contractions, and stimulation of the posterior hypothalamus produced premature ventricular contractions and T-wave abnormalities (41). Many others have also reported ECG changes and arrhythmias with cortical, hypothalamic, and basal ganglia stimulation (42,43,44,45 and 46). The insula may also be an arrhythmogenic center based on several animal studies (47,48 and 49). ST-segment changes have also been associated with ablation or stimulation of sympathetic nerve fibers at the level of the stellate ganglion in dogs (50). Stimulation of the ganglion resulted in shortening of the ventricular recovery time, and ablation resulted in prolongation of the recovery time. This is particularly important because unilateral sympathetic stimulation and ablation resulted in localized effects on cardiac recovery. Unilateral stimulation or ablation of the right stellate ganglion resulted in effects in the anterior and superior ventricular walls, whereas left stellate ganglion manipulation resulted in changes in recovery time in the posterior and inferior walls. These changes resulted in specific abnormalities with ST elevation and inverted T waves during right stellate ganglion stimulation, and ST depression and peaked T waves during left stellate ganglion stimulation. Others have found more diverse ECG changes (51). These changes may be the substrate for ventricular arrhythmias.

A few studies performed during neurosurgery have investigated the cardiac effects of cortical stimulation. The cingulate gyrus, areas of the temporal lobes, and the frontal cortex have all been shown to have cardiovascular effects when stimulated (52,53,54 and 55). In addition, stimulation of the insula, because of its connections with other deep brain structures such as the limbic system and hypothalamus, may be associated with similar cardiovascular responses as seen in animal models (56,57). Specifically, stimulation of the left insular cortex can cause bradycardia and a vasodepressor response, whereas stimulation of the right insular cortex results in tachycardia and increased vasomotor tone (56). In reports based on human models, ECG changes similar to those seen in acute CNS events have been reported after right radical neck dissection (58) and during manipulation of the carotid body and stimulation of area 13 of the frontal cortex during aneurysm repair after subarachnoid hemorrhage (20). Sympathetic trunk ablation during surgery or stimulation of known vagal centers supports the hypothesis that centrally mediated alterations in sympathetic or vagal tone result in the observed ECG changes.

These observations led others to try to determine the neuroanatomic substrate for the ECG changes seen during provocative stimulation of cerebral structures. The ECG abnormalities in cats caused by cortical stimulation were reversed with transection of the spinal cord above the level of the sympathetic outflow tracts, suggesting that alterations in autonomic outflow may cause the cardiac findings (59). Others have proposed that changes in sympathetic and vagal tone and noradrenaline were all contributing factors for the ECG changes seen in an elaborate set of studies involving hypothalamic stimulation in cats (60).

Increased circulating catecholamine levels have been proposed by some to be a potential cause of the ECG abnormalities observed in patients with an acute neurologic event (61). ECG abnormalities in dogs after brain stimulation have been reversed by propranolol administration (46). In addition, increased levels of catecholamines in hearts of animals after brain stimulation have been documented (61). Others believe that ECG abnormalities are independent of elevated plasma norepinephrine levels (62), and measurements of urinary catecholamines in humans after cerebrovascular events have been inconclusive (63).

The ECG changes seen in patients with CNS disorders are not completely explained by alterations in catecholamine levels or changes in sympathetic or vagal tone. Patients with cerebrovascular disease are also at risk for cardiovascular disease. Hertzer and colleagues performed cardiac catheterization on 1,000 patients undergoing vascular surgery (64). In the subgroup of 295 patients with a primary diagnosis of cerebrovascular disease, 59% of the patients had significant coronary artery disease, and almost one-half (44%) of the patients without symptoms of coronary disease had significant stenosis, severe operable, or severe inoperable coronary atherosclerotic disease. Patients with coronary disease may manifest symptoms of cardiac ischemia and associated ECG changes during acute CNS processes. Transient coronary vasospasm may also contribute to the ECG changes. Abnormal electrolyte concentrations, particularly hypokalemia, may also contribute to some of the ECG findings seen in patients with intracranial hemorrhage. Vomiting is common in patients with increased intracranial pressure and elevated levels of circulating catecholamines, and cortisol may be responsible for the electrolyte abnormalities.

The pathogenic mechanism for arrhythmias has not been determined clearly. Experimental studies have demonstrated that injection of blood into the subarachnoid space is associated with the rapid onset of arrhythmias. Chronic elevations of intracranial pressure, however, typically cause bradyarrhythmias (65,66 and 67). Others have observed premature ventricular contractions and ventricular arrhythmias in anesthetized cats during stimulation of the hypothalamus, particularly the posterior

hypothalamus (1). Based on these animal models and clinical observations, several mechanisms for the arrhythmias have been proposed. Sudden increases in intracranial pressure cause compression on the brainstem and diencephalic structures, which results in increased sympathetic or vagal stimulation of the heart. Alterations in cerebral vascular tone may cause changes in systemic hemodynamics. Underlying coronary artery disease and hypertensive heart disease, which are common in patients with cerebrovascular disease, may be contributing factors in some patients (11). Hypoxia caused by respiratory compromise, elevated catecholamines, and electrolyte imbalances, particularly hypokalemia, may also contribute to the arrhythmias (21).

Myocardial Damage in Patients with Intracranial Hemorrhage and Ischemic Stroke

Some controversy remains as to whether ECG abnormalities observed in patients with acute ischemic stroke or intracranial hemorrhage are caused solely by alterations in autonomic control or whether they represent primary myocardial changes. Experimental studies have shown pathologic myocardial changes after intracranial blood injection in mice (68,69). Focal myocardial lesions consisting of infiltrates of lymphocytes or histiocytes, which displaced or replaced short segments of myocardium, were seen in 45% of rats with experimentally induced intracranial hemorrhage (70). Subendocardial hemorrhages have been reported after subarachnoid hemorrhage and stellate ganglion stimulation in animals (71,72). The incidence of these myocardial changes was dramatically reduced in rats treated with propranolol. Others have reported similar findings (73,74). Several investigators have shown focal necrosis, myofibrillar degeneration, and inflammatory cell infiltration in animals after catecholamine infusions or hypothalamic stimulation (73,75,76,77,78,79,80 and 81).

Despite numerous reports of patients with normal myocardium after stroke even in the presence of ECG changes (18,20,35,82), data from human autopsy series suggest that a subgroup of patients with acute ischemic stroke or intracranial hemorrhage may have abnormal myocardial pathology. In two autopsy series, 8% to 12% of patients with intracranial hemorrhage, tumor, infection, or head injury had foci of myocytolysis predominantly in the left ventricle, without evidence of infarction (63,83). Focal myocytolysis is often seen with myocardial infarction, but is a distinctive lesion. It was first reported by Schlesinger and Reiner (84). The characteristic features of myocytolysis are loss of sarcoplasm from focal areas of myocardium with retention of the cellular nuclei and sarcolemma.

Others have also reported myocardial damage in patients with cerebrovascular events, ranging from the changes consistent with myocytolysis to foci of necrosis (85,86 and 87). The cause of these myocardial findings is unknown but may be sympathetic cardiac stimulation or excessive catecholamine levels. The significance is also unclear, and it is unknown if they contribute to the ECG changes or the arrhythmias seen in patients with neurologic lesions.

Catecholamine elevations are well known to be a nonspecific response to stress and have been shown to be elevated in some patients with intracranial hemorrhage (61). Myocardial lesions, similar to those in animal studies, have been reported in patients with pheochromocytoma (88). In addition, corticosteroids may potentiate the catecholamine effects on the myocardium and have been shown to be elevated in the majority of patients with subarachnoid hemorrhage (89).

Epilepsy

Cardiac arrhythmias are common during partial and generalized seizure activity and may be associated with significant morbidity and mortality. In several series, sinus tachycardia was the most common arrhythmia and was present during 97% of ictal episodes. By contrast, severe or life-threatening arrhythmias were present in only 5% of patients (90,91,92 and 93). There have been numerous reports of cardiac arrest and asystole associated with seizure activity, and undiagnosed seizure disorders have presented as unexplained syncope (94,95,96,97 and 98).

Even when accidental deaths that might be associated with seizure activity are discounted, epileptic patients are at significantly higher risk of sudden death than the general population (99,100). Several epidemiologic studies have suggested that sudden unexplained death may account for more than 10% of deaths in an epileptic population (99,100). Sudden death is usually attributed to neurogenic cardiac arrhythmias, although it is possible that neurogenic pulmonary edema may play a role in this phenomenon (101). There is no evidence that patients with epilepsy have a higher rate of occult cardiac disease than the general population, and many of the patients experiencing sudden death do not have known cardiac risk factors. Several series have suggested that risk factors include the presence of a structural CNS lesion, noncompliance with anticonvulsant medication, young age, and poorly controlled generalized seizures (99). As opposed to nonepileptic patients with sudden cardiac death, the cardiac pathology is usually unremarkable, although one series has reported evidence of focal areas of subendocardial fibrosis (101,102,103 and 104). These lesions could have many etiologies, although a sustained increase in sympathetic tone may cause a similar pattern of injury.

The possibility that temporal lobe discharges may produce cardiac arrhythmias is supported by animal and clinical studies. In a rat model, the stimulation of the insular cortex caused changes in cardiac rhythm. Oppenheimer and Cechetto have demonstrated chronotropic organization in this model, with the stimulation of the rostral insula causing tachyarrhythmias, and the stimulation of the caudal insula resulting in bradyarrhythmias (49). This work was extended in a clinical study examining the effects of intraoperative stimulation before temporal lobectomy for seizure control. Although there was variability between individuals, tachycardia and pressor responses were more often elicited from the stimulation of the right insular cortex, whereas bradycardia and vasodepressor responses were more common with stimulation of the left insular cortex (56). In clinical practice, however, a close correlation between type of arrhythmia and seizure focus has never been established, although some studies have suggested that temporal lobe seizures may be more arrhythmogenic (105,106).

Migraine Headache

The precise etiology of migraine headaches is unknown. Migraine headaches are generally thought to be associated with arterial vasomotor and autonomic nervous system abnormalities. There are reports of typical angina-like chest pain and myocardial infarction in patients during the acute phase of a migraine headache. A generalized vasospastic disorder has been suggested to explain these findings (107,108). Ischemic ECG changes have been reported with normal coronary angiography, supporting coronary spasm as the cause of ischemia (107,108). Sympathetic function is impaired in some patients with migraine headaches (109). Several studies of ambulatory ECG monitoring have shown altered autonomic innervation of the heart in patients with migraine compared with controls (110,111 and 112).

Common medications used to treat migraine headaches can also have cardiac effects. Ergot compounds and sumatriptan are the two most common therapies used in aborting migraine headache. Dihydroergotamine has a high affinity for 5-HT_1, 5-HT_2, dopamine, and other catecholamine receptors (113). Ergotamine has been shown to precipitate coronary spasm and chest pain in patients with migraine (114). Sumatriptan has a more specific agonist of the presynaptic and postsynaptic 5-$HT_{1B/D}$ receptor and works by constricting large intracranial vessels and blocking neurogenic inflammation (115). Sumatriptan has produced chest pain syndromes (116), and although it may affect blood pressure, the symptoms are generally not associated with ECG changes (117,118). Both agents have the potential for coronary vasoconstriction and are contraindicated in patients with ischemic heart disease or variant angina. Patients with multiple risk factors for ischemic heart disease should undergo evaluation for coronary artery disease, including ECG and stress testing before initiating therapy. Based on the success of sumatriptan, several oral second-generation triptans have also been developed, including zolmitriptan, rizatriptan, and naratriptan. Although experience with these newer agents is more limited and there are conflicting reports regarding their potential for coronary vasoconstriction, all of these drugs maintain the same precautions and contraindications as sumatriptan regarding administration to patients with coronary artery disease.

Meningitis and Encephalitis

Cardiac abnormalities may occur in patients with meningitis and encephalitis. Alterations in CNS function caused by increased intracranial pressure or involvement of specific neurologic centers known to be key in autonomic control of the heart can result in ECG abnormalities or arrhythmias.

Meningitis has been associated with several nonspecific ECG changes. Prominent P waves and U waves have been reported in 30% to 40% of patients with meningitis in one series (82). ST elevation and sinus arrhythmias were noted in one-third of the patients. QTc prolongation was not observed, and T-wave inversion was seen in only 15% of patients. Another series including echocardiographic analysis noted systolic filling abnormalities in more than 50% of patients with meningitis, but only 10% had ST-T–wave changes or QTc prolongation (119). In addition, ECG changes and arrhythmias, including sick sinus syndrome, sinus node dysfunction, complete heart block, and premature supraventricular and ventricular complexes, have been reported (82,120,121).

Encephalitis can cause severe neurologic sequelae, resulting in cardiac arrhythmias caused by compromise of respiratory or other organ dysfunction. In a systematic review of 26 noncomatose patients with encephalitis, 10 patients (38%) had abnormalities on the ECG, including sinus arrhythmia, sinus tachycardia, sinus bradycardia, sinus arrest, ST-segment changes, premature ventricular complexes, and T-wave changes (122). No QT prolongation was noted. Others have reported torsades de pointes (123) and bifascicular block (124) in patients with encephalitis.

Cranial Trauma

Patients with cranial trauma can have ECG changes and arrhythmias similar to patients with intracranial hemorrhage. In an extensive review, ECG tracings from 164 patients younger than 40 years and without a history of cardiovascular disorder were compared with those from 100 patients with limb injury, and 164 healthy age- and

sex-matched controls. Patients with head injury had an increased frequency of QTc prolongation (15% vs. 0% to 1% in other groups), increased P-wave amplitude (24% vs. 2% to 14% in the other groups), and T-wave inversion (10% vs. 0% to 6% in other groups). The incidence of ECG abnormalities increased with worsening level of consciousness. ST elevation and prominent U waves occurred in 14% to 21% of patients with limb or head trauma, without increased frequency in the head trauma group (125). Others have reported sequential ECG changes in a patient with severe cranial trauma suggestive of acute myocardial infarction, but no evidence of structural heart disease at autopsy (126).

Experimental models of head trauma in mice revealed that all mice developed increased T-wave amplitude and multiple arrhythmias, including sinus arrhythmia, premature ventricular contractions, and sinus and atrioventricular nodal block. A second group of mice pretreated with atropine did not develop significant arrhythmias. The authors proposed that these findings supported the role of vagal stimulation in the genesis of arrhythmias in the setting of head trauma (127).

NEUROMUSCULAR DISORDERS WITH CARDIAC MANIFESTATIONS

Cardiac disease may be associated with the major types of diseases of the peripheral nerves, the neuromuscular junction, and the muscles with varying characteristics and severity. The cardiac manifestations and the clinical features of the neuromuscular disorders are heterogeneous. In some disorders, the most distinguishing feature is a cardiomyopathy, whereas in other disorders, conduction abnormalities are prominent (eTable 35D.0.3). The cardiac involvement can be minimal or life threatening. Several of the more common and clinically important diseases are reviewed here.

***e*TABLE 35D.0.3** CARDIAC MANIFESTATIONS OF NEUROMUSCULAR DISORDERS
Neuromuscular disorders commonly associated with electrocardiographic abnormalities

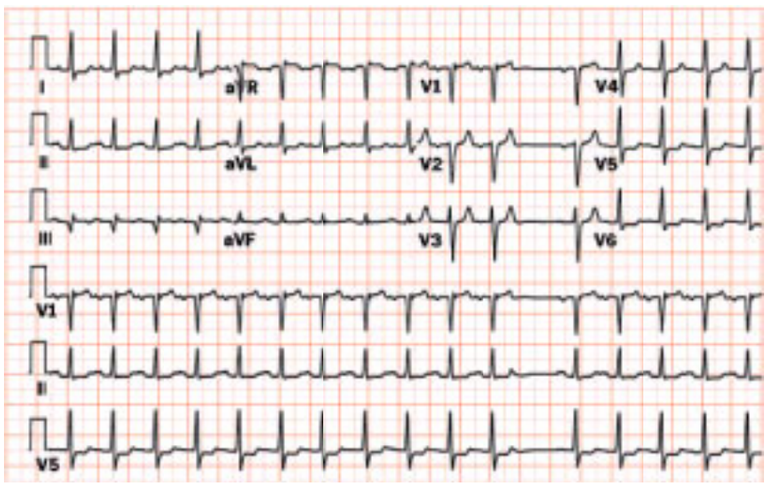
Peroneal muscular atrophy
Neuromuscular disorders commonly associated with cardiomyopathy
Duchenne's muscular dystrophy
Becker's muscular dystrophy
Centronuclear myopathy
Myasthenia gravis

Disorders of Peripheral Nerves

Guillain-Barré Syndrome

Guillain-Barré syndrome is an acute autoimmune polyneuropathy that involves inflammation and demyelination of nerves and is classically characterized by ascending motor weakness and areflexia. The diagnosis is supported by a compatible clinical presentation, cerebral spinal fluid findings of albuminocytologic dissociation, and electrodiagnostic evidence of acute demyelination. Autonomic and cardiac complications in patients with Guillain-Barré syndrome are more common than generally recognized and may significantly complicate medical management.

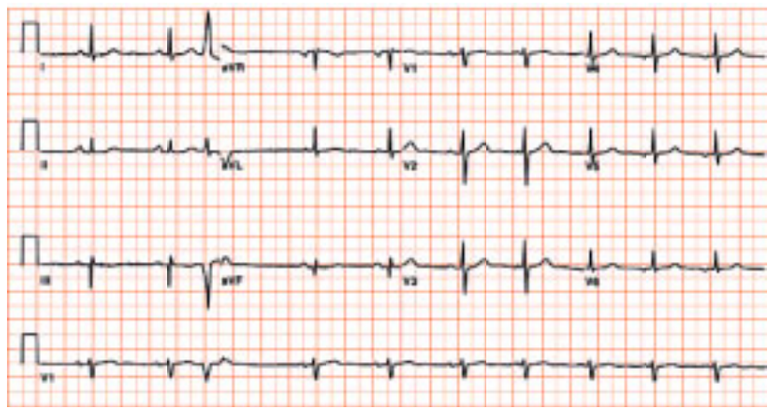
Cardiac involvement in Guillain-Barré syndrome was initially described by Sir William Osler in 1892, who made the observation that some patients with "acute febrile neuritis" succumbed to "paralysis of the heart" (128). Cardiac arrhythmias are also common. Sinus tachycardia has been reported in 45% to 79% of patients (129). Bradyarrhythmias, sinus pauses, and asystole are also common and may portend cardiac arrest (130). Some authors recommend prophylactic pacemaker insertion for patients with clinically significant bradycardias or sinus pauses (131,132 and 133). Although bradyarrhythmias may occur spontaneously, patients often exhibit vagal hypersensitivity to suctioning, and care should be taken to preoxygenate adequately, suction gently, and administer atropine when appropriate.



Sinus tachycardia with blocked premature atrial contraction. Premature atrial beat fails to conduct, producing a pause.

Other arrhythmias and conduction abnormalities, although less common, have been described: atrial fibrillation, atrial flutter, paroxysmal atrial tachycardia, and ventricular tachycardia (130,131,134). Cardiac involvement usually parallels severity of disease, and patients at the highest risk for malignant arrhythmias are often ventilator dependent and have more fulminant disease progression. ECG abnormalities have also been described in Guillain-Barré syndrome, with nonspecific ST-T–wave changes observed most commonly (130).

Acute inferior myocardial infarction complicated by atrial fibrillation. Note ST-segment elevation in the inferior leads with reciprocal changes laterally. Atrial fibrillation has complicated this acute infarct.



A 76-year-old male patient with paroxysmal ectopic atrial rhythm.

A 59-year-old female patient with atrial flutter with 4:1 atrioventricular conduction.

Autonomic neuropathy is commonly associated with Guillain-Barré syndrome and may be associated with cardiac dysfunction. Early evidence of autonomic dysfunction may become clinically manifest as abnormalities of bladder function, gastroparesis, abnormal pseudomotor activity, or blood pressure lability. Formal autonomic testing has revealed subclinical evidence of neuropathy in two-thirds of patients with Guillain-Barré syndrome. It is difficult to get a true measure of the clinically relevant autonomic neuropathy in Guillain-Barré syndrome, as most of the published observations are case reports or small series. Hypertension is common, with a reported incidence of 5% to 79%. Clinically significant hypotension may also occur and is often exacerbated by impaired venous return to the heart caused by positive pressure ventilation and paralysis of the calf and abdominal musculature. The occurrence of dysautonomia in Guillain-Barré syndrome is most likely caused by a failure of baroreflex buffering mechanisms due to deafferentation of baroreceptor impulses.

Recognition of the features of early dysautonomia in the setting of Guillain-Barré syndrome is important. Patients with these symptoms are at increased risk for developing cardiac arrhythmias, especially AV block. Identification of this population with autonomic screening tests has met with limited success (135,136). It is probable that fulminant autonomic neuropathy with inflammation of the small intramyocardial nerves is responsible for the focal myocarditis described in Guillain-Barré syndrome (137). A dysautonomia-induced hypersympathetic state may also be responsible for acute reversible left ventricular dysfunction in these patients (138).

Friedreich's Ataxia

Friedreich's ataxia is an autosomal recessive neurodegenerative disease characterized by progressive ataxia, areflexia, proprioceptive loss, and upper motor neuron findings. When strict neurologic and genetic criteria for this disorder were met, cardiac involvement was reported in more than 90% of the patients (139,140). No correlation between severity of neurologic and cardiac disease has been confirmed.

The most common cardiac abnormality in patients with Friedreich's ataxia is concentric left ventricular hypertrophy (141,142). The cardiac pathology in this disorder is differentiated from genetic hypertrophic cardiomyopathy by the lack of cellular disorganization in the ventricular septum. Echocardiographic assessment of systolic and diastolic function is usually normal. The concentric hypertrophy associated with Friedreich's ataxia also tends to have a more benign course than hypertrophic cardiomyopathy, and malignant arrhythmias are distinctly uncommon (143).

A minority of patients with Friedreich's ataxia may develop a dilated cardiomyopathy associated with global hypokinesis. Although much less common than concentric left ventricular hypertrophy, this carries a worse prognosis, and patients usually experience progressive deterioration of cardiac function (144). Symptomatic atrial and ventricular arrhythmias are more common in this subgroup (139).

Peroneal Muscular Atrophy

Peroneal muscular atrophy includes two autosomal dominant genetic disorders collectively called *Charcot-Marie-Tooth neuropathy*. The clinical features include progressive distal lower extremity muscle weakness that begins in the second or third decade of life. Peroneal muscular atrophy does not normally involve the heart. Atrial flutter has been reported (145), but more common findings are conduction disturbances with complete heart block and right bundle branch block, which have been reported in several members of a family (146,147 and 148).

Disorders of the Neuromuscular Junction

Myasthenia Gravis

Myasthenia gravis is caused by an autoimmune process that results in a decrease in the number of acetylcholine receptors at the neuromuscular junction. It affects women more frequently than men and can appear at any age, with increased frequency in the third and fourth decades in women and the sixth and seventh decades in men. Weakness and fatigue are the classic symptoms, with weakness worsening after repeated use and improving after periods of rest.

Substantial data support the association with myocardial disease, particularly with malignant thymoma, although the nature and pathology of this process are unresolved. The cardiac abnormalities may represent a progressive autoimmune process or coincidental findings from other disease processes. Typical cardiac manifestations include nonspecific ECG changes, arrhythmias, and heart failure. The ECG changes have been reversed with neostigmine treatment. Drugs used to treat arrhythmias and cardiac disease, such as quinidine, procainamide, lidocaine, and calcium channel blockers, should be used with caution as they can exacerbate symptoms of myasthenia gravis (149,150).

Disorders of Muscle

Cardiac dysfunction is relatively common with primary disorders of muscle. In some circumstances, these cardiac abnormalities are potentially life-threatening, and cardiac evaluation is an important aspect of the clinical management of these patients. In Duchenne's muscular dystrophy, a dilated cardiomyopathy is present in virtually all patients by the age of 18 years, and management of associated heart failure is an important component of care. In other conditions, such as myotonic dystrophy and polymyositis, the conduction system is preferentially affected and may lead to clinically important arrhythmias or sudden cardiac death. Table 35D.1 summarizes the key neurologic features and cardiac manifestations of these primary muscle disorders.

TABLE 35D.1 DISORDERS OF MUSCLE ASSOCIATED WITH CARDIAC MANIFESTATIONS

Duchenne's and Becker's Muscular Dystrophy

Duchenne's muscular dystrophy is an X-linked recessive disorder with an incidence of 1:3,300 male births (151). This disorder, which is caused by a mutation in the dystrophin gene, usually presents in early childhood with severe and progressive muscle wasting. Death usually occurs by the third decade of life and is caused by respiratory and cardiac compromise.

Cardiac abnormalities are common in Duchenne's muscular dystrophy and include ECG changes, dilated cardiomyopathy, and arrhythmias. Up to 90% of patients with Duchenne's muscular dystrophy have characteristic electrographic abnormalities, which include the presence of tall precordial R waves, an increase in R/S ratio in V_1, and deep, narrow Q waves in the left precordial leads (152,153). Rhythm disturbances are also quite common. The majority of patients have sinus tachycardia, which may be either sustained or labile (14). AV block is less common but has been reported. Accelerated AV conduction may lead to a decrement in the PR interval (154). Dilated cardiomyopathy is also common in Duchenne's muscular dystrophy, and heart failure may be the terminal event in 10% of patients (155). Pathologically, patients with Duchenne's muscular dystrophy demonstrate extensive myocardial fibrosis, most prominently in the posterobasal left ventricular wall (154,156,157). There is usually selective sparing of the septum, right ventricle, and atrium. Degenerative changes of the conduction system have also been described (152). Given the absence of dystrophin in all cells, it is unclear why this pattern of selective myocardial involvement occurs.

Clinical management of cardiac complications in patients with Duchenne's muscular dystrophy is an important aspect of their care. In a large, longitudinal study of more than 300 patients, preclinical evidence of cardiac involvement was present in approximately one-fourth of patients younger than 6 years. Clinically apparent cardiomyopathy typically appeared by age 10 years and was present in virtually all patients by age 18 years (158). Surprisingly, given the prevalence and severity of these cardiac abnormalities, most patients usually remain relatively asymptomatic until late in the course of their disease. This may be because of the disproportionate involvement of the muscles of respiration and because these cardiac abnormalities develop slowly enough to allow some degree of compensation (159). In approximately 10% of patients, the proximal cause of death is directly referable to a cardiac cause (155). Female carriers are not usually symptomatic, although ECG abnormalities have been reported (160).

Becker's muscular dystrophy is a milder variant of Duchenne's muscular dystrophy, which is also caused by a mutation of the dystrophin gene. Becker's dystrophy is characterized by a much later onset of weakness and less fulminant progression. Only 10% of patients are wheelchair bound by the fifth decade of life (161). Cardiac abnormalities are similar to those seen in Duchenne's muscular dystrophy, although usually not as severe. Up to 75% of patients with Becker's muscular dystrophy develop cardiac abnormalities, although the majority of these are subclinical. A subset of patients may develop severe cardiomyopathy, often disproportionate to the degree of skeletal muscle weakness (162,163). It is usual for congestive heart failure to be a presenting symptom (164). Thus, longitudinal noninvasive assessment of cardiac function is warranted in patients with Becker's muscular dystrophy. When cardiac failure occurs, symptoms may develop precipitously. Initial management should include diuretics and afterload reduction. Because Becker's muscular dystrophy is associated with a near normal life expectancy, cardiac transplantation has been performed in these circumstances (165).

Myotonic Dystrophy

Myotonic dystrophy is characterized by myotonia, muscle weakness, frontal balding, cataracts, and gonadal dysfunction. It is an autosomal dominant disease, which is caused by an unstable triple repeat expansion in chromosome 19. A variety of cardiac disturbances have been associated with myotonic dystrophy, including conduction abnormalities, mitral valve prolapse, and cardiomyopathy. These usually become clinically symptomatic several years after the onset of other symptoms associated with myotonic dystrophy.

Conduction disturbances account for the most common abnormality in this condition. Approximately 90% of patients with myotonic dystrophy eventually have ECG abnormalities (166). The most frequent abnormalities are first-degree AV block and intraventricular conduction delay (167,168). In one series, first-degree AV block was seen in approximately two-thirds of patients, and one-third had right bundle branch block or left anterior hemiblock. Left bundle branch block was less common (169). These conduction disturbances are probably progressive, but only a few small longitudinal studies have evaluated the natural history.

Approximately one-fourth of patients have evidence of mitral valve prolapse, although the significance of this is unclear given the high prevalence of this condition in the general population (170,171). In one of the few series examining the cardiac pathology of patients with myotonic dystrophy, fibrosis and fatty infiltrate of the sinoatrial and AV nodes, conduction system, and ventricular walls were noted (172). Recognition of the high incidence of cardiac pathology plays an important role in the management of patients with myotonic dystrophy. In general, the cardiac abnormalities associated with myotonic dystrophy are relatively well tolerated, although 7% of patients have clinical evidence of heart failure, and sudden cardiac death has been reported (173,174).

Periodic Paralysis

There are several forms of familial, or primary, periodic paralysis (175). Hypokalemic periodic paralysis is associated with low potassium at the onset of the paralytic attack. Hyperkalemic periodic paralysis is characterized by increased potassium concentrations at the initiation of the episodes, but normal serum potassium concentrations are common (176). These primary periodic paralyses have some common features. They are generally inherited as autosomal dominant traits with symptoms first recognized early in life and uncommonly after the third decade. Attacks of paralysis are characterized by weakness of the limbs, proximal more than distal, with respiratory muscles rarely involved. Other common features include susceptibility after strenuous exercise, termination of attacks with mild exercise, normal function between attacks (although persistent weakness may develop after years of repeated episodes), and precipitation of attacks with cold.

Cardiac manifestations include the classic ECG abnormalities associated with alterations in serum potassium concentrations. Ventricular electrical instability can occur with premature ventricular complexes, fusion beats, multiple ventricular complexes, and ventricular tachycardias, including bidirectional ventricular tachycardia, which can be treated with potassium supplementation in the hypokalemic variety and epinephrine or glucose and insulin for the hyperkalemic or normokalemic types (177,178,179 and 180).

Limb-Girdle Dystrophies

The limb-girdle dystrophies include several disorders. Autosomal recessive and autosomal dominant inheritance has been reported in different families. Muscle weakness begins in the first to fourth decades, generally in the proximal lower extremity first and the upper extremities later, with variable progression (181). Cardiac involvement is uncommon but can include nonspecific ECG changes, arrhythmias, and conduction system disturbances. Rarely, a cardiomyopathy can occur with heart failure (182,183).

Facioscapulohumeral Dystrophy

Facioscapulohumeral dystrophy is an autosomal dominant disorder characterized by onset of weakness in the first or second decade. Facial muscle weakness is generally the initial manifestation. Subsequent involvement of the upper extremities is followed by proximal lower extremity weakness. Cardiac involvement is extremely uncommon. There are sporadic cases of cardiomyopathy and conduction abnormalities. The rare entity of atrial paralysis or standstill has been reported with a familial occurrence associated with facioscapulohumeral dystrophy (184,185,186 and 187).

X-Linked Humeroperoneal Dystrophy

Typical clinical presentation is proximal upper extremity and distal lower extremity weakness beginning in the first decade of life. Progression is slow and often stabilizes by the second decade, but contractures may develop. Cardiac involvement is common and appears to exclusively affect the atrium (188). Atrial fibrosis and myocyte degeneration may occur. ECG abnormalities include small P waves, atrial fibrillation, atrial flutter, atrial paralysis, and varying degrees of AV block. Permanent ventricular pacing is recommended.

Scapuloperoneal Syndrome

Scapuloperoneal syndrome is an X-linked myopathy characterized by weakness of the shoulder girdle and distal lower extremities. Cardiac abnormalities appear to be isolated to the conduction system, and complete heart block and sudden cardiac death have been reported, generally in the third or fourth decade (189,190).

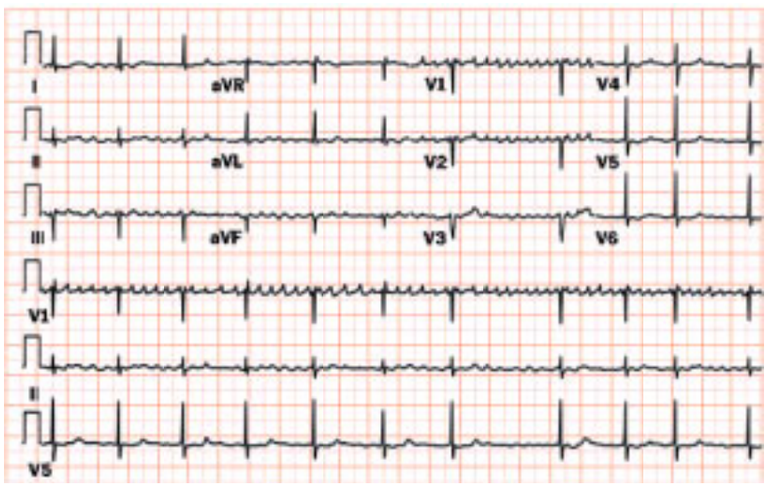
Centronuclear Myopathy

Centronuclear myopathy is a slowly progressive disease characterized by skeletal muscle wasting and characteristic central nuclei on histologic examination (191). There are several forms of the disease with onsets at birth, early childhood, or later in early adulthood. Familial occurrence is reported, but there is no definitive inheritance pattern established. Ptosis of the eyelids is almost universal, as well as hyporeflexia or areflexia. A cardiomyopathy has been described with extensive fibrosis, dilatation, and focal compensatory hypertrophy (192,193 and 194). Progressive heart failure and death can occur at an early age (192).

Polymyositis

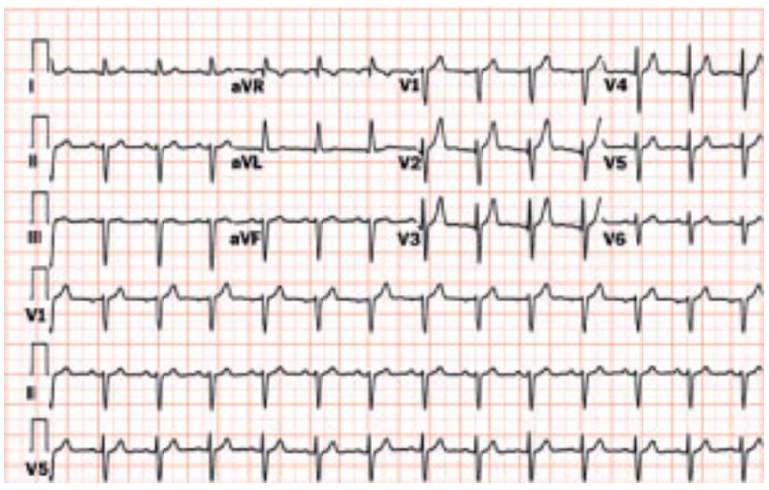
Polymyositis is a nonsuppurative inflammatory process of skeletal muscle and thought to be caused by genetic factors, viral infections, and autoimmune mechanisms. The heart is infrequently involved. The myocardium can have diffuse interstitial and perivascular mononuclear infiltrates, muscle fiber degeneration, and fibrosis (195,196). The conduction system, including the sinoatrial node, bundle of His, and left and right bundle branches, can be involved with similar histologic changes (197,198). Several series have found ECG changes and arrhythmias in more than one-half of the patients (199,200).

ECG abnormalities include atrial fibrillation, atrial flutter, atrial and ventricular premature complexes, AV conduction delay, and bundle branch blocks. Echocardiographic or cardiac catheterization findings include mitral valve prolapse and enhanced cardiac function (200,201). Contrary to these data, a cardiomyopathy with congestive heart failure also has been reported (196,202). It has not been clearly demonstrated that the cardiac abnormalities observed in polymyositis are caused by the same process involving the skeletal muscle disease or whether they represent a coincidental finding or are caused by treatment of the primary disease by agents such as corticosteroids. The high frequency rate of the findings suggests a common pathology.



Atrial fibrillation. Narrow complex QRS with irregular RR intervals. Ventricular rate is controlled.

Atrial flutter. Inverted "saw-tooth" waves in the inferior leads suggest typical atrial flutter.



Left anterior fascicular block. Note left-axis deviation and small Q waves in leads I and aVL. Small Q wave in lead V_4 strongly suggests anterior myocardial infarction.

Left bundle branch block. Wide QRS complex, negative in lead V_1, is associated with secondary T-wave inversions.

Trifascicular block. Note right bundle branch block, left anterior hemiblock, and associated first-degree atrioventricular block.

Kearns-Sayre Syndrome

The mitochondrial myopathies are a heterogeneous collection of diseases characterized by abnormal muscle fibers. Cardiac involvement is rare. The Kearns-Sayre syndrome, however, is characterized by the triad of progressive external ophthalmoplegia, retinal pigmentary degeneration, and heart block (203). The syndrome is generally thought to be acquired, afflicting both sexes equally, with onset before the age of 20. Common features include ataxia, hearing loss, dementia, short stature, delayed secondary sexual characteristics, peripheral neuropathy, and endocrine abnormalities.

Cardiac abnormalities almost exclusively involve the conduction system. Characteristic conduction abnormalities are right bundle branch block, left anterior fascicular block, and atrioventricular block (204,205 and 206). A normal PR is common because of the selective infranodal involvement. Sudden death has been recognized, and pacemaker insertion is recommended (207).

CARDIOVASCULAR ABNORMALITIES IN NEURODEGENERATIVE DISEASES

Parkinson's Disease

Cardiovascular abnormalities are common in Parkinson's disease and may be challenging to manage. In particular, autonomic dysfunction is prevalent, and orthostatic hypotension often exacerbates postural instability, one of the hallmarks of this neurodegenerative disorder. Lewy bodies, the eosinophilic cytoplasmic inclusions characteristic of Parkinson's disease pathology, have been identified throughout the autonomic nervous system, including the hypothalamus, sympathetic system (thoracic intermediolateral nucleus and sympathetic ganglia), and parasympathetic system (dorsal vagal nucleus and parasympathetic nuclei). Of note, there is also evidence of cardiac sympathetic denervation, and Lewy bodies have been identified in the cardiac plexus (208). Myocardial imaging with ^{123}I-metaiodobenzylguanidine has demonstrated functional loss of cardiac sympathetic tone associated with these anatomic abnormalities (209). Interestingly, the marked decrease in myocardial ^{123}I-metaiodobenzylguanidine uptake appears to be specific for Parkinson's disease and may have some diagnostic value in differentiating atypical Parkinson's disease from other neurodegenerative disorders associated with extrapyramidal features (209). These abnormalities in cardiac autonomic tone seen in Parkinson's disease may also have contributed to several sporadic cases of sudden cardiac death associated with a prolonged QTc interval (210).

Alzheimer's Disease

Although less systematically studied, dysautonomia has also been described in Alzheimer's disease (211). Vascular disease is also associated with dementia and is often difficult to clinically distinguish from Alzheimer's disease. A large population-based study in Rotterdam explored the relationship between atherosclerosis and dementia. Evaluation of 284 demented patients and 1,698 healthy controls revealed that the odds ratio for Alzheimer's disease in those with severe disseminated atherosclerosis compared with those with normal vasculature was 3.0 (212). Although the biology for the association between atherosclerosis and Alzheimer's disease remains undefined, presence of the APOE4 allele appears to be a risk factor. Patients with atherosclerotic cerebrovascular disease and Alzheimer's disease have a higher prevalence of the apolipoprotein E_4 genotype.

CONTROVERSIES AND PERSONAL PERSPECTIVES

A large clinical interface between the practices of cardiology and neurology is becoming increasingly apparent. As cardiac and neurologic intensivists, we see this in a number of situations. The advent of specialized neurocritical care units in parallel with coronary care units is but one example. Another is the American Heart Association emphasis on diagnosis and treatment of "brain attack." We continue to focus on the breakdown of subspecialty barriers because with this approach we will optimize the clinical management of these patient populations.

THE FUTURE

Intensive collaboration between cardiologists and neurologists is ongoing and will result in incredible advances in our understanding of disease mechanisms and therapeutic interventions. Studies evaluating the ability of the brain to withstand ischemic insults, exploration of the use of glycoprotein IIb/IIIa inhibitors and other anticoagulants in patients with both cardiovascular and cerebrovascular disease, and investigation of diagnostic strategies with various biomarkers to diagnose stroke and myocardial infarction are being conducted. Furthermore, as the genetic basis of diseases continues to be unraveled, there will be tremendous opportunities to gain further understanding of the relationships between neuromuscular disorders and associated cardiac manifestations. Work in the basic sciences, clinical trials, and the important translation of scientific discoveries to the bedside will provide ample opportunity in the coming years for cardiologists and neurologists to work together on exciting projects.

OVERVIEW

The rheumatic diseases are a heterogeneous group of illnesses with protean manifestations and multisystem organ involvement. Although each individual disorder is relatively rare, together they represent important causes of morbidity and mortality worldwide. It is not at all unusual for specialists in cardiovascular medicine to encounter patients with these disorders in the office setting, hospital, or emergency department. Cardiac manifestations range from unusual to prominent (Table 35E.1) and from mild to dramatic. Occult cardiovascular involvement is common, is frequently detectable on noninvasive studies, and has important prognostic implications. Cardiovascular death is common, may be due to disease-specific cardiac involvement or secondary effects of disease on the heart, and underscores the importance of primary and secondary preventive strategies in this patient population (Table 35E.2).

Disorder	Pericardial	Valvular	Myocardial	Coronary	Arrhythmic
Systemic lupus erythematosus	25%	Rare	5%–10%	Rare	Rare
Rheumatoid arthritis	10%	Rare	Rare	Rare	Rare
Systemic sclerosis	7–10%	–	10%	–	10%
Kawasaki disease	Rare	1%	30%	20%,[a] 8%[b]	rare
Takayasu's disease	2%	1–20%	Rare	5–10%	1%
Ankylosing spondylitis	Rare	10–20%	Rare	Rare	10%
Churg-Strauss syndrome	20–32%	–	13–48%	Rare	Rare
Polyarteritis nodosa	2–3%	–	10%	5%	Rare
Giant cell arteritis/temporal arteritis	Rare	5–10%[c]	Rare	Rare	–
Wegener's granulomatosis	6–10%	Rare	2%	1%	1–2%
Polymyositis/dermatomyositis	1%	Rare	5%	–	6%

TABLE 35E.1 INCIDENCE OF CLINICAL CARDIAC MANIFESTATIONS OF SELECT RHEUMATIC DISORDERS

Disorder	Annual incidence per million population	Clinical cardiac involvement	Cardiac involvement on autopsy	Most common causes of death
Systemic lupus erythematosus	40–80	50%	>60%	Renal, infection, cardiac
Rheumatoid arthritis	250–500	10–15%	>30%	Cardiac, infection, cancer
Systemic sclerosis	18	10%	>30%	Renal, cardiac, pulmonary
Kawasaki disease	105 (Japan); 5–15 (United States)	1–5%	>80%[a]	Cardiac
Takayasu's disease	2.6	20–30%	20–30%	Cardiac, stroke
Ankylosing spondylitis	70	10–20%	20%	Cardiac, stroke, pulmonary
Churg-Strauss syndrome	2.4	40–60%	>60%	Cardiac, renal, stroke
Polyarteritis nodosa	7	10–30%	>60%	Renal, stroke, cardiac
Giant cell arteritis	170[b]	5–10%[c]	5–10%[c]	Cardiac, stroke, renal
Wegener's granulomatosis	8.5	10–40%	>60%	Infection, cardiac, renal
Polymyositis/dermatomyositis	10	6–10%	>25%	Infection, cancer, cardiac

TABLE 35E.2 DISEASE INCIDENCE, FREQUENCY OF CARDIAC INVOLVEMENT, AND CAUSES OF DEATH IN PATIENTS WITH SELECT RHEUMATIC DISORDERS

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an autoimmune disorder characterized by antibodies against a variety of cellular antigens, resulting in multisystem organ dysfunction. Biett (1) first described the dermatologic manifestations of SLE in 1828. Nearly a half-century passed before it was recognized that SLE involved organs other than the skin, and not until a half-century after that was histopathologic proof of cardiac involvement systematically described by Libman and Sacks (2). Because of the protean manifestations of the disease, a diagnosis of SLE relies on the fulfillment, over time, of four criteria from a list of specific laboratory, histologic, and clinical findings (3). The most common presenting signs and symptoms are polyarthritis and dermatitis (4).

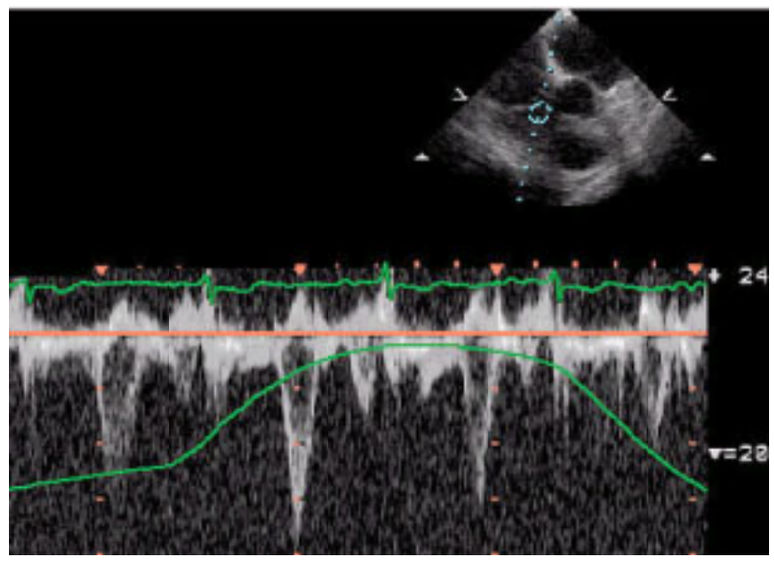
Discoid lupus. The skin lesion shown is raised and scaly, with an erythematous rim, and associated with follicular plugging and telangiectasia (*arrows*).

SLE affects 40 to 50 per 100,000 individuals (5) and has an annual incidence of 4 to 8 in 100,000 worldwide. Survival rates among patients with SLE have improved dramatically with the introduction of corticosteroid therapy and advances in supportive care. The most common causes of death in patients with SLE are active SLE (particularly nephritis), infection, and cardiovascular events (6,7). Current 5-, 10-, and 20-year survival rates are estimated to be 93%, 85%, and 68%, respectively (7). Mortality analyses have shown a reduction in the percentage of deaths due to active SLE and an increase in the percentage of deaths due to infection and cardiovascular disease.

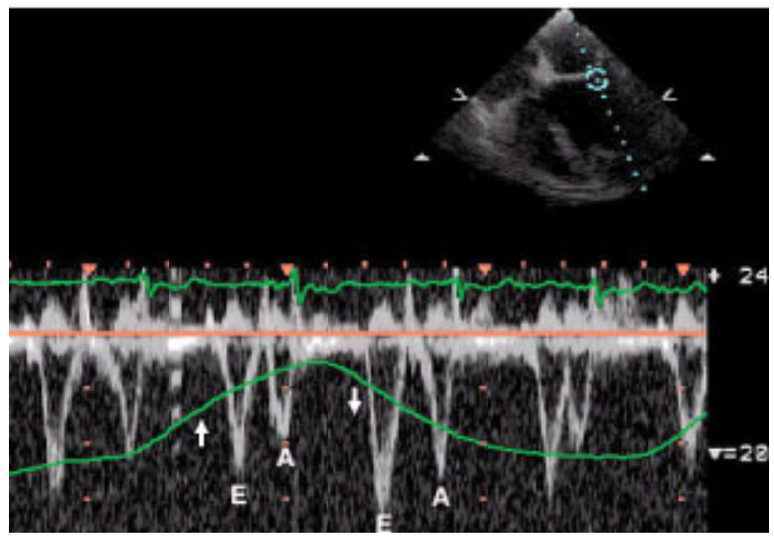
SLE is a pancarditis in which morbidity and mortality are the result of pericarditis, myocarditis, endocarditis, and coronary arteritis. More than 50% of patients with SLE experience clinical cardiovascular involvement during the course of the illness (8). Asymptomatic cardiac involvement is detected in a number of additional patients at autopsy. Cardiac involvement is rarely the initial presenting symptom of SLE (5).

Pericardial Involvement

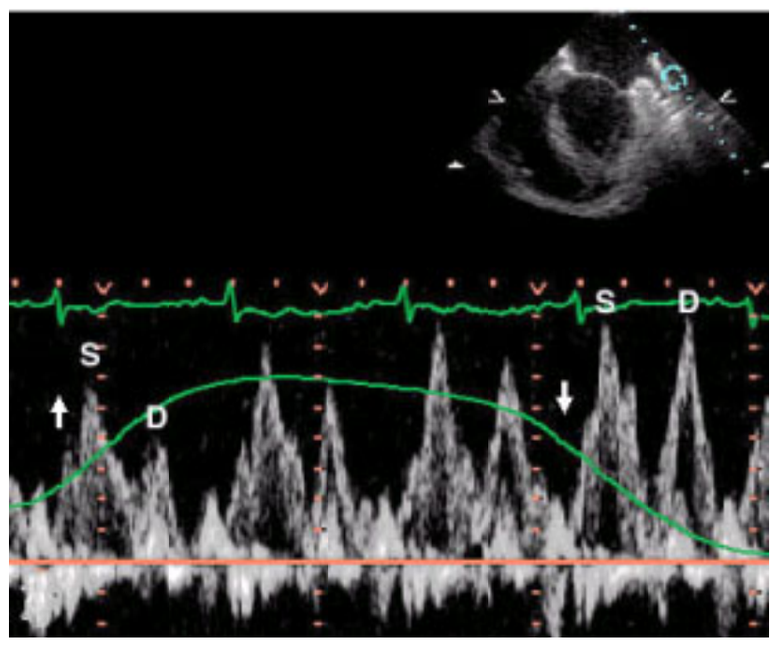
Pericarditis is the most common cardiovascular manifestation of SLE. It has an estimated clinical frequency of 25% and autopsy frequency of 62% (9). Echocardiographically, pericardial abnormalities are present in 7% to 54% of asymptomatic individuals (10,11,12 and 13). Acute pericarditis is the only cardiovascular manifestation of SLE that is included in the diagnostic criteria for the disease (3), and it commonly occurs as part of a generalized serositis. It is also the only cardiovascular manifestation strongly related to disease activity, as assessed by clinical and laboratory variables (10). Histopathology of pericardial tissue reveals proliferation of the pericardial vessels, vasculitis, fibrosis, and fibrin stranding (14).



Pulsed wave Doppler through the tricuspid valve of a patient with constrictive pericarditis. Note the decrease of the E wave with inspiration due to interventricular dependence.

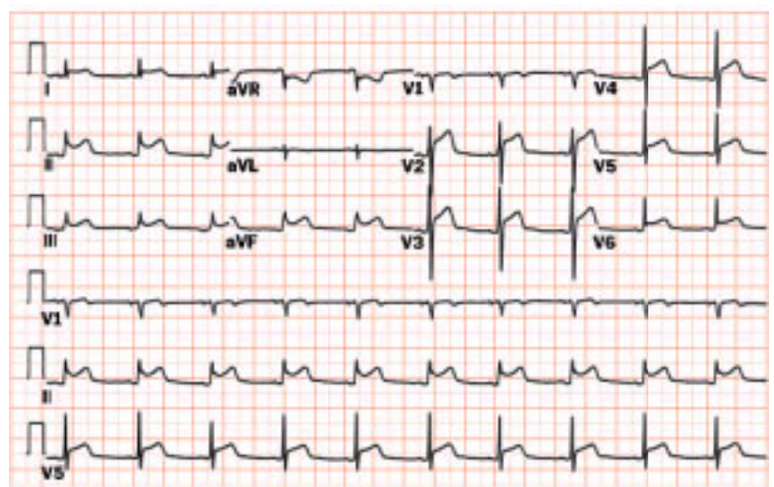


Pulsed wave Doppler of the mitral valve inflows of a patient with constrictive pericarditis. Note the decrease of the E wave during inspiration (*upward arrow*) due to interventricular dependence, and the increase in the E wave during expiration (*downward arrow*) for the same reason.



Pulsed wave Doppler of the pulmonary veins of a patient with constrictive pericarditis. Note the inspiratory decrease of the S and P waves and the expiratory increase due to interventricular dependence. (Inspiration is denoted by the upward arrow and expiration by the downward arrow).

Pericarditis associated with SLE manifests clinically as chest discomfort that is frequently pleuritic and worse in the recumbent position. Examination may reveal fever, tachycardia, a pericardial friction rub, and diminished breath sounds as a result of concomitant pleuritis with effusion. Laboratory features include leukocytosis, elevated sedimentation rate, and elevated titers of anti–double-stranded DNA, which are indicative of active SLE. Chest radiography may reveal an enlarged cardiac silhouette and pleural effusion. Electrocardiography (ECG) typically reveals diffuse ST-segment elevation and PR-segment depression, except in lead aVR, where these findings are reversed. Pericardial fluid is exudative and characterized by high protein levels, normal glucose levels, a predominance of polymorphonuclear cells, low complement levels, and the ability to fix complement (15). The presence of LE cells and immune complexes in the pericardial fluid is not diagnostic, but it supports an immune-mediated cause of pericardial disease in patients with SLE (16).



Acute pericarditis. Note diffuse, marked ST-segment elevation with PR-segment elevation in lead aVR.

Complications of pericarditis include pericardial tamponade, purulent pericarditis, and constrictive pericarditis. These entities are uncommon, but not rare, in SLE-induced pericarditis. Pericardial tamponade occurs in 0.25% to 2.50% of patients (6,9,14). It may be due to exuberant inflammation with translocation of fluid, hemorrhage, or, rarely, aortic dissection. Pericardiocentesis may be lifesaving in the critically ill patient, but a high rate of complications has been reported in this population. Pericardial window is the definitive procedure for treatment of patients with recurrence. SLE is an oft-quoted risk factor for purulent pericarditis, even though it occurs in only 0.250% to 0.375% of patients (6,9). Purulent pericarditis may be caused by hematologic seeding of an existing pericardial effusion or by direct extension from a penetrating endocardial abscess or empyema. *Staphylococcus aureus* is the most frequently encountered pathogen. Treatment includes surgical drainage and antibiotics. Constrictive pericarditis typically presents with signs and symptoms of right-sided heart failure, such as fatigue, dyspnea with exertion, jugular

venous distention, hepatomegaly, ascites, and edema. Constrictive pericarditis, when severe, is best managed with pericardiectomy.

Video 35E.1 Apical four-chamber view demonstrating a large pericardial effusion causing tamponade. Note the inability of the right side to fill. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35E.2 Subcostal short-axis view of a large pericardial effusion causing tamponade. Note that the right side is small and underfilled. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Pericardial tamponade. Low QRS voltage and electrical alternans are characteristic findings of tamponade.

Video 35E.3 Transesophageal echo (four-chamber view) demonstrating constrictive pericarditis. Note the abnormal septal bounce and the tethering of the right atrium and right ventricle by the thickened pericardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35E.4 Aortic dissection (left anterior oblique). Type A dissection of the aorta is manifested on the cine image loop by a mobile intimal flap extending from the mid–ascending aorta to the descending thoracic aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35E.5 Aortic dissection (left anterior oblique). Type B dissection of the aorta extending distally from the isthmus, just after the left subclavian artery, to the abdominal aorta. A communication between the true and false lumen is seen in the proximal portion of the descending aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Valvular Involvement

Valvular pathology that is attributable to SLE is seen in nearly one-half of all patients in whom SLE is found at autopsy (9,17,18). Libman and Sacks (2) were the first to describe the pathognomonic valvular lesion of SLE. Gross (19) later described them as gray-pink and flat or raised clusters that may be found on either side of the valves, in the valve pockets, or adherent to the chordae or myocardium (Fig. 35E.1). Antiphospholipid antibodies have also been demonstrated within valvular lesions, leading some to suggest that endocardial damage and thrombosis may initiate lesion formation (20).

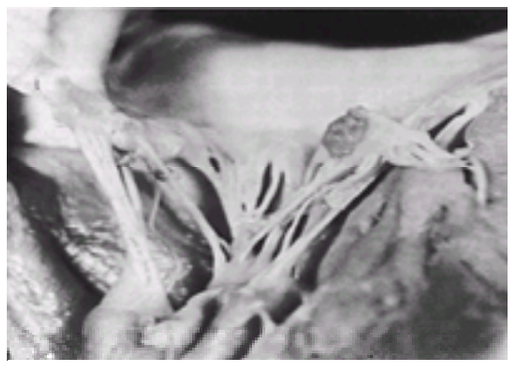


FIGURE 35E.1 Characteristic Libman-Sacks vegetation on the posterior cusp of the mitral valve. (From Cosh JA, Lever JV. *Rheumatic diseases and the heart*. Berlin: Springer-Verlag, 1988, with permission.)

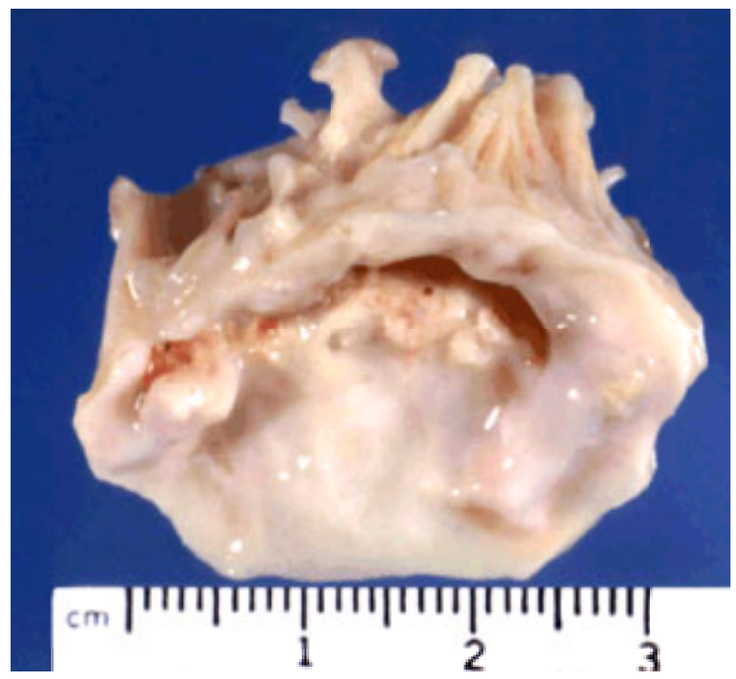
Video 35E.6 Ventricular noncompaction. Apical four-chamber view without **(A)** and with **(B)** intravenous contrast of a patient with ventricular noncompaction. Note the characteristic trabeculations and recesses that result from arrest on intrauterine development. *This video must be viewed with QuickTime. If you do not have*

QuickTime you may download it here.

Video 35E.7 Ventricular noncompaction. Apical four-chamber view without **(A)** and with **(B)** intravenous contrast of a patient with ventricular noncompaction. If you do not have QuickTime you may download it here.*



Rheumatic mitral valve. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

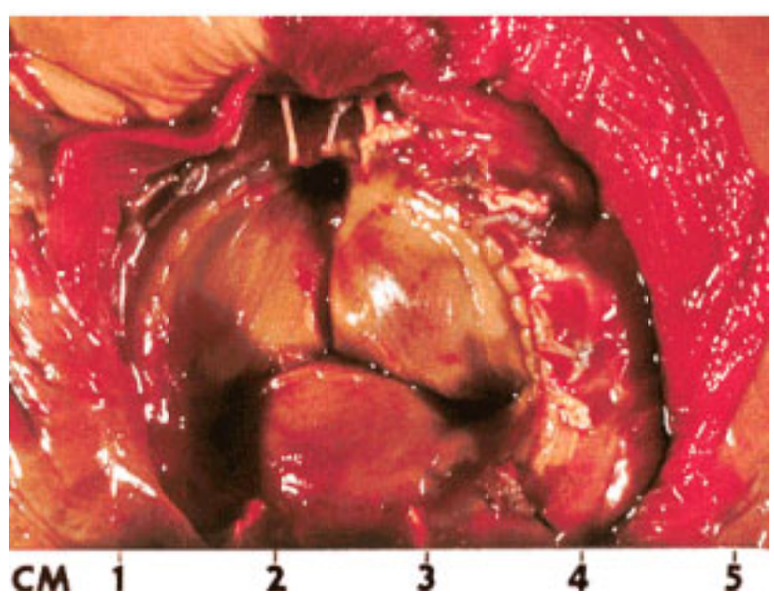
Microscopically, Shapiro identified three main zones within a valvular lesion. The zone of neovascularization is located near the normal valvular structure and consists of maturing fibroblasts, connective tissue, and inflammatory cells. The zone of organization is in the middle of the lesion and consists of proliferating blood vessels. The zone of exudation is the outermost zone and consists of fibrin, proteinaceous material, and hematoxylin-stained bodies. Shapiro (21) also identified immune complexes within the zone of neovascularization, which suggests that a pathogenic role is probable.

Improvements in survival rates and the use of corticosteroids have changed the face of valvular heart disease for patients with SLE. Roberts (22) elegantly compared valvular pathology in the pre- and postcorticosteroid eras. Early autopsy studies in the precorticosteroid era reported equal involvement of left- and right-sided heart valves and a predominance of “fresh” vegetations consisting of inflammatory cells, neovascularization, and fibrin deposition (2,17). Recent studies have found more left-sided valvular lesions and a predominance of “healed” vegetations with organization and fibrosis (18). “Healing” and fibrosis may predispose the valve to impaired mobility of the valve apparatus and thus to regurgitation.

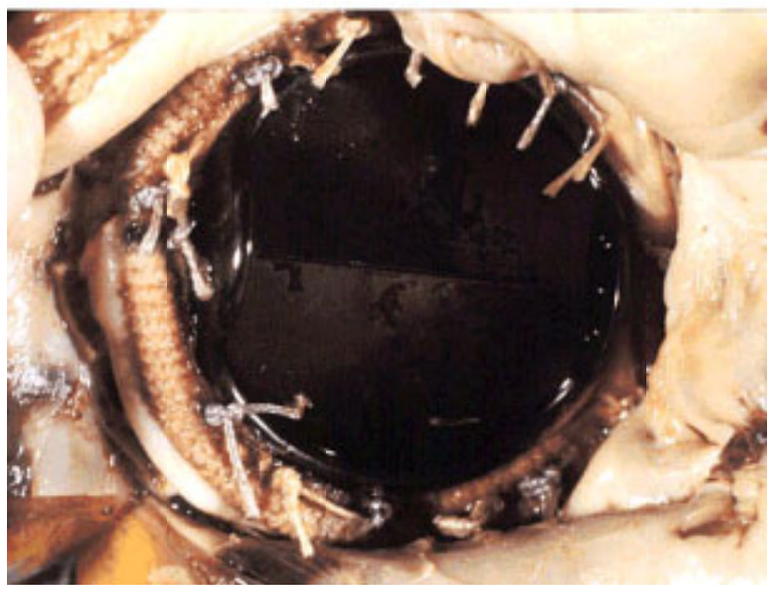
Patients with SLE who have antiphospholipid antibodies are more likely to manifest valvular abnormalities than those without these antibodies. Khamashta and colleagues (23) and Nihoyannopoulos and associates (12) independently reported an approximately threefold increase in the incidence of valvular abnormalities among unselected patients with SLE who had antiphospholipid antibodies, compared with the incidence among SLE patients who did not have antiphospholipid antibodies. In a smaller study, Roldan and colleagues (24) did not confirm this association. Whether or not antiphospholipid antibodies increase the frequency of *clinically important* valvular disease is unknown.

Clinically important valvular disease is much less common than asymptomatic disease detected by echocardiography or autopsy. Hemodynamically significant valvular disease may be caused by any combination of the following: valvulitis, fibrosis, infective or noninfective endocarditis, ischemic cardiomyopathy, papillary muscle dysfunction, and aortic dissection. Clinically important aortic regurgitation appears to be more frequent than mitral regurgitation, but the true incidence of each is unknown (9). Mitral stenosis, aortic stenosis, and right-sided valvular disease are all rare. Early reports of valve replacement in patients with SLE found an extremely high associated mortality, approaching 25% (25); however, recent reports have been more encouraging (26). Mechanical prostheses, bioprosthetic valves, and homografts have all been used to treat this condition. Patients with SLE are at high risk for hemorrhagic complications from anticoagulation therapy, because of the frequency of intracranial and pericardial disease in this population. However, they often have other indications for anticoagulation therapy, such as the antiphospholipid antibody syndrome with clinical thrombosis. Clearly, the choice of valvular prosthesis must be individualized.

Video 35E.8 Long-axis 120-degree transesophageal view of a rheumatic aortic valve with central aortic insufficiency due to furled, restricted leaflets. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Porcine prosthetic mitral valve. In this example, the valve is normal and the suture line is intact.



Normal St. Jude valve in the mitral position.

Aortic thrombus in a patient with lupus anticoagulant. A probe is placed behind the thrombus within the lumen of the aorta (*yellow arrow*).

The lesions of Libman-Sacks endocarditis act as a nidus for infective endocarditis. Clinical infective endocarditis occurs in 1% to 2% of SLE patients. At autopsy, it is found in nearly 5% (9). Patients with SLE and significant valvular dysfunction who are undergoing invasive medical or dental procedures are at moderate risk for infective endocarditis and should receive antibiotic prophylaxis, according to published guidelines (27).

Myocardial Involvement

Myocarditis is found commonly at autopsy of patients who had SLE. In the precorticosteroid era, myocarditis was found in nearly one-half of all SLE patients at autopsy (9). More recent autopsy series have shown a prevalence of less than 10% (18). When myocarditis is found, however, it typically involves only small patches of myocardium, and only 5% to 10% of SLE patients experience clinical myocarditis (9). Histopathology reveals perivascular and interstitial inflammation characterized by plasma cells, mononuclear cells, myocardial degeneration and regeneration, and, occasionally, necrosis. SLE is generally a corticosteroid-responsive disorder, but no randomized trials of the use of immunosuppressive therapy for myocarditis in patients with SLE have been performed. Trials of the use of immunosuppressive agents to treat other types of myocarditis have been disappointing. Endomyocardial biopsy should be considered when a patient with SLE develops severe myocarditis, to guide immunosuppressive therapy.

Congestive heart failure (CHF) is common and usually multifactorial in patients with SLE. It is the cause of death in 1% to 5% of patients with SLE (6,7). Ischemia, valvular heart disease, hypertension, and myocarditis may produce either systolic or diastolic dysfunction. Mild global left ventricular systolic dysfunction is present in 5% to 15% of patients with SLE (10,28). Echocardiography has detected abnormalities of myocardial relaxation in young, asymptomatic SLE patients (29,30). Other studies, however, have not reproduced this in normotensive SLE patients (31).

Coronary Involvement

Coronary artery disease (CAD) has become an increasingly important cause of morbidity and mortality among patients with SLE. Ischemic heart disease in patients with SLE presents, in order of decreasing frequency, as acute myocardial infarction (MI), CHF, sudden cardiac death, and angina pectoris. It is estimated that 3% to 15% of patients with SLE die from acute MI (7,32,33). Ischemic coronary events are attributed most frequently to coronary atherosclerosis, less frequently to coronary arteritis, and rarely to embolic phenomena involving the coronary circulation.

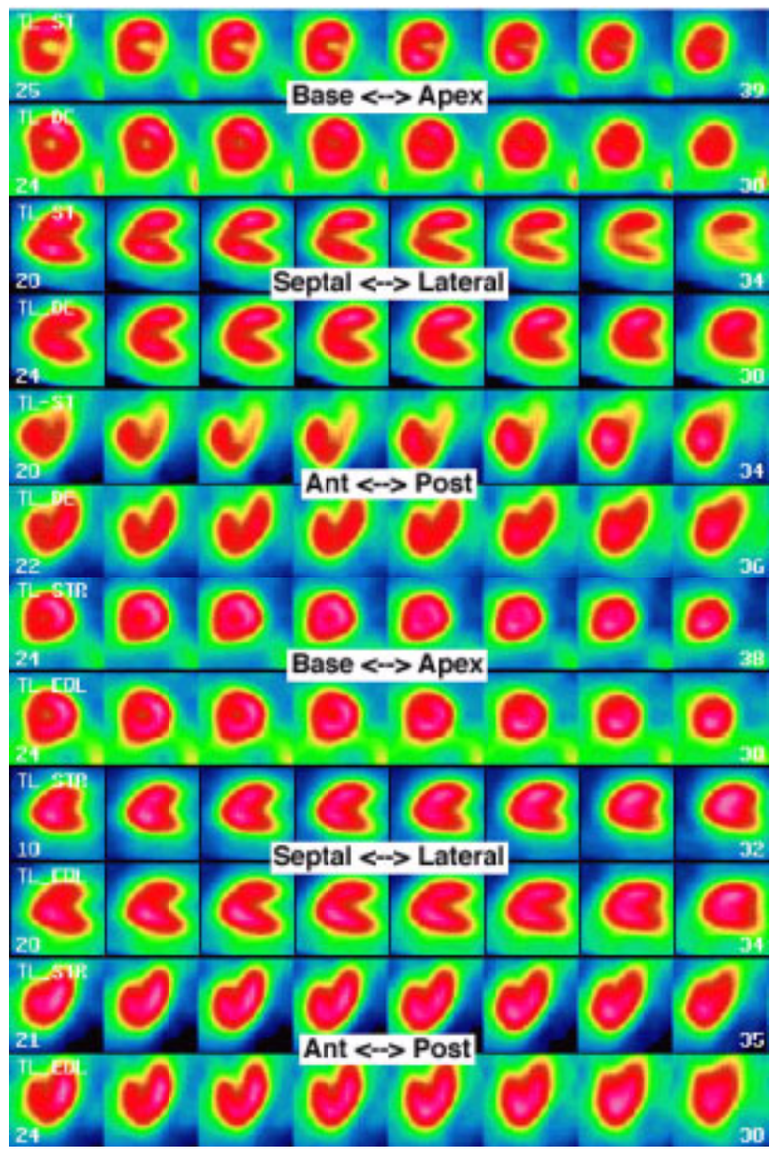
Coronary atherosclerosis is accelerated in patients with SLE. This likely is related to the effects of corticosteroids, the prevalence of traditional risk factors among patients with SLE, and coronary inflammation. The role of antiphospholipid antibodies in the pathogenesis of CAD and the occurrence of subsequent coronary events is controversial. Patients with SLE have a fivefold risk of acute MI, compared with age-matched control subjects (34). Women 35 to 44 years of age were found to have a relative risk of 52 (95% confidence interval, 21.6 to 98.5) for MI, compared with matched controls (32). Two groups have found a 40% prevalence of asymptomatic

CAD in patients by nuclear stress testing (28,35). Autopsy studies have demonstrated a 50% prevalence of moderate to severe CAD both in general SLE populations (7) and in SLE patients less than 37 years of age (36).



Thallium-201 single-photon emission computed tomography stress and delayed images (A). Traditional risk factors for CAD are present in most patients with SLE. Hypertension is present in 38% to 66%, hyperlipidemia in 5% to 50%, tobacco abuse in 38% to 50%, and diabetes mellitus in nearly 10% (32,35,37). Corticosteroid therapy may contribute to hypertension, hyperlipidemia, and diabetes.

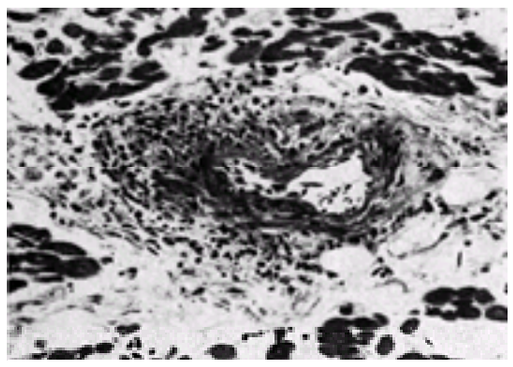
Coronary arteritis accounts for less than one-half of the cases of ischemic heart disease that occur in individuals with SLE. The diagnosis of coronary arteritis is made histopathologically, but it may be suggested during coronary angiography by aneurysmal dilation of a coronary segment or an abrupt change in lesion severity, although these changes can also be seen in the absence of arteritis. Discrepancies between angiographic and histopathologic diagnosis of coronary arteritis occur commonly. Improvements in lesion severity have been observed in coronary arteritis after high-dose corticosteroid therapy (38). A trial of corticosteroid therapy may be justified for stable patients whose clinical course is strongly suggestive of coronary arteritis, but long-term administration likely will further accelerate the atherosclerotic process.

Corticosteroid therapy and improvements in patient survival rates have also changed the face of CAD in patients with SLE (22). In the precorticosteroid era, epicardial CAD was infrequent. Small-vessel arteritis and small-vessel occlusion by fibrinous material were more prominent (17). More recent autopsy series reveal severe epicardial atherosclerosis in nearly 50% of patients (7,18,36). Important coronary events resulting from embolization of valvular vegetations have been reported (18), but these are considered rare.

Conduction System Involvement

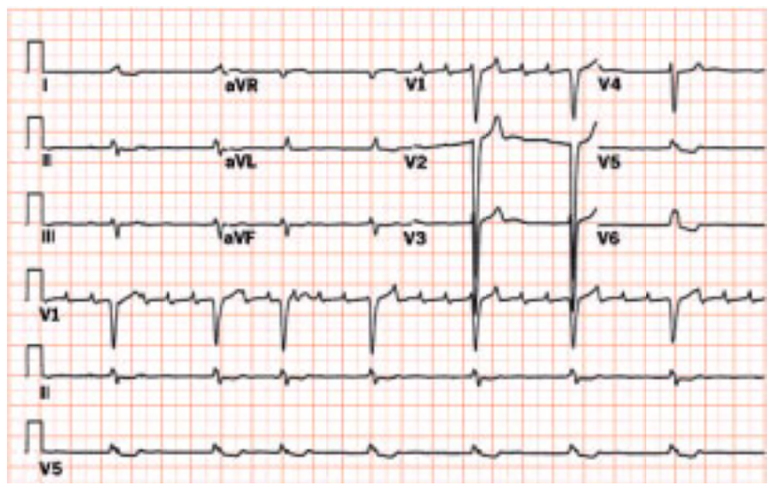
SLE infrequently causes clinical arrhythmias in adults. Histopathologic correlation of SLE-related destruction of the conduction system with cases of clinical arrhythmia has, however, been documented (39). Arteritis of the sinoatrial (SA) nodal and atrioventricular (AV) nodal arteries has been observed (*e*Fig. 35E.1.1), as has fibrosis of the SA and AV nodes.



***e*FIGURE 35E.1.1** Sinus node artery inflammation. No clinical arrhythmia was reported in this case. (Reprinted from Straaton KV, Chatham WW, Reveille JD, et al. Clinically significant valvular heart disease in systemic lupus erythematosus. *Am J Med* 1988;85:645–650, with permission.)

Evidence also exists for the occurrence of autoimmune injury to the conductive tissue. Adults with SLE and anti-Ro antibodies are more likely to have evidence of heart block on ECG than are adults with SLE and no anti-Ro antibodies (40). No recent prospective studies have addressed the prevalence of symptomatic or asymptomatic conduction system abnormalities in adult patients with SLE.

Neonatal SLE occurs in newborns of mothers with SLE, typically lasts 3 to 6 months, and resolves on clearance of maternal immunoglobulin G from the infant's circulation. Transient symptoms such as photosensitivity, cytopenias, and hepatitis may occur. Unlike these transient manifestations of neonatal SLE, congenital complete heart block (CHB) is usually permanent. The presence of anti-Ro antibodies in maternal serum was first recognized by Scott and colleagues (41) as a risk factor for congenital CHB. Anti-La antibodies are also associated with congenital CHB. The antigen against which anti-Ro antibodies are directed has been demonstrated in the nuclei of myocardial cells and conduction tissue cells (42). Immunoglobulin and complement deposition has been demonstrated in all cardiac tissues of affected infants at autopsy. Approximately 3% of infants whose mothers are antibody positive develop CHB (22).



High-grade atrioventricular block. Note marked discrepancy between atrial and ventricular heart rates.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is an autoimmune disorder of unknown etiology. It is characterized primarily by an erosive arthritis with progressive joint destruction, deformation, and immobility. RA has a prevalence of 1% worldwide and an annual incidence of 250 to 500 cases per 1 million individuals (43). The diagnosis relies on a variety of clinical, laboratory, and radiographic findings. Extraarticular manifestations are common but usually are overshadowed by joint involvement.

Four of the following criteria must be met for a diagnosis of RA to be indicated: morning stiffness that lasts at least 1 hour; arthritis affecting three or more joints; arthritis affecting the proximal interphalangeal, metacarpophalangeal, or wrist joints; symmetric arthritis; rheumatoid nodules; the presence of rheumatoid factor; and radiographic evidence of joint erosion or periarticular osteopenia (44). Symptoms should be present for 6 weeks before a diagnosis is made.

Caring for individuals with RA requires a multidisciplinary approach that includes the efforts of physicians, nurses, and physical and occupational therapists. Non–weight-bearing exercise, joint orthotics, and joint replacements may significantly improve patient function.

Steroids and nonsteroidal antiinflammatory drugs (NSAIDs), including cyclooxygenase-2 inhibitors, are the backbone of symptomatic therapy. Disease-modifying antirheumatic drugs include hydroxychloroquine, penicillamine, azathioprine, leflunomide, sulfasalazine, gold preparations, and methotrexate. Newer biologic response modulators, including etanercept and infliximab, which inhibit the activity of tumor necrosis factor-a, have been beneficial in patients who are resistant or intolerant to disease-modifying antirheumatic drugs. The use of etanercept in the treatment of heart failure is being investigated in the Randomized Etanercept North American Strategy to Study Antagonism of Cytokines trial. Conversely, concern has been raised regarding the safety of using cyclooxygenase-2 inhibitors in patients with cardiovascular disease. Anecdotal reports and initial clinical trial results suggest that these drugs have a potential prothrombotic effect, including an increased incidence of MI. Further study is required.

The profound morbidity associated with RA is undisputed. However, only recently has the substantial increase in mortality associated with the disease come to be appreciated. Standardized mortality ratios, which compare observed to expected event ratios in a population, reveal a greater than twofold increase in mortality among RA patients compared to that among epidemiologic controls (45). Cardiovascular disease is the most common cause of death in patients with RA (45,46 and 47).

Pericardial Involvement

Cardiac involvement in RA was first reported in 1881 by Charcot, who described a patient with clinical and autopsy evidence of pericarditis (48). Autopsy evidence of pericarditis is now recognized in nearly one-third of patients who have RA (49). Clinical pericarditis is much less common, occurring in fewer than 10% of patients who have RA in most series (49,50). Echocardiographic evidence of pericardial disease occurs in 8% to 50% of asymptomatic RA patients (51,52 and 53) and may be more common among those with subcutaneous rheumatoid nodules (52).

The pericardial fluid of patients who have RA with cardiac involvement is typically exudative and characterized by elevated leukocyte, protein, and lactate dehydrogenase levels. Glucose and complement levels are low, with undetectable glucose levels being reported in some instances. Histopathologic examination of removed pericardium may reveal nonspecific fibrosis or may, rarely, reveal fibrinoid necrosis, palisaded inflammatory cells, and plasma cells, changes similar to those seen in rheumatoid nodules (*e*Fig. 35E.1.2).

***e*FIGURE 35E.1.2** Chronic pericarditis in a patient with rheumatoid arthritis demonstrating rheumatoid nodules (*arrows*) with central necrosis (N) and surrounding inflammation. P, parietal pericardium; V, visceral pericardium. (Reprinted from Burney DP, Martin CE, Thomas CS, et al. Rheumatoid pericarditis. *J Thorac Cardiovasc Surg* 1979;77:513, with permission.)

Pericarditis may be asymptomatic and detected by physical examination, echocardiogram, or ECG. When symptoms are present, positional chest pain is most common, followed by dyspnea and swelling. NSAIDs or corticosteroids may be used for treatment, but trials comparing treatment strategies are lacking. Constrictive pericarditis has been reported in 0.64% of men and 0.06% of women (54). Tamponade is less common. Management of tamponade in patients with RA is complicated by a poor response to medical therapy and by frequent loculations. Pericardiocentesis may be attempted in patients with tamponade, but most patients with either tamponade or constrictive pericarditis eventually require pericardiectomy (55). Clinical predictors of poor outcome in patients with pericardial disease include advanced age, jugular venous distension, hypotension, and other extraarticular RA manifestations (50).

Valvular Involvement

Hemodynamically significant, histologically proven valvular involvement in RA is rare. Many of such patients reported in the literature showed evidence of superimposed rheumatic valvular heart disease. In 1941, Baggenstoss and Rosenberg (56) were the first to describe valvular disease in patients with RA. Roberts and coworkers (57) went on to describe in more detail the gross findings, noting firm, smooth, yellow deposits with a predilection for left-sided heart valves. Histologic changes may consist of bland fibrosis or may reveal inflammatory changes similar to rheumatoid nodules (57). Concurrent involvement of more than one valve is common among patients with valvular disease.

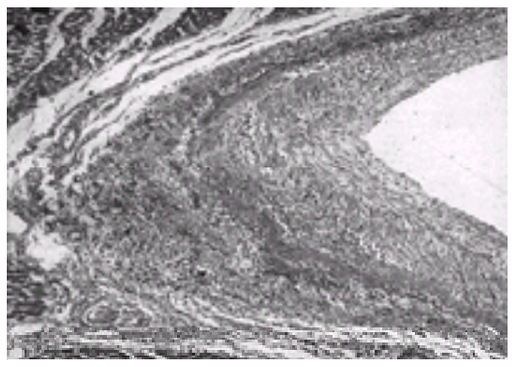
Myocardial Involvement

Rheumatoid nodules have been found within the myocardium of patients with RA. Sensitive echocardiographic techniques used to measure diastolic function have revealed abnormalities of myocardial relaxation in nearly 25% of patients with RA (53). However, clinical CHF and systolic dysfunction that can be attributed to RA are rare.

Coronary Involvement

Acute MI is common in patients with RA. This seems to reflect the high risk of MI in all adults, rather than a profound disease-specific increase in risk due to RA. A 51% excess in death due to ischemic heart disease was noted in one retrospective study (47), but another retrospective case-control series found an increase in MI only among RA patients who tested positive for rheumatoid factor (58), and other studies have found no increase in incidence of MI (46). In fact, autopsy series have actually suggested that patients with RA have a lower risk of MI than do control subjects, despite similar incidence of coronary atherosclerosis (59). The authors hypothesized that aspirin use may protect RA patients from coronary thrombosis.

Coronary atherosclerosis is an inflammatory process. Therefore, care must be taken when coronary lesions in patients with RA are ascribed to arteritis. Few reports of acute MI due to coronary arteritis, with histologic confirmation, have been published (eFig. 35E.1.3) (60,61). Coronary lesions in these patients resemble rheumatoid nodules, consisting of palisaded inflammatory cells, fibrinoid necrosis, and plasma-cell infiltration. Atheromatous changes, such as foam cells, cholesterol clefts, and calcification, were lacking.



***e*FIGURE 35E.1.3** Subacute coronary arteritis with mononuclear cell infiltration and fibrinoid necrosis in a patient with rheumatoid arthritis. (Reprinted from Karten I. Arteritis, myocardial infarction, and rheumatoid arthritis. *JAMA* 1969;210:1717–1720, with permission.)

Conduction System Involvement

CHB due to RA is rare, but it has been reported. Autopsy studies have confirmed involvement of the cardiac conduction system by rheumatoid nodules (62). Other potential mechanisms for heart block in patients with RA include vasculitis of the arterial supply to conductive tissue, hemorrhage into a rheumatoid nodule, extension of an inflammatory lesion from the aortic or mitral valve, and associated amyloid deposition. Ahern and colleagues (62) found CHB in 0.1% of RA patients and noted that it was more common among female patients, tended to be sudden in onset, and was more prevalent among patients who had subcutaneous nodules (62).

SYSTEMIC SCLEROSIS

Background

Systemic sclerosis (SSc) is a rare connective-tissue disorder of unknown etiology, characterized by abnormal collagen deposition and fibrosis of the skin, viscera, and vasculature. Five- and 10-year survival rates are 70% and 50%, respectively (63,64), although wide ranges have been reported at different centers. Variables predicting a poor prognosis include male gender, advanced age at the time of diagnosis, and visceral involvement. Renal involvement portends the worst prognosis (5-year survival rate of 10%), followed by cardiac involvement (5-year survival rate of 40%) (64).

Scleroderma. In scleroderma, there is swelling of the fingers and hands, later becoming firm, thick, and tight with flexion contractures. In the second panel, digital ulcers are shown (*arrows*). Cardiac manifestations include cardiac fibrosis, abnormality of the conduction system, and pericarditis.

Scleroderma. Calcific deposit in subcutaneous tissue in the olecranon bursa (*arrows*).

SSc is diagnosed clinically, relying mainly on the prominent dermal changes characteristic of the disease. The sole major criterion for diagnosis is proximal scleroderma. Minor criteria include sclerodactyly, digital pitting scars or loss of distal finger pads, and bibasilar pulmonary fibrosis. The presence of one major or two minor criteria has greater than 95% sensitivity and specificity for diagnosis (65). Cold-induced digital pallor, followed by cyanosis and, later, reactive hyperemic rubor (Raynaud's phenomenon), is nearly universally present. Similar pathophysiology may contribute to pulmonary, cardiac, and renal damage. Limited SSc is characterized by a more indolent course with calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, telangiectasias, and, rarely, severe pulmonary hypertension.

Cardiac dysfunction is common in patients with SSc. Symptomatic cardiac involvement occurs in approximately 10% of these patients, ECG and echocardiography detect abnormalities in 50%, and autopsy evidence of cardiac involvement is present in up to 80% (66,67 and 68). The presence of either occult or symptomatic evidence of cardiac involvement portends a poor prognosis. Clements and associates constructed a "cardiac score," based solely on the presence of left-axis deviation on ECG and the size of pericardial effusion, and found that this score was a strong independent predictor of survival in patients with SSc (69). Chest pain and shortness of breath are often ascribed to noncardiac causes, but their occurrence should prompt investigation into the possibility of cardiac involvement.

Pericardial Involvement

Pericardial disease is common in SSc; autopsy evidence of acute or chronic pericarditis is seen in 50% to 80% of patients (68,70,71), echocardiographic evidence in 10% to 40% of patients (72,73 and 74), and clinical evidence in 7% to 16% of patients (68,70). Pericardial effusion tends to be of little clinical importance, but it carries a poor prognosis if the effusion is large (greater than 200 mL). For reasons that are unclear, patients with large pericardial effusions frequently have progression to renal failure within 1 year (73,75). Pericardial fluid analysis typically reveals a bland exudate with high protein levels, high lactate dehydrogenase, normal immunoglobulin and complement levels, and a paucity of leukocytes (75,76). Patients may present with typical findings of acute pericarditis or may have nonspecific symptoms. Constrictive pericarditis is rare (67). Tamponade has been reported (77). Treatment of acute pericarditis consists of administration of NSAIDs and corticosteroids, but renal function should be closely monitored during therapy. Large effusions may require percutaneous or surgical drainage.

Valvular Involvement

Clinically important valvular heart disease is not a feature of SSc. Individual cases of severe valve dysfunction in patients with SSc have been reported, but without firm evidence of causation (78). Two echocardiographic studies involving unselected SSc patients have suggested that the prevalence of mild mitral regurgitation in this group is high, which may be related to papillary muscle fibrosis and dysfunction (74). Autopsy studies have demonstrated thickening of the mitral leaflets and chordae tendineae, but at levels no different than those in control subjects (68).

Myocardial Involvement

In 1943, Weiss (79) observed patchy myocardial fibrosis in patients with SSc, establishing sclerodermal heart disease as a clinical entity. Myocardial fibrosis has been found at autopsy in 37% to 81% of patients (67,68,80). Pathologic specimens reveal patchy areas of transmural fibrosis, which are not confined to epicardial coronary artery distributions. Areas of contraction-band necrosis, typical of myocardial ischemic injury followed by reperfusion, are well described. Myocardial injury may have a pathogenesis similar to that of the vasospasm-induced digital gangrene produced by Raynaud's phenomenon. This patchy fibrosis has, therefore, been termed the *myocardial Raynaud's phenomenon* (67). Support for this theory has been provided by investigators who have shown that cold-induced myocardial ischemia occurs in patients with SSc. This has been demonstrated by cold-induced echocardiographic wall motion abnormalities and abnormalities of thallium uptake (74,81). Interestingly, nondihydropyridine calcium channel antagonists and angiotensin-converting enzyme (ACE) inhibitors have been shown to blunt this response (82,83). Although such therapy is theoretically attractive, primary prevention of myocardial fibrosis and cardiac death with ACE inhibitors has not been studied in patients with SSc.

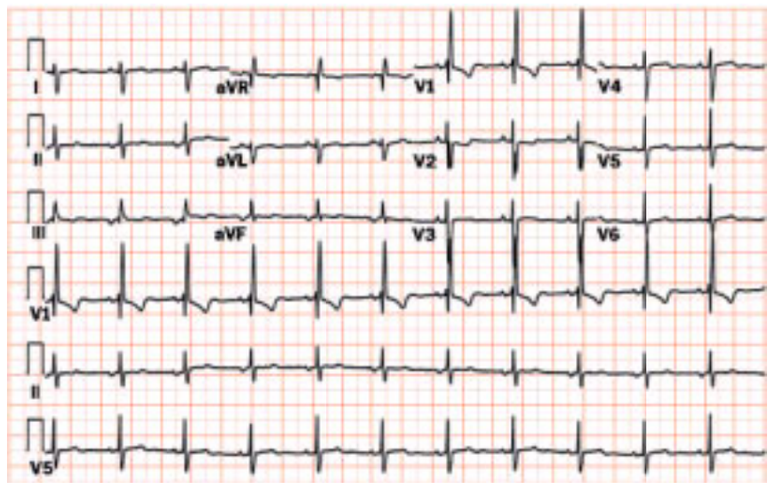
Diastolic dysfunction accompanied by echocardiographic evidence of impaired ventricular filling is common in patients with SSc (84,85). Myocardial fibrosis sufficient to produce systolic left ventricular dysfunction is uncommon but not rare and is mainly observed in autopsy studies. The prevalence of clinically apparent CHF has been reported to be 10% (86), but large series are lacking. Once thought to be contraindicated in patients with Raynaud's phenomenon, beta-blockers are now believed to be safe (87). Immunosuppressive treatment with corticosteroids is unlikely to be beneficial, because inflammation is rarely a major feature of this disease, and such treatment generally should be used only with the guidance of endomyocardial biopsy results.

Many patients who display normal systolic function at rest may demonstrate abnormal systolic responses during exercise. Follansbee and coauthors (88) found abnormal systolic response to exercise in 45% of patients with limited SSc and normal baseline ventricular function, with 14% of patients exhibiting a fall in ejection

fraction to less than 50%.

Patients with SSc and myositis of skeletal muscle appear to be at high risk of severe myocardial dysfunction and death (89). Indirect evidence points to myocarditis as the cause of death, because many of these patients have tachycardia, ST-segment abnormalities, clinical CHF, conduction delays, arrhythmias, or elevated CK-MB fractions. No records of endomyocardial biopsy are available, but one 12-year-old, whose case was reported by Follansbee and associates (89), showed evidence of contraction-band necrosis of 30% of the left ventricle at autopsy.

Right ventricular systolic and diastolic dysfunction are uncommon among patients with diffuse SSc. However, patients with CREST (*c*alcinosis cutis, *R*aynaud's phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia) syndrome may develop severe pulmonary hypertension due to primary vascular changes in the lungs, with secondary pulmonary hypertension and right ventricular dysfunction. Nondihydropyridine calcium channel antagonists and prostacyclin may reduce pulmonary artery pressure and improve symptoms, but the prognosis in these patients is grim.



Right ventricular hypertrophy. Note incomplete right bundle branch block pattern, right axis deviation, and ST-T–wave changes secondary to right ventricular hypertrophy.

Mitral stenosis. Left atrial enlargement and right ventricular hypertrophy have developed secondary to mitral stenosis, causing fixed pulmonary hypertension.

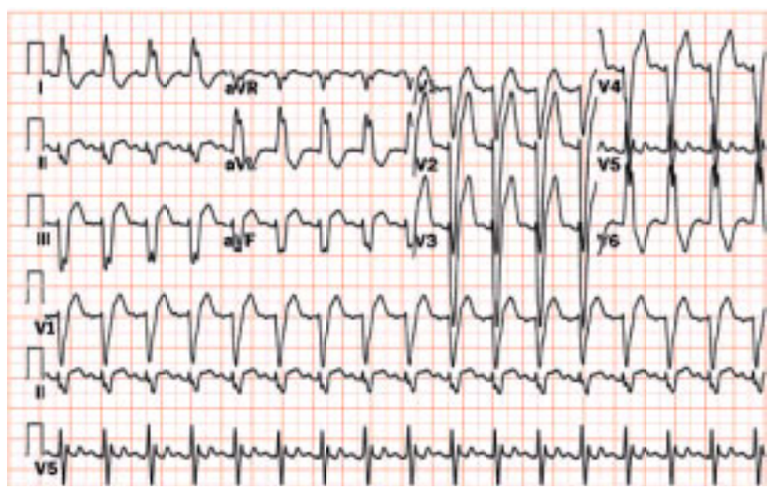
Coronary Involvement

Accelerated coronary atherosclerosis is not a feature of SSc. Chest pain, however, is a common symptom among patients with SSc and may be the result of esophageal dysfunction, lung involvement, or pulmonary hypertension. Typical angina pectoris is not characteristic of SSc, and its presence should prompt evaluation for coincidental epicardial coronary disease. As noted, many SSc patients have abnormalities of wall motion and radionuclide uptake, despite normal coronary arteries, which means that noninvasive testing has a low positive predictive value for the detection of CAD. If the index of suspicion for CAD is high, then cardiac catheterization should be considered.

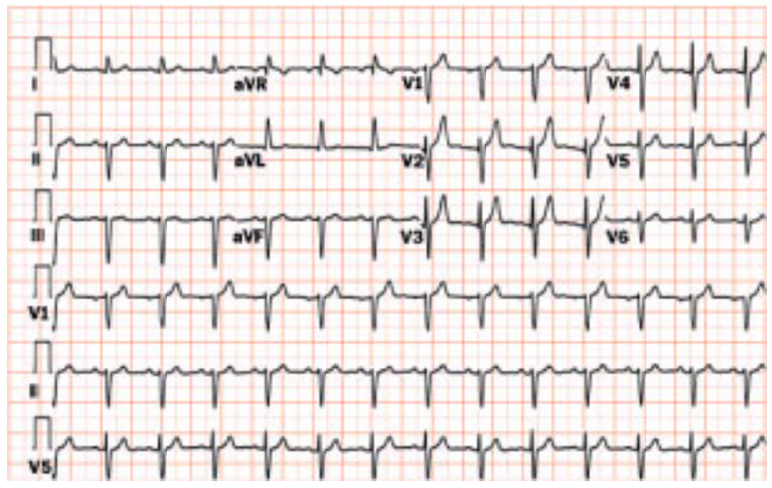
Abnormalities of small intramural coronary arteries have been reported in some studies (68,90), but not in others (67,80). James (90) described such abnormalities as "mural fibrosis, intimal proliferation and widespread fibrinoid necrosis, with occasional platelet-fibrin occlusions," and correlated the presence of small-vessel disease with the areas of myocardial fibrosis.

Conduction System Involvement

Abnormal ECG results are found in 50% of patients with SSc (91) and are an independent predictor of mortality in these patients (64,69). Nonspecific ST-T–wave abnormalities and conduction delays are most common. Autopsy studies suggest that conduction delays, such as left anterior fascicular block, left bundle branch block, and right bundle branch block, are more likely to be caused by slow conduction through fibrotic myocardium than by intrinsic disease of the conduction tissue (92). However, cases of clinical arrhythmia with pathologic evidence of direct involvement of the cardiac conduction tissue (93) and its arterial blood supply (90) have been reported.



Left bundle branch block. Wide QRS complex, negative in lead V_1, is associated with secondary T-wave inversions.



Left anterior fascicular block. Note left axis deviation and small Q waves n leads I and aVL. Small Q wave in lead V_4 strongly suggests anterior myocardial infarction.

Trifascicular block. Note right bundle branch block, left anterior hemiblock, and associated first-degree atrioventricular block.

Atrial and ventricular arrhythmias are common among asymptomatic patients with SSc and are associated with a poor prognosis. Their occurrence exemplifies the importance of detecting asymptomatic cardiac involvement in SSc. Nonsustained ventricular tachycardia (VT) has been demonstrated by 24-hour Holter monitoring in 7% to 13% of unselected patients with SSc (72,94). Supraventricular arrhythmias, such as transient atrial fibrillation, flutter, or paroxysmal supraventricular tachycardia, may be present in 20% to 30% of SSc patients (94). Patients with frequent ventricular ectopy had a 50% mortality during 33 months of follow-up. This compares with 8% mortality among patients without frequent ectopy (94). These data have led some authors to recommend use of Holter monitoring in the routine evaluation of patients with SSc (72). Patchy myocardial fibrosis provides an ideal substrate for tachyarrhythmias that are dependent on reentrant circuits, a phenomenon that has been demonstrated with electrophysiologic studies (95). Life-threatening ventricular arrhythmias have been successfully treated with implantable cardioverter-defibrillator (96) and ablative therapy (95).

KAWASAKI DISEASE

Dr. Tomisaku Kawasaki first examined a patient with what he called “mucocutaneous lymph node syndrome” in 1961, published a series of 50 cases in 1967, and reported it in English in 1974 (97). Kawasaki disease is an arteritis involving large, medium-sized, and small arteries and is associated with a mucocutaneous lymph-node syndrome (98). It is a disease of unknown etiology, with recognized perturbations of the cellular and humoral immune systems, and speculation of a viral or superantigen-driven pathologic inflammatory response (99).

The annual incidence of Kawasaki disease is 105 cases per 100,000 children in Japan (100) and approximately 10 cases per 100,000 children in the United States (101). The disease primarily affects children younger than 5 years of age. Diagnosis is based on clinical criteria. Laboratory abnormalities are nonspecific. In addition to fever of at least 5 days’ duration, four of the following criteria must be met: polymorphic exanthem, oropharyngeal erythema (including “strawberry tongue”) or fissuring, erythema and indurated edema of the palms or soles of the feet, bilateral conjunctival injection without exudate, and cervical lymphadenopathy (102).

Physical features in Kawasaki’s disease. These are capillary hemangiomas (*yellow arrow*).

Based on autopsy findings, the disease has been divided into four stages (103). Stage 1 occurs from days 0 to 9 and includes perivasculitis of small arteries and pancarditis. Stage 2 occurs from days 12 to 25 and is characterized by panvasculitis of medium-sized arteries with aneurysm formation. Stage 3 occurs from days 28 to 31 and involves intimal proliferation and resolving inflammation. Stage 4 occurs after 40 days and is characterized by arterial scarring and stenosis formation.

Kawasaki disease is the number one cause of acquired heart disease in children in Japan and in North America. Although it is primarily a disease of children, arterial damage incurred during the acute phase of the illness may result in a high prevalence of early coronary events in affected adults. Advances in early treatment have allowed more patients with Kawasaki disease to survive into adulthood.

Pericardial Involvement

Autopsy series report pericarditis in 90% of patients who have died because of Kawasaki disease (103). Pericarditis is uncommonly reported in clinical series of patients with Kawasaki disease, suggesting that it is either commonly asymptomatic or underreported or that the autopsy series are not representative of the majority of patients. Echocardiographic studies report effusions in 30% of patients during the acute phase of the illness (104).

Valvular Involvement

Clinically evident valvular heart disease develops in the acute phase of Kawasaki disease in slightly more than 1% of patients (104,105 and 106). Valvulitis is detected at autopsy in 20% of patients (103). Ischemic papillary muscle dysfunction may also contribute to valvular dysfunction. Mitral regurgitation is most commonly seen,

followed by aortic regurgitation. Severe valvular dysfunction requiring valve replacement has occurred, but most patients recover spontaneously. Valve dysfunction is more common among patients who have either prolonged fever or coronary aneurysm formation (106). The impact of intravenous immunoglobulin (IVIG) on valvular dysfunction in the acute phase of the illness has not been described.

Myocardial Involvement

Myocarditis, characterized by myocardial edema and polymorphonuclear leukocyte infiltration, is common in autopsy studies of patients with Kawasaki disease; it has an overall incidence of 45% and an incidence of 88% when death occurs between days 12 and 25 of the disease (103). Patients with myocarditis have tachycardia out of proportion to fever, a gallop rhythm, pulmonary congestion, and arrhythmia. The severity of myocarditis is not associated with the presence of coronary artery aneurysms (107). Left ventricle dimensions are increased and systolic function is abnormal in patients with Kawasaki disease in comparison with control subjects. Complete recovery is the rule, with normalization of ventricular function within 6 months in most patients (107,108). IVIG speeds recovery of myocardial function (108). CHF due to ischemia, infarction, or valvular heart disease may also occur. Heart transplantation has been required in some patients.

Coronary Involvement

Coronary artery aneurysm formation with subsequent myocardial ischemia and infarction is the most recognized and important cardiac complication of Kawasaki disease. MI is the leading cause of death in these patients. In untreated patients, 25% will develop coronary aneurysms in the acute phase of the illness (105). Within 2 years of detection, 50% of these patients will have complete angiographic resolution of the aneurysms. Giant aneurysms, those greater than 8 mm or more than four times the normal size of the vessel, occur in nearly 5% of patients and have special prognostic implications. As opposed to smaller aneurysms, giant aneurysms do not regress; frequently cause arterial remodeling, resulting in stenosis; and are prone to thrombosis, resulting in acute MI (Fig. 35E.2). More than one-third of infarctions may be silent, and more than two-thirds occur within the first year after the acute phase of the illness. Despite their young age, children with Kawasaki disease and acute MI have a 22% mortality rate (109).

(Reprinted from Ino T, Akimoto K, Ohkubo M, et al. Application of percutaneous transluminal coronary angioplasty to coronary arterial stenosis in Kawasaki disease. *Circulation* 1996;93:1709–1715, with permission.)

Video 35E.12 Aneurysmal atherosclerotic disease involving the left main trunk, proximal left anterior descending artery, and proximal left circumflex artery in a 72-year-old male patient with a long history of smoking. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

IVIG has dramatically reduced the incidence of coronary aneurysms among patients with Kawasaki disease, from 23% to approximately 8% (110). High-dose aspirin administration is used until the febrile illness has passed, at which point the dose is reduced. In patients without coronary abnormalities, the aspirin may be discontinued 6 to 8 weeks after the acute phase of the illness. Patients with giant aneurysms or numerous smaller aneurysms should receive lifelong aspirin therapy, with or without coumadin. Frequency of clinical follow-up, ECG, echocardiography, and stress testing depends on the estimated risk of the patient. Patients with giant aneurysms, especially those with known coronary obstruction, require the most frequent follow-up (111).

Given the high cost and potential morbidity associated with coronary angiography, as well as the low incidence of coronary aneurysms since IVIG treatment came into use, routine angiography is not recommended in the acute illness, convalescent phase, or long-term follow-up of patients with Kawasaki disease. In the acute and convalescent phases, echocardiography has been validated as the procedure of choice in detecting coronary aneurysms, with sensitivity of nearly 100% and specificity of 97% (112). Echocardiography performed by an experienced pediatric sonographer is recommended at the time of diagnosis, at 6 to 8 weeks, at 6 to 12 months, and when symptoms of ischemia are seen (111). Changes in patient size and artery characteristics limit the use of echocardiography beyond the first decade of life. Long-term follow-up with stress imaging procedures done at yearly intervals is recommended for patients with known stenoses and should be considered for patients with giant or multiple aneurysms. Dipyridamole-thallium testing is well validated and outperformed angiography in predicting future coronary events in one trial (113). Heart catheterization is indicated when noninvasive studies suggest the presence of flow-limiting coronary stenoses.

A number of therapeutic modalities have been used when patients with Kawasaki disease develop acute coronary syndromes or chronic ischemic heart disease. Thrombolysis has been used with good results to treat pediatric patients who have acute MI, unstable angina, and documented thrombosis in aneurysms (105). Coronary artery bypass graft surgery (CABG) is the procedure of choice for patients who require revascularization, but it is less effective in the very young patient. A recent series from Japan described surgical results in 100 patients who underwent CABG surgery, with 6.7 ± 4.5 years' follow-up. No intraoperative deaths occurred. Recurrent ischemia developed in 15% of patients, and 2% of patients died during the follow-up period. One-year, 5-year, and 10-year graft patency rates were 94%, 82%, and 78% for arterial grafts and 82%, 63%, and 36% for venous grafts, respectively (114). The use of percutaneous coronary intervention (PCI) in this setting has been somewhat disappointing, characterized by high procedural mortality rates, frequent procedural failure, formation of new aneurysms, and high restenosis rates (115). There are no series that used state-of-the-art PCI with stents and glycoprotein IIb/IIIa antagonists.

Conduction System Involvement

Nonspecific ECG abnormalities are present in one-third of patients in the acute phase of the illness. Inflammation of the AV node, bundle of His, and bundle branches are present in 25% of patients at autopsy (103). Bradyarrhythmias and CHB may occur. Ventricular arrhythmias are more likely to be mediated by ischemia or infarction than by inflammation.

TAKAYASU'S DISEASE

Takayasu's disease is a chronic arteritis of the aorta, its major branches, pulmonary arteries, and coronary arteries. Takayasu, an ophthalmologist, first reported the ischemic retinal findings of the disorder in 1908. It is a rare disorder of unknown etiology with an annual incidence of 2.6 cases per 1 million individuals. It typically affects women of childbearing age, although cases affecting men are increasingly reported. Survival rates at 5 and 10 years are 91% and 84%, respectively. Clinical variables associated with poor outcome include hypertension, cardiac involvement, and poor functional capacity (116). Cardiac failure is the most common cause of death (116,117).

Diagnosis of Takayasu's disease relies on clinical, laboratory, and angiographic variables (118). Vascular bruits are the most common examination finding, followed by diminished or absent pulse. Claudication is the most common symptom, with upper extremity symptoms being more common than lower extremity symptoms (119). Arterial involvement includes, in order of decreasing frequency, the innominate and subclavian arteries, aorta, common carotid arteries, and renal arteries (120). Arterial lesions are occlusions or long, smooth stenoses more commonly than they are aneurysms or areas of ectasia.

Immunosuppression using corticosteroids and cytotoxic agents is the mainstay of medical therapy. A stepwise approach to medical therapy is advised, with initial corticosteroid therapy followed by the addition of cytotoxic agents, until clinical remission is achieved (119). No randomized, controlled trials of medical therapy have

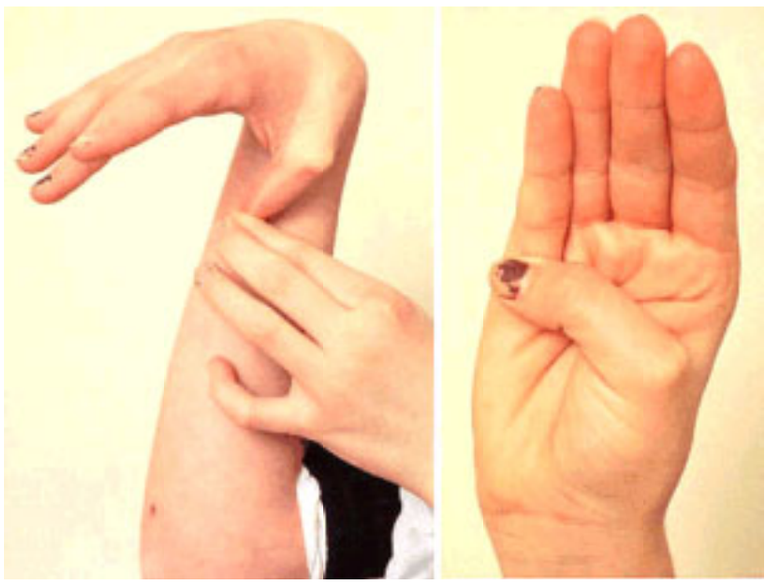
been performed, but observational data suggest that immunosuppression improves symptoms and may be associated with arterial lesion regression (119,121). Surgical and percutaneous revascularization of coronary and peripheral arteries has been described. In general, medical therapy may be pursued when symptoms are chronic and stable, but revascularization should be pursued when ischemia threatens life or limb.

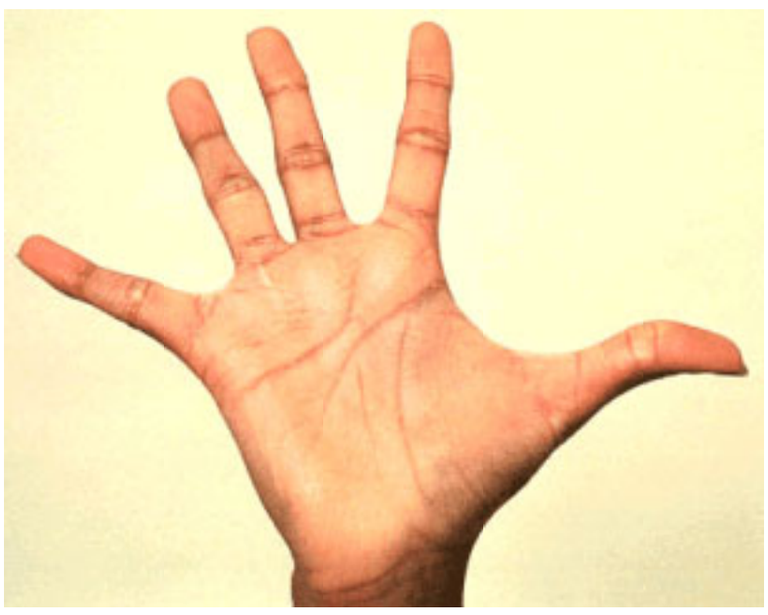
Pericardial Involvement

During phases of clinical disease activity, patients may experience systemic findings such as fever, malaise, new arterial lesion formation, arterial tenderness, erythema nodosum, myalgias, arthralgias, weight loss, and night sweats. Pericarditis may occur as part of this symptom complex. Overall, however, pericarditis is uncommon in Takayasu's disease and has an estimated clinical frequency of only 2% (117). Cases of patients presenting with large effusions have been reported, and steroids have been used, with anecdotal success (122).

Valvular Involvement

Aortic regurgitation is common among patients with Takayasu's disease, is frequently severe, and is an independent predictor of mortality in these patients. Clinically detectable aortic regurgitation is present in 7% to 20% of patients (116,117,119,123). Aortic valve replacement is necessary in approximately 1% of patients. Regurgitation is usually the result of aortic root dilation and requires combined valve and root replacement. Leaflet thickening due to inflammation and subsequent fibrosis may contribute to valvular dysfunction (124).





Ehlers-Danlos syndrome. There is severe joint laxity and hypermobility that may produce joint dislocations (A–C).

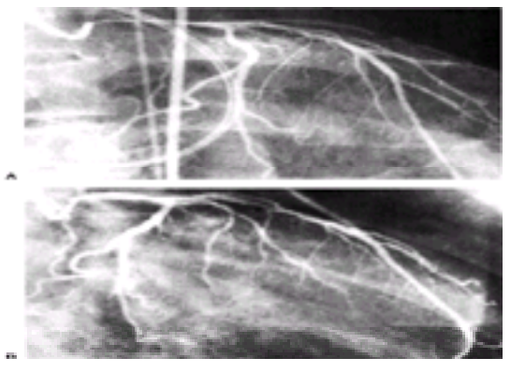
Video 35E.13 Intraoperative transesophageal echo (120-degree view) with color Doppler demonstrating aortic insufficiency due to aortic dilatation (sinuses measure 5.0 cm) causing failure of leaflet coaptation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Myocardial Involvement

CHF is the most common cause of death among patients with Takayasu's disease (116,117). CHF in these patients is usually multifactorial, with contributions from aortic regurgitation, hypertension, coronary involvement, and pulmonary artery involvement. Two-thirds of juvenile patients present in CHF, and one-third of adults experience heart failure (117). CHF with global left ventricular systolic dysfunction has been reported in the absence of hypertension or aortic regurgitation. When other markers of systemic inflammation are present, most of these patients exhibit myocarditis on endomyocardial biopsy, characterized by mononuclear cell infiltrate, necrosis, myocytolysis, and edema (125). Dramatic but anecdotal improvement has been noted after administration of corticosteroid therapy. Treatment with steroids must be done, with careful clinical follow-up, because of the capacity of steroids to increase sodium retention and raise blood pressure.

Coronary Involvement

Clinically important coronary artery involvement associated with Takayasu's disease occurs in 5% to 10% of patients (116,117). Three patterns of coronary involvement have been described: ostial stenosis; long, smooth stenoses; and aneurysm formation. The first two patterns predominate, and patients usually present with recent-onset exertional angina or non–ST-segment elevation MI (eFig. 35E.2.1). Thrombosis of a coronary aneurysm resulting in abrupt vessel occlusion that presents as an ST-segment elevation MI is distinctly rare. Because of the frequency of occurrence of ostial stenosis, CABG has been the treatment of choice. However, graft survival is poor, which is likely a reflection of aortic disease at the proximal graft anastomosis. The high likelihood of subclavian artery disease precludes the use of internal thoracic artery grafts (126). When possible, surgery is delayed for these patients until medical therapy has induced remission of active aortic inflammation. PCI has been used with increasing frequency, but no large series are available that would allow the risk of procedural failure or restenosis to be estimated. Unprotected angioplasty of the left main coronary artery was undertaken in an 11-year-old girl in one case report. This is unconventional therapy, and the authors acknowledge that "acute obstruction is an inherent risk of PTCA [percutaneous transluminal coronary angioplasty] and can be deleterious in left coronary artery main stem lesions" (127).



***e*FIGURE 35E.2.1** Severe left main coronary artery stenosis in a patient with Takayasu's arteritis **(A)**. The stenosis improved after immunosuppressive therapy **(B)**. An internal mammary artery bypass graft to the LAD can be seen in **B**. (Reprinted from Iga K, Gohma I, Hori K. Regression of the left main trunk lesion by corticosteroid administration in Takayasu's aortitis. *Chest* 1991;99:509, with permission.)

Conduction System Involvement

ECG results are abnormal in 78% of patients with Takayasu's disease (117). The most common abnormality is left ventricular hypertrophy, followed by left atrial enlargement. These changes are frequently secondary to hypertension and aortic regurgitation, rather than to primary involvement of the conductive tissue. Holter monitoring of patients with Takayasu's disease reveals frequent ventricular ectopy in one-third and nonsustained ventricular tachycardia in 5%. The appearance of frequent ventricular ectopy during Holter monitoring is associated with echocardiographic evidence of aortic regurgitation and with the appearance of perfusion defects on thallium imaging. Patients who have Takayasu's disease and frequent ventricular ectopy have an increased risk of sudden cardiac death (128).

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is a seronegative spondyloarthropathy characterized by ankylosis and sacroiliitis, peripheral arthritis, iritis, and aortitis. It is a relatively common disorder, with a prevalence of 1% in white individuals (129). The pathogenesis is thought to have both heritable and environmental components. HLA-B27 is thought to be not only a marker of the disease, but pathologically involved. The diagnosis of ankylosing spondylitis is made on the basis of clinical and radiographic features. Cardiac involvement is associated with the presence of peripheral arthritis and with disease duration; it usually occurs after 10 to 20 years of disease (130). Heart disease is the most common cause of death among patients with ankylosing spondylitis (131). Reiter's syndrome, psoriatic arthritis, and inflammatory bowel disease have similar cardiac manifestations and are not discussed separately.

Pericardial Involvement

Pericarditis is rarely reported among patients with ankylosing spondylitis. Bulkley and coworkers, in a small autopsy series, found the pericardium to be normal in patients who had not had prior open heart surgery. Echocardiographic studies in unselected patients, however, have revealed a 5% to 10% incidence of pericardial thickening and effusion (132). Complicated pericardial disease would be reportable.

Valvular Involvement

Valvular heart disease occurs in approximately 10% of patients with ankylosing spondylitis (132,133 and 134). Pathology reveals fibrous thickening 1 to 2 cm superiorly and inferiorly from the aortic valve. Histopathology reveals adventitial scar, intimal proliferation, and inflammation of the vasa vasorum with lymphocytes and plasma cells (135). A "ridge" or "bump" of fibrous tissue may accumulate below the aortic valve on the membranous portion of the interventricular septum. Aortic regurgitation caused by fibrotic shortening of the aortic valve leaflets and aortic root dilatation occurs in approximately 8% of patients and may be severe. Mitral regurgitation due to extension of the fibrotic process to the anterior mitral leaflet has been reported (136). Mitral valve prolapse has been reported in as many as 10% of patients (132). Disease duration, advanced patient age, and the presence of peripheral arthritis predict valvular involvement. Echocardiography is a sensitive method for detection of preclinical valvular involvement, but whether early detection will affect late outcomes is unclear. Patients in whom careful clinical examination detects murmurs of aortic regurgitation should undergo echocardiography.

Myocardial Involvement

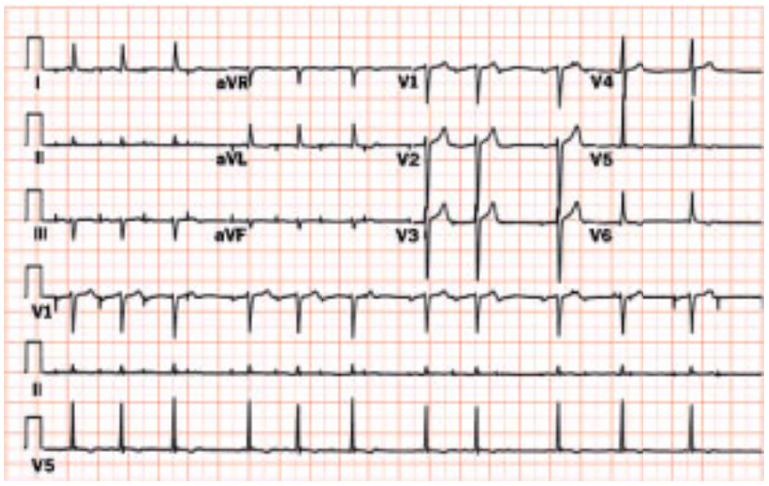
CHF is rarely reported among patients with ankylosing spondylitis, and systolic ventricular dysfunction is rare in the absence of ischemia, valvular heart disease, or hypertension. Diastolic dysfunction, however, has been found in up to 55% of patients (137). Diffuse myocardial connective tissue deposition in the absence of valvular heart disease, CAD, or hypertension has been observed histologically (137).

Coronary Involvement

Patients with ankylosing spondylitis do not appear to be at an increased risk for atheromatous CAD, and significant inflammation of the epicardial coronary arteries has not been reported. Despite this, MI is an important cause of death in these patients, because of its high incidence in the general population (130). Extension of aortic pathology with ostial coronary artery narrowing presenting as stable angina has been reported in one patient with Reiter's syndrome (138).

Conduction System Involvement

Abnormalities of cardiac impulse formation or conduction are common among patients with ankylosing spondylitis and occur in 10% of patients (133). Sinus node dysfunction may be manifest as asymptomatic sinus pauses or sinus bradycardia (132,134). AV block is common, ranging from first-degree block to CHB. It is more common among patients with aortic regurgitation and occurs in as many as 44% of these patients (139). This is consistent with the known pathology of the disease, in which the fibrotic process extends into the interventricular septum, through which the conduction system traverses. Aortic regurgitation usually precedes heart block in the course of the disease (130). Bergfeldt and coauthors (140) studied a group of 223 consecutive men referred for pacemaker implantation and found 15 cases of ankylosing spondylitis, many of which were undiagnosed, suggesting that spondyloarthropathies may be an underappreciated cause of bradycardia.



Mobitz I second-degree atrioventricular block. Note electronic atrial pacemaker with progressive PR segment prolongation before dropped QRS complex.

CHURG-STRAUSS SYNDROME

Churg-Strauss syndrome (CSS) is characterized by eosinophil-rich and granulomatous inflammation that involves the respiratory tract and necrotizing vasculitis that affects small to medium-sized vessels, associated with asthma and eosinophilia (98). It is a rare disorder of unknown etiology, with an estimated annual incidence of less than one case per 100,000 individuals (141). Current therapy consists of administration of corticosteroids and cytotoxic agents, and the survival rate is 72% at 7 years (142). Cardiac involvement is a prominent feature of CSS; it occurs in 60% of patients in some studies and is the most common cause of death in most studies (142,143,144 and 145). Heart disease in patients with CSS is predictive of a poor outcome.

Pericardial Involvement

Clinically diagnosed pericarditis occurs in 20% to 32% of patients with CSS (142,145,146). Constrictive pericarditis and tamponade are rare but reported complications. Pericardial fluid may be bland or rich in eosinophils (147,148). Pericardial histopathology can be diagnostic and may reveal necrotizing granulomata, fibrosis, and prominent eosinophils. Acute management includes administration of corticosteroids and cytotoxic agents and drainage of the effusion when it causes hemodynamic compromise. Surgical creation of a pericardial window may be required for patients with recurrent disease and provides tissue for pathologic evaluation when the diagnosis is in doubt.

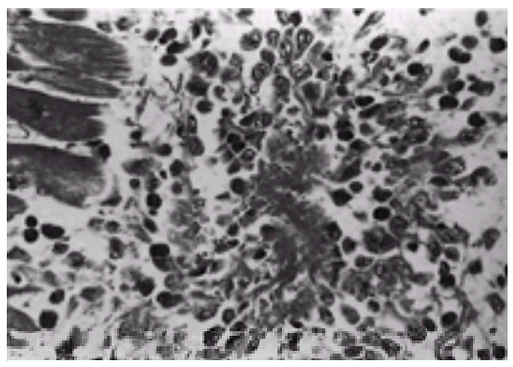
Valvular Involvement

Valvular heart disease is not a consequence of CSS.

Myocardial Involvement

Patients with CSS suffer considerable morbidity and mortality from CHF. Clinical evidence of CHF is present in 13% to 48% of patients (142,145). As noted earlier, cardiovascular disease is the most common cause of death among patients with CSS, and CHF is the most common cause of cardiovascular death. CHF that results from systolic dysfunction, diastolic dysfunction, and restrictive physiology may all be important. Ventricular thrombosis and thromboembolism resulting from underlying myocardial involvement have been reported (149).

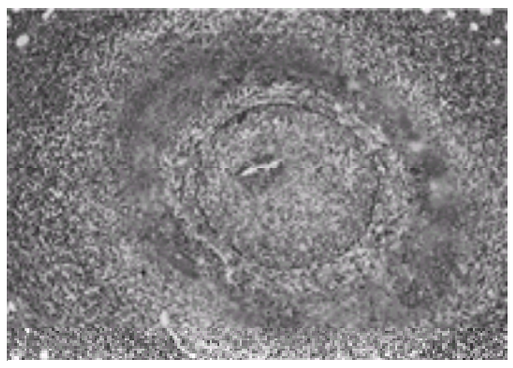
Unlike many of the other connective tissue disorders and vasculitic syndromes, left ventricular dysfunction in association with CSS is frequently the result of primary myocardial involvement by the inflammatory process. Endomyocardial biopsy may show necrotizing granulomata and, frequently, eosinophils during the acute phase of the illness (*e*Fig. 35E.2.2) (150). Anecdotal reports are available of dramatic improvement in left ventricular function after immunosuppressive therapy is begun (150,151). Heart transplantation has been performed in a patient with CSS and fulminant myocarditis (152). Immunosuppression should be guided by endomyocardial biopsy, when possible, because fibrotic changes alone may be present if patients present late in the course of the illness (151).



***e*FIGURE 35E.2.2** Myocarditis in a patient with Churg-Strauss syndrome, revealing granulomatous and eosinophilic inflammation. (Reprinted from Sasaki A, Hasegawa M, Nakazato Y, et al. Allergic granulomatosis and angiitis. *Acta Pathol Jpn* 1988;38:781–788, with permission.)

Coronary Involvement

Autopsy evidence of coronary arteritis is present in more than one-half of patients with CSS (144). Acute MI is responsible for up to 20% of deaths in some series (143) (*e*Fig. 35E.2.3). Angiographic improvement of coronary arteritis after the start of medical therapy has been documented (153). Because of the difficulty in distinguishing between coronary arteritis and atherosclerotic CAD by angiography, corticosteroid therapy may be added to conventional therapy in select patients whose clinical course is stable and is strongly suggestive of arteritis.



***e*FIGURE 35E.2.3** Arteritis of the left anterior descending coronary artery in a patient with Churg-Strauss syndrome. Fibrinoid necrosis of the media and eosinophilic infiltration can be seen. (Reprinted from Sasaki A, Hasegawa M, Nakazato Y, et al. Allergic granulomatosis and angiitis. *Acta Pathol Jpn* 1988;38:781–788, with permission.)

Conduction System Involvement

Although ECG abnormalities are present in up to 50% of patients who have CSS, arrhythmias are uncommon. Those that have been reported are conduction abnormalities that appear in the setting of myocardial disease and respond to medical therapy (142).

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is a rare (154), nongranulomatous, necrotizing vasculitis of medium-sized and small arteries that is not accompanied by glomerulonephritis or microscopic angiitis (98). It is diagnosed by a combination of clinical and laboratory features, including weight loss, livedo reticularis, testicular pain, myalgias, neuropathy, diastolic hypertension, renal insufficiency, abnormal results of serologic testing for hepatitis B virus, and arteriographic or biopsy evidence of arteritis (155). Historically, survival rates have been only 13% 5 years after diagnosis (156). Advances in supportive care and medical treatment with corticosteroids and cyclophosphamide have improved the survival rate to 82% at 5 years (157). Death is usually the result of renal failure or infection. Cardiac involvement occurs in more than one-half of patients but is symptomatic in only 10% to 30% (154). The heart may be a direct target of the disease process, or it may be secondarily affected by hypertension, renal insufficiency, and corticosteroid use.

Livedo reticularis. Mottled reddish discoloration of the lower extremities with accompanying multiple ulcerations associated with atheroemboli.

Pericardial Involvement

Clinically apparent pericarditis is uncommon in PAN and occurs in 2% to 5% of patients (154). At autopsy, however, pericarditis is observed in 27% of patients with PAN (158). It may be fibrous or fibrinous. Pericardial involvement complicated by purulent pericarditis, tamponade, or constrictive pericarditis would be worth reporting.

Valvular Involvement

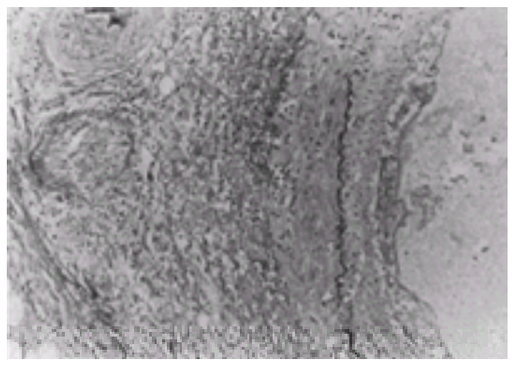
PAN does not appear to be associated with valvular heart disease.

Myocardial Involvement

CHF is common among patients with PAN, occurring in 10% to 15%, but is usually secondary to associated hypertension, renal failure, or coronary involvement. Limited myocarditis has been reported in approximately 15% of patients with PAN at autopsy and is more common among patients with active arteritis (158). It is usually mild and of little clinical significance.

Coronary Involvement

Symptoms of coronary insufficiency occur in 4% to 15% of patients with PAN (154). Acute MI due to epicardial coronary artery necrotizing inflammation has been documented (*e*Fig. 35E.2.4) (159), but its exact incidence is unknown. Hypertension, corticosteroid use, and renal failure contribute to the high prevalence of atheromatous CAD among patients with PAN. Retrospective cohort series of patients with PAN report the occurrence of MI in 1% to 5% (154). MI in patients with PAN may be silent, or CHF may be the presenting symptom. PAN patients who present with chest pain and ST-segment elevation should be treated with either thrombolysis or primary coronary angioplasty, because occlusive lesions are typically caused by thrombus overlying areas of inflammation.

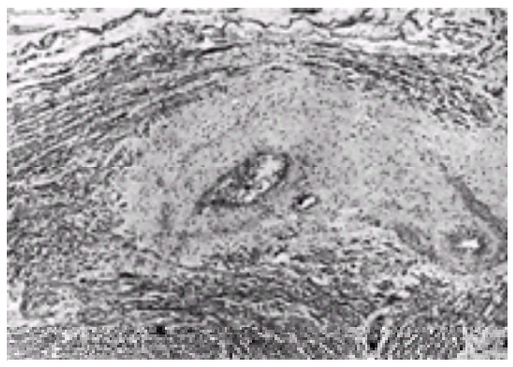


***e*FIGURE 35E.2.4** Necrotizing arteritis of the left anterior descending coronary artery in a patient with polyarteritis nodosa. [Reprinted from Odhav S, McKown K, Lohr KM. Polyarteritis nodosa presenting as recurrent myocardial infarction (letter). *Chest* 1994;105:1615, with permission.]

Pathologic evidence of coronary arteritis is more common than symptomatic disease and is found in one-half of all patients at autopsy (158). Arteritis begins with granulocytic infiltration of the vessel wall, followed by mononuclear cell predominance and then by fibrotic healing. Inflammation of epicardial coronary arteries may occur, but PAN more typically causes inflammatory lesions in intramyocardial coronary arteries (158). The clinical importance of this inflammation is unknown.

Conduction System Involvement

Autopsy evidence of involvement of the cardiac conduction system is commonly found in patients with PAN; however, clinically important arrhythmias are uncommon. Schrader and associates (158) reported sudden cardiac death to be the cause of death in 11% of their autopsy subjects, although detailed descriptions of the conductive tissue were not provided. Pathology of the AV nodal and SA nodal arteries, due to both ischemia and inflammation extending from the vessel into the conductive tissue, has also been implicated in clinical arrhythmias (*e*Fig. 35E.2.5) (160).



***e*FIGURE 35E.2.5** Healed arteritis in the atrioventricular nodal artery with residual intraluminal thrombus and perivascular fibrosis in a patient with polyarteritis nodosa. GIANT CELL (TEMPORAL) ARTERITIS

Giant cell arteritis (GCA) is a granulomatous arteritis of the aorta and its major branches that has a predilection for the extracranial branches of the carotid artery, often involves the temporal artery, and usually occurs in patients older than 50 years (98). The first case description is attributed to Hutchinson, in 1890 (161). The cause of GCA is not known, but it appears to be pathologic inflammation driven by a specific antigen and mediated by CD4+ lymphocytes, resulting in cytokine release and macrophage-induced oxidative damage (162). Diagnosis is based on clinical and pathologic criteria, including three of the following: age older than 50 years, new-onset headache, clinical abnormality of the temporal artery, elevated erythrocyte sedimentation rate, and diagnostic temporal artery biopsy (163). Its annual incidence in a predominantly white population is 17.8 in 100,000, but may reach 50.0 in 100,000 among elderly patients (164). Cardiac dysfunction occurs in 5% to 10% of patients with GCA (165). It is usually secondary to disease of the ascending aorta, rather than to primary cardiac involvement. Cardiac disease is the most common cause of death among patients with GCA (166).

Giant cell myocarditis. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Coronary Involvement

Coronary involvement in GCA appears to be rare, but it may be underreported. A number of case reports of histopathologically confirmed GCA of the coronary arteries have been published and summarized by Paulley (167), but the true incidence of coronary involvement is unknown. Acute MI has been reported (168). General angiographic predictors of arterial involvement by GCA include the presence of long, smooth stenoses; involvement of arch vessels; tapered occlusions; and the presence of skip lesions with diseased segments interspersed with normal segments (169). Traditional risk factors for the development of CAD are prevalent in patients with GCA. Hypertension has been noted in 43% of these patients, tobacco use in 14%, diabetes mellitus in 6%, and a positive family history of CAD in 31% (170). Risk factors should be aggressively treated, as should established CAD.

Aortic Involvement

Large arteries are involved in the cases of almost 15% of patients with GCA (171). The incidence of thoracic aortic aneurysms among these patients is 17.3-fold higher than that in the general population. On average, more than 5 years passes between diagnosis of GCA and diagnosis of aortic aneurysm. No clinical predictors of aneurysm development have been identified (165). Aortic dissection or rupture may occur. Despite this, life expectancy for patients with GCA is similar to that in the general population (165,166). Therefore, radiographic screening for aortic aneurysm in patients with GCA is not advocated. However, careful clinical examination may reveal evidence of aortic aneurysm or large-vessel involvement, and further evaluation in these patients is warranted.

Ascending aortic dissection extending into the left main. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Valvular Involvement

Aortic regurgitation has been described in 5% to 10% of patients with GCA. Histologic examination has shown that the valve itself is an innocent bystander. Aortic valve regurgitation is due to ascending aortic aneurysm formation with aortic root dilatation (Fig. 35E.3). Aortic valve replacement with aortic root reconstruction should be undertaken when patients develop large ascending aortic aneurysms or severe aortic regurgitation with either symptoms of CHF or signs of ventricular dysfunction.

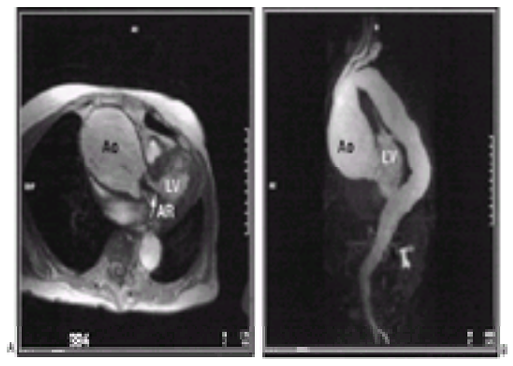

FIGURE 35E.3 Cross-sectional **(A)** and left anterior oblique **(B)** cardiac magnetic resonance images of a 72-year-old woman with giant cell arteritis/temporal arteritis, revealing an 8-cm ascending aortic aneurysm (Ao) and aortic regurgitant jet (AR, *arrow*). LV, left ventricle.

Pericardial involvement, myocardial involvement, or conduction system involvement in GCA with pathologic confirmation would be reportable.

WEGENER'S GRANULOMATOSIS

Wegener's granulomatosis (WG) is a rare systemic disorder of unknown etiology that is characterized by granulomatous inflammation involving the respiratory tract, necrotizing vasculitis of small and medium-sized vessels, and, commonly, necrotizing glomerulonephritis (98). Diagnosis relies on fulfillment of clinical criteria, including two or more of the following: nasal or oral inflammation, abnormal results of chest radiography, hematuria or red blood cell casts in urine, and granulomatous inflammation on examination of biopsy specimens. The presence of cytoplasmic patterned antineutrophil cytoplasmic antibody aids in diagnosis, but its pathologic role is uncertain. Once WG was almost uniformly fatal within months of diagnosis, but medical therapy with corticosteroids and cytotoxic agents has improved survival rates to 87% at 8 years (172). Despite this, patients with WG have standardized mortality ratios of more than 4, compared with the general population (173). Causes of death in these patients, in order of decreasing frequency, include infection, cardiovascular disease, renal failure, cancer, unknown causes, pulmonary disease, and stroke

(173). Pulmonary and renal disease accounts for the majority of disease-related deaths. As the life expectancy for WG patients increases, cardiovascular disease is emerging as an important cause of morbidity and mortality. Cardiac involvement occurs in 12% to 14% of patients with WG (173,174).

Pericardial Involvement

Pericarditis is the most common cardiac manifestation of WG, occurring in one-half of patients with cardiac involvement (175) and in 6% to 10% of the overall patient population (172,173 and 174). It presents most commonly as acute pericarditis, but tamponade and constrictive pericarditis have been rarely reported (176,177). Histopathologic examination reveals fibrinous pericarditis with occasional pericardial granulomata (176,178). When pericarditis associated with WG is part of a systemic flare, it should be treated with initiation or intensification of steroid and cyclophosphamide therapy.

Valvular Involvement

Hemodynamically significant valvular dysfunction is uncommon, although not rare, in patients with WG. Clinical or autopsy evidence of valvulitis is found in 21% of patients with WG and cardiac involvement (175). Numerous case reports of severe aortic regurgitation with echocardiographic and histopathologic evidence of involvement by WG are available in the literature (176,179,180). Aortic valve leaflet perforation seems to have been reported with disproportionate frequency, relative to aortic regurgitation from other causes (181,182). Mitral valve regurgitation and stenosis appear to be less common than aortic regurgitation. When tissue is available from intraoperative or autopsy specimens, bland fibrosis with degeneration of collagen has been found more commonly than has active inflammation.

Myocardial Involvement

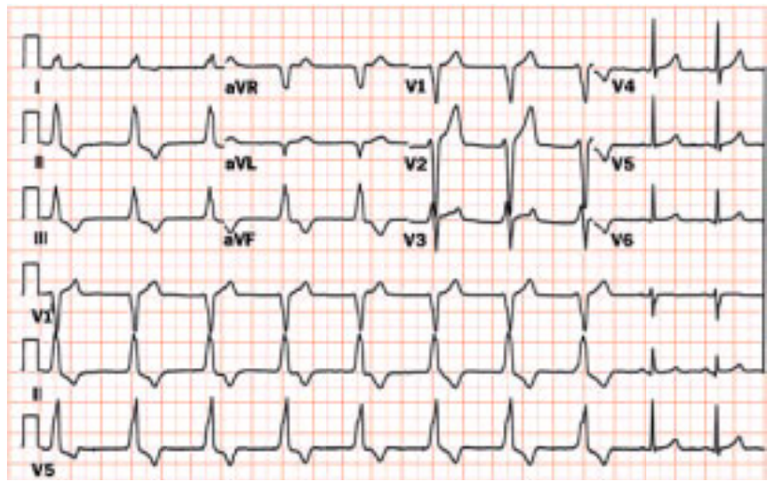
Myocarditis occurs in approximately 2% of patients with WG (174). Myocarditis may present as diffuse myocarditis, myocardial mass, or arrhythmia. Severe left ventricular systolic dysfunction due to myocarditis may respond to treatment with prednisone and cyclophosphamide, with resolution of symptoms and normalization of ventricular function (183). Kosovsky and associates (184) reported the case of a patient with a well-defined right ventricular mass, presenting as ventricular tachycardia, that was revealed on resection to be composed of granulomatous inflammatory tissue. Fauci and coauthors (174) also reported cases in which cardiomyopathy in patients with WG presented as ventricular tachycardia. On the basis of anecdotal improvements in left ventricular function that have been reported in patients with WG, it is reasonable to initiate or intensify immunosuppressive therapy in patients who present with new left ventricular systolic dysfunction, while standard heart failure therapy is started concurrently. This is particularly true if myocarditis occurs in conjunction with other signs or symptoms of active vasculitis.

Coronary Involvement

Coronary arteritis presenting as acute MI is rare but has been reported in patients with WG (185). Coronary arteritis at autopsy is present in one-half and evidence of MI in 11% of patients who have WG and known cardiac involvement (175). Histopathologic examination reveals epicardial arteritis with fibrinoid necrosis of the media and small-vessel fibrinoid occlusion (178). Patients with WG may, of course, have atheromatous CAD, and MI is a common cause of death in these patients (173).

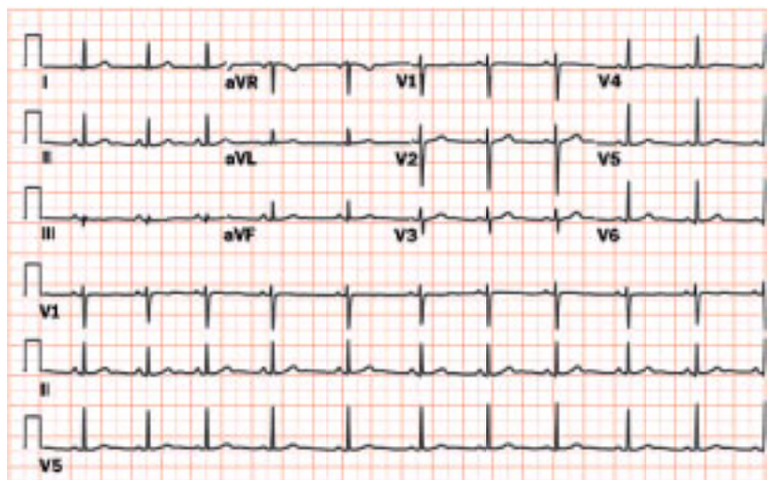
Conduction System Involvement

A variety of arrhythmias have been described in patients with WG. CHB may be caused by granulomatous inflammation of the AV node, bundle of His, or bundle branches, or by inflammation of the artery to the AV node (175,178). Immunosuppressive therapy allowed pacemaker insertion to be avoided for one patient with CHB who had a stable ventricular response (177), and extraction of a pacemaker was possible for another patient (175). Sinus node dysfunction and atrial arrhythmias may be caused by inflammation of the sinus node artery or by extension of inflammation from overlying pericarditis. As noted, patients with WG and myocardial involvement may also present with ventricular tachycardia. A short trial of temporary pacing may be considered for patients who have symptomatic bradycardia, while immunosuppressive therapy is initiated.



Isorhythmic dissociation. In the rhythm strip there is no relationship between the P waves and QRS complexes for the first eight beats. Subsequently, the QRS complex narrows and a P wave is well seen. This is consistent with isorhythmic dissociation.

Ashman's phenomenon. Underlying rhythm is atrial fibrillation. QRS complex with right bundle branch block morphology after long-short coupling interval is diagnostic of Ashman's phenomenon.



Sinus arrhythmia. Young female patient with sinus rhythm characterized by irregular RR intervals.

POLYMYOSITIS AND DERMATOMYOSITIS

Background

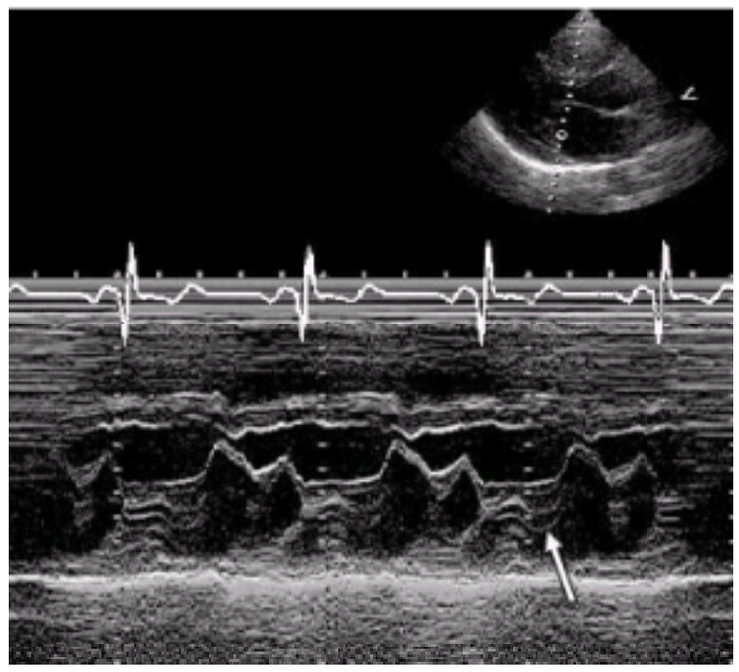
Polymyositis (PM) and dermatomyositis (DM) are inflammatory myopathies of unknown etiology. Diagnosis is based on fulfillment of clinical criteria put forth by Bohan and colleagues (186), which include proximal muscle weakness, serum enzyme abnormalities, abnormal results of electromyography, abnormal results on examination of muscle biopsy specimens, and, for diagnosis of DM, typical cutaneous manifestations. The survival rate is 73% at 8 years. The major causes of death are sepsis, malignancy, and cardiovascular disease (187). Cardiac involvement is the worst prognostic sign that may be found in patients with PM and DM (187). Symptoms suggesting cardiac involvement occur in 6% to 10% of patients.

Pericardial Involvement

Pericarditis is an uncommon but reported feature of PM and DM. Hochberg and colleagues (187) reported that 7% of the patients they followed for a mean time period of 8 years developed pericarditis. Echocardiography of unselected patients who have PM/DM reveals pericardial effusion in 8% (188). Complicated pericardial disease, such as purulent pericarditis, constrictive pericarditis, or tamponade, would be reportable.

Valvular Involvement

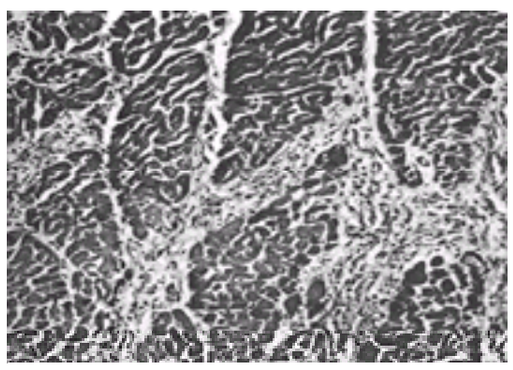
Clinically important valvular dysfunction is exceedingly rare in patients with PM/DM.One report suggests that the prevalence of mitral valve prolapse is 65%, diagnosed by both echocardiography and the presence of an audible mid-systolic click (189). None of those patients had hemodynamically significant regurgitation, and subsequent autopsy and echocardiographic studies have not supported so prominent an association (188,190).



M-mode tracing of posterior leaflet mitral valve prolapse. Note the posterior displacement of the posterior mitral leaflet after the leaflets close in systole.

Myocardial Involvement

A number of clinical, echocardiographic, biopsy, and autopsy studies have confirmed the occurrence of myocardial involvement in patients with PM/DM. Systolic dysfunction, diastolic dysfunction, and hyperdynamic states have all been described. Large retrospective studies report an incidence of symptomatic CHF that is lower than 5% (186). Autopsy studies find clinical CHF in nearly 50% of patients with PM/DM. At autopsy, approximately one-half of these patients are found to have myocarditis (*e*Fig. 35E.3.1) (190,191). Diastolic dysfunction has been reported in 42% of patients with PM/DM (188). The relative contributions of myocarditis, chronic corticosteroid use, and hypertension are unknown. PM and DM generally are steroid-responsive diseases. A trial of high-dose corticosteroids may be warranted in patients with PM/DM who present with fulminant heart failure due to systolic left ventricular dysfunction; however, because of the rarity of the condition, no trials have been performed.



***e*FIGURE 35E.3.1** Interstitial myocarditis in a patient with polymyositis. (Reprinted from Denbow CE, Lie JT, Tancredi RG, et al. Cardiac involvement in polymyositis: a clinicopathologic study of 20 autopsied patients. *Arthritis Rheum* 1979;22:1088–1092, with permission.)

A small percentage of patients with PM/DM have hyperdynamic cardiac function characterized by left ventricular ejection fractions of greater than 75% and an elevated cardiac index. This has been demonstrated in the absence of anemia, infection, hyperthyroidism, and hepatic or renal disease (188,189).

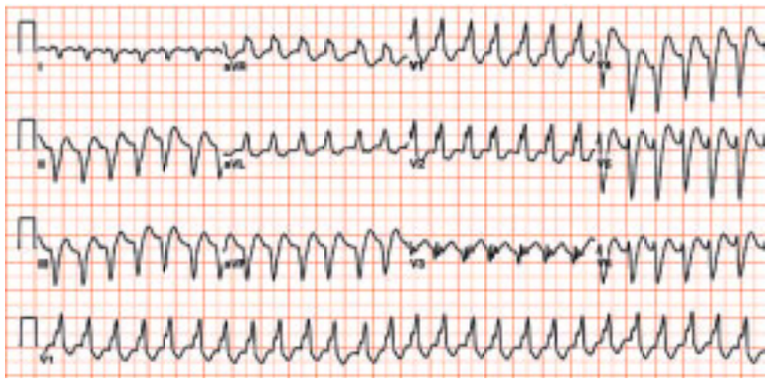
Coronary Involvement

Patients with PM/DM are not prone to accelerated atherosclerosis or to inflammation of the epicardial coronary arteries. Small-vessel disease, which is characterized by medial hypertrophy and hyperplasia, may be present in up to 20% of patients (191). Occasionally, this is associated with myocardial scar in the absence of epicardial CAD or myocarditis. Its clinical importance, however, is unknown. Patients with PM/DM may have an elevated CK-MB level and an elevated CK-MB index in the absence of myocardial necrosis induced by myocarditis or MI. This may be caused by injury-induced regression to a more juvenile skeletal muscle composition (192) and may result in diagnostic confusion when patients present with chest pain.

Conduction System Involvement

Conduction system involvement in association with myocardial involvement may be a prominent feature in patients with PM/DM. ECG abnormalities occur in one-half of all patients and consist mainly of conduction delays and chamber hypertrophy (188,189). Holter monitoring detects abnormalities in more than 75% of patients, and important atrial and ventricular arrhythmias are found in 26% of patients. CHB is the most clinically important electrophysiologic manifestation of PM/DM. High-grade AV block occurs in 2% of patients (186), and autopsy studies reveal lymphocytic infiltration and fibrosis of the conduction system (190).

A 71-year-old patient with left ventricular hypertrophy and negative U waves.



An 81-year-old male patient with ventricular tachycardia.

OTHER DISEASES

Behçet's disease is a rheumatic disease of unknown etiology that is characterized by orogenital ulcers, chronic uveitis, skin lesions, and, frequently, arthritis. Patients with the disease are prone to aortic aneurysms and venous and arterial thrombosis. MI due to thrombosis of an epicardial coronary artery may occur (193). Aortitis with resultant aortic regurgitation, myocarditis, pericarditis, and noninfective endocarditis has also been reported. Echocardiographic studies done on asymptomatic patients, however, reveal no differences from control subjects (194).

Relapsing polychondritis is a disorder characterized by nasal, auricular, and laryngeal cartilage inflammation and peripheral arthritis. Cardiac involvement affects 6% to 12% of patients. Aortic regurgitation is most common, with aortitis, coronary arteritis, and heart block also described (195).

Adult-onset Still's disease is a variant of juvenile RA characterized by maculopapular rash, fever, arthritis, leukocytosis, and myalgias. Pericarditis is common in this disease, affecting as many as one-fourth of patients (196,197). Myocarditis has rarely been described but may be fulminant when it occurs (197). Treatment consists of administration of NSAIDs, corticosteroids, and cytotoxic agents, depending on disease severity.

THERAPY

Primary prevention for patients with rheumatic diseases includes not only traditional risk-factor modification, but also minimization of cardiotoxic and atherogenic medications. Nonpharmacologic methods of prevention include smoking cessation, dietary changes, and exercise. Pharmacologic methods to prevent coronary events include 3-hydroxy-3-methylglutaryl coenzyme reductase inhibitors for hyperlipidemic patients, antihypertensive therapy for patients with hypertension, and aspirin and ramipril for high-risk patient groups. Newer immunomodulating therapies and cytotoxic agents may allow reduction of steroid doses, which may translate into a reduction in the incidence of manifest cardiac disease.

Patients with established CAD and heart failure are candidates for secondary prevention strategies. These include nonpharmacologic methods such as sodium restriction, dietary changes, exercise, and smoking cessation. Secondary prevention for patients with CAD includes administration of aspirin and ACE inhibitors for all patients, beta-blockers for patients with a history of MI, and include 3-hydroxy-3-methylglutaryl coenzyme reductase inhibitors for patients with hyperlipidemia. Patients with chronic heart failure who have systolic left ventricular dysfunction benefit from ACE inhibitors, beta-blockers, digoxin, and diuretics. The optimal treatment of heart failure due to diastolic dysfunction is less well characterized; control of hypertension is paramount. Standard recommendations for use of revascularization, valvular surgery, pacemakers, and implantable cardioverter-defibrillators apply. No randomized controlled trials have evaluated any of these therapies specifically for use in patients with rheumatologic disease, and therefore therapy should be tailored to the individual patient.

The use of immunosuppressive therapy for patients with pericarditis, myocarditis, valvulitis, or coronary arteritis should be guided by adjunctive clinical, histologic, or laboratory evidence of inflammation, when possible. The treatment of myocarditis demands special attention, because trials addressing immunosuppressive therapy for "idiopathic" myocarditis have been disappointing. Endomyocardial biopsy may allow the clinician to distinguish between active inflammation and the subsequent fibrotic response that occurs in many of these illnesses. The rheumatic diseases, with few exceptions, are generally steroid-responsive. Immunosuppressive therapy should be considered when these patients present with biopsy-proven, symptomatic myocarditis.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The rarity and clinical heterogeneity of both the cardiac and noncardiac manifestations of the rheumatic diseases have precluded prospective, randomized, controlled trials of therapeutic strategies. The clinician, therefore, is called on to draw from general principles of physiology and pharmacology, as well as the observational experience of the medical community, to guide individual patient care. This frequently involves a team approach, with internist, rheumatologist, cardiologist, and surgeon collaborating to benefit the patient.

The cardiac manifestations of the rheumatic diseases may be dramatic but more frequently are subtle, or patients may even be asymptomatic. The presence of these manifestations below the level of clinical detection belies their prognostic importance. The proper vigor with which to seek out cardiac involvement in these disorders remains to be defined. Careful attention should be paid to the cardiovascular system during physical examination and on any incidentally obtained studies.

THE FUTURE

Progress in the treatment of the cardiac manifestations of the rheumatic diseases will require continued diligence, both at the bench and at the bedside. Basic research in immunology and the infectious diseases will, hopefully, provide insight into disease etiology and guide development of disease-specific therapies. Clinical research in rheumatology and cardiology may provide better treatment of established disease. Multicenter randomized controlled trials will be required to accrue adequate numbers of patients to draw firm conclusions with regard to detection and treatment of cardiovascular involvement in the rheumatic diseases.

OVERVIEW

Infections of the heart are increasingly more prevalent and more serious causes of morbidity and mortality. Infective endocarditis is the most common clinically important entity and is occurring more frequently as greater numbers of prosthetic devices are being implanted into patients, predominantly in the form of valves, leads for pacemakers and defibrillators, and patches to repair various anatomic abnormalities (see Chapter 25). Although infectious myocarditis occurs less frequently than infectious endocarditis, it remains an important cause of both fulminant and chronic heart failure. Systemic infections, such as infection with the human immunodeficiency virus (HIV) and Chagas' disease, are common causes of profound heart failure, particularly in developing countries. A method for accurately diagnosing infectious myocarditis premortem remains elusive, and diagnosis currently relies largely on circumstantial evidence, such as increases in serum antibody titers. Newer techniques, such as gene amplification by reverse transcription polymerase chain reaction (rt-PCR) and nucleic acid hybridization of right ventricular endomyocardial biopsy (EMB) tissue, suffer from a lack of sensitivity. Furthermore, once the diagnosis of infectious myocarditis is made, treatment is mainly focused on providing hemodynamic support and symptom relief, as opposed to counteracting the pathogenic organism. Nevertheless, full recovery of cardiac function is common, although not uniform. Infectious pericarditis is also a common clinical cardiac infection (see Chapter 26).

Infectious pathogens have also been implicated as potential etiologic agents for the development of coronary atherosclerosis or restenosis after percutaneous coronary interventions. Although a causal relationship has yet to be established, this idea has given rise to several large prospective trials, which are currently ongoing.

CLINICAL PRESENTATION IN INFECTIOUS MYOCARDITIS

There is a wide spectrum of clinical presentations associated with infectious myocarditis, ranging from a clinically silent syndrome that ends in complete recovery to acutely or chronically decompensated irreversible heart failure that leads either to death or to heart transplantation. The symptoms of mild to moderate infectious myocarditis are relatively nonspecific, consisting of fever, sweats, or chills associated with mild dyspnea and palpitations. In severe cases of infectious myocarditis, symptoms relate to hypoperfusion and cardiac congestion, for example, mental status changes, limb or gut ischemia, and shortness of breath. Chest pain is relatively infrequent and usually results from accompanying pericarditis. The signs of infectious myocarditis are also nonspecific, and they include frequent atrial and ventricular extrasystoles, sinus tachycardia that is out of proportion to the degree of hyperthermia, and, in severe cases, more significant arrhythmias, a soft first heart sound, a third heart sound, and pulmonary edema. Varying degrees of atrioventricular heart block may develop transiently and usually resolve spontaneously and completely (1). In the majority of cases, the initial infection remains completely unrecognized, and full recovery of cardiac function ensues. However, for unclear reasons, the infectious insult leads in a minority of patients to progressive myocardial dysfunction either acutely or, more commonly, many years after the original insult. This is felt to be one of the more common etiologies for dilated cardiomyopathy (DCM), and it accounted for 12.8% of all cases in a recent study (2). Most commonly (in 51.2% of all cases), no etiology is discovered, and the cardiomyopathy is thus called *idiopathic*.

DIAGNOSIS OF INFECTIOUS MYOCARDITIS

In light of the lack of specific signs and symptoms for infectious myocarditis, accurate and early diagnosis of this condition relies on a high level of clinical suspicion in the practitioner. Often the earliest evidence of active myocarditis is nonspecific changes seen on the resting electrocardiogram. These changes usually involve the ST segment and the T wave, but, in severe cases, significant intraventricular conduction delays can develop, either transiently or permanently. A pseudoinfarction electrocardiographic pattern with Q waves and ST-segment elevation indicates a particularly poor prognosis and is often associated with a rapidly fatal course of the disease (3). Abnormal QRS morphology and left bundle branch block are also indicative of a worse prognosis, although clinical deterioration usually is the result of progressive congestive heart failure that occurs over a protracted time course (1). These electrocardiographic changes are more helpful when a baseline electrocardiogram is available for comparison.

Left bundle branch block. Wide QRS complex, negative in lead V_1, is associated with secondary T-wave inversions.

Serum creatinine kinase levels, particularly the MB fraction (4), as well as both serum troponin I (5) and T levels (6), can be elevated as a reflection of ongoing myocardial necrosis resulting from the inflammatory process. The degree of elevation, and indeed whether these levels are elevated at all, is a function of the severity of the inflammatory insult and its acuity. Both the sensitivity and specificity of these markers of myonecrosis are particularly poor.

A documented fourfold rise in serum viral antibody titers from the acute to the convalescent stage of the infection is reasonable, but delayed, indirect evidence of viral infection does not assist in the management of the patient in the acute phase of the illness (7). A significant rise in virus-specific immunoglobulin M (IgM) antibody titers is an earlier serologic finding, although it is still not rapid enough to have therapeutic implications.

Various imaging modalities can also be used, with varying degrees of success, to assist in the diagnosis of acute infectious myocarditis. Echocardiography is of limited

use and serves mainly to confirm left ventricular systolic dysfunction and to eliminate other potential etiologies, particularly valvular cardiomyopathies and anatomic abnormalities, such as atrial and ventricular septal defects. In antimyosin scintigraphy, a radiolabeled antimyosin antibody is infused and binds to cardiac myosin heavy chains that are exposed to the circulation. In highly selected patient populations, this diagnostic tool is reasonably specific, but it is less sensitive than EMB with immunohistologic analysis (8). However, the specificity of antimyosin scintigraphy is dramatically reduced in less selective populations, because a positive study is a reflection of active myonecrosis, regardless of its etiology, including myonecrosis that occurs after a myocardial infarction. For these reasons, this method has not been widely implemented. Similarly, gadolinium-enhanced magnetic resonance imaging has proven to be relatively sensitive in the detection of acute myocarditis (9). However, it lacks specificity, because abnormal myocardial enhancement reflects only active inflammation, regardless of the etiology, including inflammation that occurs after myocardial infarction and various other cardiomyopathic processes (10). Magnetic resonance imaging may play a more important role in the future, once effective and specific therapies have been discovered and serial assessments can be used to determine the adequacy of therapy.

Video 35F.1 Normal parasternal short-axis view of the left ventricle by transthoracic echo. The anterior wall is located at the top and the inferior and posterior walls are located towards the bottom of the screen. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

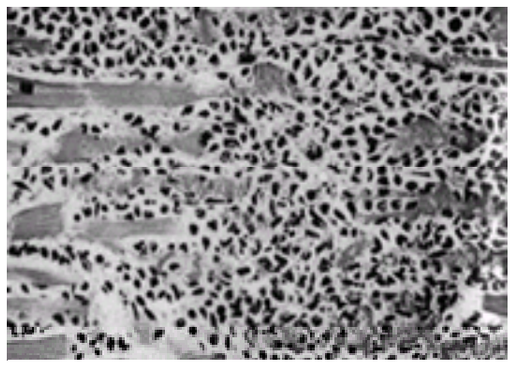
Video 35F.2 Normal parasternal long-axis view in a transthoracic echocardiogram. The mitral and aortic valves are well seen, as are the anteroseptal and posterior walls of the left ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35F.3 Normal apical five-chamber view in a transthoracic echo obtained by angling the transducer anteriorly from the four-chamber view to bring the aortic valve into view (see the center of screen). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35F.4 Normal apical four-chamber view of a transthoracic echo. Note that the left ventricle is on the right of the screen showing the septum and lateral walls, and the right ventricle is to the left. The left atrium is in the lower right of the screen and the right atrium to the lower left. The mitral and tricuspid valves can be seen in this view. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35F.5 Normal apical two-chamber view of a transthoracic echocardiogram. The anterior wall of the left ventricle is on the right of the screen and the inferior wall is to the left. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The EMB remains the gold standard for diagnosis of acute viral myocarditis, despite its many imperfections. The Dallas criteria were created by a panel of cardiac pathologists in 1986 to standardize the pathologic requirements for a diagnosis of myocarditis (11). In brief, a diagnosis of myocarditis in this classification system requires the simultaneous finding of lymphocyte infiltration and myocyte necrosis (eFig. 35F.0.1). Biopsy samples in which one criterion is met but not the other indicate borderline myocarditis. Despite this attempt to create worldwide uniformity in histologic diagnosis, there remains significant interobserver variability (12). Furthermore, lymphocytic myocarditis is a patchy disease that is unevenly distributed throughout the myocardium (13). In some patients, the pathologic myocardium is not easily accessible by the bioptome, which, by definition, is limited to sampling subendocardial tissue. Even when the inflammatory process involves the subendocardium, a tremendous sampling error may be present when only three to five biopsies are obtained (14). The rate of false-negative results of EMB is as high as 83% for individual biopsies and as high as 55% when five biopsy samples are obtained in a single patient with autopsy-proven myocarditis (13). In addition, there is a high rate of false-positive results of EMB because of the small numbers of lymphocytes that are normally present in the interstitium and because of the difficulty in distinguishing between lymphocytes and interstitial macrophages, fibroblasts, endothelial cells, and pericytes using light microscopy (15). Efforts to improve on this histologic classification system by adding a clinical perspective have not been widely accepted or implemented (16). Newer techniques developed to detect intramyocardial viral genome products in EMB samples using cloned DNA fragments that are complementary to the viral genome (*in situ* DNA hybridization) and rt-PCR have generally been successful (17,18). However, these techniques require adequate biopsy samples and thus suffer from significant sampling errors. Furthermore, they have yet to be implemented in the clinical setting, because few virus-specific therapies exist that could be initiated should a specific etiology be identified.



***e*FIGURE 35F.0.1** Example of severe diffuse lymphocytic myocarditis in a human right ventricular endomyocardial biopsy sample. An extensive interstitial lymphocytic infiltrate and myocyte necrosis are readily seen. (Reprinted from Hauck AJ, Kearney DL, Edwards WD. Evaluation of postmortem endomyocardial biopsy specimens from 38 patients with lymphocytic myocarditis: implications for role of sampling error. *Mayo Clin Proc* 1989;64:1235–1245, with permission.)

Because of the relatively low sensitivity and specificity of all of the aforementioned diagnostic studies, the diagnosis of myocarditis at this time and for the foreseeable future remains mainly a clinical one.

ETIOLOGIC AGENTS OF INFECTIONS IN THE HEART

Table 35F.1 lists pathogenic causes of acute infectious myocarditis.

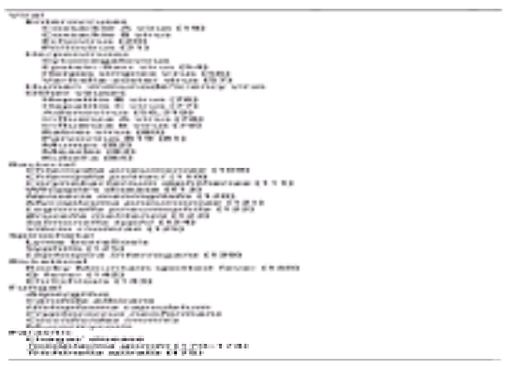


TABLE 35F.1 PATHOGENIC CAUSES OF ACUTE INFECTIOUS MYOCARDITIS

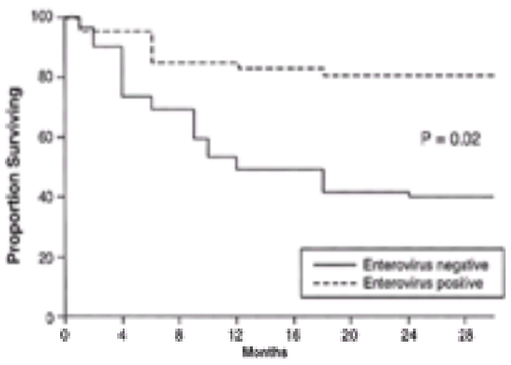
Viruses

Enteroviruses

The enteroviruses, as their name implies, are a group of single-stranded RNA viruses pathogenic to the gastrointestinal and upper respiratory tracts. Individual species in this group, such as coxsackie A and B viruses, echovirus, and polioviruses, have been implicated as etiologic agents of viral myocarditis (19,20 and 21). Coxsackie B viruses (CBV) appear to be the most common pathogens. Serologic studies have revealed that 36% of all adults with acute myocarditis have demonstrable rises in either serum anti-CBV antibody titers or IgM (22,23). The full epidemiologic impact of CBV-induced myocarditis is difficult to assess because of the ubiquitous nature of this organism, as evidenced by the high rate of similar findings in control populations (22,23). Elements of the CBV genome have also been detected using rt-PCR in EMB of patients that met the Dallas criteria for diagnosis of acute myocarditis (17,24,25). The specificity of this finding is questionable, however, because of the unexpectedly high finding of enteroviral RNA on autopsy of patients who did not have cardiac disease (24). Furthermore, delineation of the exact viral species using this method is difficult, because significant nucleic acid sequence homology exists at the 5'-untranslated region of the RNA of all enteroviruses (26). However, probes do exist to species-specific regions of the RNA that are thus able to differentiate among various species using *in situ* hybridization.

In the majority of patients infected with CBV, cardiac manifestations are not found, although cardiac involvement has been estimated to be as high as 5.3% (27). Findings most frequently consist of asymptomatic and nonspecific electrocardiographic changes (28). In most cases, the signs and symptoms of infection are benign and resolve spontaneously. Some investigators have nevertheless proposed that some cases of nonischemic DCM may represent the end stage of either a previously detected (29) or undetected (30) enteroviral infection. Much of this speculation has arisen as a result of the frequent, although not uniform, detection of enteroviral RNA in EMB from patients who have nonischemic DCM without clinical evidence of myocarditis (18,24,30). In addition, recent studies have suggested that patients with DCM in whom persistent enteroviral RNA can be detected on EMB have a much poorer clinical prognosis (eFig. 35F.0.2) (25,31). However, because of the high prevalence of enteroviral infections in the community, these studies provide only circumstantial evidence of a link between enteroviral myocarditis and DCM without offering definitive proof. In fact, in one study, enteroviral RNA was detected more frequently in control patients undergoing either heart or lung transplantation for ischemic heart disease or primary lung disease than in patients with nonischemic DCM (30). This finding has been confirmed by another, similar study (32). The clinical association between enteroviral myocarditis and DCM, therefore, remains controversial and is yet to be proven.



***e*FIGURE 35F.0.2** Survival curves for patients for whom results of right ventricular endomyocardial biopsies, using *in situ* DNA hybridization, were enterovirus positive or enterovirus negative. (Reprinted from Why HJ, Meany BT, Richardson PJ, et al. Clinical and prognostic significance of detection of enteroviral RNA in the myocardium of patients with myocarditis or dilated cardiomyopathy. *Circulation* 1994;89:2582–2589, with permission.)

Some investigators have suggested that enteroviruses have a potential role in the genesis of coronary atherosclerosis (33). However, the evidence is not very compelling, and the current focus of investigational attention has shifted toward more promising organisms.

Herpesviruses

Cytomegalovirus (CMV) is a double-stranded DNA herpesvirus readily identified in infected cells by its characteristic microscopic nuclear and paranuclear inclusion bodies. CMV is a ubiquitous organism that, in the immunocompetent host, commonly produces an asymptomatic primary infection, demonstrated by the presence of circulating anti-CMV antibodies in the majority of the population (34). Even in immunocompetent patients, CMV has been shown to cause myocarditis (35), albeit rarely. More commonly, however, as with all herpesviruses, CMV may remain latent intracellularly indefinitely in the host, until it is reactivated and leads to a systemic infection when the patient becomes immunocompromised, usually as a result of HIV infection, neoplasia, immunosuppression for rheumatologic or pulmonary disease, or after transplantation (34,36). One component of this generalized infection may be acute CMV myocarditis, which can be adequately treated with ganciclovir (37,38). Systemic CMV infection has been associated with a higher rate of acute allograft rejection in the first 3 months after heart transplantation (39), although other studies have failed to confirm this finding (40,41). Furthermore, CMV has been associated with accelerated cardiac allograft vasculopathy, which is generally believed to be reflective of chronic allograft rejection (39,42). This hypothesis also remains controversial; other investigators have not been able to confirm the findings (43,44). Even more intriguingly, however, treatment of heart transplant recipients immediately postoperatively with ganciclovir appears to lower the incidence of allograft vasculopathy, regardless of whether the recipients developed a systemic CMV illness (45).

Of greater importance epidemiologically is the link between CMV seropositivity and development of primary coronary atherosclerosis (46), although the majority of studies have not confirmed this result (47,48 and 49). Pre-procedural CMV seropositivity has even been linked to restenosis after percutaneous transluminal coronary atherectomy (50,51) but not to restenosis after percutaneous transluminal coronary balloon angioplasty (52,53). The reason underlying this apparent discrepancy is unclear and is the focus of current investigation. At this time, the best that can be said with regard to the potential association between coronary atherosclerosis and CMV is that it is circumstantial and rather tenuous.

Epstein-Barr virus, the organism responsible for infectious mononucleosis, is a double-stranded DNA herpesvirus that can rarely cause symptomatic myocarditis (54). Epstein-Barr virus has also been implicated in the development of lymphoproliferative disease after heart transplantation (55), a life-threatening complication that is often treated by lowering of the patient's immunosuppression with or without antiviral therapy.

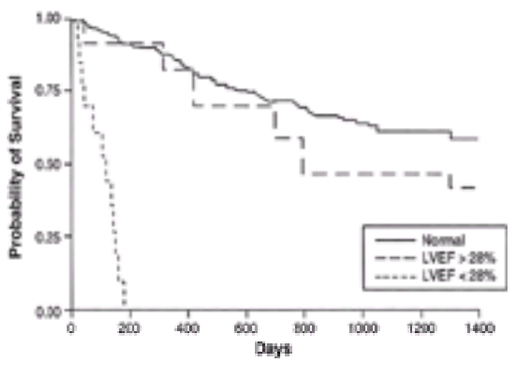
Herpes simplex virus (HSV) is a double-stranded DNA herpesvirus that has been implicated as a rare etiologic agent of acute myocarditis (56). Current data do not support an etiologic role for HSV in the development of coronary atherosclerosis; evidence from studies of patients who have HSV seropositivity is conflicting (46,47,49).

Varicella-zoster virus, another herpesvirus, has also been infrequently associated with acute myocarditis (57).

Human Immunodeficiency Virus

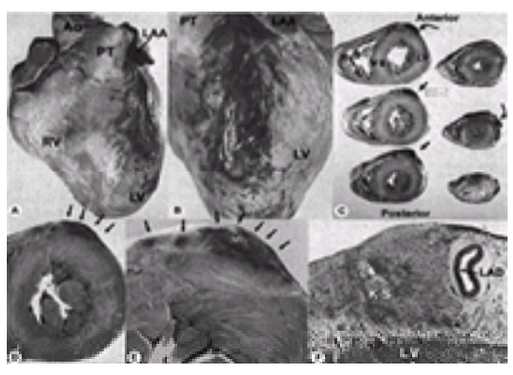
Acquired immunodeficiency syndrome (AIDS) is the end stage of HIV infection. As the number of worldwide HIV infections has reached epidemic proportions, and because advances in medical therapies have prolonged survival of patients with AIDS and various opportunistic infections, the cardiac manifestations of this disease have become more apparent. These cardiac manifestations include the direct effects of HIV itself and effects resulting from opportunistic infections that arise as a consequence of a profoundly immunosuppressed state.

EMB-proven acute or chronic lymphocytic myocarditis is a frequent finding in patients with AIDS (58,59). Most frequently, this is a consequence of a superimposed opportunistic infection (36,58). HIV RNA and DNA have been detected in such biopsies but are usually very sparse, most often appearing in areas of myocardium where there is no inflammatory infiltrate or ongoing myonecrosis, and are frequently associated with other opportunistic pathogens (60,61). A causal relationship between HIV and myocarditis has therefore not been firmly established. It must be noted, however, that no pathogen is identified in a large percentage of cases of AIDS-associated cardiomyopathy (36), a finding not dissimilar to that among patients whose cardiomyopathy is not related to AIDS. Some investigators have proposed that AIDS-associated cardiomyopathy may result from antiretroviral therapy, specifically from administration of the nucleoside analogue azidothymidine (62,63). Multiple cytokines, vascular changes, nutritional deficiencies, and illicit drug use have also been implicated (64). However, regardless of the etiology of the cardiomyopathic process associated with AIDS, the diagnosis is a harbinger of an extremely poor clinical prognosis, irrespective of the adequacy of the anti-HIV therapy itself (*e*Fig. 35F.0.3) (65).



***e*FIGURE 35F.0.3** Survival curves for 296 human immunodeficiency virus–positive patients who had structurally normal hearts or cardiac dysfunction. LVEF, left ventricular ejection fraction. (Modified from Currie PF, Jacob AJ, Foreman AR, et al. A review of endocarditis in acquired immunodeficiency syndrome and human immunodeficiency virus infection. *Eur Heart J* 1994;309:1606, with permission.)

Marantic endocarditis (66), infective endocarditis (usually found in intravenous drug users) (66), pericardial effusions (67), infective pericarditis (particularly that caused by *Mycobacterium tuberculosis* in Africa) (68), and pulmonary hypertension with cor pulmonale (69) are all infrequent findings in patients with HIV. Cardiac neoplasms also develop in these patients. Cardiac Kaposi's sarcomas are not usually isolated to the heart but rather are part of a widely metastatic process (70). They are usually asymptomatic and involve the subepicardium (*e*Fig. 35F.0.4) (70) or the pericardium, where they can lead to effusions (71). Most cases are discovered unexpectedly at autopsy. Cardiac non-Hodgkin's B-cell lymphoma is also usually associated with a widely disseminated malignant process in HIV patients, but it can be a primary lesion as well (72).



***e*FIGURE 35F.0.4 A–F:** Gross appearance of cardiac Kaposi's sarcoma (KS) (*arrows*) in a 44-year-old man with acquired immunodeficiency syndrome. LAA, left atrial appendage; LAD, left anterior descending coronary artery; LV, left ventricle; PT, pulmonary trunk; RV, right ventricle. [Reprinted from Silver MA, Macher AM, Reichert CM, et al. Cardiac involvement by Kaposi's sarcoma in acquired immune deficiency syndrome (AIDS). *Am J Cardiol* 1984;53:983–985, with permission.]

Accelerated coronary atherosclerosis has also been observed on autopsy of relatively young HIV patients, although a causal relationship has yet to be established (73). Recent studies have also implicated protease inhibitors, antiretroviral agents used to treat patients with HIV, in the development of coronary atherosclerosis (74,75); a profound deleterious effect on the serum lipid profile is the likely mechanism.

Other Viruses

Several other viruses have also been proven to rarely cause acute myocarditis, including hepatitis B virus (76), hepatitis C virus (77), adenoviruses (56), influenza A (78) and B (79) viruses, rabies virus (80), and parvovirus B19 (81). Cases of mumps (82), measles (83), and rubella (84) myocarditis have all been reported, and fetal rubella infection, resulting from early gestational maternal transmission, can lead to multiple congenital heart defects. However, mumps, measles, and rubella have largely been eradicated as a result of widespread childhood immunization programs.

Bacteria

Rheumatic Fever

Acute rheumatic fever is characterized by a systemic inflammatory response that occurs approximately 3 weeks after an untreated group A streptococcal pharyngeal infection but never after a cutaneous infection. The incidence of acute rheumatic fever in the developed world is on the decline as a result of widespread use of antistreptococcal antibiotic therapy for upper respiratory tract infections and general improvements in living conditions. The same is not true in the developing world. Administration of appropriate antibiotic therapy during pharyngeal infection essentially eliminates the future risk of developing rheumatic fever (85).

The diagnosis of acute rheumatic fever is mainly a clinical one, using the revised Jones criteria of 1992 (86) (Table 35F.2). Evidence of two major criteria or one major criterion and at least two minor criteria is required for a presumptive diagnosis of acute rheumatic fever and is enhanced by either a history of a recent upper respiratory tract infection, a positive throat culture, or a positive antistreptococcal antibody test.

Major criteria
Carditis
Polyarthritis
Chorea
Erythema marginatum
Subcutaneous nodules
Minor criteria
Arthralgia
Fever
Elevated erythrocyte sedimentation rate
Elevated C-reactive protein levels
First-degree atrioventricular block

Adapted from Guidelines for the diagnosis of rheumatic fever: Jones criteria, 1992 update. Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association. JAMA 1992;268:2069–2073, with permission.

TABLE 35F.2 REVISED JONES CRITERIA FOR THE DIAGNOSIS OF ACUTE RHEUMATIC FEVER, 1992

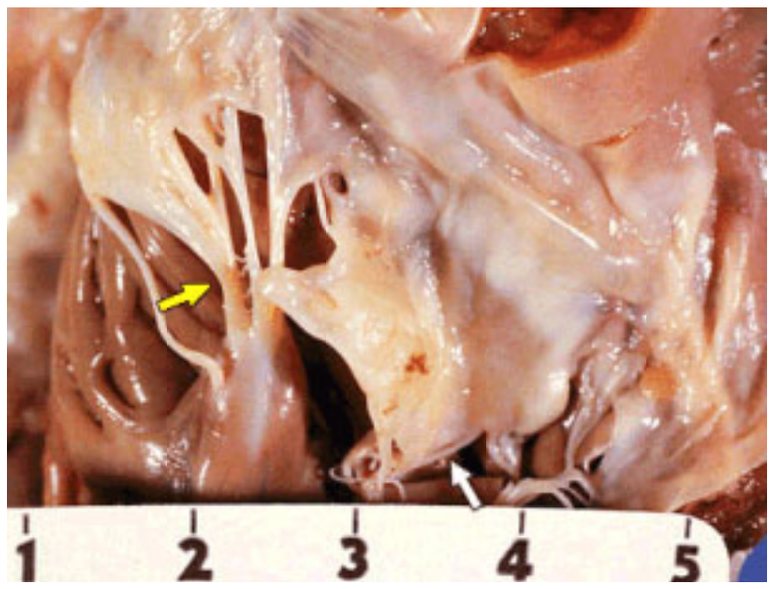
Rheumatic carditis can involve the endocardium, myocardium, or pericardium. Most commonly, there is variable involvement of the cardiac valves, particularly the mitral valve and its subvalvular apparatus, including papillary muscles and their attached chordae tendineae. Severe clinical decompensation is the exception rather than the rule. The most feared consequence of this pathologic process is chronic scarring that leads to mitral, and potentially aortic, valvular stenosis and/or regurgitation.

Video 35F.6 Parasternal long-axis view of a rheumatic mitral valve with thickened, restricted, doming leaflets. Severe mitral regurgitation is the primary functional problem with this valve with only mild mitral stenosis. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35F.7 Parasternal long-axis view of a rheumatic mitral valve with color Doppler. Mitral regurgitation is the primary problem seen by color Doppler, with only mild mitral stenosis due to the thickened and doming leaflets. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35F.8 Apical four-chamber view of a patient with severe rheumatic mitral stenosis with marked thickening and doming of the mitral leaflets, with severe ALE and spontaneous echo contrast within the left atrium. Note the left ventricle remains small. Because of long-standing severe mitral stenosis, the patient has severe pulmonary hypertension with right ventricular hypertrophy and right ventricular failure and severe right atrial enlargement. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 35F.9 Long-axis 120-degree transesophageal view of a rheumatic aortic valve with central aortic insufficiency due to furled, restricted leaflets. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Rheumatic disease of the tricuspid valve. Note the shortened cordae (*yellow arrow*) and thickened valve leaflet (*white arrow*).

Treatment of mild cases is usually administration of high doses of aspirin (87). Corticosteroids can be added to this regimen for severe cases. To prevent recurrences of carditis and acute rheumatic fever, long-term, perhaps even lifelong, antibiotic prophylaxis involving administration of benzathine penicillin G intramuscularly every 3 weeks is recommended, although the duration of therapy should be individualized, depending on the patient's risk of recurrence (88).

Chlamydia pneumoniae

The chlamydiae are ubiquitous obligate intracellular gram-negative bacteria that have generated tremendous interest recently as a result of the purported association between *C. pneumoniae* and the development of coronary atherosclerosis. Seroepidemiologic studies initially demonstrated increased anti–*C. pneumoniae* antibody titers in patients who had acute myocardial infarctions (68%) or chronic angina (50%) as compared to control subjects (17%) (89). This concept, however, remains controversial—several studies have since confirmed this finding (90,91 and 92), but others have refuted it (93,94 and 95), mainly because of a prevalence of high seropositivity in the control groups of the latter studies. Nevertheless, the potential evidence supporting this association is strengthened by the vast majority of studies, which have readily demonstrated the presence of *C. pneumoniae* organisms in atherosclerotic plaques (96,97 and 98) but rarely in normal coronary arteries. This evidence is weakened, however, by the finding that although *C. pneumoniae* DNA could be detected in the presence of coronary atherosclerosis, it did not reflect either the extent or severity of the disease (99). In this study, *C. pneumoniae* DNA could be detected only at one site in one patient with severe diffuse atherosclerosis, whereas another patient with only mild coronary atherosclerosis had detectable DNA in every arterial segment examined. Furthermore, in contrast to CMV, no evidence exists to support an association between *C. pneumoniae* and the occurrence of restenosis after percutaneous coronary atherectomy (100).

The ability to detect *C. pneumoniae* in coronary atherosclerotic plaques does not prove that the organism plays a role in the genesis of the disease. The evidence would be more convincing if a reduction in cardiovascular events could be shown after eradication of the organism using antibiotic therapy. Thus far, one small study has demonstrated a fivefold reduction in cardiovascular events after short-term therapy with azithromycin in patients who had experienced a myocardial infarction (101). In the ROXIS study (Randomized Trial of Roxithromycin in Non–Q-Wave Coronary Syndromes), a small but statistically significant reduction in cardiovascular events at 30 days was found in patients who had unstable angina and were treated with roxithromycin, although this effect was not sustained to 90 days (102). The ACADEMIC study (Azithromycin in Coronary Artery Disease: Elimination of Myocardial Infection with *Chlamydia*) failed to show any benefit at 6 months in a lower-risk population of individuals with stable coronary disease who were treated with azithromycin, although the primary end point of cardiovascular events at 2 years has yet to be completed (103). Nevertheless, two large randomized, placebo-controlled trials using prolonged treatment courses of azithromycin are currently under way (WIZARD [Weekly Intervention with Zithromax (Azithromycin) for Atherosclerosis and Its Related Disorders] [104] and ACES [Azithromycin and Coronary Events Study] [105]). However, because antibiotics such as azithromycin produce key antiinflammatory effects by virtue of matrix metalloproteinase inhibition, it will not be possible to assert fully the role of *C. pneumoniae* in the atherosclerotic process on the basis of the aforementioned studies alone. At this juncture, therefore, insufficient data exist to justify the widespread use of antibiotic treatment in patients with coronary atherosclerosis.

Intriguingly, it has recently been hypothesized that the early lesions found in nonrheumatic aortic stenosis have striking similarities to the early lesions of coronary atherosclerosis, including the predominance of inflammatory cells, the accumulation of lipid, and the thickening of the fibrosa (106). In recent data very reminiscent of those collected for coronary atherosclerosis, several small studies have found evidence of *C. pneumoniae* in aortic valve lesions in patients who have nonrheumatic aortic stenosis (107,108), although a causal link has yet to be established.

C. pneumoniae (109) and *Chlamydia psittaci* (110) have also both been implicated in cases of acute myocarditis, albeit rarely.

Other Bacteria

Corynebacterium diphtheriae infection can commonly lead to myocarditis by virtue of the associated exotoxin, which has a high affinity for the cardiac conduction system. Once myocardial involvement occurs, the patient has a much poorer prognosis, and the mortality rate is higher than 50% (111). This disease has largely been eradicated in the developed world as a result of widespread childhood immunization programs, but it persists in the developing world, where such programs have not been implemented. Treatment of this life-threatening condition consists of both antitoxin towards the exotoxin and antibiotics effective against the infecting organism.

Whipple's disease, or intestinal lipodystrophy, is a rare chronic systemic bacterial infection caused by *Tropheryma whippelii*. Cardiac involvement in Whipple's disease is common, with histologic evidence in up to 78% of patients including the pericardium (112), myocardium (113), valves (114), and coronary arteries (115). Patients are rarely symptomatic.

Initially, *Helicobacter pylori* was serologically linked to coronary atherosclerosis in several small studies (116,117). However, the results of several larger studies have since contradicted this finding (118,119), and further investigation of this organism has largely been abandoned.

Many other bacteria have also been associated with myocarditis, including *Neisseria meningitidis* (meningococcus) (120), *Mycoplasma pneumoniae* (121), *Legionella pneumophila* (122), *Brucella melitensis* (123), *Salmonella typhi* (124), and *Vibrio cholerae,* by way of its cholera toxin (125).

Spirochetes

Lyme Disease

Lyme disease is a systemic illness caused by the spirochete *Borrelia burgdorferi,* whose primary vector is the ixodid tick. Carditis is a common manifestation thought to occur in approximately 10% of all patients in the disseminated phase of the illness, often weeks to months after the initial infection (126,127). Because it can take as long as 8 weeks for serologic conversion to occur, signs and symptoms of Lyme borreliosis frequently precede positive serologic tests, and many false-negative results may be seen before seroconversion. The most common cardiac finding in patients with Lyme disease is varying degrees of atrioventricular heart block, which can fluctuate from normal to first-degree atrioventricular block to complete heart block in the same patient within minutes (126,127). Although patients are often asymptomatic, some may become syncopal during periods of high-degree atrioventricular block and may benefit from temporary transvenous pacing (127,128). Permanent pacing is rarely indicated, and complete resolution of the conduction disturbance usually occurs within 1 to 2 weeks (126,127).

Less commonly, Lyme borreliosis can also cause acute myopericarditis (126,128,129), and *B. burgdorferi* has been isolated from EMB from patients with acute (128,130) and chronic (131) cardiomyopathies. Furthermore, patients with chronic DCM are more likely to have positive results of serologic testing for *B. burgdorferi* than are control subjects (132), although the association seems to be weak and has not been confirmed by other studies (133). This hypothesis is enhanced by the finding in one study that ceftriaxone reversed the cardiomyopathic process in 9 of 42 patients who were seropositive for *B. burgdorferi* (134), although other studies have been unable to demonstrate such a reversal (131,132). Suffice it to say, the evidence supporting an epidemiologic role for *B. burgdorferi* in DCM is very circumstantial, fails to prove causation, and is not currently the subject of major investigative efforts.

Current recommendations for treatment of Lyme disease carditis are listed in Table 35F.3 (135). Treatment during the early phase of the disease seems to eliminate the potential for development of future disseminated disease, including carditis (136). No evidence exists, however, demonstrating administration of appropriate antibiotic therapy after carditis has developed leads to more rapid resolution of the carditis, since Lyme disease carditis is usually self-limited, with complete recovery in most cases. Nevertheless, administration of antibiotic therapy is now common clinical practice, used mainly to prevent further dissemination of the disease, including avoidance of neurologic sequelae. Others have advocated the use of corticosteroids and salicylates for patients with severe cases (126,127), but this approach has not been proven by prospective studies to confer any therapeutic advantage.

Early Lyme disease
Doxycycline, 100 mg twice daily for 10–21 d; amoxicillin, 500 mg three times daily for 10–21 d
Lyme carditis
Ceftriaxone, 2 g i.v daily for 14 d
Penicillin G, 20 million U i.v. daily for 14 d
Alternatives, for mild cases of Lyme carditis only
Doxycycline, 100 mg orally twice daily for 14–21 d
Amoxicillin, 500 mg three times daily for 14–21 d

Adapted from Rahn DW, Malawista SE. Lyme disease: recommendations for diagnosis and treatment. *Ann Intern Med* 1991;114:472–481, with permission.

TABLE 35F.3 RECOMMENDATIONS FOR THE TREATMENT OF LYME CARDITIS

Other Spirochetes

In the early part of the twentieth century, syphilitic aortitis, caused by the spirochete *Treponema pallidum,* was relatively common and resulted in aortic aneurysms, aortic valvular insufficiency, and coronary ostial stenoses (137). However, this condition has largely been eradicated by widespread public health measures put in place to stop the spread of sexually transmitted diseases and by the development of effective antibiotic therapy (see Chapter 109). Localized gummatous myocarditis was exceedingly rare even before the eradication of this disease (137).

VIDEO

Transesophageal view of the aortic arch demonstrating an arch aneurysm (*thin arrow*) with layering of thrombus inferiorly (*thick arrow*).

Patients with severe leptospirosis, caused by the spirochete *Leptospira interrogans,* often have transient electrocardiographic changes (138) and can develop acute myocarditis (139). Acute coronary arteritis and aortitis are also common postmortem findings in patients with severe leptospirosis (139).

Rickettsiae

Rocky Mountain spotted fever is a tick-transmitted systemic illness caused by *Rickettsia rickettsii* that is characterized by a generalized vasculitis. Acute myopericarditis and atrioventricular conduction disturbances are relatively common and can be fatal (140) but are usually not clinically significant (141).

Q fever is a systemic rickettsial illness caused by *Coxiella burnetii*, usually inhaled by humans after aerosolization from the placenta of farm animals. Valvular endocarditis is by far the most common clinical presentation of chronic Q fever infection (142). Conversely, acute myopericarditis is a rare phenomenon, although it portends a much worse prognosis (142).

Ehrlichiosis is caused by *Ehrlichia*, a tick-borne rickettsial organism that infects circulating monocytes and granulocytes. It can also rarely cause acute myocarditis (143).

Fungi

Fungal infections of the heart are uncommon and generally occur only in patients who are immunosuppressed after chemotherapy, after organ transplantation, or because of HIV (36,144). Fungal endocarditis can also occur after cardiac surgery, intravenous drug abuse, or prolonged central venous access (145,146). Although disseminated *Aspergillus* and *Candida* infections are common after heart transplantation (147), involvement of the myocardium is exceedingly rare. Fungal myocarditis has been reported as a result of infection with *Aspergillus* (144,145,148), *Candida albicans* (145,149), *Histoplasma capsulatum* (36), *Cryptococcus neoformans* (36,150), *Coccidioides immitis* (151), and mucormycosis (152). In postmortem studies, myocardial fungal involvement is characterized by diffuse myocardial abscesses and coronary artery occlusion by fungal mycelia and thrombus (145,149,152). However, direct invasion via the mediastinum has also been observed (153).

Parasites

Chagas' Disease (Trypanosomiasis)

Chagas' disease is a protozoal infestation caused by *Trypanosoma cruzi* and is transmitted to humans in the feces of the reduviid bug as it bites. Chagas' disease is endemic to Central and South America, where more than 20 million people are currently estimated to be infected (154). More rarely, it may be transmitted by blood transfusions from a previously infected donor (155). The acute phase of the human disease is usually benign and clinically asymptomatic, with the exception of a mild fever, although acute myocarditis can be demonstrated by EMB in most patients and can be fatal (156). More commonly, a slowly progressive cardiomyopathic process ensues that may remain clinically unrecognized for more than 20 years (154). During this indeterminate phase, 30% to 40% of infected patients (and more than 80% of those who go on to develop a cardiomyopathy) develop cardiac conduction abnormalities due to extensive myocardial fibrosis. Right bundle branch block and left anterior hemiblock are the most frequently seen abnormalities and can progress to higher degrees of atrioventricular heart block (157).

Chronic Chagasic cardiomyopathy develops in approximately 10% to 30% of all infected patients. The pathogenesis of this disease remains highly controversial, but it is likely multifactorial, including a continued direct parasitic effect on the myocardium (158), autoimmune-mediated myocyte injury (159), and parasite-mediated microvascular endothelial injury resulting in compromised myocardial perfusion (159). Anatomically, Chagas' disease can be distinguished from other cardiomyopathies by the classical finding of apical thinning and aneurysm formation (eFig. 35F.0.5) (154,157). Functionally, multiple segmental wall motion abnormalities are common, as is global systolic dysfunction (157), highlighting the need to rule out a coronary etiology for the cardiomyopathy. These apical aneurysms and their accompanying left ventricular systolic dysfunction place patients at risk for thromboembolism (160) and potentially lethal ventricular arrhythmias (161,162). Alternatively, the cardiomyopathic process may progress unrelentingly until the patient develops overt congestive heart failure, a harbinger of a very poor prognosis (eFig. 35F.0.6) (163).

Antiparasitic therapy at this stage is generally thought to be ineffective, although recent studies have suggested that treatment may prevent disease progression in a minority of patients (164,165). Because the prognosis for these patients is relatively poor, it would seem appropriate to attempt one course of antiparasitic therapy in virtually all patients, although this is controversial. Despite the inflammatory nature of this disorder, immunosuppression is not advised because of the potential for reactivation of otherwise latent organisms (166). Because iatrogenic immunosuppression is routinely used to prevent rejection after heart transplantation, concerns have arisen with regard to the candidacy of patients with end-stage Chagasic cardiomyopathy for transplantation. However, successful heart transplantation can be performed if it is accompanied by careful follow-up with serologic testing to detect and treat any reactivation of the disease, which occurs at some point in nearly all patients (167,168). However, the higher incidence of malignant neoplasms that has been observed in these patients in comparison with control subjects is of great concern and may be related to parasite reactivation or to the specific antiparasitic therapy they received (169). Further follow-up studies are required to examine this issue.

Other Parasites

Acute myocarditis resulting from parasitic infestation is a rare phenomenon, although multiple parasites have been implicated. *Toxoplasma gondii* may cause acute myocarditis in the immunocompetent (170) as well as the immunocompromised patient, including patients with HIV (171), patients who have undergone chemotherapy (172), and after transplantation (173). *T. gondii* can be transmitted to a heart transplant recipient through the donor allograft (174), which indicates that there is a need for careful preoperative serologic screening of both the donor and recipient.

Trichinella spiralis may also cause acute myocarditis (175). Acute cardiac decompensation can also rarely occur with *Plasmodium falciparum* infection (malaria), as a result of parasitic coronary occlusion (176). Patients with hepatosplenic schistosomiasis can develop portal hypertension and, consequently, via collateral circulation, *Schistosoma mansoni* eggs can embolize and occlude the pulmonary arteries, leading to pulmonary hypertension and cor pulmonale (177). Hydatid cysts can form within the myocardium, can compress or obstruct the adjacent chamber (178), and can be safely treated with surgical excision.

MECHANISM OF INJURY IN VIRAL MYOCARDITIS

Current knowledge about the pathogenesis of viral myocarditis is derived almost exclusively from animal studies and remains controversial and incomplete (Fig. 35F.1). There are at least three phases of injury: (a) a direct effect of the viral pathogen on the myocyte, (b) an acute inflammatory response resulting in viral clearance and myocytolysis of infected cells, and (c) a chronic phase that occurs in animals that are unable to eradicate the virus. Although the time sequence in the murine viral myocarditis model is more rapid, it is generally thought to accurately reflect the sequence of events in humans.

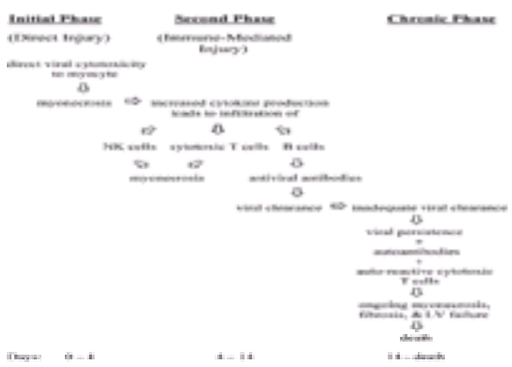

FIGURE 35F.1 Pathogenesis of acute infectious myocarditis. LV, left ventricular; NK, natural killer.

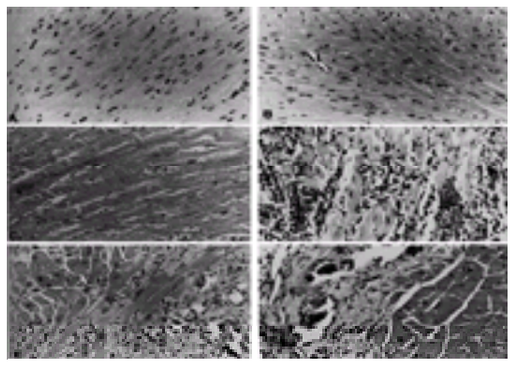
The initial phase in this murine model is characterized by the direct cytotoxic effect of the virus on the myocyte during the first 4 days after inoculation. At this time, no inflammatory infiltrate is visualized histologically (179,180), yet myocyte necrosis is seen (*e*Fig. 35F.1.1) (179,181). This hypothesis is strongly supported by the finding that mice with severe combined immunodeficiency syndrome, which therefore have no B- or T-cell immunologic response, have widespread myonecrosis without accompanying inflammatory cells (182).



***e*FIGURE 35F.1.1** Typical histopathologic findings in the murine experimental myocarditis model. **A:** Control subject. **B:** One day after inoculation, no histologic changes are seen. **C:** Three days after inoculation, small foci of degenerated myocytes can be seen. **D:** Seven days after inoculation, extensive cellular infiltration and myonecrosis are visible. **E:** Fourteen days after inoculation, reduced mononuclear cell infiltration and fibrosis around necrotic zones are present. **F:** Eighty days after inoculation, dense fibrosis surrounding calcification is visible. (Modified from Shioi T, Matsumori A, Sasayama S. Persistent expression of cytokine in the chronic stage of viral myocarditis in mice. *Circulation* 1996;94:2930–2937, with permission.)

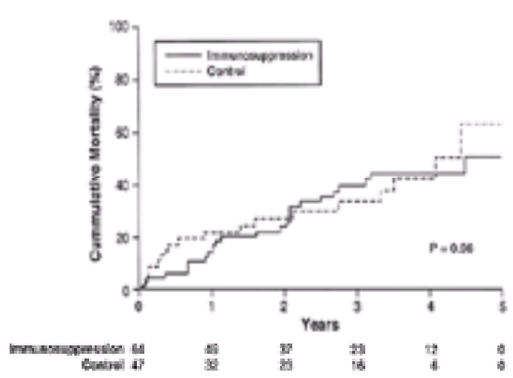
The second phase, which usually occurs from days 4 through 14, is characterized by a large increase in cytokine production that leads to severe inflammatory cell infiltration and myocyte necrosis (*e*Fig. 35F.1.1) (179). Similar cytokine elevations have also been observed in humans who have acute myocarditis (183). Natural killer cells appear in this inflammatory milieu on approximately day 4 and inhibit viral replication, which is also peaking at this time (184), resulting in cytolysis of infected cardiac myocytes (185). Viruses are also cleared via B lymphocyte–derived antiviral antibodies, which appear after day 4 with a rapidly rising titer (186,187). T lymphocytes are also crucial in this phase, and concentration of these cells peaks on days 7 through 14, resulting in widespread myonecrosis of infected cells (188). The importance of lymphocytes to the process of virus load clearance has been confirmed in mice with severe combined immunodeficiency syndrome, in which viremia persisted throughout the duration of the study (182). T lymphocytes recognize viral proteins expressed on the surface of infected myocytes, resulting in further myocytolysis (189). However, T lymphocytes are not critical for virus load clearance and seem to play a role that is more harmful than helpful by increasing the severity of the resulting myonecrosis (180,190) and perhaps also by killing uninfected myocytes through autoimmune mechanisms (190,191). Therefore, in this model, humoral immunity is responsible for virus clearance, and cellular immunity inflicts much of the pathologic damage to the myocardium.

The chronic phase is characterized by progressive myocardial dysfunction and left ventricular dilation. Several different mechanisms have been proposed to explain this deterioration, but, in all likelihood, the process is multifactorial. With more sensitive diagnostic tools such as rt-PCR and *in situ* DNA hybridization, persistence of viral RNA has been demonstrated in the hearts of patients with chronic cardiomyopathy, raising the possibility that virus-specific immune-mediated damage is ongoing (18,24,192). Alternatively, ongoing myonecrosis may be caused either by autoantibodies, which cross-react between viral antigens and cardiac myocyte antigens (193,194 and 195), or by autoreactive cytotoxic T lymphocytes, which cross-react in a similar manner (191). In this scenario, uninfected cells are also irreversibly injured.

TREATMENT OF INFECTIOUS MYOCARDITIS

Treatment for both acute and chronic infectious myocarditis is generally aimed at reducing congestion, improving cardiac hemodynamics, and prolonging survival, irrespective of the etiology of the disease. Several guidelines exist and are updated regularly to assist in this endeavor (196,197). This topic is covered in greater detail in Chapter 91 and Chapter 92. However, it is important to note that, in murine models of acute myocarditis, high doses of digoxin increased mortality, presumably by increasing the production of various cytokines, in contrast to congestive heart failure from other etiologies (198).

Immunosuppression by means of corticosteroids, cyclosporine, azathioprine, or a combination was once advocated for the treatment of new-onset myocarditis. However, the Myocarditis Treatment Trial showed no survival benefit or improved myocardial recovery among patients who received immunosuppression (*e*Fig. 35F.1.2) (199). Nevertheless, no harmful effect from immunosuppression could be demonstrated, raising the possibility that patients with infectious myocarditis may have a poorer prognosis when they receive immunosuppression as a result of increased virus proliferation, whereas patients with a purely inflammatory or autoimmune etiology may in fact improve with such therapy. The ongoing European Study of Epidemiology and Treatment of Cardiac Inflammatory Diseases is addressing this issue by treating patients for whom viral etiologies have been identified with a specific antiviral agent, whereas patients in whom no viral etiology has been found are treated with corticosteroids (200). Immunosuppression has also been shown to be clinically ineffective when used to treat patients with DCM (201,202), although a more recent nonrandomized study has contradicted this finding (203).



***e*FIGURE 35F.1.2** Actuarial mortality in the Myocarditis Treatment Trial. The numbers of patients at risk are listed at the bottom of the graph. (Reprinted from Mason JW, O'Connell JB, Herskowitz A, et al. A clinical trial of immunosuppressive therapy for myocarditis. The Myocarditis Treatment Trial Investigators. *N Engl J Med* 1995;333:269–275, with permission.)

Intravenous immunoglobulin therapy had also recently been advocated for patients with acute myocarditis, including pathogen-specific immunoglobulin (such as for CMV) (204) and nonspecific high-dose immunoglobulin (205,206 and 207). A recently completed randomized trial—Intervention in Myocarditis and Acute Cardiomyopathy—failed to demonstrate any therapeutic effect of intravenous immunoglobulin therapy (207a). Treatment of patients with acute myocarditis with immunomodulating agents such as interferon-a or thymomodulin, which reduces viral replication and myocardial inflammation, has been proposed (208,209). Although this suggestion is supported by results of a study using a murine model (210), larger randomized human studies are necessary before such treatment is widely implemented.

Specific antimicrobial therapy should always be tried when it is available. This is particularly true for patients infected with CMV, bacteria, spirochetes, rickettsiae, or parasites. However, the most common viral species have no specific antiviral therapy. Ribavirin, a nucleoside analog with potent nonspecific antiviral activity, has been shown to prevent the development of viral myocarditis in a murine model (211,212). Ribavirin was only effective, however, when it was administered before or at the same time that inoculation with the viral pathogen occurred. Any delay in the administration of the ribavirin rendered it useless, which may explain its apparent ineffectiveness in humans (212).

Infrequently, acute myocarditis may become fulminant and lead to circulatory collapse and cardiogenic shock. Such patients can be hemodynamically supported with extracorporeal membrane oxygenation (213) or ventricular-assist devices (214). Most patients can be successfully weaned from these devices within a few days, as ventricular function improves. If ventricular function does not improve, these devices can serve as a bridge to transplantation. Initial concerns about decreased survival after heart transplantation in the setting of active myocarditis (215) have been recently contradicted by a large retrospective analysis (216). However, a greater frequency of episodes of acute rejection, particularly in the first 4 months after transplantation, is observed in patients who have preoperative myocarditis (215,217), which may predispose them to an increased risk of transplant vasculopathy (218). At this juncture, it seems prudent to attempt to stabilize patients medically for as long as possible, to allow them a chance to recover ventricular function, or, at the very least, to perform transplantation in a less inflammatory or infectious milieu (214).

CONTROVERSIES AND PERSONAL PERSPECTIVES

A clinician's ability to accurately diagnose and specifically treat patients with acute infectious myocarditis has not progressed at the same rate as it has with other cardiac ailments. This stems from four fundamental difficulties associated with this disease process: (a) patients do not present to a physician before most of the damage is already done, (b) clinicians have a low index of suspicion for this disorder, (c) identifying the exact causative pathogen in a time-efficient manner is difficult, and (d) few specific therapies are available once a pathogen has been identified. Although the EMB remains the current gold standard for the diagnosis of acute infectious myocarditis, it will always suffer from a lack of sensitivity and specificity. The addition of rt-PCR and *in situ* DNA hybridization has enhanced this diagnostic modality, but they are targeted at identification of specific DNA sequences and thus require knowledge of which organisms should be sought. In light of the plethora of potential pathogens, such testing could become an expensive and time-consuming endeavor, like searching for the proverbial needle in a haystack. Furthermore, the lack of specific antimicrobial therapies renders the identification of the pathogen mainly an academic exercise. Therefore, it seems to me that any advancement in this field must begin with the development of either specific effective therapies against the offending pathogen or immunomodulatory therapies that would reduce the extent and severity of the immune-mediated injury. Only then will improvements in diagnostics become clinically meaningful.

THE FUTURE

The greatest worldwide epidemiologic impact on infectious myocarditis could be achieved via improved living and health standards in the Third World, including methods for prevention of sexually transmitted diseases. Clearly, the incidence and prevalence of HIV and Chagasic cardiomyopathies could be significantly reduced with such measures.

Further investigations are currently under way to determine whether coronary atherosclerosis is truly an infectious disease. These results should be available within a few years and may alter the way in which this disease process is perceived. At the very least, it is likely that infectious diseases serve a facilitative role in promoting vascular inflammation and, in some patients, may represent the principal pathway to decompensation of vulnerable atherosclerotic plaque.

OVERVIEW

Cocaine may be associated with myocardial ischemia and myocardial infarction (MI). A physician who sees a young person with an unexplained MI should consider cocaine use to be a possible cause. Cocaine may also cause hypertension, cardiomyopathy, arrhythmias, and sudden death. Whether coffee is associated with cardiovascular disease remains highly controversial. Anabolic steroids and amphetamines have been associated with cases of MI. Excessive alcohol consumption causes dilated cardiomyopathy and hypertension, although small doses of alcohol may reduce coronary disease. Tobacco use is unquestionably a strong risk factor for coronary artery disease.

COCAINE CARDIOTOXICITY

Of the various substances of abuse that may affect the heart, cocaine has received the most attention over the last 10 years (1,2,3,4,5,6,7,8 and 9). This is largely a result of its widespread use, especially in large urban areas of the United States; the relative ease with which the substance can be obtained; and the occurrence of sudden death among athletes who have used cocaine. In this section, we review the history of cocaine use, describe the basic science of the effect of cocaine use on the heart, detail the results of clinical and autopsy reports of cocaine use in humans, and describe the clinical approach to and therapy for patients who have cocaine cardiotoxicity.

History

Cocaine is an alkaloid from the *Erythroxylon coca* plant, which grows primarily in South America (10). The Indians of South America have chewed coca leaves for thousands of years. During the Inca empire, coca leaves were used as part of religious ceremonies and given as gifts for special services. In the eleventh century, coca leaves lost their religious significance, and chewing of the leaves spread across all social classes; the leaves were often used as payment for labor in the fields. Writings tell of the restorative powers of coca leaves, including their ability to satisfy hunger and provide a sense of strength and power to the weary. Albert Nieman identified cocaine as the active substance in coca leaves in the late 1850s, and as early as 1880, experimental studies in dogs showed that cocaine had a cardiac-accelerating effect. Sigmund Freud advocated the use of cocaine for a host of ailments, and Carl Koller and William Halstead demonstrated that cocaine had local anesthetic properties.

In the 1860s, a wine known as Vin Mariani, which contained cocaine as a stimulant, was introduced to the market, and in 1886, the drink Coca-Cola was introduced, with cocaine as the active ingredient in the original preparation. Cocaine has since been removed from Coca-Cola, but in the late 1800s, a number of wines and tonics contained cocaine. The first death associated with cocaine use was reported in the 1890s, and numerous reports of addiction and death—including death from use of cocaine as a local anesthetic—occurred in the early 1900s.

That cocaine could affect the human heart was suggested by an article by Lewin, in 1931, which stated, “Experiments carried out years ago in Europe roved that drinking of an infusion of 12 g of coca leaves, occasioned—besides a greater frequency of pulse, palpitations of the heart, faintness, seeing of sparks and tinnitus aurium—a feeling of augmented power and a greater desire for activity” (11,12).

By the early 1900s, cocaine was regarded as a dangerous and addictive substance. President William Howard Taft, in an address to Congress in 1910, said that “cocaine posed the most dangerous drug problem that the United States ever faced.” The Pure Food and Drug Act of 1906 required that cocaine be listed as an ingredient whenever it was included, and the Harrison Narcotic Act of 1914 permitted sale of cocaine by prescription only and banned the use of cocaine in patented remedies. Public sentiment was in favor of these regulations, and medical problems caused by cocaine use were relatively infrequent until the 1970s, when cocaine gained prominence as a recreational drug. In the mid-1980s, several highly publicized cases of deaths in athletes who used cocaine and various reports (13) that linked the recreational use of cocaine to cardiac events stimulated renewed interest in the medical consequences of cocaine abuse. (The chewing of coca leaves is still common in South America, where, in general, serious medical consequences have not been reported; this may be because a lower dose of the substance is extracted when the plant leaves are chewed, because cocaine is degraded by gastric acid, and because only a small amount of gastrointestinal absorption occurs when cocaine

is taken in this fashion.)

It is estimated that approximately 5 to 6 million people in the United States use cocaine on a regular basis, that approximately 1 million are addicted, and that 25 to 30 million Americans have tried cocaine at least once (2,3).

Forms of Cocaine

Cocaine hydrochloride is a water-soluble form of cocaine in which the alkaloid extract of the *E. coca* plant is dissolved in hydrochloric acid to form a white crystalline powder (14,15). Because the white powder can be absorbed by the mucous membranes, intranasal insufflation (snorting) of this white powder is the most common route of administration. The powder also can be injected intravenously. Cocaine is not readily absorbed gastrointestinally, and the low pH of the gastric mucosa may inactivate the alkaloid (14,15).

Crack cocaine is produced by mixing cocaine powder with baking soda and water and then heating the results. The alkaloid base precipitates into a soft mass that hardens and is then smoked. The term “crack” derives from the cracking or popping sound heard when the cocaine crystals are prepared in this fashion.

Freebase cocaine is made by mixing the cocaine powder with a base (such as ammonia) and a solvent (such as ether). The alkaloid base or “free base” is extracted from the ether by evaporation. Like crack, freebase cocaine is smoked. The flammability of ether poses yet another danger in the preparation of this form of cocaine. Freebase use has declined as crack has become more available, and because crack does not pose the problem of flammability.

An estimated 90% of cocaine use in the United States is carried out through nasal snorting. In addition, approximately one-third of cocaine users have smoked crack. Less than 10% have injected the drug intravenously. Because cocaine is rapidly absorbed through the respiratory tract, smoking of either crack or freebase cocaine rapidly delivers cocaine to the circulation. Cocaine enters the brain within 6 to 8 seconds by the respiratory route (smoking) and within 10 to 15 seconds by an intravenous route. Snorting cocaine results in eak cocaine concentrations in 30 to 60 minutes (15). The amount of cocaine that can be absorbed through the nasal route may be self-limited to some extent because of vasoconstriction of the nasal mucosa induced by cocaine itself.

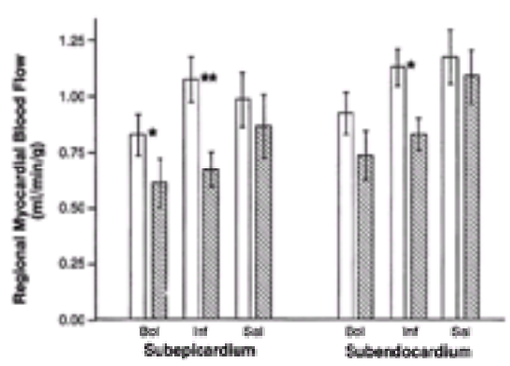
Cocaine is often combined with other substances, most commonly ethanol. An estimated 9 to 12 million individuals use this combination on a recreational basis (16,17). Cocaethylene is the cocaine metabolite formed in the presence of ethyl alcohol and may be more potent than cocaine itself (see Cocaethylene).

Pharmacology

The pharmacology of cocaine is complex and has been the subject of a vast amount of basic science research during the last 10 years. First, cocaine is a local anesthetic. It blocks sodium and potassium channels (6) and thus blocks initiation and conduction of electrical impulses. This effect accounts for prolongation of electrocardiographic (ECG) intervals and decreases in cardiac contractility and may lead to a proarrhythmic effect (18). Second, cocaine blocks the reuptake of neurotransmitters at the presynaptic endings of nerves. As a result, neurotransmitters such as dopamine and norepinephrine accumulate in the synaptic cleft, which results in an intense sympathomimetic effect (6). This second major action of cocaine accounts for increases in heart rate, blood pressure, and contractility and, by stimulation of alpha receptors in the vasculature, contributes to vasoconstriction. A third pharmacologic action of cocaine that affects the cardiovascular system is a decrease in vagal tone, which also contributes to an increase in heart rate (19). Thus, on the one hand, cocaine may have a cardiodepressive effect resulting from its effect on sodium and potassium channels. On the other hand, it has a stimulatory effect because of its sympathomimetic properties. These opposing forces may result in very complex outcomes (20).

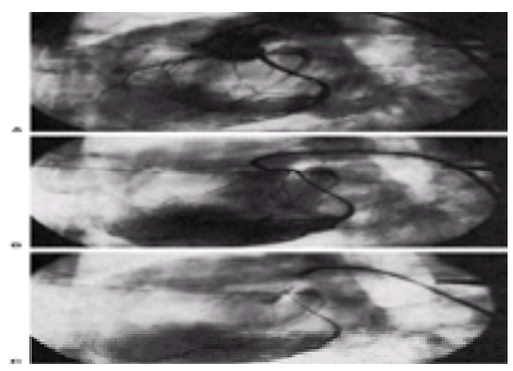
Effects of an Acute Dose of Cocaine on the Heart in Experimental Studies

A number of studies have investigated the acute effects of cocaine on the heart. In one study involving canines anesthetized with sodium pentobarbital (21), the hemodynamics, regional myocardial blood flow, and echocardiographic effects of an intravenous dose of cocaine, 10 mg per kg—a dose that simulates the use of either intravenous cocaine or inhalation of crack smoke—was assessed. Cocaine caused no significant effect on heart rate or blood pressure in this model, probably because the animals were already influenced by the sympathomimetic effect of sodium pentobarbital. In awake, conscious preparations, cocaine typically produces an increase in both heart rate and blood pressure (22,23). Cocaine caused a significant depression in the change of ventricular pressure over time (dP/dT) and an acute dilatation of the left ventricle seen on echocardiography, with increases in both end systolic and end diastolic left ventricular (LV) cross-sectional area (21). Regional myocardial blood flow, assessed by radioactive microspheres, showed an acute reduction in global flow, most impressive in the subepicardium (eFig. 36.0.1).

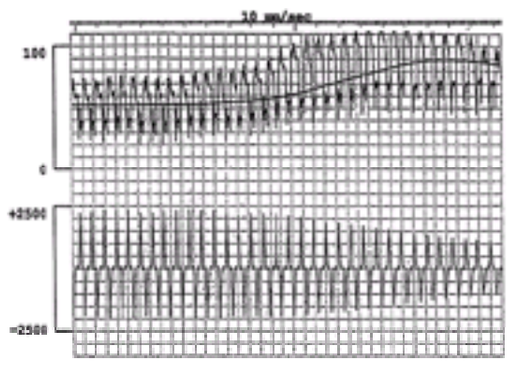


***e*FIGURE 36.0.1** Regional myocardial blood flow in the subepicardium and subendocardium of anesthetized dogs before (*open bars*) and 15 minutes after (*hatched bars*) administration of cocaine or saline. Bol, bolus cocaine administration; Inf, cocaine infusion; Sal, saline; **p* <.04; ***p* <.004. (From Hale SL, Alker KJ, Rezkalla S, et al. Adverse effects of cocaine on cardiovascular dynamics, myocardial blood flow, and coronary artery diameter in an experimental model. *Am Heart J* 1989;118:927–933.)

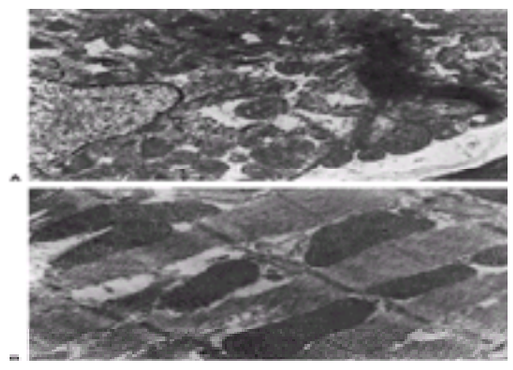
Coronary angiography in dogs receiving an acute bolus of cocaine showed diffuse coronary vasospasm in all epicardial coronary arteries (eFig. 36.0.2). An assessment of timing of acute depression of ventricular function versus blood flow revealed a fall in dP/dT before a fall in coronary blood flow (eFig. 36.0.3), suggesting that depression of ventricular function was a primary effect of cocaine, followed by a further secondary fall in ventricular function caused by subsequent reduction in coronary flow (24). Other investigators have described an acute fall in LV function with administration of cocaine. Sequential intravenous boluses of cocaine administered to dogs resulted in a progressive deterioration of both positive and negative dP/dT (25). Cocaine administration to anesthetized rabbits resulted in acute regional wall motion abnormalities seen on two-dimensional echocardiography (26). In some animals, ultrastructural abnormalities were identified, including contraction-band necrosis and sarcoplasmic reticular edema (eFig. 36.0.4).



***e*FIGURE 36.0.2** Cineangiograms of coronary arteries of a dog before **(A)**, during **(B)**, and after **(C)** cocaine administration. The circumflex artery is to the right. Note the considerable reduction in circumflex artery and left anterior descending diameter after cocaine administration. (From Hale SL, Alker KJ, Rezkalla S, et al. Adverse effects of cocaine on cardiovascular dynamics, myocardial blood flow, and coronary artery diameter in an experimental model. *Am Heart J* 1989;118:927–933.)



***e*FIGURE 36.0.3** Recording showing changes in coronary blood flow (mL/min, *top channel*) and left ventricular dP/dT (change of ventricular pressure over time; mm Hg/sec, *bottom channel*) that occur shortly after cocaine bolus in anesthetized dog. Note that flow increases concurrent to a decrease in contractility, suggesting that the reduced dP/dT at this phase is unrelated to any fall in blood flow. (From Hale SL, Alker KJ, Rezkalla SH, et al. Nifedipine protects the heart from the acute deleterious effects of cocaine if administered before but not after cocaine. *Circulation* 1991;83:1437–1443, with permission of the American Heart Association.)

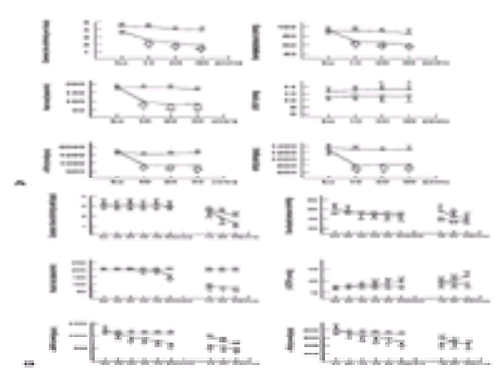


***e*FIGURE 36.0.4 A:** Electron micrographs of biopsy specimens of rabbit ventricular myocardium from rabbits that received acute doses of cocaine. A dark contraction band is observed in the upper right. **B:** Mild intermyofibrillar edema (*clear spaces*) and swollen sarcoplasmic reticulum in a rabbit that received an acute dose of cocaine. (From Gardin JM, Wong N, Alker K, et al. Acute cocaine administration induces ventricular regional wall motion and ultrastructural abnormalities in an anesthetized rabbit model. *Am Heart J* 1994;128:1117–1129.)

Because cocaine can increase blood pressure, its effect on cardiac contraction may be clouded by changes in afterload. Several studies, therefore, have investigated the effect of cocaine either in models in which loading conditions could be accounted for or in isolated heart models or cultured myocytes to determine more directly its effect on contractility.

In one study, cocaine depressed contractility in conscious dogs, independent of loading conditions (27). In another, cocaine was administered to isolated perfused rabbit ventricular septal preparations while coronary flow of oxygenated Kreb's solution and constant heart rate were maintained by pacing the septa (28). Cocaine at various concentrations caused a reduction in developed tension, maximum contraction velocity, and maximum relaxation velocity. LV function recovered completely after washout of the cocaine. The authors concluded that cocaine has an acute direct, though reversible, depressant effect on the myocardium, independent of coronary flow.

The effects of an acute dose of cocaine in the Langendorff-perfused isolated rabbit heart have been reported (29). In nonpaced hearts, 10-, 25-, and 50-µM concentrations of cocaine caused a dose-dependent deterioration in cardiac contractility, manifest by reductions in positive and negative dP/dT (*e*Fig. 36.0.5). At 50-µM doses, the decrease in cardiac contractility during the first 60 seconds of infusion preceded a fall in coronary flow or a change in heart rate. Thus, a rapid decrease in contractility was the first manifestation of the direct cardiotoxic effects of cocaine in this isolated heart model. Experiments carried out in isolated cardiomyocytes in culture have confirmed a direct negative inotropic effect of cocaine (30).



***e*FIGURE 36.0.5** Early and late effects of cocaine, 50 µM versus control, on hemodynamic variables in isolated nonpaced retrogradely perfused rabbit hearts **(A)** and in isolated paced retrogradely perfused rabbit hearts **(B)**. Ordinate: hemodynamic variables. Abscissa: Time in protocol. Values are mean ± standard error of the mean. *Open circles,* control group (n = 6); *open triangles,* cocaine-treated group (n = 6). bs, baseline; HR, heart rate; LVEDP, left ventricular end diastolic pressure, +dP/dT, positive change in ventricular developed pressure over time; –dP/dT, negative change in developed pressure over time; **p* <.05 versus control group; ***p* <.05 versus bs. (From Simkhovich BZ, Kloner RA, Alker KJ, et al. Time course of direct cardiotoxic effects of high cocaine concentration in isolated rabbit heart. *J Cardiovasc Pharmacol* 1994;23:509–516.)

In chronically instrumented conscious dogs, the effect of cocaine on cardiac hemodynamics differs from that observed in anesthetized animal models (22). In the awake state, 1 mg per kg of cocaine caused a transient reduction in LV dP/dT, followed by a 25% increase at 15 minutes. Beta-blockers prevented the positive inotropic effects. The authors concluded that acute intravenous cocaine (0.1 to 2.0 mg per kg) results in a "biphasic effect on myocardial and left ventricular function with a transient depression followed by a significant sustained increase in left ventricular contractility" (22). These observations are consistent with an initial local anesthetic or sodium channel blocking effect (cardiodepressive) followed by sympathetic stimulation.

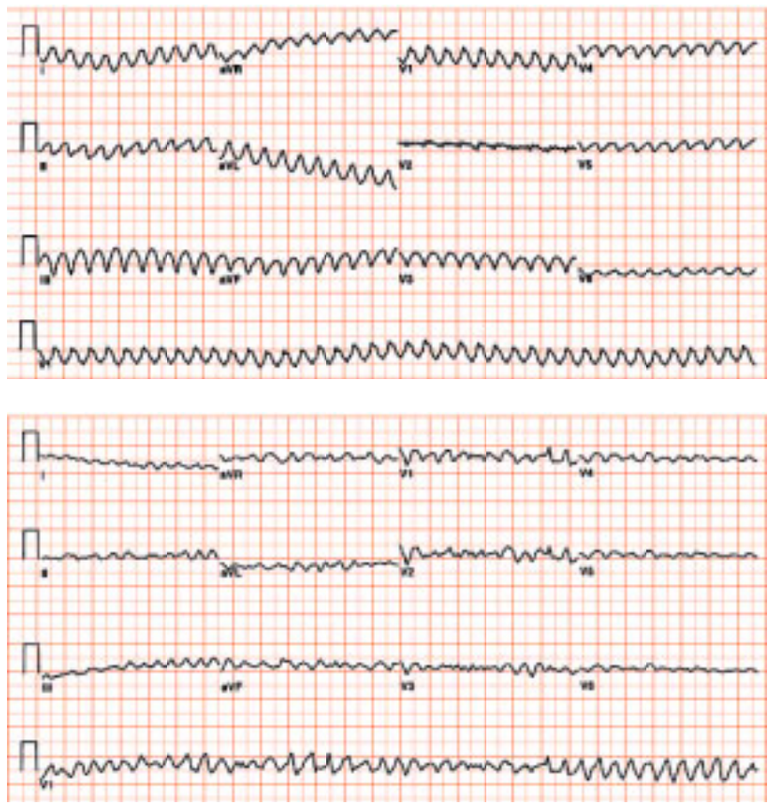
Not only did cocaine reduce coronary blood flow in the canine model with an associated diffuse coronary vasospasm of the epicardial arteries (21,31), but it also induced coronary vasospasm within arterioles (32). Several investigations have observed that isolated vascular rings constrict when exposed to cocaine (1) or the cocaine metabolite norcocaine.

Effects of an Acute Dose of Cocaine on Cardiac Rhythm

As shown in experimental animal studies, cocaine can affect cardiac rhythm by several mechanisms: (a) a sympathomimetic effect with stimulation of alpha and beta receptors may increase ventricular excitability, (b) an increase in intracellular calcium may be linked to alpha-receptor stimulation and result in oscillatory after-depolarizations, (c) vagolytic effects may be present, and (d) the local anesthetic effect (blocking sodium channels) inhibits the generation and conduction of

action-potential generation in nerve and heart tissue.

Cocaine induced ventricular tachycardia and fibrillation during catecholamine injections in anesthetized animals and ventricular fibrillation during exercise-induced ischemia in conscious animals (10). The accentuation of the sympathetic nervous system by cocaine may contribute to these lethal arrhythmias.



Ventricular flutter (A). Same patient with degeneration into ventricular fibrillation (B).

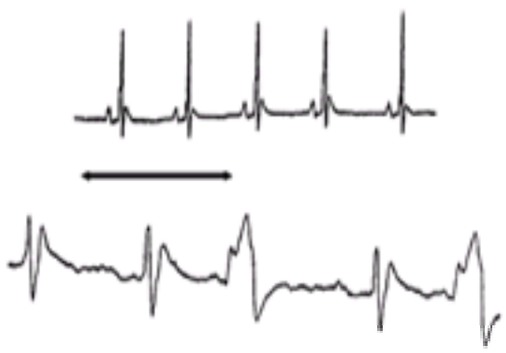
An 81-year-old male patient with ventricular tachycardia.

It has been suggested that, although stimulation of both beta and alpha receptors may play a role in cocaine-induced arrhythmias, alpha-adrenergic stimulation may be especially crucial (10). By increasing catecholamine levels, cocaine may stimulate alpha adrenergic receptors in the myocardium, resulting in an increase in intracellular calcium concentrations that can trigger delayed after-depolarizations and arrhythmias. Prazosin (an alpha-blocker) reduced the incidence of ventricular arrhythmias when administered to animals stressed by cocaine and exercise-induced ischemia. It prevented ventricular fibrillation in most cases. Propranolol was effective but lost its efficacy when its negative chronotropic effect was counteracted by pacing.

Studies have shown that cocaine increases intercellular calcium levels (33,34). Calcium channel blockers, which would reduce intracellular calcium concentrations, have been shown to be beneficial in cocaine-induced arrhythmias. This observation would also support the alpha receptor–calcium influx theory of cocaine-induced arrhythmias. Verapamil, nifedipine, and other calcium channel blockers reduce ventricular arrhythmias induced by cocaine in experimental models (10).

Recent reports have suggested that not only does cocaine increase cardiac sympathetic activity, which could predispose the heart to ventricular arrhythmias, but it also reduces vagal activity, manifested by a significant reduction in heart-rate variability (18,19,35). This withdrawal of vagal tone is very prominent when cocaine is administered during an episode of myocardial ischemia.

In a study of the effects of a 3-hour infusion of cocaine compared with saline in anesthetized rats, cocaine increased both heart rate and blood pressure during the first hour of administration, but by the second and third hour, these parameters were no longer increased (36). In cocaine-treated hearts, a significant increase in PR, QRS, QT, and corrected QT intervals on the ECG persisted for 3 hours. In four of six cocaine-treated rats, frequent atrial extrasystoles or atrial tachycardia was observed, and one rat demonstrated ventricular extrasystoles (eFig. 36.0.6). The lengthening of both intraventricular conduction and repolarization time (QT interval) may have been related to cocaine's depressant effect on action potential upstroke (local anesthetic effect) or to "quinidine-like properties of the drug." A marked prolongation of the effective refractory period in paced isolated rabbit hearts exposed to cocaine was also described (37). Several other reports have documented electrophysiologic abnormalities induced by cocaine in intact animals, including prolonged PR, QRS, and QT duration and increase in the bundle of His–ventricular HV interval (38,39,40 and 41). High doses of cocaine have induced asystole and conduction block (42,43). These effects probably result from cocaine's ability to reduce the automaticity of Purkinje cells and depress phase O of the action potential (44). Cocaine also results in delayed repolarization because of its blocking action on the calcium-dependent potassium channel (45).



***e*FIGURE 36.0.6** Electrocardiogram from a rat before (*top*) and 3 hours after (*bottom*) administration of cocaine. After cocaine, PR interval and QRS duration are markedly lengthened and there are ventricular premature beats. Distance between arrows is 1 second. (From Hale SL, Lehmann MH, Kloner RA. Electrocardiographic abnormalities after acute administration of cocaine in the rat. *Am J Cardiol* 1989;63:1529–1530.)

Conduction delays and heterogeneity of repolarization may also lead to serious ventricular arrhythmias. Thus, the local anesthetic effect of cocaine contributes to life-threatening rhythm disturbances. Bauman and associates stated that the nature of cocaine-induced sudden death in humans suggested a proarrhythmic effect of the drug similar to that of agents such as flecainide (18).

In summary, studies analyzing the effects of acute doses of cocaine in animals suggest that cocaine has both cardiodepressive and cardiostimulatory effects on the

heart. The cardiodepressive effects include reductions in contractility, blood flow, and conduction abnormalities, probably related to its local anesthetic effects. The cardiostimulatory effects are increases in heart rate, blood pressure, contractility, and ventricular excitability, and coronary vasoconstriction related to cocaine's sympathomimetic and vagolytic effects.

Another action of cocaine that can affect the cardiovascular system includes an increase in platelet aggregation, which has been documented in a rabbit model (46) as well as *in vitro* in human blood (47). his is likely caused by platelet activation and the release of alpha granules (48).

Effects of Chronic Cocaine Administration in Experimental Models

Fewer data are available on the effects of chronic cocaine use in animal models. Rats (49) given 10 mg per kg of intraperitoneal cocaine every 12 hours for 10 days developed several histochemical abnormalities, including reduction in cardiac enzymes (glucose-6-phosphate dehydrogenase, lactate dehydrogenase, and myosin-adenosinetriphosphatase). Rats receiving 8 days of cocaine administration developed electron microscopical abnormalities, including contraction bands and mitochondrial swelling (50). Rabbits kept on high-cholesterol diets developed acceleration of atherosclerosis when cocaine was administered daily (51,52). These experiments and observations made at autopsy in young patients who died of cardiovascular complications of cocaine (see below) have led some investigators to suggest that chronic cocaine use damages the endothelium, resulting in acceleration of atherosclerosis (53).

Controlled Studies of Administration of Cocaine in Humans

Cocaine is known to increase both heart rate and blood pressure in awake individuals. Fischman and coworkers (54) demonstrated a dose-related increase in these parameters when patients received intravenous cocaine. Although small doses did not have a significant effect, an intravenous injection of cocaine, 16 and 32 mg, resulted in a significant rise in both heart rate and blood pressure in human volunteers. The changes peaked at 10 minutes after administration and returned to baseline in approximately 1 hour.

To examine the acute effects of cocaine in humans, investigators administered low doses (2 mg per kg) of intranasal cocaine to patients in the cardiac catheterization laboratory (3,55,56 and 57). They observed increases in heart rate and blood pressure but only mild, diffuse reductions in coronary caliber (8% to 12% of normal), a 33% increase in coronary vascular resistance, and a 17% reduction in coronary sinus blood flow. Thus, even though myocardial oxygen demand increased—with an increase in double-product—these patients exhibited a decrease in coronary blood flow. It is likely that in cocaine abusers, who often use much higher doses than those administered in this controlled study, the imbalance in oxygen supply and demand is even worse. It was shown that the cocaine-induced coronary vasoconstriction could be reversed with the alpha adrenergic blocking agent phentolamine, suggesting that alpha-receptor stimulation by cocaine is a crucial aspect of the vasoconstriction. The vasoconstriction was worse at sites of atherosclerosis and could be relieved by nitroglycerin (58). The beta-blocker propranolol potentiated the cocaine-induced vasoconstriction, presumably because the beta receptors were blocked, leaving the alpha receptors unopposed. Investigators showed (59) that accumulation of cocaine metabolites may also contribute to coronary vasospasm. Addition of ethanol to intranasal cocaine did not worsen coronary vasospasm (16). Isolated human coronary arteries from patients undergoing cardiac transplantation have also been shown to undergo vasospasm when exposed to cocaine.

Administration of cocaine as a local anesthetic agent for use in laryngoscopy increased the frequency of ventricular premature beats (60). There have been occasional case reports of acute MI when intranasal cocaine was used as a topical anesthetic for nasal operative procedures. The effects of cocaine on human fetal left ventricles were studied (61). Cocaine reduced action potential amplitude, depressed the force of ventricular contraction, and then, at 90 minutes of exposure, resulted in electrical and mechanical arrest, which also suggests that cocaine has a direct cardiodepressant effect on cardiac muscle. And finally, we observed that when human blood is exposed to cocaine, in approximately one-half of the samples, platelet aggregation to adenosine diphosphate but not collagen or epinephrine is increased (Fig. 36.1) (47).

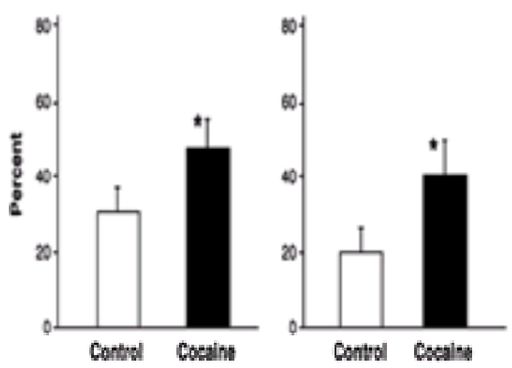


FIGURE 36.1 Platelet aggregation from humans (1 µg, adenosine diphosphate) after incubation with saline or cocaine. Peak aggregation (*left*) and aggregation at 15 minutes (*right*). Data are expressed as mean ± standard error of the mean; *p <.02. (From Rezkalla SH, Mazza JJ, Kloner RA, et al. Effects of cocaine on human platelets in healthy subjects. *Am J Cardiol* 1993;72:243–246.)

In summary, controlled studies in humans receiving low doses of intranasal cocaine showed that cocaine increases heart rate and blood pressure but causes coronary vasoconstriction at the same time. Thus, the potential for ischemia through an imbalance between oxygen supply and demand may occur, especially when even higher doses of cocaine are used.

Cardiovascular Disease Associated with Cocaine Use

Most of our knowledge regarding the clinical complications of cocaine use in patients comes from clinical reports and autopsy studies. A number of cardiovascular diseases associated with cocaine use have been reported in the literature. These are summarized in Table 36.1, and mechanisms of cocaine action are illustrated in Fig. 36.2.

Myocardial infarction and myocardial ischemia
Myocarditis
Cardiomyopathy: dilated and hypertrophic
Arrhythmias: tachy- and bradyarrhythmias
Hypertension
Aortic dissection
Endocarditis
Acceleration of atherosclerosis?

TABLE 36.1 CARDIOVASCULAR COMPLICATIONS OF COCAINE USE

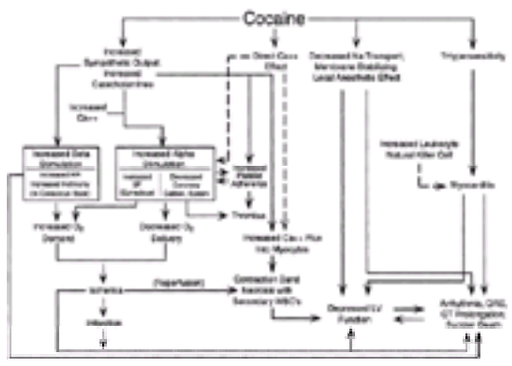

FIGURE 36.2 Schematic diagram describing potential mechanisms of the cardiotoxic effects of cocaine. Two primary mechanisms are suggested. First, cocaine inhibits presynaptic reuptake of catecholamines, resulting in a potentiation of the sympathetic nervous system and an increase in catecholamine levels. Second, cocaine inhibits sodium transport across the sarcolemmal membrane, leading to a membrane-stabilizing or local anesthetic effect that has been likened to a type I antiarrhythmic effect. In conscious preparations, increased sympathetic output and catecholamine levels result in an increase in heart rate and, in some studies, inotrophy, which can increase oxygen demand. a-Stimulation of blood vessels causes a vasoconstrictor response with increase in blood pressure in conscious preparations, also resulting in increased oxygen demand. a-Sympathetic stimulation decreases coronary artery caliber, increases coronary vascular resistance, and may lead to coronary spasm in both conscious and anesthetized preparations, thus reducing oxygen supply. Repetitive bouts of coronary spasm might alter or damage the endothelium, contributing to accelerated atherosclerosis, which has been reported with use of cocaine. Increased platelet aggregability has been reported with use of cocaine (and may be related to increased catecholamine levels), which can contribute to thrombus formation. All of these factors contribute to an imbalance between oxygen supply and demand and may thus lead to myocardial ischemia with subsequent infarction and associated left ventricular dysfunction and arrhythmias. Increased sympathetic output may also contribute to tachyarrhythmias. Catecholamine excess is known to lead to contraction-band formation, and this is thought to be related to calcium overload. Isner and Chokshi (1) postulated that cocaine may have a direct effect on calcium flux into blood vessels (and perhaps myocytes), leading to vasoconstriction that may be independent of the sympathetic nervous system (*dashed lines*). The local anesthetic effect of cocaine may cause direct depression of inotrophy (which in some studies surpasses any indirect positive inotropic response caused by sympathetic simulation) and can lead to a transient cardiomyopathic presentation. This local anesthetic effect can also lead to prolongation of electrocardiographic intervals, including QRS and QT duration, perhaps resulting in arrhythmias and sudden death, much like the proarrhythmic effects of agents such as quinidine. Hypersensitivity to cocaine has been postulated but not absolutely proved to be a cause of myocarditis. In addition, an increase in natural killer cell activity (which may be related to increased catecholamines) has been reported with cocaine and could lead to myocarditis. Scattered foci of myocarditis could lead to a cardiomyopathic presentation and form the nidus for arrhythmias. BP, blood pressure; HR, heart rate; LV, left ventricular; WBC's, white blood cells. (From Kloner RA, Hale S, Alker K, et al. The effects of acute and chronic cocaine use on the heart. *Circulation* 1992;85:407–419, with permission of the American Heart Association.)

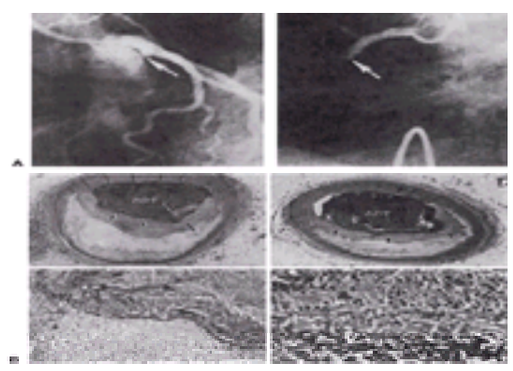
Acute Myocardial Infarction

Four possible causes of MI are related to cocaine use. (a) Coronary artery spasm is caused by the intense alpha-sympathetic stimulation associated with use of cocaine. (b) Thrombus formation was observed in 24% of patients in whom coronary artery disease was absent (62). Thrombus may have occurred on top of an area of vasospasm that was then relieved, and increased platelet aggregability may contribute (47). Thrombus formation may also occur on top of atherosclerotic narrowing (eFig. 36.2.1). Plaque fracture or rupture, which is common in most Q-wave MIs, is usually not observed in cocaine-related infarcts (53,63). (c) Increased myocardial oxygen demand may occur in the presence of a fixed lesion. Chronic use of cocaine may cause an acceleration of atherosclerosis, resulting in atherosclerotic narrowing in young patients (53). The sympathomimetic responses of increased heart rate and blood pressure, in addition to the stenosis, may contribute to infarction. (d) Some combination of the above three may cause MI.



***e*FIGURE 36.2.1 A:** *Left,* Selective injection into left coronary artery in left anterior oblique projection, demonstrating proximal occlusion of left anterior descending artery (*arrow*). *Right,* Injection into right coronary artery in left anterior projection, demonstrating proximal occlusion of right coronary artery (*arrow*) from a 38-year-old man with acute myocardial infarction and history of both chronic and acute use of cocaine. **B:** Histopathologic features of coronary arteries from the same patient. *Top left,* Low-magnification photomicrograph of proximal left anterior descending coronary artery shows atherosclerotic plaque, thin layer of organizing mural thrombus (MT) (*arrowheads*), and large acute occlusive thrombus (AOT). (From Stenberg RG, Winniford MD, Hillis LD, et al. Simultaneous acute thrombosis of two major coronary arteries following intravenous cocaine use. *Arch Pathol Lab Med* 1989;113:521–524.)

At least 114 cases of cocaine-related MI have been reported in the literature (64). Many more probably occur but are never reported. Clinical, angiographic, and autopsy features reveal some unique properties of cocaine-related infarction. MI after cocaine use typically occurs within 3 hours of use of cocaine, but this period ranges from minutes to a few days. The median time of onset of chest pain in the infarct patient depends on the route of administration (62). Onset of chest pain occurred at a median time of 30 minutes with intravenous use, 90 minutes with use of crack cocaine, and 135 minutes with nasal insufflation. In a study of 3,946 patients with acute MI (65), 38 patients reported cocaine use before the clinical presentation. The risk appears to be higher in the 60 minutes after cocaine administration, and it rapidly decreases after the first hour. In one study, the description of chest pain was typical: "pressure, crushing, squeezing, tightness, discomfort, heaviness, and in one case, sharp." Forty-four percent of patients had a history of chest pain (62). There may be a vasospastic component to some of these cases, as suggested by Holter monitoring studies of cocaine use (66). In 1988, at Montefiore Medical Center in Bronx, New York, 35 patients were admitted for chest pain associated with cocaine use. Of these, 11 developed infarction (67). Chest pain after the use of cocaine is not always caused by MI and may indicate the presence of angina or be noncardiac in nature.

In one report, the mean age of patients with acute MI associated with cocaine was 33 years, and 92% of patients were male (67). The most common associated risk factor was cigarette smoking. There does not appear to be any clear-cut dose relationship between the use of cocaine and development of MI. Chronic, occasional, and first-time users may develop infarction. The ECG was abnormal in 90% or more of patients in the emergency department. ECG abnormalities included ST segment elevation, T-wave inversion, and Q waves. Both Q- and non–Q-wave infarcts have been reported after cocaine use. High creatine kinase (CK) levels may be present as a result of trauma or rhabdomyolysis. Therefore, CK–MB elevation is needed to document damage to the myocardium (68). Cocaine users who develop coronary artery disease and MI tend to be older and to have multiple risk factors, such as smoking, compared with users who do not have evidence of coronary disease (69).

Coronary vasospasm has been well documented in only a few cocaine-related infarct patients. Coronary stenosis is present in 29%. Thrombosis is present in approximately one-fourth of the cases. In an analysis of 92 cases in which either coronary angiographic or coronary anatomic data were collected at autopsy (64), 38% of patients had normal coronary anatomy. Of these, 77% had infarcts of the anterior wall.

In a review of the literature (62), 22 of 91 cases of cocaine-induced infarction had some complication: six had congestive heart failure, three had cardiogenic shock, 11 had potentially life-threatening arrhythmias, three had ventricular fibrillation, six had ventricular tachycardia, and two had cardiac arrests. Three deaths occurred. In the series from Montefiore Hospital (67), among 22 patients with cocaine-related acute MI, no in-hospital deaths occurred, and only one episode of heart failure and

ventricular tachycardia was seen. A case report of a patient who developed an intraventricular thrombus after cocaine-induced MI was recently described (70).

Management of Cocaine-Induced Myocardial Ischemia and Myocardial Infarction

No controlled, randomized, prospective trials clarify the best way to manage cocaine-induced ischemia or infarction. As stated earlier, not all episodes of chest pain associated with cocaine are necessarily MIs. The incidence of MIs associated with cocaine-induced chest pain was 0% to 31% in retrospective analysis and approximately 6% in prospective analyses (71). In addition, not all cocaine-related chest pain is necessarily ischemic; pleuritic pain has been reported. Chest radiographs should be obtained to rule out pneumothorax and pneumomediastinum, which have both been reported with cocaine use. Initiation of thrombolytic therapy should not be delayed while chest radiographs are awaited, however, unless physical examination strongly suggests conditions other than MI.

Patients who enter the emergency department with pain that suggests ischemia (but do not have evidence of infarction) after cocaine use should be observed (71,72 and 73). One report (71) favors a 12-hour observation period during which ECG and serial CK-MB measurements are obtained to rule out MI. Total creatine phosphokinase level elevation appears to occur in a significant number of cocaine users. This is an unreliable screening test for the detection of myocardial injury (74). Myoglobin level is not reliable in detecting MI secondary to cocaine use, but troponin-1 and CK-MB appear to have a good specificity (75). If possible, previous ECGs should be obtained, because cocaine users not infrequently also have early repolarization variants on their ECG or LV hypertrophy.

Medical therapies for cocaine-related chest pain that is ischemic (anginal) but is not infarction include nitroglycerin, oxygen, aspirin, and benzodiazepines (71,72 and 73). Verapamil or other calcium channel blockers and phentolamine may be considered if pain continues (71). If the ECG suggests MI, administration of thrombolytic agents (intravenous or intracoronary) (76) and aspirin should be considered. Some investigators (73) suggest the use of two-dimensional echocardiography to confirm regional wall motion abnormalities before thrombolysis is instituted in patients in whom ST segment elevation is not clearly present. Thrombolytic therapy has, in fact, been used successfully, but no contraindications, such as severe hypertension, intracerebral hemorrhage, or seizures, all of which may occur with cocaine, should be present. A few case reports have raised some safety issues regarding thrombolytic agents in the setting of cocaine. One death has occurred from intracerebral hemorrhage. Thus, primary angioplasty may be another approach. A recent case report described the efficacy of platelet glycoprotein IIb/IIIa inhibitor, given intravenously, with complete resolution of a thrombus in the coronary artery that was temporally related to use of crack cocaine (77). Primary coronary intervention has been tried in cocaine users with success (78). One 36-year-old cocaine user presented to the emergency department with acute MI and ventricular fibrillation. During emergency catheterization, a significant stenosis of the circumflex artery was found, and a coronary stent was successfully deployed. The authors noted that before the stent deployment, intense and frequent coronary spasms were seen.

Because beta-blockers may exacerbate coronary vasospasm in cocaine-induced coronary ischemia secondary to unopposed alpha-receptor stimulation, they should be used with extreme caution, if at all, in the acute setting. The available data are from scattered case reports, and no final conclusion has been drawn (79). At the time of the patient's discharge, however, beta-blockers should be considered part of routine postinfarction therapy. The benefits of beta-blockers may outweigh the potential risk of increasing the vasomotor tone, particularly because the cocaine effect should be gone by the time of discharge. If, however, the patient begins to use cocaine again after discharge, beta-blockers could worsen vasospasm. Labetalol might be a safer choice, but its primary effect is beta-blockade, not alpha-blockade, and therefore even this agent is controversial.

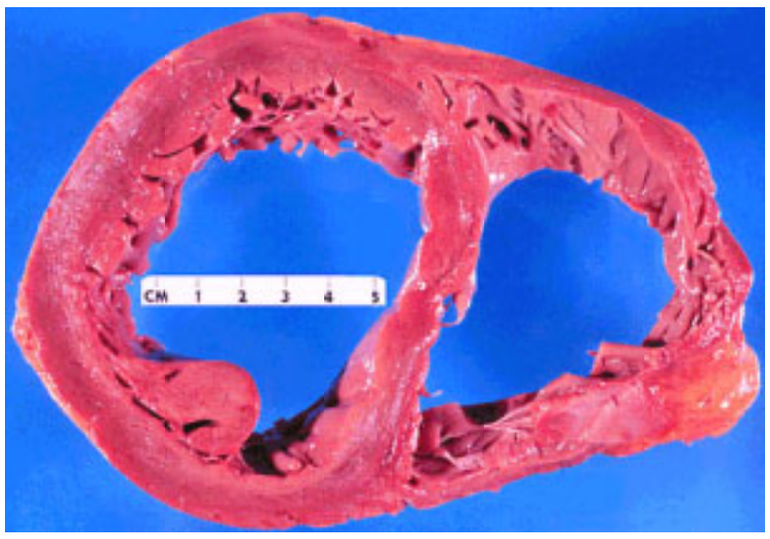
The best therapy for cocaine-induced ventricular arrhythmias remains to be determined. In experimental studies, sodium bicarbonate reverses QRS prolongation caused by cocaine (80). The use of lidocaine is debated, because lidocaine, a sodium channel blocker and local anesthetic, could theoretically worsen the proarrhythmic effect of cocaine. Some studies, however, suggest that lidocaine is safe when it is administered several hours after the use of cocaine.

Obviously, it is crucial that patients stop using cocaine and that they be educated about the dangers of this substance. Concern that cocaine may accelerate atherosclerosis is an additional reason to recommend drug rehabilitation programs.

Our own experience in an inner-city hospital was that acute MI occurring in an otherwise healthy young person may be related to cocaine, and a history of cocaine use and urine testing for cocaine should be considered. Urine testing may detect cocaine or its metabolites as long as 3 weeks after use. Various methods are used, including enzyme-multiplied immunoassay technique, gas chromatography, and mass spectrometry. A skin patch has recently been tested as an easy-to-use screening tool. When a young person has an MI, the physician should remember to ask whether the patient has been using cocaine (81).

Cocaine-Induced Cardiomyopathy and Myocarditis

Cases of transient congestive heart failure have occurred after use of cocaine (82). In some cases, this has involved global hypokinesis, typical of a cardiomyopathy, that may be accompanied by normal coronary angiograms (83,84). Clinically unrecognized reduction in LV function was reported in 7% of chronic cocaine users in one study (85). A case of recurrent dilated cardiomyopathy in a patient who quit and then began reusing cocaine was also reported (86).



Dilated congestive cardiomyopathy. Both the left and right ventricles are significantly enlarged. In this example, the left ventricular wall thickness falls within normal limits.

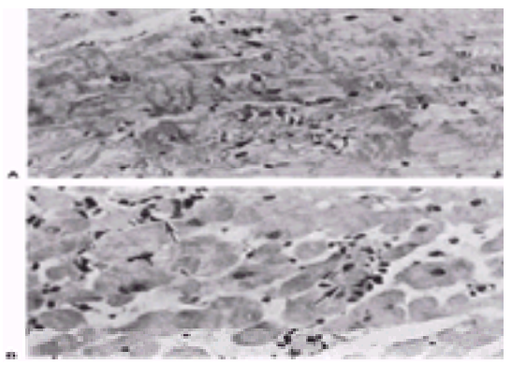
Video 36.2 Standard anterior view of a 16-frame nuclear ventriculogram (multiple gated acquisition scan) demonstrating global hypokinesis and a reduced left ventricular ejection fraction of 25% in a patient with nonischemic dilated cardiomyopathy. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

In a controlled, randomized study, intracoronary cocaine or saline was administered to 20 patients during cardiac catheterization. Cocaine, but not saline infusion, led to an increase in LV end diastolic pressure and a decrease in LV ejection fraction (87). These findings suggest that cocaine can induce a global toxic effect on myocytes. Autopsy reports have described a mononuclear cell–type myocarditis in chronic cocaine users (88). Lymphocytes and macrophages were observed in the region of myocyte necrosis (eFig. 36.2.2). A second common morphologic finding among chronic cocaine users is the presence of contraction bands. Myocardial

contraction-band necrosis occurs with catecholamine excess and calcium overload, as well as after reperfusion of ischemic tissue. In an experimental study involving rabbits, we observed that an acute infusion of cocaine caused foci of contraction-band necrosis in some of the animals (26).



***e*FIGURE 36.2.2 A:** Endomyocardial biopsy of a 24-year-old woman with a history of cocaine abuse and chest pain shows multifocal myocyte necrosis (*arrows*). Necrotic myocytes with contraction bands are smudgy with disruption of membranes, granulation, and vacuolization and stain purple-blue on Mallory trichrome staining (×100). **B:** Endomyocardial biopsy from a 33-year-old woman with a history of cocaine abuse and congestive heart failure and ventricular fibrillation shows multifocal myocyte necrosis (*arrows*). Necrotic myocytes are smudgy, vacuolated, and surrounded by lymphocytes (×100). (From Peng SK, French WJ, Pelikan PC. Direct cocaine cardiotoxicity demonstrated by endomyocardial biopsy. *Arch Pathol Lab Med* 1989;113:842–845.)

As is true for MI, no controlled studies are available that clarify the best therapy for cocaine-induced cardiomyopathy. Limited data suggest that this condition may be reversible after cessation of cocaine use for 2 to 7 months. Administration of diuretics and angiotensin-converting enzyme inhibitors certainly should be considered.

In addition to dilated cardiomyopathy, LV hypertrophy has been reported with chronic cocaine use. It is presumably caused at least in part by the elevations in blood pressure that occur with cocaine (89).

Cocaine-Induced Hypertension

The hypertension induced by cocaine use is most likely secondary to the drug's sympathomimetic effect (90). Labetalol has been suggested as therapy because it blocks both alpha and beta receptors. This agent is primarily a beta-receptor blocker, however, and therefore unopposed alpha-receptor stimulation could increase both peripheral vascular and coronary vascular resistance. Calcium channel blockers and alpha-blocking agents such as prazosin and phentolamine might be a better choice.

Cocaine-Induced Arrhythmias

Case reports have described a variety of arrhythmias associated with cocaine use, including ventricular tachycardia, ventricular fibrillation and sudden death (2,91), and supraventricular arrhythmias (42). Ventricular arrhythmias may be associated with MI. One case report described a patient who developed ventricular tachycardia and fibrillation after using cocaine but who had no infarct and had normal coronary arteries at catheterization. After defibrillation, the ECG showed ST segment elevation in leads V_1 and V_2, suggesting that the arrhythmia may have been related to transmural ischemia (possibly caused by transient vasospasm). A case report of torsades de pointes in a patient with cocaine-related prolongation of the QT interval was described. On the basis of these and other case reports, six potential types of cocaine-induced arrhythmias in humans are thought to be likely: (a) those associated with structural damage (i.e., cocaine-induced MI or cardiomyopathy); (b) those caused by QT prolongation, the direct effect of cocaine on the myocardium; (c) those resulting from cocaine's sympathomimetic and vagolytic effects; (d) those resulting from cocaine-induced ischemia; (e) those caused by reperfusion after resolution of coronary artery vasospasm; and (f) those resulting from the systemic effects of cocaine, such as hyperthermia, seizures, and acidosis.

On rare occasions, bradyarrhythmias and sinus arrest have been described in cocaine users (92). This could be related to cocaine-induced myocardial ischemia. No controlled studies in humans have determined the best approach to cocaine-induced arrhythmia. In animal studies, sodium bicarbonate has been shown to reverse cocaine's prolongation of the QRS interval. Concerns about the use of beta-blockers have been described. Antiarrhythmic agents, such as lidocaine, procainamide, and quinidine, have the potential to compound cocaine's depressant effects on the conduction system and prolongation of the QT interval. Calcium channel blockers, such as nitrendipine and verapamil, have shown promise in experimental animal studies. If the arrhythmia is thought to be caused by ischemia or infarction, then the antiischemic and antiinfarction agents described earlier should be used to relieve ischemia.

Acceleration of Atherosclerosis Associated with Cocaine Use

Severe atherosclerosis of the coronary arteries has been described in young patients who died from cocaine (53). In one study (52), the average age of patients who developed cocaine-induced thrombus was only 29 years. It is important to remember, when interpreting these studies, that cocaine users tend also to be cigarette smokers, which might contribute to acceleration of atherosclerosis. An increase in adventitial mast cells within the atherosclerotic coronary arteries of cocaine users has been described (52). It was suggested that release of vasoactive substances by the mast cells could explain the acceleration of atherosclerosis in cocaine users (88). Elevation of catecholamine levels can increase low-density lipoprotein (LDL) uptake by the arterial wall. Hence, increases in catecholamine levels in cocaine users might also help explain this acceleration of atherosclerosis. Jones and colleagues (93) observed that cocaine had a direct toxic effect on coronary endothelium, resulting in endothelial denudation. Repetitive episodes of coronary vasospasm might also eventually lead to endothelial damage.

In addition to an acceleration of atherosclerosis, a few cases of intimal hyperplasia have been described as a cause for coronary narrowing (94,95). Another study (96) described thickening of intramural coronary arteries in young men who had ischemic chest pain related to cocaine use and had epicardial coronary arteries of normal appearance.

Miscellaneous Cardiac Conditions Reported with Cocaine Use

Cocaine use has been associated with aortic dissection, presumably because of the associated acute elevation of blood pressure (4), and intravenous cocaine use has been associated with bacterial endocarditis. It has been suggested that left-sided endocarditis is more common than right-sided endocarditis in this setting (4). Cocaine users are also prone to developing paravalvular abscesses.

The best way of avoiding cocaine-induced cardiovascular diseases is total abstinence. Various methods for treatment of cocaine addiction exist, including aversion therapy and narcotherapy. No long-term comparative studies on the usefulness of various programs are available, and the most optimistic success rate at 1 year is approximately 60%. It seems that greater efforts should be directed at preventing substance abuse before it starts, particularly in adolescents and in young adults.

Cocaine has also been shown to have a deleterious effect on other blood vessels, including peripheral (97,98), intestinal (99), and cerebral vessels (100,101). A summary of the effects of cocaine on the heart is shown in Fig. 36.2.

COCAETHYLENE

Cocaethylene is a pharmacologically active cocaine metabolite that has been detected in patients who simultaneously abuse cocaine and ethanol. It has been estimated that 9 to 12 million people in the United States use a combination of cocaine and ethanol (16,17), which accounts for more than 1,000 yearly deaths. The combination may be more toxic than either agent alone. Studies have suggested that their simultaneous use markedly increases the rate of sudden death (102), and that patients dying from the combination had cocaine blood concentrations lower (900 mg per mL) than those in patients dying of cocaine abuse alone (2,800 mg per mL), suggesting a synergistic effect (103). Other studies (104), however, have suggested that blood cocaine concentrations become elevated when oral ethanol is given to people snorting cocaine. Cocaethylene was more potent in killing mice than cocaine alone (105).

The mechanism whereby cocaethylene has such deleterious effects has been the subject of recent research. Combinations of cocaine and alcohol result in greater increases in heart rate, cardiac output, diastolic blood pressure, and myocardial depression than either agent alone (106,107 and 108). Although both cocaine and

cocaethylene produced direct negative inotropic effects on isolated cardiac myocytes by decreasing the availability of calcium, the negative inotropic effect was more potent with cocaethylene, and this was related to an additional action, reduction of myofilament responsiveness to calcium (30).

Cocaethylene is more potent than cocaine in depressing contraction of myocardial cells in culture (17). In a study comparing cocaine, ethanol, and a combination of both, cocaine alone increased heart rate and blood pressure and, as previously observed, decreased coronary artery diameter (16). In patients receiving both substances, rate-pressure product increased, but coronary diameter increased as well. Therefore, ethanol did not potentiate the vasoconstrictor effect of cocaine; in fact, it appeared to counteract it. This study suggested that the combination of cocaine and alcohol probably does not exacerbate ischemia. However, the doses of cocaine used were low.

Although the exact mechanism whereby the combination of cocaine and ethanol causes increased rates of sudden death in humans remains to be elucidated, it is a deadly combination with which physicians should be familiar.

CAFFEINE AND COFFEE

Few areas in the medical literature are as confusing as the question of whether coffee and caffeine have deleterious effects on the cardiovascular system. Numerous studies describe data that conflict with others, and, in the end, it is difficult to draw conclusions. Recent reviews have described some of the difficulties in the papers published to date on this issue (109,110). Often, animal studies have used doses of caffeine that are “hundreds to thousands of times those achieved by normal human consumption.” In addition, tolerance to caffeine is common in humans who regularly drink coffee, and most animal studies do not include conditioning protocols. Coffee and caffeine consumption is often associated with other variables and risk factors for coronary artery disease that are not always taken into account. For example, coffee consumption is more common among people with higher education levels and incomes, more common among white people, and more common among Catholics. It is less common among Mormons and Seventh Day Adventists, for religious reasons. Coffee is more commonly consumed among patients who are depressed and are experiencing anxiety and is commonly used by people who also smoke cigarettes. Most physiological studies in humans and animals test the effects of caffeine and relate this to coffee use. However, coffee may have compounds other than caffeine that can affect the cardiovascular system. Nevertheless, caffeine is an important compound in coffee that has been implicated in cardiovascular events.

Physiology of Caffeine Use

Caffeine is a methylxanthine found in a variety of products, including coffee, tea, chocolate, soft drinks, and many over-the-counter medications. Coffee is the predominant source of caffeine in the Western Hemisphere, and tea is the most common source in the rest of the world. Ninety-nine percent of caffeine from beverages is absorbed by the gastrointestinal tract and peaks in the serum within 30 to 60 minutes of ingestion. Caffeine is metabolized by the liver, and a very small percent is excreted unchanged by the kidneys.

Caffeine’s major mechanism of action is to antagonize adenosine receptors. A second, less important action at the usual levels of consumption is phosphodiesterase inhibition. By antagonizing adenosine, caffeine blocks the vasodilatory effect of adenosine and adenosine’s inhibitory effects on platelet aggregation, catecholamine levels, and renin release, as well as lipolysis. Thus, acute caffeine administration may increase blood pressure and increase levels of plasma catecholamine, renin (111), and free fatty acid. Tolerance develops within hours to days of caffeine use, and the effect of caffeine on any individual is highly dependent on the individual and the pattern of consumption.

In general, the effects of caffeine on heart rate and blood pressure in humans are quite variable, and contradicting statements about those effects can be found in the literature. In people who do not regularly drink caffeinated beverages, caffeine may initially increase blood pressure, but the effect is lessened or absent in those who regularly consume caffeine. In one study, a 10 mm Hg increase in blood pressure was seen after consumption of 3 to 5 mg per kg of caffeine. There was an initial *decrease* in heart rate during the first hour after consumption, followed by an *increase* from 2 to 3 hours after consumption (111). Prolonged exposure to caffeine results in tolerance, but chronic drinkers of caffeinated coffee may still exhibit small long-term increases in blood pressure, which seems to be worse among drinkers of boiled rather than filtered coffee (112,113). The increase in both systolic and diastolic blood pressure is more consistent in hypertensive patients, particularly in older men and women (114,115). In one study of 499 hypertensive men, the risk of thromboembolic stroke increased significantly in coffee drinkers (116). However, this finding requires confirmation in larger-scale epidemiologic studies.

Coffee and Coronary Heart Disease

Debate about whether coffee consumption and coronary heart disease are associated continues. Some epidemiologic studies suggest that they are, and that the prevalence of coronary disease increases among coffee drinkers, especially with intake of five or more cups of coffee per day. In a study of 1,130 male medical students older than 25 years, daily consumption of one to two cups of coffee resulted in a relative risk of coronary heart disease of 1.3; more than five cups of coffee daily increased the risk to 2.5 (117). The investigation did not fully control for all risk factors, but it did control for smoking. Other studies also suggested a relationship between increased coffee consumption and coronary events (118). Many studies (usually with a shorter period of follow-up), however, have been entirely negative. In a study of 45,589 men, daily consumption of four or more cups of coffee increased the risk of a cardiovascular event to only 1.04 (119). The study concluded that consumption of caffeinated coffee is in most cases unlikely to be a risk factor for cardiovascular disease.

A recent epidemiologic study suggested that tea drinking may reduce the risk of MI (120). In the Rotterdam study, tea drinking was associated with less atherosclerosis, as determined by radiographic examination of the abdominal aorta (121). This beneficial effect likely is secondary to the flavonoids present in tea and perhaps to other unknown products. Until the controversy regarding the effect of caffeinated coffee on coronary heart disease events is resolved, it might be prudent to limit patients with ischemic heart disease to fewer than four cups of coffee per day (122). Tea drinking, however, appears to be safe and may even be beneficial.

Coffee and Lipid Alterations

There is also ongoing debate about whether coffee increases serum cholesterol levels. Many of the studies that have shown a correlation between coffee consumption and increases in serum cholesterol levels have been performed outside the United States, whereas some of the studies that showed no association were performed in the United States.

It has been suggested that the method of brewing the coffee may be important. In some of the European studies, coffee was prepared by boiling, whereas in the United States, coffee is brewed mainly by filtering. Boiled coffee appears to have a greater adverse effect than filtered coffee on total serum cholesterol, LDL cholesterol, and apoprotein B levels. It has been postulated that the caffeine in coffee plays a minimal role in altering lipid levels, and that a surfactant in coffee (which is removed by filtration) is responsible for the elevation in lipid levels observed in some of the European studies (110,123). Other factors associated with boiled coffee that have been implicated in increasing serum lipids include cafestol and kahweal, two subfractions that can be found within the lipid fraction of coffee.

Studies in the United States did not report any increase in total or LDL cholesterol levels in patients who consumed filtered coffee (124,125). Thus, at least in the United States, the use of filtered coffee does not seem to cause an increase in cholesterol levels, and in European studies in which boiled coffee did seem to have this effect, a component other than caffeine appeared to be the culprit.

Coffee and Homocysteine Levels

Several studies have demonstrated a positive correlation between heavy coffee consumption and elevated homocysteine levels. These studies included drinking of filtered and unfiltered coffee (126,127 and 128). In a controlled crossover study, 64 healthy volunteers were randomly assigned to receive 1 L of unfiltered coffee daily for 2 weeks or to ingest a coffee-free diet (129). In the heavy coffee-drinking group, plasma fasting homocysteine levels were elevated by 10%. These studies were short-term studies and did not investigate whether a concomitant increase in cardiovascular events occurred. The results may, however, explain the reported increase in cardiovascular events among people who consume large amounts of coffee, particularly unfiltered coffee, in some studies.

Coffee and Arrhythmias

Although a common belief exists that caffeine can exacerbate arrhythmias, the evidence supporting this in humans is limited. Animal studies have examined this question, but studies demonstrating an association between caffeine and arrhythmia have usually involved doses that were several times higher than those ingested by humans.

One study demonstrated that caffeine had little or no effect on cardiac conduction in humans but might exacerbate underlying susceptibilities to arrhythmias (130). Although earlier studies found an increase in ventricular premature beats on the ECGs of patients who drank nine or more cups of coffee or the equivalent amount of

tea (131), more recent studies have been negative.

In a study that examined the effect of caffeine on 50 patients with histories of symptomatic ventricular arrhythmias, continuous ECG recordings at rest and during exercise revealed no increase in ventricular arrhythmias after caffeine consumption, despite an increase in plasma norepinephrine and epinephrine levels (132). During programmed ventricular stimulation, the effect of caffeine varied among the patients. Some patients required an increase, others a decrease, and others no change in the extra stimuli needed to induce arrhythmias during exposure to caffeine (133). Although moderate caffeine ingestion produces a slight prolongation of QRS complexes seen on signal-averaged ECG (134), many studies suggest that moderate ingestion of caffeine does not exacerbate arrhythmias (135,136 and 137).

ANABOLIC STEROIDS AND CARDIOVASCULAR DISEASE

It is estimated that approximately 1 million Americans use anabolic steroids (138). Recent case reports suggest that anabolic steroids used primarily among bodybuilders may be associated with MI. Kennedy (139) described a 24-year-old bodybuilder who presented with 3 days of dull chest pain. He had been taking anabolic steroids, including oral stanozolol, intramuscular nandrolone, and intramuscular sustanon. He also had a history of smoking. The patient developed a lateral-wall MI, demonstrated by ECG and enzyme criteria. He was found to be hypertensive, his total serum cholesterol level was observed to be high, and his high-density lipoprotein (HDL) levels were observed to be low.

Acute MI was also reported in a young power lifter who was taking androgenic steroids (140). This patient had hypercholesterolemia, hyperaggregable platelets, and normal appearance of coronary arteries on angiography. Other cases have been documented in which MI, thrombotic occlusion of the coronary artery, and strokes were associated with use of anabolic steroids (140).

In a literature review on the link between anabolic steroids and atherogenic changes, anabolic steroids caused a 52% decrease in HDL levels, a 78% decrease in HDL b levels, and a 36% increase in LDL levels (141). Some studies reported depression of apolipoprotein A-1 and increases in apolipoprotein B. Commonly used anabolic steroids were stanozolol, oxandrolone, testosterone, methandrostenolone, nandrolone decanoate, and oxymetholone—usually in various combinations.

Changes in serum lipid levels after administration of anabolic steroids are rapid, occurring within days to a week. Lipid levels return to baseline approximately 3 to 5 weeks after cessation of anabolic steroid use, according to some reports, whereas other reports suggest that a prolonged residual effect may be seen, with lipid levels abnormal even at 6 months after steroid use has ended.

It has been estimated that the deleterious effects of anabolic steroid use on serum lipid levels might increase the risk of coronary heart disease to three to six times normal (141). The actual incidence of cardiovascular events among anabolic steroid users is probably underreported, however, and is limited to occasional case reports. Moreover, many young patients likely conceal their use of anabolic steroids when questioned. It is important to point out that physiologic doses of testosterone do not seem to adversely affect lipid levels. No effect on HDL levels was seen after administration of such doses in older men, and epidemiologic studies actually suggest a positive correlation between endogenous testosterone and HDL levels (142).

Exogenous steroids can also increase blood pressure (143) and hence cause LV hypertrophy and possibly increase thrombosis. A link between androgen use and thrombus formation is largely derived from experimental animal studies. In experimental thrombosis models, administration of exogenous androgens resulted in development of a larger experimental thrombus and reduced time to blood vessel occlusion (144,145,146 and 147). Use of exogenous androgens has also been reported to enhance platelet aggregation (148).

QT dispersion is increased in athletes who take anabolic steroids (149). QT dispersion reflects the heterogeneity of ventricular repolarization and is known to be associated with increased risk of ventricular arrhythmias. Atrial fibrillation was also reported in young athletes who abuse anabolic steroids (150).

AMPHETAMINES

Amphetamines are stimulants that are noncatecholamine sympathomimetic agents. Use of amphetamine and its derivatives may increase blood pressure and has been associated with lethal arrhythmias and MI (151,152,153,154,155 and 156). A 27-year-old man who developed an acute MI and ventricular fibrillation after intravenous amphetamine and was successfully cardioverted was shown to have normal coronary arteries during angiography (152). It was suggested that amphetamines might cause coronary artery vasospasm followed by thrombus formation (157). Cases of cardiomyopathy have also been reported with use of amphetamines (158,159), including smoking of crystal amphetamine, or “ice” (159).

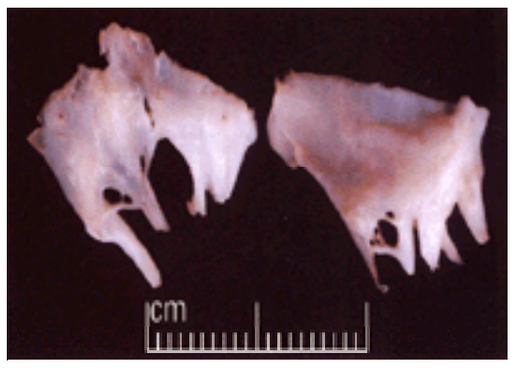
ECSTASY

Ecstasy is 3,4-methylendioxymethyamphetamine, a very popular designer drug that is gaining popularity among young adults. The drug has potent sympathomimetic properties and has been linked to a variety of vascular emergencies. Intracerebral hemorrhage, stroke, hypertension, ventricular arrhythmias, and even death have been described with use of the drug (160,161 and 162). The deaths reported after ecstasy use were related to massive cerebral hemorrhage and, less often, ventricular fibrillation.

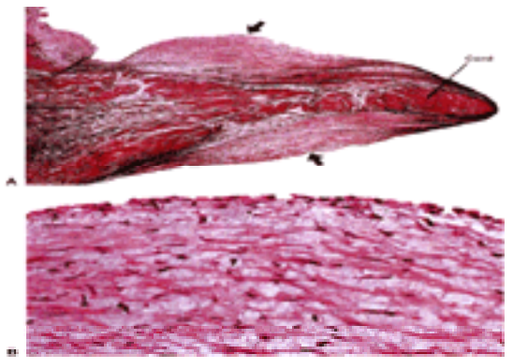
PHENTERMINE-FENFLURAMINE (PHEN-FEN)

Phentermine is a nonsympathomimetic stimulant that inhibits the clearance of serotonin in the lungs. Fenfluramine is a sympathomimetic amine that promotes the release of serotonin (163). Both drugs in combination were widely used as anorexigenic agents for management of obesity. Shortly after their release, a variety of side effects were reported, including valvular regurgitation, primary pulmonary hypertension, endomyocardial fibrosis, and retroperitoneal hemorrhages.

In 1997, the cases of a group of 24 women who developed valvular heart disease after phentermine-fenfluramine therapy were reported (164). Twenty patients presented with various cardiovascular symptoms, and a new murmur was discovered in four patients during physical examination. The most common valvular abnormalities were mitral regurgitation and aortic regurgitation. The valves showed a glistening appearance on inspection (*e*Fig. 36.2.3). On histopathologic examination, proliferation of fibroblasts and an increase in extracellular matrix were found (*e*Fig. 36.2.4). These patients were young and had no previous histories of heart disease. Surgical intervention was performed in five patients.



***e*FIGURE 36.2.3** Explanted mitral valve from a patient reveals valve thickening and glistening white leaflet appearance. (From Connolly HM, Crary JL, McGoon MD, et al. Valvular heart disease associated with fenfluramine-phentermine. *N Engl J Med* 1997;337:581–588.)



***e*FIGURE 36.2.4** Histopathology of a mitral valve in a patient who was receiving fenfluramine-phentermine, stained with hematoxylin and eosin, under low-power **(A)** and high-power **(B)** views. Arrows point to valve thickening. (From Connolly HM, Crary JL, McGoon MD, et al. Valvular heart disease associated with fenfluramine-phentermine. *N Engl J Med* 1997;337:581–588.)

Further epidemiologic studies confirmed a relationship between phentermine and fenfluramine and valvular regurgitant lesions, but to a much lesser extent (165,166,167 and 168). The incidence of valvular abnormalities ranges between 6% and 30% among patients who are taking phentermine-fenfluramine, with the most common lesion being aortic regurgitation. The incidence appears to be higher among patients who have undergone longer treatment with the drugs (169) and may regress after the cessation of therapy (170). The United States Department of Health and Human Services recommends that patients exposed to these medications undergo cardiovascular and echocardiographic examination, and that antibiotic prophylaxis be administered when appropriate (171).

A less common but more serious complication of phentermine-fenfluramine therapy is primary pulmonary hypertension (172). This occurs after exposure of at least a few months and has a 3-year survival rate of 50% (173). In one study, histologic examination at autopsy revealed intimal hyperplasia, medical hypertrophy, intimal fibroelastosis, and plexogenic arteriopathy of the pulmonary arteries (174).

Another rare complication of phentermine-fenfluramine therapy is restrictive cardiomyopathy secondary to endomyocardial fibrosis (175). A case report of ruptured retroperitoneal aneurysm had been described (176) and was felt to be secondary to enhanced sympathetic activity.

ALCOHOL

It is estimated that alcohol is consumed by two-thirds of the adult population in the United States, which makes alcohol one of the most widely used addictive drugs. It is also a unique substance in that a small amount may have some benefit on cardiovascular morbidity and mortality rates, but consumption of larger amounts can have devastating effects. The toxic effect of alcohol extends to the brain, liver, skeletal muscle, and many other organs. In this section, we focus on its cardiovascular effects.

Epidemiology

Approximately two-thirds of the adult population in the United States report alcohol consumption, and 10% of these are heavy drinkers. Men drink more than women, but women are more sensitive to the cardiac effects of alcohol. In one study, even though women drank only 60% of the lifetime alcohol dose consumed by men, they had a higher incidence of alcoholic cardiomyopathy (177). Alcohol consumption is also prevalent among adolescents, with rates ranging from 10% to 35% (178). It is more prevalent among young men than young women and among white students than black students; white male adolescents have the highest rate of consumption. Alcohol abuse is present in approximately 15% of the geriatric population. Depression, anxiety, and loneliness are some of the precipitating factors, and patients in that age group are more susceptible to the side effects of alcohol use (179).

Metabolism

Alcohol is absorbed from the stomach and small intestine. It is then distributed to tissues rich in water content and blood flow. Thus, the heart, liver, and brain are prime targets for alcohol's effects (180). In the liver, ethylalcohol is metabolized first to acetaldehyde and then to acetate. Acetate leaves the liver and is metabolized in extrahepatic tissues.

Cardiovascular Effects of Alcohol

Alcoholic Cardiomyopathy

Chronic ingestion of alcohol produces a decrease in both systolic and diastolic function of the myocardium. The condition is clinically indistinguishable from idiopathic dilated cardiomyopathy. Grossly, the myocardium is dilated and flabby, with diffuse areas of fatty degeneration and fibrosis (181). The condition is also histologically similar to idiopathic dilated cardiomyopathy, but the degree of myocyte hypertrophy and the extent of fibrosis are less pronounced (182). Ethanol and its metabolites, acetaldehyde and acetate, exert direct cardiac toxic effects. Although the nutritional deficiencies associated with alcoholism may play some role in alcoholic cardiomyopathy, they probably are not the only source; dietary supplementation fails to prevent the condition.

VIDEO

Video 36.3 Apical long-axis view of a patient with severe left ventricular dysfunction and annular dilatation causing 4+, centrally directed mitral regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Initially, loss of the integrity of the sarcolemmal membrane occurs, resulting in loss of its function. This leads to an increase in the concentration of intracellular calcium. Animal studies showed that alcohol administration for 12 weeks led to a threefold increase in intracellular calcium (183). Furthermore, investigators found that administration of verapamil prevents alcohol-induced LV dysfunction (184). Ethanol also affects the sarcoplasmic reticulum, the mitochondria, and contractile protein synthesis and may produce oxygen free radicals (185,186). All of these adversely affect the structure and function of the myocardium.

The symptoms of alcoholic heart disease include dyspnea on exertion, orthopnea, fatigue, and peripheral edema. On examination, signs of right-sided and left-sided heart failure may be present. In addition, signs of chronic alcoholism, such as telangiectasia, spider angioma, and hepatic enlargement are a clue to the diagnosis. Chest radiography shows cardiomegaly and pulmonary congestion. A 12-lead ECG may show LV hypertrophy, nonspecific ST- and T-wave abnormality, and various cardiac arrhythmias.

One clue to the diagnosis of alcoholic myopathy is the presence of skeletal myopathy presenting as muscle weakness. Because the direct toxic effect of alcohol is usually exerted on the striated muscle, the effects are typically present in both heart and skeletal muscle. In a cross-sectional study (187), 24 patients with alcoholic cardiomyopathy were compared to chronic alcohol drinkers with normal heart function and to patients with idiopathic and ischemic cardiomyopathy. Only patients with alcoholic cardiomyopathy had significant skeletal myopathy as determined by muscle biopsy.

Individuals who drink alcohol may have various nutritional deficiencies, among them thiamine deficiency. Thiamine deficiency may lead to beriberi, which may also present with dilated cardiomyopathy. It is, however, distinct from pure alcoholic myopathy in that it is a form of high cardiac output failure (188). The two conditions may coexist.

The most sensitive and clinically useful tool in management and diagnosis of alcoholic cardiomyopathy is echocardiography. This technique usually reveals dilation of all chambers of the heart, and Doppler echocardiography shows valvular regurgitation, particularly of the mitral and tricuspid valves. Alcohol affects both systolic and diastolic function. Studies have shown a decrease in ejection fraction and stroke index (189). Doppler echocardiography is quite sensitive in evaluating diastolic dysfunction, even before the development of clinically evident dysfunction. Thirty-two alcohol users with no clinical evidence of cardiomyopathy were studied by

Doppler echocardiography (190). Patients had a prolonged relaxation time, a decrease in peak early diastolic velocity, and a slower acceleration of early diastolic flow. Diastolic dysfunction, as detected by Doppler studies, may precede systolic dysfunction and may be the only manifestation seen in some patients with chronic alcoholism (191).

The hearts of alcoholic cardiomyopathy patients may have an increased uptake of antimyosin antibody, which may decrease after alcohol withdrawal (192). The natural history of alcoholic cardiomyopathy depends largely on the patient's drinking habits. If treatment is started early and the patient stops drinking, it may be partially reversible (193). Well-developed disease, however, is usually fatal if the patient continues to consume alcohol.

Treatment of alcoholic cardiomyopathy usually follows several paths. Treatment of the manifestation of congestive heart failure with angiotensin-converting enzyme inhibitors and diuretics is helpful. Nutritional deficiency, such as thiamine deficiency, and various electrolyte abnormalities, such as hypophosphatemia (194), hypomagnesemia, and hypokalemia, should be corrected. The mainstay of therapy is cessation of alcohol use. The earlier abstinence occurs in the course of the disease, the more pronounced is the benefit. In a group of patients with pure alcoholic cardiomyopathy (195), patients who abstained had a marked improvement in their ejection fraction, as measured by radionuclide angiography, and in their cardiothoracic ratio, as seen by chest radiography. Most of the improvement occurred in the first 6 months of abstinence, but improvement continued through up to 2 years of observation. Patients who did not abstain showed no improvement. In alcoholic cardiomyopathy, the benefit of abstinence from alcohol exceeds the benefits of medical therapy alone (196). The prognosis of alcoholic myopathy is similar to that of idiopathic dilated myopathy (197).

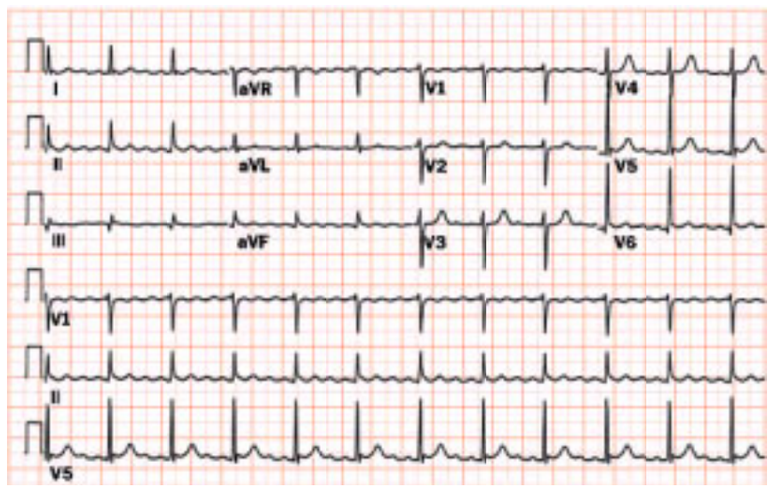
Hypertension

A link between alcohol use and high blood pressure has long been suspected (198). Social drinking is associated with a mild rise in systolic pressure, whereas those who drink heavily may have a substantial rise (199,200). Several mechanisms have been proposed. However, the exact mechanism is not clear. This may, at least in part, explain the increase in LV mass. However, even alcoholic individuals who are normotensive may have an increase in LV mass (201). Blood pressure may normalize after a short period of abstinence.

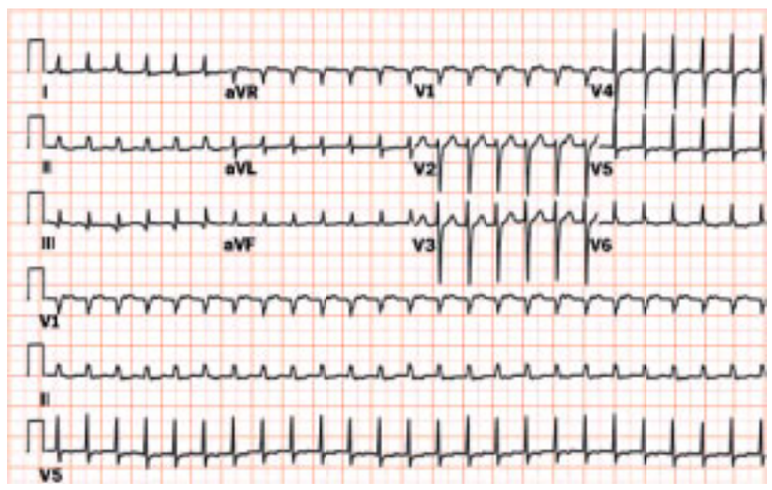
Cardiac Arrhythmias

Alcohol use is associated with a variety of atrial and ventricular arrhythmias, regardless of whether the patient has overt alcoholic heart disease. Possible mechanisms include electrolyte imbalance, the hypercatecholamine states often seen during alcohol withdrawal, and a patchy delay in conduction that results in increased reentry (202). The QT-interval prolongation seen in alcoholic patients may be implicated in the genesis of ventricular arrhythmias (203). Atrial arrhythmias include premature atrial contractions, supraventricular tachycardia, and atrial flutter and fibrillation. Ventricular arrhythmias include premature ventricular depolarization and ventricular tachycardia or fibrillation. The most common arrhythmia, however, appears to be atrial fibrillation.

Acute inferior myocardial infarction complicated by atrial fibrillation. Note ST-segment elevation in the inferior leads with reciprocal changes laterally. Atrial fibrillation has complicated this acute infarct.



Atrial flutter. Atrial rate of 300 beats/min with upright P waves inferiorly. This is consistent with atypical atrial flutter.



Supraventricular tachycardia. Note narrow QRS complex with short RP interval.

In a study of 32 episodes of cardiac arrhythmias in 24 patients who used alcohol, patients reported consuming alcohol every day for an extended period of time, yet had a marked increase in alcohol consumption on weekends or near holidays. No overt signs of alcoholic heart disease were seen. The most common arrhythmia noted was atrial fibrillation. The majority of episodes was seen in the hospital at the beginning of the week or after holidays; hence the term "holiday heart" (204).

In patients with new onset of atrial fibrillation, alcohol was responsible for 35% of the cases and up to two-thirds of the cases in patients younger than 65 years (205). It was also found to be an independent risk factor for recurrence of atrial fibrillation (206). Electrophysiologic testing in humans showed that alcohol enhances the vulnerability of normal hearts to induction of atrial flutter and fibrillation (207). The treatment is cessation of alcohol consumption; most rhythm disturbances disappear with little or no intervention.

Sudden Death

Heavy alcohol drinking is associated with an increase in sudden death. In one study, the increased incidence of sudden death was reported regardless of whether patients had coronary artery disease (208). The increase was also more pronounced in older age groups, regardless of social class. For nonsudden death, alcohol drinking had a biphasic effect, depending on the amount of alcohol consumed. Heavy drinkers were at a greater risk for death from noncardiovascular causes, particularly cirrhosis, accidents, and tobacco-related cancer. This increased risk was higher among women and among younger persons (209). Lighter drinkers, however, were at a lower risk for death from cardiovascular diseases, particularly coronary artery disease. In a prospective 13-year follow-up of 12,321 male British doctors, the consumption of one or two drinks each day was associated with a significantly lower mortality rate than that seen among heavy drinkers or nondrinkers (210). The mechanism of this benefit was not apparent in that study, yet it was postulated that a beneficial effect on coronary artery disease might be responsible.

Coronary Artery Disease

Heavy alcohol drinking is associated with an increased incidence of coronary artery disease and cardiovascular death. This is not surprising—such patients have an increased tendency for hypertension with increased cardiac muscle mass and hypertriglyceridemia, and they also tend to be smokers. Alcohol use is paradoxical; mild to moderate alcohol intake is associated with a decreased risk of MI and cardiovascular death. Various mechanisms contribute to that result, including the effect of alcohol consumption on HDL.

Investigators examined the relationship between alcohol ingestion and MI among 340 patients with MI, compared with an age- and sex-matched control group (211). Alcohol intake was inversely related to the risk of MI. Furthermore, a substantial component of that benefit resulted from an increase in HDL and its subfractions. It also appeared that this benefit derived from the alcohol itself and was not specific to any particular alcoholic drink (212). Most of this benefit is achieved by consumption of as little as half a drink per day (213,214). Other mechanisms that may play a role in this effect on coronary artery disease are the effects of alcohol on endogenous tissue–type plasminogen activator and on platelet function. In a study of 631 healthy male doctors, moderate drinking increased plasma levels of endogenous tissue plasminogen activator antigen (215). In addition, alcohol consumption resulted in the inhibition of platelet aggregation and prolongation of blocking time (216). These effects likely decrease the occurrence of coronary thrombosis in moderate alcohol drinkers.

What advice should physicians give their patients with regard to alcohol consumption? We must remember that alcohol is an addictive drug, and it may be difficult for some people to control their drinking. Heavy drinking increases overall mortality rates (217). Other risk factor modifications should be the priority in patients who have coronary artery disease. Mild alcohol drinking may, however, have a role in the subgroup of patients who have low HDL levels as the sole risk factor for coronary artery disease and in whom other measures to improve HDL levels have failed.

Alcohol Withdrawal

Alcohol withdrawal is usually managed in a quiet, supportive environment. The importance of close supervision cannot be understated. Benzodiazepines are the mainstay of therapy. Two cardiovascular effects commonly occur during alcohol withdrawal: significant hypertension and cardiac arrhythmias. They are likely related to the activation of the autonomic nervous system and usually subside spontaneously but may require a temporary pharmacologic intervention. In patients who have acute ischemic syndromes and are also experiencing alcohol withdrawal, control of blood pressure and heart rate is crucial. Liberal use of beta-blockers and intravenous nitroglycerin is recommended.

Prevention of Alcohol Addiction

Attempts to cure alcohol addiction are not always successful and often begin after many years of drinking, when significant health problems have already developed. Thus, efforts toward prevention of drinking should be the goal. Various programs are already in place that have had some success (218).

TOBACCO

A cigarette is a controlled device that delivers nicotine and many other substances to the human body. With each puff, approximately 100 µg of nicotine is absorbed through the lungs, with an average drug delivery of 1 to 2 mg of nicotine per cigarette. With the widespread use of smoking and its significant effects on the cardiovascular system, cigarette smoking has a major impact on public health.

Epidemiology

The number of tobacco smokers in the world exceeds 1.1 billion. Approximately 300 million smokers live in developed countries, and more than 800 million smokers live in developing countries. Globally, smoking is responsible for 3 million deaths per year, and this number is expected to reach 10 million per year in the year 2020, if current trends continue. It is estimated that 50 million Americans smoke on a regular basis. Although the overall number of adult smokers has decreased in the United States, smoking among teenage girls is on the rise. The prevalence of smoking among the African-American and Hispanic populations has surpassed that in the white population, but white smokers smoke more cigarettes per day, seem to be more addicted to smoking, and report more smoking-related illnesses than African-American and Hispanic smokers (219). Although some decline has been seen in the overall incidence of cigarette smoking in the United States, cigar smoking is on the rise, and smoking in general is not showing any significant decline in developing countries.

Tobacco Addiction

Drug addiction or dependency is described as “a behavioral pattern in which the use of a given psychoactive drug is given a sharply higher priority over other behaviors which once had a significantly higher value” (220). In other words, addiction is defined as loss of control over use of the drug and an inability to quit despite obvious risks associated with drug use. In the case of cigarette smoking, the drug is nicotine. Smokers report pleasure, relaxation, reduction of anxiety and stress, and improved attention after cigarette smoking (221). Within seconds of smoking a cigarette, nicotine is absorbed through the lung alveoli and taken up by the bloodstream to the brain and other tissues. In the brain, it acts at the nicotinic receptors, which are known to be increased in the brain tissues of smokers. As a result, dopamine, norepinephrine, acetylcholine, and endorphins are released. This results in the reported feelings of decreased anxiety and tension, pleasure and relaxation, and increased performance. Cigarette smoking may also be associated with a decrease in the enzyme monoamine oxidase, which is responsible for the breakdown of dopamine, in the brain (222). Thus, cigarette smoking not only increases the secretion of dopamine, but it also slows its metabolism.

With each cigarette smoked, tolerance to the effects of nicotine develops. But with abstinence at night, the effects are renewed, so that the first cigarette of the day produces the maximal psychological effect. When smoking ceases, symptoms of restlessness, irritability, impatience, and increased anxiety occur. Most symptoms gradually disappear in 1 to 2 weeks, but the desire to smoke may persist for a very long time.

Despite a recent controversy regarding whether cigarettes should be considered addictive, the balance of the arguments strongly suggests that they are (223). It has also been suggested that an individual’s genetic composition may influence smoking behavior (224).

Cardiovascular Effects

The main components of cigarettes that exert cardiovascular effects are nicotine and carbon monoxide. The former may lead to the release of norepinephrine, which increases pulse rate, blood pressure, and platelet aggregability. It may also cause endothelial injury and adversely affect events that occur during atherosclerotic plaque rupture (225). Carbon monoxide displaces the oxygen from hemoglobin, interfering with oxygen delivery to cardiac tissue. Cigarette smoking has also been associated with hyperfibrinogenemia and low levels of HDL (226). These mechanisms lead to the devastating effects of smoking, regardless of the method used.

In a major epidemiologic study, 10,914 subjects were followed to assess the progression of atherosclerotic disease (227). Carotid ultrasounds were performed on the subjects, and the intimal medial thickness was measured at baseline and at 3 years of follow-up. Current smokers had a 50% increase in the rate of progression of atherosclerosis compared to nonsmokers. Past smokers had a 25% increase in atherosclerosis. Even passive smokers who had never smoked had more progression than control subjects. The increase in the rate of atherosclerosis progression associated with smoking was more marked in diabetic and hypertensive patients.

Smoking results in an increase in heart rate and blood pressure. In a study of 135 healthy subjects, 24-hour ambulatory blood pressure monitoring revealed an increase in both heart rate and blood pressure (228). In addition to an increased cardiovascular risk profile, this increase in myocardial oxygen demand may increase, at least theoretically, anginal episodes in patients who already have coronary artery disease.

Active Smoking

Although cigarette smoking had long been suspected to increase the risk of cardiovascular diseases, the two were formally linked in 1958 (229). Subsequently, pathologic studies showed more-advanced coronary artery disease among heavy smokers than among light smokers (230). Smoking is associated with a two- to fourfold increase in coronary artery disease and an increased risk of MI and sudden death (231). Furthermore, if patients with MI continue to smoke, the rate of reinfarction and death also increases. The risk appears to be related to the duration of smoking and the number of cigarettes smoked per day. Smoking also has a synergistic effect with other coronary risk factors, particularly hypercholesterolemia.

Passive Smoking

Passive smoking is the involuntary inhalation of air contaminated by cigarette smoke. It affects both smokers and nonsmokers. Smokers have an increased risk of developing various cardiovascular effects, whereas nonsmokers may have an increased incidence of MI with chronic exposure and impaired cardiac performance with acute exposure. Investigators exposed patients who survived a first heart attack to passive smoking during an exercise stress test. During passive-smoking exposure, exercise tolerance decreased, time to recovery to baseline heart rate was prolonged, and the occurrence of cardiac arrhythmias increased (232).

Passive environmental smoking results in a 25% increase in the risk of coronary artery disease (233) and death (234) and is now estimated to be the third leading preventable cause of death after active smoking and alcohol abuse (235). Controlled studies showed that passive smoking impairs endothelial-dependent coronary vasodilation (236), and this is only partially reversible after exposure has ended (237). Passive smoking also leads to accelerated lipid peroxidation and accumulation of LDL cholesterol in human macrophages (238). These effects contribute to accelerated atherosclerosis (227) and subsequently to increased mortality rates (235). Educating smokers about the risk of passive smoking appears to be more important than ever in the face of these data.

Cigar and Pipe Smoking

Although cigarette smoking overall is on the decline in the United States, cigar smoking is rising. Regular cigar smokers who inhale smoke or are heavy smokers have an increased risk of coronary artery disease (239). One prospective study, however, suggested that the cardiovascular risk associated with cigars is less than that associated with cigarettes (240).

Smokeless Tobacco

Smokeless tobacco refers to tobacco snuff, chewing tobacco, and the recently introduced smokeless cigarette. Smokeless tobacco delivers an average amount of nicotine similar to smoking and may produce similar cardiovascular effects. In addition, chewing tobacco leads to a variety of cancerous and precancerous conditions, commonly oral leukoplakia (241). An epidemiologic study from Sweden, however, failed to show an increased risk of MI in people who use tobacco snuff (242).

Smoking Cessation

Smoking cessation includes three phases (243): preparation, intervention, and maintenance. The preparation phase primarily includes motivation of the patient. The intervention phase involves initiation of a specific method of smoking cessation, which ordinarily includes the daily use of nicotine gum or a patch and a gradual decrease in the dose of nicotine delivered. Other methods used alone or in combination are behavioral therapy, acupuncture, and hypnosis. The maintenance phase ensures that the patient continues to not smoke and includes stress reduction as an integral part of management, because the urge to return to smoking is accentuated by stressful conditions.

Nicotine patches are probably the most commonly used method of smoking cessation. Nicotine patches are safe, particularly because they deliver less nicotine in a slow, steady state, as opposed to the pulsatile nature of cigarette delivery. Investigators compared the effects of cigarette smoking, nicotine patches, and placebo patches on platelet aggregation in a crossover design (244). Smoking was associated with an increase in platelet activation, but nicotine patches were not. Use of nicotine patches should be limited to patients who have stable cardiovascular disease and avoided in patients who have unstable ischemic syndromes, because cases of MI during the use of such patches have been reported (245,246). The antidepressant drug bupropion is also effective in smoking cessation and may even be more effective than nicotine-containing products (247).

Smoking Prevention

Despite the widespread availability of high-quality programs for smoking cessation, the rate of success is lower than desired. This low rate may result in part from the strongly addictive nature of tobacco use and the ease of obtaining cigarettes. Smoking prevention appears to be the best way to decrease the number of smokers and the incidence and prevalence of smoking-related illness (248). Every day, approximately 3,000 young people start smoking (249); individuals who do not smoke their first cigarettes as teenagers are less likely to start smoking as adults (250). School-based programs need to be initiated at an early phase in a child's education (251) to have an impact on the number of adult smokers.

INFECTIVE ENDOCARDITIS IN DRUG ADDICTS

Infective endocarditis (IE) is an infection of the endocardial surface of the heart. Although it primarily affects heart valves, it may also involve mural endocardium, cause septal defects, and extend into the subendocardial region. This section focuses on IE in drug addicts.

The term "infective endocarditis" was first suggested by Thayer in 1931 (252) and was later popularized by Lerner and Weinstein in 1966 (253). Lerner and Weinstein found that the incidence of reported cases of IE was dropping with the emergence of antibiotics. The rise in intravenous drug abusers, however, was accompanied by a surge in cases of IE, and its presentation was somewhat different from the classic form of the disease.

Epidemiology

A population-based study of IE was conducted in Olmsted County, Minnesota, between 1950 and 1981. An incidence of 3.8 cases per 100,000 residents was reported (254). The most common underlying cause was rheumatic heart disease, and no intravenous drug abusers were identified in that study. In a second, recent study of the epidemiology of IE in an urban community, the incidence was 6.2 cases per 100,000 individuals (255). That study included intravenous drug users and showed a higher incidence among women and older patients. Further studies have suggested that the increased incidence of IE is likely to be explained by a progressive increase in the number of drug addicts who contract the disease (256).

Bacteriology

In a 2-year review of cases of IE among drug addicts, *Staphylococcus aureus* was the most commonly identified causative organism, accounting for 50% of cases. Enterococci accounted for 26% of cases, and *Pseudomonas aeruginosa* accounted for 10% (257). Methicillin-resistant and methicillin-tolerant *S. aureus* are isolated with increasing frequency from patients with IE in some areas of the United States, particularly in the Midwest. These microorganisms tend to be present in older patients who are addicted to intravenous drugs, in patients who were hospitalized in the past, and in patients who used nonprescribed antibiotics.

Clinical Presentation

Symptoms

The symptoms of endocarditis in drug addicts vary widely. These patients may present at the emergency department with vague, nonspecific complaints of symptoms that resemble those of a viral syndrome, or they may present with full-blown classic endocarditis that culminates in neurologic or cardiovascular catastrophe (258). Thus, IE should be suspected in drug addicts who present with fever and no obvious source of infection.

In a study of 55 episodes of IE in drug addicts, the most common symptoms were fever and chills, chest pain, and cough. Other symptoms were headache, nausea, vomiting, diarrhea, and arthritic pain (259). The duration of symptoms before admission averaged 8.1 days, with a range of 1 to 30 days. Temperature is almost always elevated and tends to be much higher in IE patients than in patients addicted to drugs who present with only bacteremia. Fever may persist for longer than 1 week, even after a regimen of appropriate antibiotics has been started. The chest pain associated with IE is usually pleuritic in nature and, if accompanied with a cough, is

likely an indication of pulmonary septic emboli. Shortness of breath may occur, either from pulmonary involvement or from the development of valvular regurgitation. Occasionally, symptoms may be nonspecific, and the diagnosis may first be made at autopsy (260).

Signs

In a study of drug addicts in Detroit Medical Center, cardiac murmurs were found in 35% of patients on admission (261). In right-sided endocarditis, the murmur is often that of tricuspid regurgitation and less often of pulmonic stenosis. In left-sided endocarditis, the murmur is usually that of mitral regurgitation and less frequently of aortic regurgitation. Patients may develop new murmurs during therapy. Pulmonary rales and rhonchi may be found and are likely an indication of pulmonary septic emboli or of the development of congestive heart failure. As congestive heart failure progresses, jugular venous distention, liver congestion, and peripheral edema may be observed. Roth's spots and Osler's nodes may be present; Janeway lesions are less often seen. Splinter hemorrhages are not uncommon.

Laboratory Findings

Leukocyte counts are usually elevated in these patients. Anemia is often present and is likely a nonspecific finding because it is present in most addicts who do not have IE (intravenous drug addicts usually lose blood each time they inject). Sedimentation rate may be elevated. Mild hyponatremia may be seen and is usually an indication of the severity of the disease. Elevation of blood urea nitrogen or serum creatinine levels may be seen if congestive heart failure or glomerulonephritis develops.

Causative Microorganisms and Clinical Presentation

S. aureus affects primarily the right side of the heart, causing the development of tricuspid vegetations and tricuspid regurgitation. Complications of infection with *S. aureus* include pulmonary septic emboli and congestive heart failure. Streptococci infect left-sided valves, particularly the mitral valve, which can lead to systemic emboli and pulmonary edema. In *Pseudomonas* endocarditis, multivalvular involvement is common. Polymicrobial endocarditis tends to run an aggressive course with an increased possibility of valve destruction and the need for surgical intervention.

Left-Sided Endocarditis

Although IE in drug addicts is more commonly seen on the right side of the heart, left-sided endocarditis is not uncommon, and it is associated with a significantly worse prognosis. In a study of 67 patients with IE, left-sided endocarditis was more common in women, and 8% of the cases ended with valve replacement or death (262).

Infectious Endocarditis in Acquired Immunodeficiency Syndrome

Autopsy studies may show thrombotic nonbacterial endocarditis in patients who have acquired immunodeficiency syndrome (AIDS). In AIDS patients, however, IE occurs almost exclusively in intravenous drug users (263). Human immunodeficiency virus (HIV) infection, regardless of whether AIDS has developed, does not seem to affect the incidence or the clinical course of IE in these patients (264). However, rate of death from IE is increased among HIV patients who have severe immunosuppression (265).

Diagnosis

IE should be suspected in any intravenous drug user who presents with fever, cardiac murmur, and absence of any other source of infection. Blood cultures are almost always positive. In clinical practice, however, establishing a diagnosis may be difficult (266), although various attempts have been made to establish diagnostic criteria for IE. The von Reyn criteria were published in 1981 (267). They include categories for definite, probable, and possible endocarditis. "Definite" endocarditis should have direct evidence based on histologic studies done at surgery or autopsy. "Probable" endocarditis includes cases in patients who have persistently positive blood cultures, new cardiac regurgitant murmur, or predisposing cardiac disease, and a vascular phenomenon such as Osler's nodes or splinter hemorrhages. "Possible" endocarditis includes cases in patients who have positive blood cultures with predisposing heart disease or a vascular phenomenon. With the emergence of echocardiography, Durack and associates (268) proposed a classification that includes two major and six minor criteria. Major criteria include typical blood cultures and positive signs on echocardiograms. Minor criteria are predisposition to IE, fever, vascular phenomena, immunologic phenomena, suggestive results of echocardiography, and suggestive results of microbiologic testing. Diagnosis requires two major criteria, one major and three minor criteria, or five minor criteria. A more practical method was proposed by Levine and coauthors (261), who found that persistent positive blood culture with no apparent extracardiac source and two or more of the following suggests endocarditis: significant cardiac murmur, pulmonary or peripheral septic emboli, positive echocardiogram, and elevated teichoic acid antibody.

Echocardiography has emerged as one of the most important tools in diagnosis and management of IE. It may show various valvular abnormalities, vegetations, and evidence of perivalvular abscess or fistula. It is also useful in assessing the effects of therapy. An enlarging vegetation, extension of infection outside the valve, or increase in valvular regurgitation may be an indication of failure of medical treatment and the need for surgical intervention. Transthoracic echocardiography often is limited by the inability to obtain adequate imaging, and this has led to the more recent use of transesophageal echocardiography (TEE).

In experienced hands, TEE should be considered in patients in whom endocarditis is suspected. Negative results of a technically adequate TEE study usually mean that the probability of infection is low (269). TEE shows abscesses in 5% to 30% of patients with IE (270). It also has prognostic value, because aortic involvement, growth in the size of the vegetation, and presence of spontaneous echocardiographic contrast are indicators of high-risk endocarditis (270). In 121 patients with IE, TEE added additional information in 32% of patients, resulting in appropriate surgical intervention in 22 instances (271). To clearly assess the value of TEE in IE, 118 consecutive patients were studied prospectively with two-dimensional transthoracic echocardiography and with TEE. Results were correlated with direct inspection of

the valve at surgery or at autopsy. Compared to transthoracic echocardiography (28.3%), TEE was more sensitive and more specific for abscess detection (98.6%). Abscesses were detected in 40 instances, were commonly located in the aortic valve region, and were frequently secondary to *S. aureus* infection (272).

Cardiac catheterization may have an important role in some cases, particularly before surgical intervention. Catheterization is of greater value when more than one left-sided valve lesion is present and when an extravalvular infection is suspected. It should not be performed routinely in all cases before surgical intervention, because it has a somewhat increased morbidity (273).

Gallium-67 myocardial imaging detects increased activity in patients with IE, and positive scans may be seen if imaging is done 3 to 8 days after injection (274). Imaging with technetium-99m–labeled antibacterial antibody was successful in the experimental setting (275). Advances in echocardiography have meant that nuclear studies are rarely used.

Management

The mainstay of therapy for IE is sterilization of the vegetation. Details of therapy for endocarditis are covered elsewhere in this book. The general principles are to identify the causative organism, make an *in vitro* determination of its susceptibility, and select a bactericidal antibiotic (276). Patients infected with methicillin-sensitive *Staphylococcus* may be treated with nafcillin. Patients with methicillin-resistant *Staphylococcus* endocarditis may be treated with vancomycin with or without rifampin. Recent randomized studies have suggested that in uncomplicated, right-sided endocarditis caused by methicillin-sensitive *S. aureus*, a 2-week course of therapy may be sufficient to eradicate the disease (277). Outpatient therapy for IE has been attempted in some countries (278), and although inpatient therapy is still recommended, some hospitals have begun to adopt outpatient treatment protocols.

Surgical treatment for IE should be considered in patients who have congestive heart failure, recurrent embolic phenomena, and persistent sepsis despite administration of appropriate antibiotic therapy (279,280 and 281). Other conditions that favor surgical intervention include IE with echocardiographic evidence of definite abscesses or mycotic aneurysms, embolic complication with persistent mobile vegetation, aortic valve endocarditis with significant regurgitation, and possibly polymicrobial endocarditis. Surgical correction includes valvulectomy with a prosthetic valve replacement, valvulectomy without valve replacement in right-sided valve endocarditis, vegetectomy with or without valve reconstruction surgery, and drainage of abscesses.

Valve replacement is associated with high mortality rate, which is the result of early prosthetic valve endocarditis, the return of approximately 50% of drug users to drug injection with subsequent development of severe prosthetic valve endocarditis and poor compliance with anticoagulant regimens, and the development of fatal complications.

In right-sided endocarditis, Arbulu and colleagues performed tricuspid valvulectomy without valve replacement (282). Since the initial description of this procedure, Arbulu has performed the operation on at least 53 patients. At 22 years after surgery, the actuarial survival rate was 64% (283). Patients who survive are expected to lead a normal life, provided they abstain from intravenous drug injection, even though they may have variable degrees of systemic congestion. This operation appears to be the operation of choice for right-sided intractable endocarditis in patients who are addicted to injection drug use. Vegetectomy is another option, in which the vegetation is excised with full preservation of the valve and its supporting structures (284), but experience with and usefulness of this technique are quite limited.

Prognosis

Mortality rates among patients with IE are high in the initial phase. The risk decreases significantly 1 year after infection. In follow-up of 330 patients with IE, survival was 75% at 6 months and 57% at 5 years (285). The most important prognostic factor is age at onset of infection.

CONTROVERSIES AND PERSONAL PERSPECTIVES

A few controversies still persist regarding substance abuse and the heart. Some of the controversy regarding how an acute dose of cocaine affects the heart depends on the model being studied. When cocaine is administered to awake, conscious animals and humans, the sympathomimetic effects predominate, with increases in heart rate and blood pressure. When the drug is administered to pentobarbital-anesthetized animals, the sympathomimetic effects appear to be masked and the cardiodepressive effects predominate. This has caused some confusion in the literature regarding the acute effects of cocaine on the heart. Some debate exists as to whether cocaine actually accelerates atherosclerosis, because many of the clinical reports suggesting such an effect involved patients who also have other risk factors, especially tobacco smoking. No general agreement exists regarding the best way to treat acute cocaine cardiotoxicity, and virtually no controlled studies have addressed this issue. The use of beta-blockers remains controversial. Although they decrease the heart rate and blood pressure, they block the beta receptors, leaving the alpha receptors unopposed, with the potential to worsen coronary artery vasospasm.

My personal observation (R.A.K.), in a large inner-city county hospital, is that cocaine cardiotoxicity is probably more common than we realize, especially in that type of environment. When a younger person presents with an acute MI, especially if other risk factors are not present, it is very important to remember to ask about a history of substance abuse, especially cocaine. Initially, patients may be reluctant to divulge this information. However, eventually, with compassionate persistence, the story often emerges. Patients then need to be educated about the hazards of substance abuse. Most will not be aware that cocaine can affect the heart.

It is likely that the controversy regarding whether coffee and caffeine are deleterious to the cardiovascular system will continue for some time. Until the controversy is resolved, coffee should be consumed in moderation, especially by individuals with a history of coronary artery disease.

SUMMARY

Substance abuse remains an ongoing public health problem in the United States. Several common agents of abuse contribute to heart disease. The types and frequency of heart disease related to substance abuse probably vary depending on the prevalence and frequency of the type of drug being used. An acute dose of cocaine can have several adverse effects on the heart, including cardiodepressor effects, reductions in contractility and coronary artery blood flow, and conduction abnormalities, which are probably related to its local anesthetic properties. At the same time, cocaine has cardiostimulatory effects, increasing heart rate, blood pressure, contractility, ventricular excitability, and coronary vasoconstriction, related to its sympathomimetic and vagolytic effects. Cocaine has the potential for exacerbating ischemia in patients by increasing heart rate and blood pressure at the same time that it causes coronary vasoconstriction. The following common cardiovascular diseases have been associated with cocaine abuse in patients: acute MI and myocardial ischemia, dilated and hypertrophic cardiomyopathy, myocarditis, hypertension, arrhythmias, and possibly acceleration of atherosclerosis. Aortic dissection has been reported (286).

Controversy regarding the safety of caffeine and coffee use among coronary artery disease patients is ongoing. The consumption of filtered coffee does not cause an increase in cholesterol levels, whereas boiled coffee may negatively affect lipid levels. Moderate consumption of coffee probably is safe for most patients who have coronary artery disease. Anabolic steroid abuse has been associated with acute MI and lipid abnormalities. There are case reports of MI and cardiomyopathy after use of amphetamines. Small amounts of alcohol may have some benefit on cardiovascular morbidity and mortality rates, but excess use is associated with alcoholic cardiomyopathy, hypertension, arrhythmias, and sudden death.

Tobacco use is a risk factor for coronary artery disease. Both active smoking and exposure to passive smoke increase the risk of coronary artery disease events. Substance abuse associated with injection of intravenous material results in a risk of IE.

The best approach to long-term therapy for heart disease related to substance abuse is to avoid the deleterious substances. Rehabilitation programs play an important role in this regard. Specific therapies for cardiotoxicity in general are lacking. Anecdotal reports regarding therapy for acute ischemic cocaine cardiotoxicity favor nitrates, oxygen, aspirin, benzodiazepines, alpha-blockers, and possibly calcium channel blockers. If acute MI is present, use of thrombolytic agents and aspirin may be considered, unless contraindications such as severe hypertension, intracerebral hemorrhage, or seizures are present. Future studies are necessary to help clarify the best therapy for cocaine cardiotoxicity.

Primary prevention of substance abuse is clearly the most important goal for our society—although a formidable one, it is worth striving for. The cardiotoxicity of substance abuse is generally serious and potentially life-threatening, and treatment is far less optimal than preventing the behavior that causes disease in the first place.

THE FUTURE

The association between substance abuse and heart disease is one that has received increased attention, largely as a result of publicity surrounding the deaths of athletes and stars who have used drugs such as cocaine. Given the prevalence of drug abuse in this country, it is a topic that likely will remain important over the next decade. Its importance may vary, depending on which drugs are most used at a given point in time.

ACKNOWLEDGMENT

We thank Alice Stargardt for a superb job and outstanding editorial assistance in preparing this chapter.

OVERVIEW

Athlete's heart was first described by Henschen in 1899 and is now recognized as a constellation of clinical findings known as *the athletic heart syndrome*. These findings include sinus bradycardia, atrioventricular (AV) conduction delay, systolic flow murmurs, and cardiac chamber enlargement with normal or augmented function. All four cardiac chambers may be enlarged. Chamber enlargement may rarely exceed the upper limits of normal, but marked enlargement of the right ventricle or either atrium suggests a pathologic process. Clinical findings of the athletic heart syndrome are limited to athletes whose sports and training require a large aerobic or endurance exercise component. Left ventricular (LV) wall thickness can be slightly thickened, but this thickening is generally restricted to athletes with LV chamber enlargement and rarely reaches the thickness of pathological states such as hypertrophic cardiomyopathy (HCM). Physicians often are required to evaluate asymptomatic athletes before participation and to evaluate symptomatic athletes before permitting their return to vigorous exercise training. In these situations, the athletic heart syndrome must be differentiated from pathological conditions associated with cardiac complications during exercise, including HCM, coronary artery anomalies, aortic stenosis, right ventricular or LV cardiomyopathy in young athletes, and coronary artery disease in adults.

GLOSSARY

Athlete's heart or athletic heart syndrome: a constellation of clinical, electrocardiographic, and echocardiographic variants of normal found in well-trained athletes who participate in sports requiring prolonged aerobic exercise training.

Endurance or isotonic exercise: generally rhythmic, physical exertion (e.g., running, swimming, and bicycling) that requires significant, sustained increases in oxygen uptake.

External workrate: the amount of work an individual can perform on the environment. External workrate can be measured by oxygen uptake.

Internal workrate: the myocardial oxygen consumption during exertion. Internal workrate can be estimated by the triple product (heart rate × systolic blood pressure × LV ejection time) or double product (heart rate × systolic blood pressure).

Maximal oxygen uptake ($\dot{V}O_2max$): the physiologic and highly reproducible upper limit of an individual's ability to extract and use oxygen during progressive isotonic exercise.

Onset of blood lactate accumulation (OBLA): the point during exercise at which the accumulation of lactate can be detected in blood samples. This point corresponds to an abrupt increase in the respiratory rate and often is referred to as the *anaerobic threshold*.

Relative workrate: the percentage of maximal oxygen uptake required to perform a certain physical task.

Strength exercise: physical exertion that requires lifting or moving objects against resistance. Strength exercises can result in motion against resistance (e.g., weightlifting) or require exertion against a fixed object, referred to as isometric exercise.

HISTORICAL PERSPECTIVE

The history of the athlete's heart is as clouded by myth and misinformation as the condition itself. Take, for example, the legend of Pheidippides, who reportedly ran 40 km (24 miles) from the battlefield at Marathon to Athens to announce the Athenians' victory over the Persians. After announcing the victory, he collapsed and died. This story provides a marvelous introduction to the risks of exercise, but it is probably not true. Pheidippides was more likely named Philippids or Phidippus. His run was not from Marathon to Athens to announce victory but from Athens to Sparta to solicit military aid, then back to Athens with the bad news that the Spartans were not coming. This distance was not 40 km but closer to 500 km (300 miles). Most distressing of all to those who cite this event, our runner, name uncertain, probably survived. Herodotus, the major historian of the event, never mentioned the runner's demise (1).

Similar confusion has plagued the concept of the athlete's heart—what we prefer to label *the athletic heart syndrome*—because this condition is often a constellation of findings. Indeed, as with the story of Pheidippides, the first telling was probably the most correct. Subsequent versions only distorted or embellished the truth.

The first description of the athletic heart syndrome was provided more than 100 years ago. Henschen used percussion of the chest to determine heart size in cross-country skiers before and after a ski race (2). His report in 1899 concluded that skiing produces a physiologic cardiac enlargement that enables the athlete's heart to perform more work than the heart of an untrained individual. He also noted that the right and left sides of the heart were enlarged. He concluded that this enlargement is due to athletic activity, and he called the condition "the athlete's heart." Subsequent studies by a plethora of others using roentgenographic, echocardiographic, computerized tomographic, and magnetic resonance imaging techniques have confirmed Henschen's conclusion that exercise training produces a generalized cardiac enlargement.

Henschen also noted acute cardiac dilation after exhaustive exercise, and he attributed this dilation to cardiac failure. This conclusion has long been considered incorrect, although more recent echocardiographic studies have resurrected the possibility that prolonged, exhausting, competitive events such as triathlons may produce a cardiac fatigue typified by temporarily decreased LV contractility (3). Perhaps Henschen was not as wrong as previously thought.

How could Henschen, over 100 years ago and using a technique as crude as chest percussion, have reached such accurate conclusions? The answer is that he picked the right athletes, but this simple response obscures several principles critical to understanding the athletic heart syndrome. First, Henschen studied endurance-trained athletes. Strength-trained athletes such as weightlifters have increased cardiac dimensions, but their hearts' enlargement is related to body size and muscle mass (4).

Only endurance-trained athletes or athletes training with endurance and strength modalities develop the athletic heart syndrome. Second, Henschen selected cross-country skiers—endurance athletes whose exercise uses arm and leg muscles. Cardiac dimensions and stroke volume are greatest in athletes whose training requires use of the most muscle mass.

NORMAL RESPONSE TO EXERCISE AND EXERCISE TRAINING

A basic understanding of the acute response to endurance exercise and of the exercise training response is useful in evaluating athletes with possible athletic heart syndrome.

Acute Response to Exercise

Compared to the general population, endurance athletes are characterized by a higher ability to perform maximal dynamic exercise. This ability can be measured as $\dot{V}O_2$max. $\dot{V}O_2$max is expressed as liters of oxygen per minute or is "normalized" for body weight as milliliters of oxygen per minute per kg of body weight. $\dot{V}O_2$max is physiologically limited by the ability of the cardiopulmonary system to deliver oxygen and the ability of the exercising muscles to use oxygen. Rearranging the Fick equation for cardiac output [cardiac output = volume of oxygen/arteriovenous oxygen difference ($\dot{V}O_2$/A-V O_2)] demonstrates that $\dot{V}O_2$max is the product of maximal cardiac output and the maximal A-V O_2 difference. Maximal cardiac output is the product of maximal heart rate and stroke volume. Because maximal heart rate among healthy individuals varies primarily by age, and because the ability to increase the A-V O_2 difference is limited, the major factor responsible for the higher $\dot{V}O_2$max among endurance athletes is an increased stroke volume. The clinical findings typical of the athletic heart syndrome are generally manifestations of this increased stroke volume.

Although higher $\dot{V}O_2$max values distinguish endurance athletes from sedentary individuals, $\dot{V}O_2$max is not a good discriminator of superior athletic performance among endurance athletes. This is because $\dot{V}O_2$max does not measure an individual's ability to maintain exertion over a long period of time. Other factors, including the athlete's mechanical efficiency and "anaerobic threshold," or OBLA, contribute to submaximal work capacity and are better discriminators of competitive exercise performance among athletes. Enhanced mechanical efficiency means that an athlete can perform a physical task while consuming less oxygen than a less efficient athlete. A higher OBLA means that the athlete can perform more mechanical work without producing lactate. OBLA indicates the onset of several factors that eventually reduce exercise capacity. OBLA is associated with a higher respiratory rate stimulated by the production of carbon dioxide from buffering lactic acid ($HLactate + HCO_3^- \rightarrow H_2CO_3 + lactate^- \rightarrow H_2O + CO_2$). In addition, the lactate production indicates a level of exertion requiring glycogen catabolism, and glycogen depletion is one potential limiting factor in endurance performance. Finally, lactic acid itself contributes to fatigue.

Acute cardiovascular adaptations to exercise in young, healthy subjects are mediated by several mechanisms. The increase in heart rate initially is due primarily to withdrawal of resting vagal tone. At approximately 50% of maximal heart rate, additional acceleration of heart rate is associated with increased sympathetic nerve activity and norepinephrine spillover into the circulation (5). Peak heart rate is estimated as 220 – age, but the standard deviation of this estimate is ± 11 to 22 beats/min (6). Therefore, the 95% confidence limits are ± 22 to 43 beats/min, and the range of normal can be 44 to 86 beats/min. These limits underscore the problem of estimating heart rate by age. Changes in stroke volume during exertion are influenced by body position. During supine exercise, the increase in stroke volume is due primarily to increases in end diastolic volume. During upright exercise, increases in stroke volume are produced by increases in end diastolic volume and decreases in end systolic volume (5). The increase in the A-V O_2 difference is produced by redistribution of blood from nonexercising tissue to the exercising musculature, increased extraction of oxygen over the exercising muscle bed, and hemoconcentration (5). Sweat loss is not required for this hemoconcentration, because plasma fluid moves into exercising muscle to produce the muscle swelling obvious in recently exercised muscle. These changes and the mediating mechanisms apply to young, healthy subjects such as those most likely to present with clinical findings of the athletic heart syndrome. Altered responses and different mechanisms are observed in elderly subjects and in patients with disease.

It is important for clinicians to recognize that any change in any component of this system can affect maximal exercise capacity. Cardiologists tend to focus on changes in maximum heart rate and stroke volume, but changes in hemoglobin concentration, the ability to fully oxygenate red blood cells, the capacity to shunt blood to exercising muscle, or the ability of the muscles to extract the available oxygen can affect exercise performance. These factors should be considered in evaluating athletes for problems with exercise performance.

As mentioned above, there are differences in mechanical efficiency among different athletes performing identical exercise tasks. Nevertheless, in general, a specific physical task requires approximately the same oxygen uptake when performed by different individuals. Consequently, knowing the workrate of exercise permits a general estimation of the $\dot{V}O_2$ required, even when the $\dot{V}O_2$ is not measured. The oxygen consumption required by a physical task is referred to as the *external workrate* (7). The external workrate also determines the cardiac output response to the exercise task. In general, a 1-L increase in oxygen consumption produces a 6-L increase in cardiac output (8). The external workrate is also referred to as the *absolute workrate* or the *absolute* $\dot{V}O_2$. The *relative workrate* refers to the percent of an individual's $\dot{V}O_2$max that is required for that person to perform a certain physical task. In other words, relative workrate is the required $\dot{V}O_2$ relative to the individual's maximum. Individuals differ in their maximal exercise capacity, primarily because maximal stroke volume and maximal cardiac output vary among individuals. Because of differences in individual exercise capacity, the same physical task usually requires approximately the same absolute workrate for different individuals, but the task often requires markedly different relative workrates.

Identical external workrates can produce markedly different myocardial oxygen demand. Myocardial oxygen demand has been referred to as the *internal workrate* (7). Myocardial oxygen demand increases with increasing heart rate and systolic blood pressure (9). The product of heart rate and systolic blood pressure or rate pressure product is used clinically to estimate the myocardial oxygen demand of exertion (9). Heart rate and systolic blood pressure increase linearly with the relative workrate. Consequently, identical external workrates can produce markedly different internal workrates or myocardial oxygen demands, depending on the individual's $\dot{V}O_2$max. The implication of this observation is that a physical task requires less myocardial oxygen supply for an individual with a high $\dot{V}O_2$max than for a less fit individual.

Effect of Exercise Training on Exercise Performance

The increase in $\dot{V}O_2$max produced by 2 to 3 months of exercise training in young subjects is produced by increases in maximal stroke volume and the maximal A-V O_2 difference. It is generally stated that approximately 50% of the increase in $\dot{V}O_2$max is due to increases in stroke volume and 50% to changes in the A-V O_2 difference (10), but these amounts vary greatly among studies (11). Increases in $\dot{V}O_2$max are greater with increasing duration and intensity of the exercise training program and with the amount of muscle mass used in training (5). Also, with prolonged training, more of the increase in exercise capacity is due to increased stroke volume. Apparently, the increase in the A-V O_2 difference is an early adaptation to habitual exercise, whereas large increases in stroke volume require cardiac adaptations over a longer, albeit undefined, period of time. The average increase in $\dot{V}O_2$max in healthy subjects after jogging or cycling for 3 to 12 months is approximately 20% (12), but it is less in more fit and older individuals. Increments in $\dot{V}O_2$max can be considerably larger if training is prolonged over years rather than months.

The increase in absolute work capacity produced by exercise training means that the same external workload after training represents less of the individual's relative workload. Because exercise-induced increases in heart rate and systolic blood pressure are related to the relative, as opposed to the absolute, exercise workload, the same external workload after training elicits smaller increments in heart rate, blood pressure, and myocardial oxygen demand.

CLINICAL COMPONENTS OF THE ATHLETIC HEART SYNDROME

Variants Attributed to Enhanced Parasympathetic Tone

Several of the findings of the athletic heart syndrome (e.g., resting bradycardia, sinus arrhythmia, and AV conduction delay) are generally attributed to changes in the sympathetic nervous system with enhanced parasympathetic tone and reduced sympathetic tone. Of these two factors, enhanced parasympathetic tone is most important (13). These alterations in the sympathetic nervous system control are unlikely to be the entire explanation, however. The resting heart rates of endurance athletes remain lower than those of sedentary subjects, even after sympathetic nervous system control is theoretically eliminated in both groups with large doses of atropine and beta-adrenergic blockade; these circumstances suggest that other factors such as larger cardiac dimensions also contribute to the reduced heart rate (14,15). Similarly, athletes may demonstrate ST–T-wave changes of early repolarization and T inversions, which are also attributed to sympathetic nervous system alterations (Fig. 37.1 and Fig. 37.2). Some of the T-wave changes can be quite bizarre and may be similar to changes seen with conditions known to affect the parasympathetic nervous system, such as subarachnoid hemorrhage.

FIGURE 37.1 Electrocardiogram from a 53-year-old physician who has run a minimum of 60 km weekly for 40 years. The axis is 70 degrees—somewhat unusual in a healthy individual in this age group—and there is ST elevation of early repolarization in leads V_3–V_6.

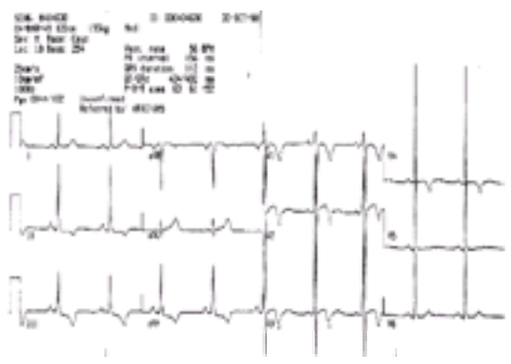

FIGURE 37.2 Electrocardiogram (ECG) from a 49-year-old white physician showing diffuse T-wave inversions. He had run 58 to 108 km weekly and ridden a bicycle 32 km weekly for 20 years. The ECG was obtained when he volunteered for a study of healthy subjects. An echocardiogram showed left ventricular (LV) internal dimensions at end diastole and systole of 50 mm and 20 mm, respectively, and LV posterior and septal wall thickness of 12 mm each. He was not restricted from athletic competition.

Nevertheless, not all extreme T-wave abnormalities in athletes are due to athletic heart syndrome. For example, among 26 Spanish athletes evaluated for negative T waves ³2 mm, four were found to have HCM (16) (eFig. 37.2.1). Many of the changes typical of athletic heart syndrome (e.g., sinus arrhythmia and the ST changes of early repolarization) are also characteristic of young, healthy individuals, but they are more marked or more frequent in athletes and may persist into middle age among physically active subjects. All of these abnormalities in sinus rate, AV conduction, and the ST changes of early repolarization should resolve with exercise with its attendant withdrawal of vagal tone and increased sympathetic activity. This is not always true for marked T-wave inversions (16), however, so their failure to resolve does not necessarily imply a pathologic process.

***e*FIGURE 37.2.1** Electrocardiogram from a 45-year-old African-American man who experienced cardiac arrest while playing basketball. The tracing shows a prolonged PR interval, impressive left atrial enlargement, anterior T abnormalities, and an abnormal QRS pattern. These findings are not typical of the athletic heart syndrome. Echocardiography showed findings of hypertrophic cardiomyopathy, including an enlarged septum (17 mm), a reduced ejection fraction, and no resting outflow tract gradient.

Sinus Bradycardia

$\dot{V}O_2$max and maximal cardiac output are increased in endurance athletes, but there is little change in resting oxygen consumption or cardiac output. Consequently, the larger resting stroke volume characteristic of endurance athletes permits a reduction in resting heart rate. Sinus bradycardia, generally defined as a heart rate <60 beats/min, is typical of athletic heart syndrome and reported in up to 91% of endurance athletes (17). Bradycardia in athletes can be profound, and a rate of 25 beats/min has been reported in one distance runner (18). In addition to sinus bradycardia, sinus pauses or “sinus arrest” of >2 seconds have been documented during sleep in endurance athletes (17) (Fig. 37.3).

FIGURE 37.3 Electrocardiogram from a 36-year-old physician showing marked bradycardia of 46 beats/min, voltage criteria for left ventricular (LV) hypertrophy (note the 1/2 standard calibration), and a prolonged QT interval in lead V3. He was 180 cm (5'10") tall and weighed 67 kg (147 lb). He had played college lightweight American football and rowed in lightweight crew. Over the past 5 years, he had run 100 to 130 km weekly and competed in 42-km foot races. He was asymptomatic and had no family history of cardiac complications. His echocardiogram showed LV internal dimensions at end diastole and systole to be 54 and 37 mm, respectively. The LV posterior wall thickness was 10 mm, and the septal thickness was 11 mm. He was not restricted from athletic participation, despite the QT interval, because he was totally asymptomatic.

Sinus Arrhythmia

Sinus arrhythmia refers to variation in sinus rate with respiration. Specifically, the sinus rate decreases slightly at the start of the expiratory phase of the respiratory cycle. Sinus arrhythmia is common in young, healthy subjects, but it is more marked in endurance athletes.

Atrioventricular Conduction Delay

First degree AV block, defined as a PR interval of >0.20 seconds, is reported in 10% to 33% of endurance athletes (19). Second degree AV block of the Mobitz I or Wenckebach pattern is characterized by progressive prolongation of the PR interval before a nonconducted P wave and is also seen more commonly in the athletic heart syndrome (19). Second degree AV block with Mobitz II appearance is characterized by a nonconducted P wave without preceding PR prolongation, but it is not typical of the athletic heart syndrome. Mobitz II block typically occurs at the level of the His-Purkinje system, whereas Mobitz I block is due to progressive slowing of conduction in the AV node. An AV block with Mobitz II appearance may occur in well-trained athletes due to enhanced vagal tone, but this is rare (17) (Fig. 37.4 and *e*Fig. 37.4.1). The presence of Mobitz II block should prompt a search for other causes and should be attributed to athletic training only if the athlete is asymptomatic and no other abnormalities are detected.

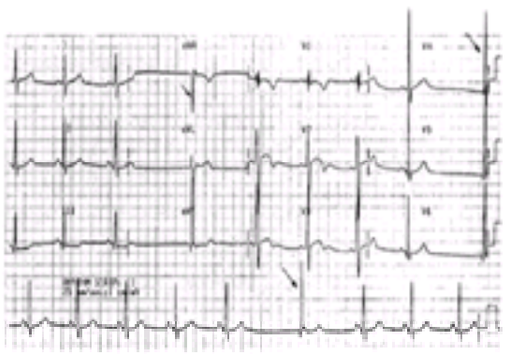

FIGURE 37.4 Electrocardiogram (ECG) from a 28-year-old man who had run 42 km in 2 hours and 17 minutes. He was evaluated for momentary chest discomfort felt in 1984, several days after the death of James Fixx, the author of *The Complete Book of Running*. The ECG shows an axis of 110 degrees, incomplete right bundle branch block, sinus pauses with junction "escape" beats (*arrows*), slight P-wave enlargement in lead II, increased precordial voltage, and biphasic T waves in V_2 and V_3. He was otherwise asymptomatic, had a normal echocardiogram, and was treated with reassurance. (Reproduced from Thompson PD. Cardiac evaluation of the young or old, competitive or recreational athlete. In: Strauss RH. *Sports medicine*, 2nd ed. Philadelphia: WB Saunders, 1991, with permission.)

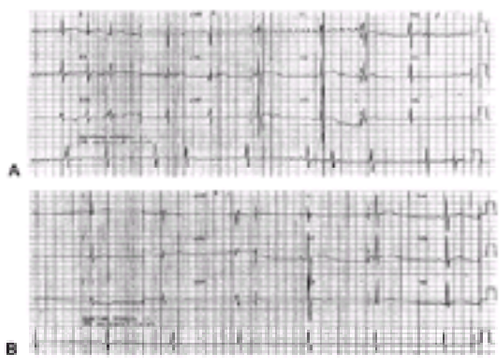

***e*FIGURE 37.4.1** Electrocardiograms during **(A)** and after **(B)** an episode of atrial fibrillation in a 42-year-old man who ran 70 km weekly. The ventricular rate was only 100 beats/min during atrial fibrillation despite no medication and only 43 beats/min after cardioversion, illustrating the slow heart rate of endurance-trained individuals. The tracings also show incomplete right bundle branch block, precordial ST elevations, and T inversions in V_3—all of which can be normal in endurance-trained patients. (Reproduced from Thompson PD. Cardiac evaluation of the young or old, competitive or recreational athlete. In: Strauss RH. *Sports medicine*, 2nd ed. Philadelphia: WB Saunders, 1991, with permission.)

The prolongation of the AV interval and decrease in AV conduction velocity previously described may also unmask ventricular preexcitation—also known as Wolff-Parkinson-White (WPW) syndrome—when accompanied by symptomatic arrhythmia. Indeed, a WPW conduction pattern is more common in endurance athletes (19). Cardiologists should be cognizant of this fact when evaluating athletes for an asymptomatic WPW conduction pattern, because the risk of sudden death in asymptomatic subjects with this abnormality is low.

Vasovagal Syncope

Vasovagal syncope appears to occur more frequently in endurance-trained individuals because it is related, in part, to these athletes' enhanced vagal tone. Lower-body negative pressure is a research technique used to examine blood pressure control and an individual's response to orthostatic stress. Compared to nonathletes and strength-trained athletes, endurance-trained individuals have a reduced ability to maintain blood pressure during lower-body negative pressure (20). The clinical implications of this reduced ability are that endurance-trained individuals are more vulnerable to vasovagal syncope or simple fainting and that positive tilt-table responses are almost the norm in well-trained endurance athletes. These athletes have a large venous capacity, enhanced vagal tone, and reduced sympathetic tone—all of which make them vulnerable to postural hypotension and a positive tilt-table response. Tilt-table results should not be interpreted as an adequate explanation for syncope in athletes, therefore, unless the clinical situation also strongly supports this explanation.

Electrocardiographic ST–T-Wave Changes

ST elevation of the early repolarization pattern is so common in endurance-trained athletes that it should be considered the norm rather than the exception. Persistent training into advanced age can preserve this pattern in older athletes. ST depression, in contrast, is rare and should prompt a search for other causes. Peaked, biphasic, and inverted T waves in the precordial leads are frequently seen in endurance athletes. The biphasic T waves typically occur in the precordial "transition" leads, where the QRS complex is changing from a primarily negative deflection in the right precordial leads to a primarily positive deflection in the left-sided leads. Deeply inverted T waves can also be normal in athletes, but they are rare and require the exclusion of significant disease (16). Of 952 healthy, Italian, national-caliber athletes, only 27 had marked T-wave inversions. Three-hundred seventy-five had abnormal or mildly abnormal electrocardiograms (ECGs), suggesting HCM in 11 and arrhythmogenic right ventricular cardiomyopathy in 16. Only one of these athletes actually had HCM, however (21).

Evidence of Cardiac Enlargement

Habitual endurance exercise produces a global cardiac enlargement that may affect the atria and ventricles. The most consistent enlargement is seen in the LV chambers, where intracavity dimensions and, rarely, wall thickness, can be large enough to raise the suspicion of cardiac disease. Mild enlargement of both atria and the right ventricle can occur, but marked enlargement of these structures is suggestive of a disease process and is not observed in the athletic heart syndrome.

Electrocardiographic Evidence of Chamber Enlargement

The ECG in well-trained athletes may show mildly increased P-wave amplitude that suggests right atrial enlargement, P-wave notching that suggests left atrial enlargement, incomplete right bundle branch block (IRBBB), and voltage criteria for right ventricular and LV hypertrophy (17) (Fig. 37.5).

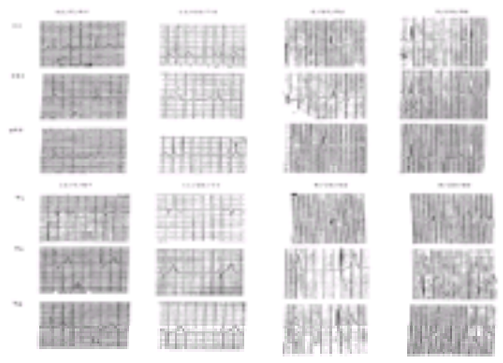

FIGURE 37.5 Selected leads from the serial electrocardiograms (ECGs) of a 42-year-old physician who began running in the late 1960s and progressed to running multiple 42-km foot races. The tracings show the development of the classic ECG of the athletic heart syndrome, including increased P-wave height (lead II), increased P-wave negativity (V_1), increased right-sided R wave (V_1), increased precordial voltage (V_5 and V_6). These developments suggest right and left atrial and ventricular enlargement, respectively. There are also progressive T-wave changes with increased precordial T waves (V_5 and V_6) and increasing negative T waves in the inferior leads (III and aVF). The presence of all of these findings in a single ECG is unusual, even among well-trained, elite athletes. This individual remains healthy in his mid-50s.

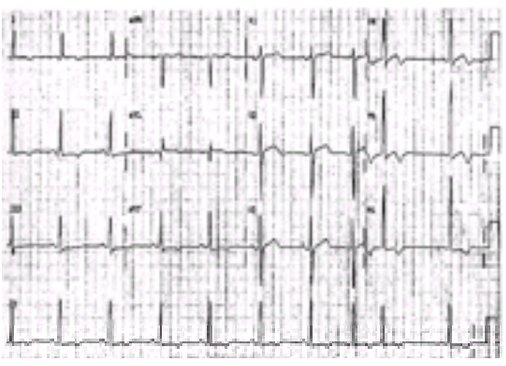
Among endurance athletes, voltage criteria for right ventricular hypertrophy are noted in 18% to 69% of subjects (19). This ECG evidence for atrial and right ventricular enlargement does not usually suggest extreme enlargement, so marked evidence of atrial or right ventricular enlargement should prompt a search for pathologic causes. Similarly, although IRBBB is common, complete heart block generally is not accepted as part of the athletic heart syndrome (17).

In contrast to ECG evidence of atrial and right ventricular enlargement, the voltage criteria for LV hypertrophy can be extreme in endurance athletes (*e*Fig. 37.5.1). QRS voltage is greater in endurance athletes than in other subjects, even after adjusting for LV mass, suggesting that some of the extreme voltage seen in endurance-trained subjects is due to thinner chest walls (4).



***e*FIGURE 37.5.1** Electrocardiogram showing left ventricular hypertrophy and premature atrial contractions in an asymptomatic, healthy, 31-year-old, nonhypertensive athlete.

Echocardiographic Evidence of Cardiac Enlargement

Echocardiography frequently is performed in evaluating symptoms in athletes, so it is important for clinicians to know the limits of cardiac enlargement produced by exercise training.

Thomas and Douglas have recently summarized the topic of echocardiographic dimensions in athletes (3). At least 59 studies have used echocardiography to examine cardiac dimensions in athletes (3). These studies consistently documented increased LV dimensions. Thirteen studies comparing right ventricular dimensions in athletes and controls demonstrated that the right ventricular transverse dimension was increased an average of 24% in the athletes (22 mm vs. 17 mm) (3). Fourteen studies comparing the left atria of athletes and controls demonstrated that the transverse dimension was 16% larger in the athletes. To our knowledge, only one study has documented a larger right atrial size in the athletes (3).

Pelliccia and colleagues have explored the upper limits of echocardiographic dimensions in athletes using data obtained in studies of Italian national athletes at the Institute of Sports Science in Rome. These authors examined LV wall thickness in 947 athletes, 209 of whom were women (22). Only 16 athletes (1.7%) had an LV wall thickness >12 mm, the upper limit of normal. Fifteen of these athletes participated in rowing or canoeing, sports that require isotonic and isometric effort and involve a large muscle mass. These 15 athletes represented 7% of the rowers and canoeists studied. The only other athlete with increased wall thickness was a cyclist. All athletes with increased wall dimensions had won medals in international competition. The largest wall thickness in any athlete was 16 mm. All of the female athletes had wall thicknesses less than 11 mm.

Six of the athletes with marked LV wall enlargement discontinued exercise training and were restudied after 40 to 240 (average = 90) days of reduced activity. Average wall thickness decreased from 12.8 ± 0.9 mm to 10.5 ± 0.4 mm, $p < .05$. Three of the athletes—none of whom had increased wall thickness—had localized apical hypertrophy suggestive of apical HCM, but none of these subjects had the marked apical T-wave abnormalities characteristic of this condition. All of the athletes with increased wall thickness also had increased cavity dimensions, which suggests that the increase in wall thickness in these subjects is an adaptation to maintain normal wall stress.

These results are extremely useful in differentiating the athletic heart syndrome from HCM. LV wall thickness >12 mm was unusual, even in elite athletes. Consequently, the presence of increased wall thickness in recreational or elite athletes should prompt a search for pathologic causes. No athlete had an LV wall thickness >16 mm, and values above this range should raise the possibility of HCM. Wall hypertrophy above the normal range was not observed in female athletes. All athletes with wall hypertrophy also demonstrated increased cavity dimensions, which are not seen in HCM or in other diseases with pathologic wall thickening. Finally, wall thickening in high-caliber athletes should regress with detraining.

In another study, Pelliccia et al. examined LV cavity dimensions in 1,300 elite athletes participating in 38 different sports (23). The LV end-diastolic diameter (LVEDD) was greater in male (55 mm) than in female (48 mm) athletes. The LVEDD was >55 mm (i.e., the upper limits of normal) in 45% of the athletes and exceeded 60 mm in 14% of the subjects. The largest cardiac dimensions by gender were 66 mm for a female athlete and 70 mm for a male athlete. Regression analysis demonstrated that body surface area (r = 0.76), heart rate (r = –0.37), and age (r = 0.29) correlated with the LVEDD, indicating that these three variables accounted for 60% of the variability in the LVEDD. Adding gender and the type of sport to these factors accounted for 72% of the variability. Age may function in this group as a surrogate for the duration of training, but this is not certain because age did not differ between athletes whose LVEDD was >60 mm or <60 mm. The sports that were most associated with an LVEDD ³60 mm were cycling (49% of cycling athletes), ice hockey (42%), basketball (40%), rugby (39%), canoeing (39%), and rowing (34%). All are sports that require a large endurance component or a combination of moderate endurance training and increased body size. Systolic and diastolic function were normal in the athletes. Once again, few athletes had evidence of LV wall hypertrophy. Only 14 of the athletes (1.1%) had a septal thickness >12 mm, and only four athletes (0.3%) exceeded this posterior wall thickness. Wall thickness among all of the athletes correlated with cavity dimensions. Athletes with increased cavity dimensions also tended to have larger left atrial and aortic root dimensions.

Throughout this chapter we have emphasized that the largest changes in cardiac dimensions occur with endurance exercise training or the combination of endurance and strength training in large individuals. Nevertheless, the concept that endurance and strength exercise training produce different cardiac adaptations is widely accepted by many clinicians. Habitual, high-dynamic exercise training is presumed to increase primarily LV volume, whereas exercise with a high static component is presumed to increase LV wall thickness. This concept has been challenged by investigators who could find no significant differences between strength-trained athletes and controls (24). In the most comprehensive examination of this issue, Pluim and colleagues performed a metaanalysis on all 59

echocardiographic studies of athletes published from 1975 to 1998 (25). They divided the 1,451 subjects into endurance-trained athletes (e.g., long-distance runners), strength-trained athletes (e.g., weight lifters), and combined static- and dynamic-trained athletes (e.g., rowers and cyclists). These reports included 31 studies of endurance athletes, 24 studies of strength athletes, and 23 studies of combination athletes. Septal thickness in endurance athletes (10.5 mm) was significantly greater than that in controls (8.8 mm) but less than that in strength-trained subjects (11.8 mm) and combination athletes (11.3 mm). Posterior wall thickness, in contrast, was actually greater in endurance athletes (10.3 mm) than in controls (8.8 mm), but it was not different from combination (11 mm) or strength-trained (11 mm) subjects. Pluim et al. concluded that the differences in the cardiac dimensions of endurance- and strength-trained athletes are relatively minor and that there is no clear dichotomy in the cardiac adaptations to endurance or strength training. None of the cardiac dimensions are adjusted for body size, nor are any of the included studies prospective, so it is possible that some of the septal thickness in strength-trained and combination-trained athletes results from body size and not the training modality.

The clinical significance of these findings is that clinicians should avoid ascribing cardiac wall hypertrophy to the effects of exercise training—even among strength-trained athletes—because the effects of such activity alone on cardiac wall thickness is minor.

Functional Cardiac Murmurs in Athletes

Both young and old endurance athletes often have functional cardiac murmurs created by cardiac adaptations to exercise training. Blood flow is laminar and without turbulence until a critical Reynolds number (Re) is exceeded. Re is determined by the following formula:

$$\text{Re} = \frac{\text{average velocity} \times \text{tube diameter} \times \text{fluid density}}{\text{fluid viscosity}}$$

Laminar flow is disrupted above an Re of 2,000, creating turbulence and murmurs. As previously discussed, endurance exercise training reduces resting heart rate, increases resting stroke volume, and enhances cardiac performance. Training does not change resting cardiac output, which is delivered via a slower heart rate and a larger stroke volume. Much of the larger stroke volume is delivered more vigorously in early systole by a more dynamic ventricle. This delivery increases blood velocity. The pulmonic and aortic valve orifices do not increase with exercise training, so the increased blood velocity produces early systolic “flow murmurs.” Such flow murmurs in young athletes are due to flow across the pulmonic valve and often vary with respiration. Athletes aged 50 years and older may have mild sclerosis of the aortic valve leaflets, and their flow murmurs are often due to aortic valve sclerosis and the turbulence mentioned above. These murmurs are less “innocent” because they may progress to important aortic stenosis, especially in athletes with other risk factors for atherosclerosis such as hypercholesterolemia (26,27). Treatment of these risk factors may reduce the development of important aortic stenosis, but this has not been studied. Nevertheless, we often recommend 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors in adult patients with noncritical aortic stenosis in the hope of preventing such progression.

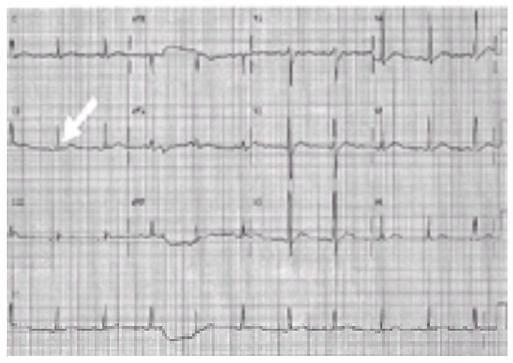
EXERCISE-RELATED CARDIAC EVENTS

Clinicians are often required to differentiate the athletic heart syndrome from life-threatening cardiac disease and to make recommendations about the risks of exercise in individuals with diagnosed abnormalities. This section discusses the risks of exercise and the conditions associated with exercise-related cardiac events. There is little doubt that vigorous physical exertion increases the risk of cardiac events in children and adults with cardiovascular abnormalities. This increased risk of exertion has been quantified and documented conclusively only in adults in whom the risk of sudden death (28,29) and acute myocardial infarction (30,31 and 32) is increased by exercise. The data are less definitive in children, but the clinical association of exertion and sudden death in children with a variety of congenital and acquired cardiac diseases leaves little doubt that exercise has a provocative role in these events.

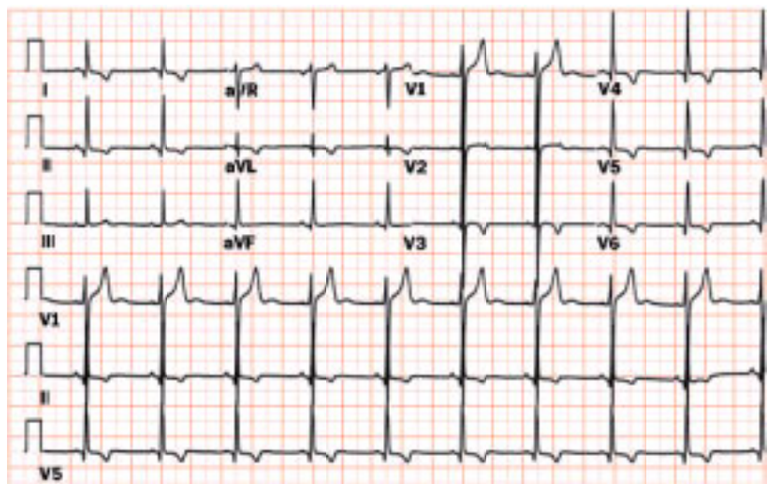
Pathology of Exertion-Related Cardiac Events

The causes of exertion-related cardiac events varies by the age of the subject. Among adults older than 29 or 39 years, atherosclerotic vascular disease is the cause of almost all exercise-related cardiac complications (32,33). A rare exercise-related death in an adult is due to other causes such as HCM, infiltrative diseases such as amyloidosis (34), and intramyocardial coronary arteries (35). Among younger subjects, the causes of death are usually congenital cardiac abnormalities or acquired myocarditis or cardiomyopathy. The prevalence of various causes of exercise-related events may vary by geographic distribution. HCM repeatedly has been shown to be the dominant cause of exercise-related deaths in young American athletes (36,37), whereas right ventricular dysplasia is the primary cause of such events in Italian athletes, especially in the Veneto region of Italy (38). The reasons for this discrepancy are unclear, but it has been attributed to a required national screening program for Italian athletes that has identified and excluded athletes with HCM (39). Other factors such as a regional interest in the disease, an increased prevalence of the condition in the Mediterranean area (40), or recent international recognition of right ventricular dysplasia may also contribute to the discrepancy (*e*Fig. 37.5.2 and *e*Fig. 37.5.3).

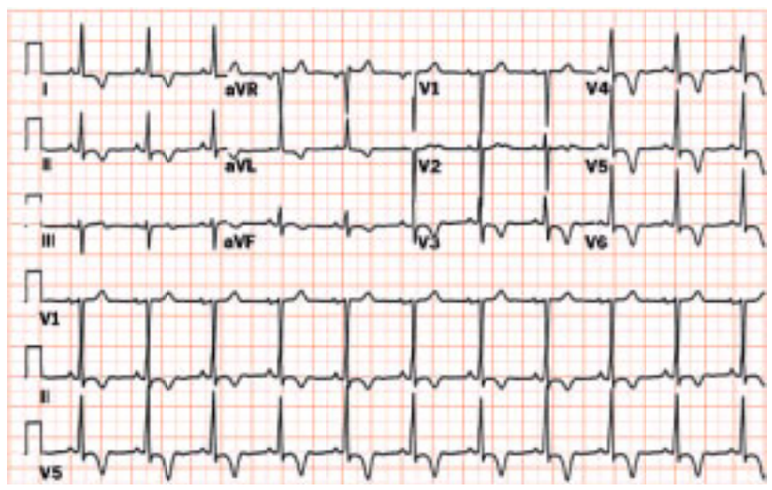
***e*FIGURE 37.5.2** Electrocardiogram (ECG) from a 22-year-old woman who experienced cardiac arrest while playing soccer. Echocardiography demonstrated right ventricular cardiomyopathy. The ECG shows T-wave inversions in leads V_1–V_3. She was treated with an implantable defibrillator.



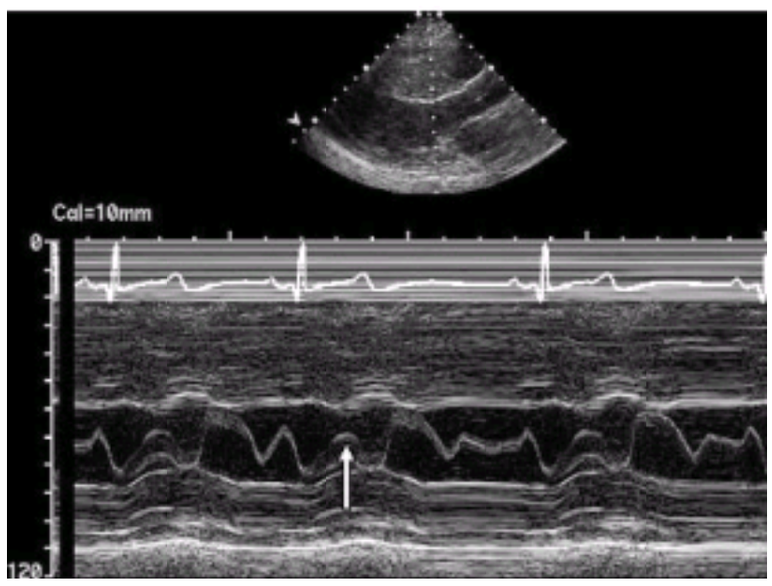
***e*FIGURE 37.5.3** Electrocardiogram from a 28-year-old African-American man who experienced cardiac arrest during basketball. Echocardiography and angiography confirmed right ventricular cardiomyopathy. Note the epsilon waves in lead II (*arrow*), lead III, and the augmented voltage unipolar left foot lead (aVF). Epsilon waves represent delayed depolarization of the right ventricle.



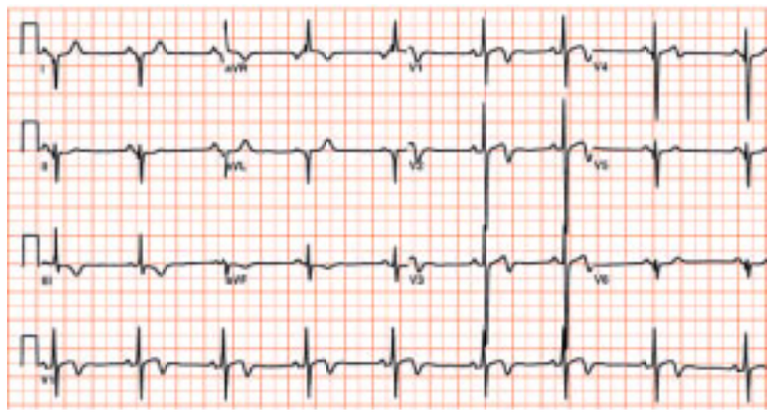
Hypertrophic cardiomyopathy. Inverted precordial T waves associated with hypertrophic cardiomyopathy.



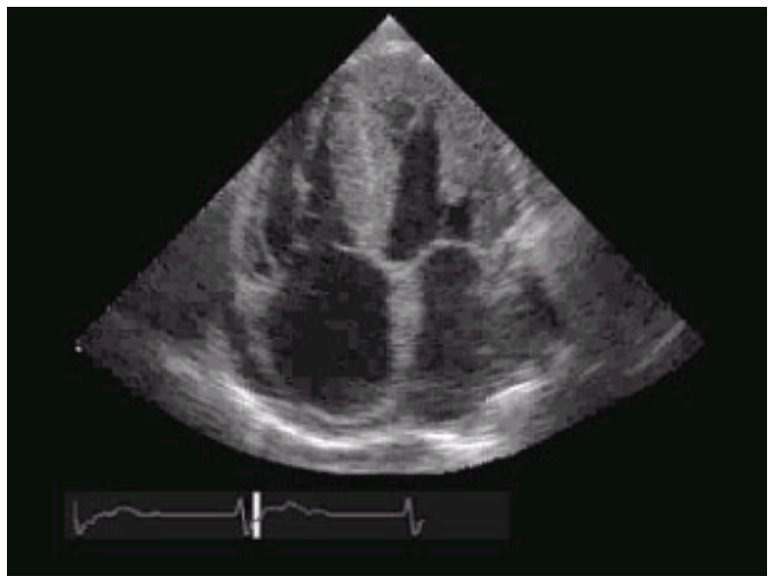
Yamaguchi's disease. Note anterior precordial T-wave inversion in this Asian patient with apical hypertrophy.



M-mode tracing of hypertrophic cardiomyopathy with severe septal hypertrophy seen at the top of the trace and systolic anterior motion (SAM) of the mitral valve in systole seen in the middle of the trace (designated by the arrow).



A 28-year-old Caucasian male patient with hypertrophic obstructive cardiomyopathy.



Apical four-chamber view of amyloid heart disease. Note the significant thickening of the left ventricle and right ventricle walls due to infiltration. There is also characteristic thickening of the valves and biatrial enlargement. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)

VIDEO

Video 37.1 Transthoracic apical four-chamber view of a patient with amyloidosis. Note the thickened “sparkling” walls of the right and left ventricles. Both the mitral and tricuspid valves are mildly thickened and there is biatrial enlargement and a trivial pericardial effusion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 37.2 Transthoracic subcostal view of a patient with amyloidosis showing markedly thickened right and left ventricular walls, showing the characteristic “sparkle.” The right ventricle is towards the top of the screen and the right ventricle free wall is 1.5 cm thick. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

In contrast to the findings in adults, atherosclerotic coronary artery disease is a rare cause of exercise-related deaths in younger subjects. The conditions associated with exercise-related sudden death in young athletes has been presented by Van Camp et al. with data from the National Center for Catastrophic Sports Injury Research (37). These authors examined 136 deaths in American athletes that occurred during or within 1 hour of sports participation. Cardiac conditions were associated with 100 deaths, including HCM (50% of the cases), coronary artery anomalies (13%), myocarditis (7%), aortic stenosis (6%), and dilated cardiomyopathy (6%) (Table 37.1). The coronary artery anomalies included anomalous origin, intramyocardial course, and an ostial ridge at the coronary origin. Some coronary anomalies, such as an acute take-off of the artery from the aorta (41), may be overlooked or unappreciated during autopsy. Only one case was attributed to right ventricular dysplasia, contrasting with the findings in Italian subjects, as previously discussed. Other investigators have presented similar data for American athletes (42).

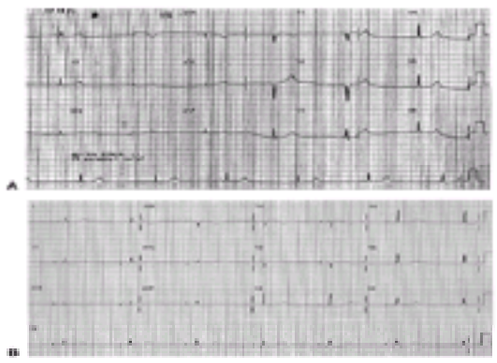
The cardiovascular risks of exercise. In: Thompson PD, ed. Exercise and sports cardiology. New York: McGraw-Hill, 2000, with permission.
[b]Three subjects also had coronary anomalies, one subject had Wolff-Parkinson-White syndrome.
[c]This category includes anomalous left coronary artery (LCA) from right sinus of Valsalva (n = 6), intramural left anterior descending (n = 6), anomalous LCA from pulmonary artery (n = 2), anomalous right coronary artery (RCA) from left sinus (n = 2), hypoplastic RCA (n = 2), and ostial ridge of the LCA (n = 2). Three subjects with coronary anomalies also had hypertrophic cardiomyopathy and are tabulated with that group.

TABLE 37.1 CARDIAC CAUSES OF DEATH IN HIGH SCHOOL AND COLLEGE ATHLETES[a] (n = 100)

These reports do not include all of the cardiac conditions for which exercise increases the risk of sudden death and should not be used to decide to permit an individual with a diagnosed cardiac condition to participate in vigorous exercise and competitive sports. Cardiac arrhythmia and sudden death in the long-QT syndromes, for example, are often associated with physical activity (43), especially swimming (44) (eFig. 37.5.4 and eFig. 37.5.5). Long-QT syndrome was not identified as a cause of death in these studies (37,42), because the diagnosis can only be made with a surface ECG antemortem or postmortem by molecular genetic testing of autopsy material (44). Recommendations for athletic participation for various cardiac conditions are available elsewhere (45).



***e*FIGURE 37.5.4 A,B:** Electrocardiogram from a 40-year-old woman showing QT prolongation. She presented with presyncope and syncope due to torsades de pointes during running and swimming. Her symptoms responded to beta-blockade, but marked sinus bradycardia required pacemaker placement with atrial pacing **(B)**.

***e*FIGURE 37.5.5 A,B:** Electrocardiogram from a 27-year-old man who experienced cardiac arrest. **(A)** shows unusual repolarization abnormalities in leads V_1–V_3 not typical of those seen with the athletic heart syndrome. Challenge with flecainide 150 mg by mouth produced right bundle branch block and repolarization changes consistent with Brugada's syndrome **(B)**. Brugada's syndrome usually produces syncope or sudden death unassociated with physical exertion.

There are several clinically important lessons to learn from these pathologic studies of exercise-related events. Several of the conditions identified at autopsy could have been detected before death. These conditions include valvular and subvalvular aortic stenosis, Marfan syndrome as a cause of aortic rupture, and possibly HCM, although a murmur in the later condition is detected in only 25% of cases. Few of the victims were women, which is consistent with other observations that women are protected, to some extent, from sudden death (46).

Incidence of Exercise-Related Cardiac Event

Although vigorous exertion acutely increases the risk of sudden death during exercise for individuals with known or occult cardiac disease, it is important for clinicians to remember that the absolute risk of a cardiac event during exercise is extremely low. The estimated annual incidence of exercise-related deaths among high school and college athletes is only one death per 133,000 men and 769,000 women, respectively (37). These estimates include 36 noncardiac deaths and thereby overestimate the cardiac risks of athletic competition. The death rate is higher among college men than high school men (1.45 vs. 0.66 events per 100,000) for unclear reasons, but it may be related to cardiac size because cardiac size itself is a risk factor for cardiac death (47,48), and more mature athletes should have larger hearts. These reports do not provide any information on how many individuals with cardiac conditions were prohibited from participating in sports and thereby escaped an exercise-related complication.

The risk of exercise-related sudden death is considerably higher in adults because of the increased prevalence of coronary disease, but it has been estimated that there is only one death per year for every 15,000 to 18,000 asymptomatic middle-aged men (28,29). Published studies on adults have wide confidence limits, however, because they are based on few subjects. Using the 95% confidence limits from a study done in Rhode Island, the death rate may vary from one death per year for every 4,000 to 26,000 asymptomatic men (28).

PREPARTICIPATION SCREENING OF COMPETITIVE ATHLETES

There is ongoing debate about the value of screening competitive athletes and the extent to which such screening should go. It is critically important that cardiologists know the issues involved, because they are frequently asked to evaluate athletes with possible abnormalities detected during screening. Often, these abnormalities are bradycardia or functional murmurs and are of no significance, but on rare occasions, a completely asymptomatic athlete with a major cardiac abnormality is identified.

The American Heart Association has issued a medical and scientific statement on the cardiovascular preparticipation screening of competitive athletes (49). This document recommends a personal and family history and a physical examination before high school participation in sports, with the examination repeated at least every 4 years. This statement does not advocate routine echo- or electrocardiography.

Others maintain that routine electrocardiography should be required for all young athletes (50). Fuller and colleagues obtained a medical history, had a cardiologist perform cardiac auscultation, and recorded a resting ECG on 5,615 athletes. Cardiovascular abnormalities were detected in 582 of the athletes (10.4%). These abnormalities included an abnormal cardiac history in 2.0%, abnormal auscultatory findings in 3.0%, hypertension in 0.3%, and an abnormal ECG in 2.6% of the athletes. Only 22 athletes were ultimately denied participation in sports due to severe aortic insufficiency (AI) (n = 1), severe hypertension (n = 5), WPW ECG pattern (n = 6), premature ventricular contractions (n = 5), RBBB (n = 4), and supraventricular tachycardia (n = 1). The reasons for excluding the athletes with WPW pattern, premature ventricular contractions, and RBBB were not provided. Among the 22 excluded athletes, the patient with severe AI underwent valve replacement, the hypertensive patients were treated, and the patient with supraventricular tachycardia underwent therapeutic ablation. Fifteen of the excluded subjects were lost to follow-up, greatly reducing the value of the study. Over the 3 years of the study, there was one cardiac arrest in an athlete. This occurred in an athlete with an anomalous right coronary artery who had successfully passed screening. Fuller et al. reason that including electrocardiography in the evaluation of high school athletes increases the detection of cardiac abnormalities. An alternative interpretation is that sphygmomanometry and auscultation alone could have detected most important abnormalities, and that the ECG only increases the detection of asymptomatic abnormalities unlikely to be of major significance.

Because HCM is the predominant cause of exercise-related sudden death in young athletes, other physicians have reasoned that echocardiography should be included routinely in the preparticipation screening of all young athletes (51). Italian investigators have been among the more enthusiastic supporters of this approach (39). Italy has had a national law since 1971 requiring athletes to undergo an examination that includes a medical history, physical examination, ECG, and step test. Athletes with abnormal findings are referred for other testing, including a 24-hour ECG recording, an echocardiogram, and a formal exercise test. This program has screened 33,735

athletes and referred 3,016 for echocardiography. Of the referred athletes, 621 were disqualified from competition—58.7% because of cardiac issues, including 22 athletes with HCM. Four disqualified athletes died over 8.2 ± 5.0 years (mean ± standard deviation) of follow-up. None of the 22 athletes with HCM died. A total of 49 nondisqualified athletes died, yielding an annual death rate of 1 per 62,500 athletes. The authors compared the frequency of HCM as a cause of exercise deaths in the United States and in Italy and concluded that the low prevalence of HCM among their athletes who died was most likely a result of the screening program.

Several problems limit the widespread application of these results. The prevalence of HCM in the Italian athletes is low. Only 0.06% of the athletes had this diagnosis, whereas the expected prevalence in a sample of healthy young Americans is 0.20% (52). Only 4 of 365 athletes who were excluded from participation in sports died of a cardiac condition. We do not know how these excluded athletes were medically managed, but the death rate is extremely low, which raises the possibility that screening prohibited the sports participation of individuals who were not at great risk for exercise-related sudden death. The annual death rate of 1 per 62,500 athletes is similar to, if not higher than, the death rate of 1 per 133,000 American male athletes who presumably underwent far less screening (37). Consequently, instead of supporting extensive screening, these results actually raise questions about its effectiveness.

Cardiac Examination of Competitive Athletes

The components of the cardiovascular examination are detailed elsewhere in this text, and a consensus statement on the components of the preparticipation cardiac examination has been published (49). The following section emphasizes clinical principles useful when examining athletes as part of a preparticipation examination or when evaluating athletes for suspected cardiac abnormalities.

Preparticipation Screening of Athletes

The preparticipation screening of athletes should include an inquiry about (a) exertional symptoms including chest discomfort, syncope, dyspnea, and fatigue; (b) a history of cardiac murmurs, hypertension or cardiac diagnoses; and (c) a family history of sudden death or of any of the conditions known to be associated with sudden death (49). The physical examination should include brachial artery blood pressure measurement, precordial auscultation with the athlete supine and standing, simultaneous palpation of the radial and femoral pulses to exclude coarctation, and an assessment for stigmata of Marfan syndrome.

Examining Athletes for Suspected Disease

The examination of athletes for suspected cardiac disease should be considerably more detailed than the preparticipation examination. Even with modern diagnostic techniques, the cardiac evaluation remains an important part of evaluating athletes. The severity of valvular lesions, for example, can be over- or underestimated by echocardiography, cardiac catheterization, and the physical examination. The best decisions are made when the results of several examination techniques are compared for agreement or discrepancies and the cardiologist does not rely on clinical, echocardiographic, or catheterization data alone. We have seen multiple athletes with clinical symptoms and physical examination findings of severe aortic stenosis that were not repaired because the catheterization data did not indicate a “critical” valve area. Mild, moderate, and severe aortic stenosis are classified as a calculated aortic valve area >1.5 cm^2, 1.0 to 1.5 cm^2, and <1.0 cm^2, respectively, but these values are not normalized for body surface area (53) and may severely underestimate the severity of the stenosis in large individuals.

Someone trained to avoid the digit selection and rounding to tens that are common in most blood pressure “determinations” should measure blood pressure in both arms. The average systolic pressure is several millimeters higher in the right arm, probably because of the more direct course of the pulse wave to the innominate and right subclavian arteries. A systolic pressure >15 mm higher in the right arm, if associated with a systolic ejection murmur, suggests supravalvular aortic stenosis (54). A widened pulse pressure >40 mm Hg suggests a regurgitant murmur and should prompt auscultation for AI.

Elevated blood pressure in a young athlete requires simultaneous palpation of the radial and femoral pulses to exclude a radial/femoral pulse delay suggestive of aortic coarctation. It is often incorrectly assumed that the mere presence of a femoral pulse excludes coarctation, but some patients can reconstitute a palpable femoral pulse via collaterals. In these patients, it is the delayed impulse between the radial or brachial and femoral pulse that suggests the diagnosis (54).

Palpating the carotid pulse is an important maneuver in athletes because aortic stenosis remains a frequent, easily identified cause of sudden cardiac death. A carotid pulse that is low volume, has a slow upstroke, or is difficult to locate should increase suspicion of important aortic stenosis.

During cardiac auscultation, the examiner should ignore any obvious murmur and proceed with a sequential systematic examination of the heart sounds, possible gallops and clicks, diastolic murmurs, and, finally, systolic murmurs. The intensity of the first heart sound (S_1) is partly determined by the degree of mitral and tricuspid leaflet separation at the onset of ventricular contraction. S_1 is generally soft in well-trained athletes because heart rate is slow, lengthening diastole and allowing approximation of the mitral leaflets. If the mitral leaflets are widely separated to accommodate delayed ventricular filling, such as with mitral stenosis, the valve leaflets travel farther at the onset of systole and S_1 is loud. If the leaflets have been partially closed by the regurgitant jet of AI, S_1 is soft. AI and isolated mitral stenosis are notoriously difficult to hear and often require special maneuvers. The intensity of S_1 helps indicate when these additional maneuvers are required.

The second heart sound (S_2) is produced by closure of the aortic valves followed by the pulmonic valves. During inspiration, filling of the right ventricle is augmented. The larger volume of blood in the right ventricle shifts the intraventricular septum leftward, compromises LV filling, and reduces the LV stroke volume (55). This process hastens aortic closure so that the aortic valve closes earlier in the cardiac cycle during inspiration. On the right side, the larger right ventricular volume delays pulmonic valve closure. The earlier aortic closure and the delayed pulmonic closure increase the splitting of S_2 during inspiration. This process is best appreciated when the patient is in the seated position. In the supine position, venous return from the legs can nearly maximize right ventricular filling so that any additional increase in the splitting of S_2 is difficult to detect. This is especially true in endurance athletes, whose plasma volume can average 800 mL larger than comparison subjects (56). In the supine position, part of this increased plasma volume shifts to the central circulation. During the expiratory phase of the cardiac cycle, aortic and pulmonic closure occurs almost simultaneously, and S_2 should be single or nearly so. If there is an intracardiac connection between the right and left sides of the heart, such as an atrial septal defect (ASD), there is no or little differential in right and left cardiac filling during respiration. Right ventricular filling is also increased from left to right intracardiac shunting, which increases the right ventricular stroke volume. S_2, therefore, is often widely split, does not move during respiration, and fails to close during expiration. Several clinical characteristics of ASDs are also found in the athletic heart syndrome, including a systolic murmur similar to the benign pulmonic flow murmur common in athletes and right ventricular conduction delay on the ECG. The behavior of S_2 is useful for distinguishing an ASD from the athletic heart syndrome.

The gallops of the third and fourth heart sounds are common in athletes and are of no importance unless the gallops are loud or associated with other abnormalities.

The initial auscultatory examination of the athlete is performed with the athlete seated. This reduces the chance of producing a flow murmur, facilitates hearing AI, and maximizes the splitting of S_2. The upright position reduces ventricular volume and increases the chance of detecting a murmur in obstructive HCM. Auscultation should be repeated with the athlete in the supine and left-lateral positions. If there is any suspicion of HCM, the athlete should also be examined standing and squatting. Squatting increases ventricular afterload, which decreases the murmur of obstructive HCM, whereas standing often increases the murmur if obstruction is present.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Our perspective on the athletic heart syndrome is indeed personal. One of us (P. D. T.) started training for competitive distance running events at age 12 and ultimately qualified for the 1972 U.S. Olympic Marathon Trials as a medical student. However, during the first year of medical school, he had a murmur detected during a demonstration of cardiac auscultation. His subsequent ECG showed marked LV hypertrophy and early repolarization changes, prompting an interest in cardiology and the medical problems of endurance athletes. The other author (N. A. M. E. III) developed his interest in athletic heart syndrome in part from his experiences as a secondary school and collegiate athlete. We have had the privilege of providing advice and medical care to hundreds of competitive athletes, including two medalists in the Olympic Marathon. The opportunity to combine our personal interest in athletics with our professions as cardiologists has enriched our academic careers.

In evaluating athletes for cardiac abnormalities, we make a strong distinction between abnormalities discovered during screening examinations and those discovered during the evaluation of symptoms. Most screening examinations do not detect real disease, but they do detect a high frequency of normal variants common in young, healthy subjects and part of the athletic heart syndrome. In our experience, physicians frequently overreact to mild abnormalities detected during screening because of legal concerns and the lack of appreciation for the magnitude of changes that can be produced by extreme endurance exercise.

On the other hand, symptomatic athletes require a thorough examination. We are repeatedly impressed with the number of well-known athletes who die during exercise after having presented with symptoms that were ignored or inadequately evaluated. Excluding important cardiac disease in symptomatic athletes may be the most efficient way to prevent exercise-related complications.

In evaluating symptoms, it is extremely important to evaluate any possible cardiovascular disease in the context of the athlete’s total physical and psychological

situation. Many young, competitive athletes face enormous pressure from coaches, parents, and peers. Failure to achieve the desired level of success is extremely stressful on competitors at any age. Young athletes who present with fainting, for example, may be simply seeking a medical way out of a difficult, stressful situation. It is easier to claim a medical reason for failure than to simply not be good enough. We refer to this condition as *the athletic swoon syndrome*. Typically, this condition occurs in a young athlete in an individual sport who competes well when winning but collapses dramatically when losing, often within sight of the finish line. We do not mean to minimize the importance of this problem. The athlete often needs reassurance, both medically and personally, to place winning and losing in a more healthy perspective. Athletic swoon syndrome must be differentiated from true exercise-induced syncope and long-QT syndrome. True exercise-induced syncope is a threatening symptom associated with important cardiac disease, and patients with long-QT syndrome are occasionally misdiagnosed as having hysterical syncope (57).

We strongly recommend that individuals who serve as trainers and coaches or who officiate at sporting events should learn and update yearly their cardiopulmonary resuscitation skills. We also recommend that automatic defibrillators be available in areas where athletes train and compete. Coaches and officials are often present when athletes collapse. If properly trained in resuscitation and the use of automatic defibrillators, coaches and trainers may be able to resuscitate potential victims of exercise-related sudden death. We believe that competency in these skills should be a prerequisite for physical educators, coaches, and sports officials.

THE FUTURE

The future of research and treatment of athletic heart syndrome, as with many aspects of medicine, will be greatly influenced by the revolution in genetic medicine. Molecular biologic approaches have already led to an understanding of the genetic basis for a number of cardiovascular conditions associated with cardiovascular complications during exercise. The genetic basis for HCM, arrhythmogenic right ventricular cardiomyopathy and the closely related Naxos disease, congenital long-QT syndromes, idiopathic ventricular fibrillation, familial atrial fibrillation, and familial dilated cardiomyopathy have all been partially elucidated. There will be an ongoing evolution of molecular biologic techniques and their application to the prediction, prevention, and treatment of cardiovascular disease. We foresee at least three ways in which this evolution may influence the cardiac care of athletes.

First, genetics will likely be used to predict which individuals with a disease phenotype are at risk for an exercise-related complication. HCM is the leading cause of exercise-related deaths among American athletes, and those with this condition are routinely restricted from athletic competition. There are reports, however, of athletes who have had successful athletic careers despite presence of the disease (58). Among the nonathletic population with HCM, those genetic mutations associated with a change in the electrical charge of their encoded amino acid in the myosin heavy chain appear to be associated with the greatest cardiac risk (59). Consequently, it may eventually be possible to predict by genetic analysis which athletes are or are not at risk of exercise-related events. Before such techniques can be used clinically, however, there will need to be widespread availability of the testing methods that are now available only for research, as well as careful clinical studies to determine the ability of genetic analysis to predict prognosis.

Second, genetics will be increasingly used to diagnose disease and may ultimately have a role in the preparticipation screening of athletes. This possibility is illustrated by the case report of a physically active 19-year-old woman who died after a near drowning. Molecular genetic screening of a sample of the deceased's myocardium demonstrated a novel genetic mutation of the long-QT 1 locus. The woman's 18-year-old sister had a similar mutation and was counseled about the risks of strenuous exercise, as well as the potential benefits of beta-adrenergic blockage (44).

Third, genetic analysis may help differentiate disease from normal physiologic adaptations to physical training. Some athletes appear to experience especially large changes in cardiac dimensions with endurance training. This response is influenced by genetic variants. The angiotensin-converting enzyme gene has two common variants. One variant, referred to as the *D*, or *deletion allele*, has a 287–base pair deletion and is associated with higher angiotensin-converting enzyme blood levels than the I or insertion allele. Among military recruits subjected to 10 weeks of intense physical training, echocardiographic changes in LV mass and ECG evidence of LV hypertrophy were greatest in individuals with the D allele (60). Additional genetic factors influencing the cardiac response to exercise training will undoubtedly be found. Knowledge of such variants may ultimately help in separating athletes with an excessive physiologic response to training from individuals with HCM.

OVERVIEW

Among young people, trauma is the most common cause of death, with cardiovascular mortality being the major contributor. Patients with injury to the thorax, blunt or penetrating, should be transferred rapidly to a trauma center for fast and expert surgical evaluation. In unstable patients, echocardiography helps to identify critical injury and facilitates early surgical exploration, which can be lifesaving. In more stable patients, the goal of evaluation is to rule out significant occult cardiac and thoracic great vessel injury. Echocardiography, computed tomographic (CT) scan, thoracoscopy, and magnetic resonance imaging (MRI) can make accurate diagnosis of these injuries. Although normal electrocardiography (ECG) helps to identify low-risk patients with blunt cardiac injuries, the significance of abnormal ECG and cardiac enzyme elevation in this setting remains unclear.

INTRODUCTION

Trauma is a leading cause of death for young adults in the United States (1), with thoracic trauma accounting for 30% to 50% of 150,000 total deaths from trauma occurring annually (2,3 and 4). The heart and thoracic great vessels are commonly involved in blunt and penetrating trauma. Most serious injuries to these vital organs are rapidly fatal. Therefore, fast transport of the patients to trauma centers, rapid recognition of injury, and expeditious expert treatment are essential for better survival.

INJURY TO THE HEART

Classification of Cardiac Injury

Physical trauma to the heart can be penetrating or blunt. A penetrating injury results when a foreign object enters the body and pierces the heart. Blunt injury, on the other hand, results from physical forces acting externally on the body. Iatrogenic injuries to the heart and great vessels from invasive procedures are not uncommon. Electrical and radiation injury are other uncommon mechanisms of cardiovascular trauma.

Penetrating Cardiac Injury

Historical Perspective

Penetrating cardiac injury has been well-recognized for centuries, with earliest descriptions by Homer in *The Iliad* (5). Beck has aptly divided the history of cardiac trauma into three historical periods (6). First is the period of mysticism, when cardiac wounds were thought to be necessarily fatal. In this period, even scholars such as Aristotle thought that “[t]he heart alone of all the viscera cannot withstand serious injury. This is to be expected because when the main source of strength (the heart) is destroyed there is no aid that can be brought to the other organs which depend on it.” This era of pessimism extended to the seventeenth century, followed by a period of observation and experimentation. In 1761, Morgagni (7) noted that blood in the pericardial sac could lead to compression of the heart. In 1810, Larrey (8) performed the first drainage of pericardium, but the patient died of suppurative pericarditis. Fischer (9), in 1868, reported pericardial drainage after injury in 452 cases, with 10% survival. But, even in this era, there was serious skepticism about the therapy. One of the prominent surgeons of this time, Billroth, stated, “The surgeon who should attempt to suture a wound of heart would lose respect of his colleagues” and “Let no man dare to operate on the heart” (10). The third era started when Block, in 1882, showed in the rabbit model of heart injury that successful suturing of cardiac wound was feasible (6). In 1896, for the first time in a human, Cappelen repaired the left ventricle and left anterior descending artery, but the patient did not survive. Rehn (11), at approximately the same time, is credited with the first right ventricular repair in which the patient survived. In 1902, Hill (12), of Montgomery, Alabama, became the first American surgeon to suture a myocardial injury, in a 13-year-old boy by the flickering lights of kerosene lamps on a kitchen table. Two other surgeons had first repaired the pericardium in the United States approximately 10 years before Hill, but their work was not recognized until later (13,14).

Anatomic Considerations

The classic precordium is defined as an area of chest bounded by sternal notch superiorly, xyphoid process inferiorly, and nipples laterally. Most stab wounds injuring the heart enter through the classic precordium. The majority of gunshot wounds strike the heart without entering this zone. The relative frequency of cardiac chamber involvement depends on the anatomic location of the chamber as well as the type of penetration. The right ventricle, with its maximum anterior exposure, is at the greatest risk for injury. In a series of penetrating wounds to the heart, the right ventricle was involved 42% of the time, left ventricle 33%, left atrium 6%, and right atrium 15% (15). Pericardial reflections are important to recognize, as they are positioned on portions of ascending aorta, portions of main pulmonary artery, portions of right and left pulmonary arteries, portions of pulmonary veins, and portions of superior and inferior vena cava. This is important because even trivial injuries to the intrapericardial portions of these vessels can result in cardiac tamponade. Typically, wounds to the base of the heart are rapidly fatal due to involvement of the aortic root and coronary arteries. However, stab wounds to the root of the aorta are extremely uncommon, as the sternum protects this portion.

Etiology

Penetrating wounds to the heart commonly result from puncture wounds, knife wounds, and gunshot wounds (16). Puncture wounds are caused by ice picks, needles, or pellets from an air gun or a distant shotgun, typically involving a single chamber. Knife injuries also frequently involve a single chamber, producing a slit-like defect. Small-caliber gunshot wounds can cause multiple-chamber perforations along with injuries to the great vessels. In contrast, large-caliber gunshot wounds result in fatal gaping cardiac defects.

Pathophysiology

The size of pericardial defect and the severity of cardiac injury determine the clinical presentation and subsequent outcome. If the defect in the pericardium is small,

blood clot may seal this defect. If the bleeding from the heart or proximal vessels continues in the closed pericardial sac, intrapericardial pressure rapidly increases. Rapid accumulation of blood, even when small (100 mL or less), leads to sufficient rise in intrapericardial pressure to cause tamponade. On the other hand, if the defect in the pericardium is large, there is rapid exsanguination and death. The number of cardiac structures involved determines the severity of cardiac injury. Multiple-chamber injury is usually fatal. Involvement of one or more cardiac valves with damage to the leaflets, annulus, chordae, or papillary muscle can lead to hemodynamic compromise (17). Conduction system damage (18) and coronary artery injury, although less common than in blunt trauma, has been reported with penetrating injury (19).

Clinical Profile

Patients presenting to the emergency room (ER) with penetrating cardiac injury may be dead on arrival, alive but hemodynamically compromised, or hemodynamically stable. A few patients that are dead on arrival can be revived with resuscitative thoracotomy in the ER. Identifying this small subgroup of patients is important to conserve resources because the yield of indiscriminate resuscitative thoracotomy is very low (less than 5%). Patients who show some signs of life on transport have up to a 30% chance of successful resuscitation (20). Patients with stab wounds compared with gunshot wounds and patients presenting with cardiac tamponade have a better chance of survival.

In the second group of patients with hemodynamic compromise, it is important to recognize cardiac tamponade. Dyspnea, diaphoresis, agitation, confusion, apathy, or a feeling of strangling oppression should alert the physician to look for cardiac tamponade (21). Only 10% to 40% of trauma victims with tamponade present with the Beck's triad of hypotension, jugular distention, and muffled heart sounds (22). Neck vein distention may be absent due to accompanying hypovolemia. Pulsus paradoxus is neither sensitive nor specific for tamponade in this situation.

The third, more stable group should be examined in detail after primary assessment of airway, breathing, and circulation. The entry site is especially important with stab wounds. An entrance wound high on the right side is likely to involve the aorta and right atrium. Lower right and left parasternal wounds involve the right ventricle, whereas inferolateral left parasternal wounds typically signify left ventricle involvement (23). In a gunshot wound, the entry site may be deceptive. If the entry site involves the "danger zone" of Suer and Mordax, which includes the precordium, epigastrium, and superior mediastinum, cardiac injury is typically present (15). Trajectory of the gunshot should also be determined. If the trajectory suggests juxtacardiac passage, the physician should keep a high index of suspicion for cardiac injury.

Management

Rapid transport of the patient to the trauma center is essential for better outcome. The so-called scoop and run policy, without an attempt to stabilize the patient in the field, is the best approach (24). Even roadside thoracotomy done by medical teams flown to the scene is without benefit (25). Intubation is beneficial for patients with cardiac arrest or hemodynamic instability (26). Closed-chest cardiopulmonary resuscitation (CPR) is not only ineffective but also contraindicated if an impaling weapon is present. An intravenous line can be started en route to the hospital, although the role of intravenous fluids is controversial (27).

For patients who are dead on arrival, a diagnostic and therapeutic procedure is an ER thoracotomy with a goal to relieve tamponade, control hemorrhage, and restore cardiac function (28). After resuscitation, the patient should be rapidly transferred to the operating room for definitive surgery.

In patients with hemodynamic compromise, rapid operating room thoracotomy by a cardiothoracic trauma surgeon appears to be the most effective. The role of ER thoracotomy has been a constant source of debate but it should be restricted to patients who arrive in a moribund state or who rapidly deteriorate after arrival (29,30,31 and 32). ER thoracotomy with use of staples to control cardiac bleeding and to minimize risk of personal contamination from a needle stick remains controversial (33). Staples to the heart can enlarge the wound and at times are difficult to remove during definitive surgery. Definitive surgical treatment is detailed elsewhere, but the general principles are as follows (34). Myocardial rupture is repaired in all cases. With distal coronary artery injury, ligation is sufficient. Definitive valve or shunt surgery is usually deferred until later. Approach to a foreign body is variable, but most commonly only those projecting into cavities or involving the left ventricle are removed.

In hemodynamically stable patients or those stabilized with volume, transthoracic echocardiography (TTE) should be performed rapidly to diagnose pericardial effusion (PE). PE, however small, serves as a marker for cardiac penetration (35). When compared prospectively with a surgical gold standard (subxyphoid window), echocardiography has high specificity and sensitivity in diagnosing PE (36). It has rapidly become a modality of choice to assess patients with thoracic trauma (37). However, in the presence of hemothorax, its sensitivity is significantly decreased (38). Transesophageal echocardiography (TEE) can overcome this limitation of TTE, but in many patients it either is not feasible due to other injuries or is not expeditiously available and hence is of limited usefulness (39,40). Subxyphoid pericardial window was the traditional way to rule out PE in patients with suspected penetrating wound to the heart. It is best performed in the operating room under light general anesthesia. Although it is a safe procedure and provides a definitive diagnosis of hemopericardium (41,42,43 and 44), it is a surgical procedure that typically results in 75% to 80% negative explorations (43). The availability of TTE in the ER has significantly reduced the frequency of this operation, which is now used only in few difficult situations to complement echocardiography (45). Thoracoscopic pericardial window is another alternative that has been shown to be safe and effective in diagnosing cardiac injury (46). However, echocardiography has other advantages in that it is a reliable tool to localize foreign bodies (Fig. 38.1) (47,48) and helps in diagnosing and monitoring structural abnormalities such as valvular regurgitations and shunts (Fig. 38.2, Fig. 38.3, Fig. 38.4, Fig. 38.5, Fig. 38.6, and Fig. 38.7) (49). Therefore, availability of TTE in the ER is shown to decrease time to definitive therapy, leading to a better outcome (50,51).

FIGURE 38.1 A transthoracic echocardiogram, a parasternal long-axis view, demonstrating a shotgun pellet (*white arrow*) in the distal posterior wall of the left ventricle. The pellet was identified years after the injury, and the patient was asymptomatic. Note how the pellet casts an acoustic shadow (*black arrow*). AO, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle. (Courtesy of Dr. Carlos Antonio Da Mota Silveira and Dr. Roberto Pereira, Pernambuco University, Brazil.)

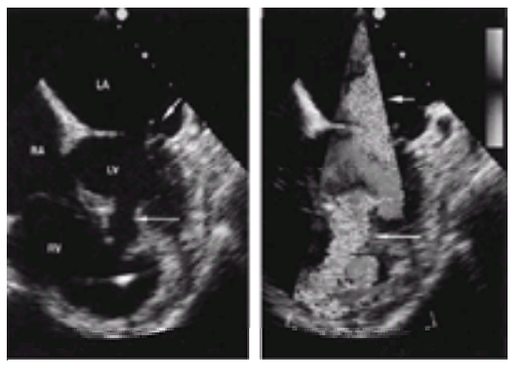

FIGURE 38.2 A transesophageal echocardiogram demonstrating a traumatic ventricular septal defect (*long arrow*) and mitral regurgitation (*short arrow*) from a gunshot wound. Swan-Ganz catheter is seen in the right ventricle (RV). LA, left atrium; LV, left ventricle; RA, right atrium. (From the DICOM demonstration DISC 96.)

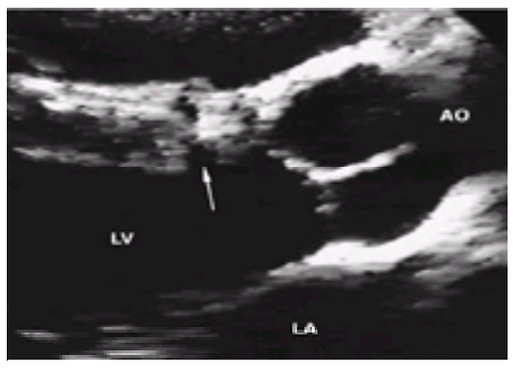

FIGURE 38.3 A transthoracic echocardiogram, a parasternal long-axis view, showing an interventricular septal defect (*arrow*) from a stab wound. This was successfully repaired. AO, aorta; LA, left atrium; LV, left ventricle. (Courtesy of Dr. Carlos Antonio Da Mota Silveira and Dr. Roberto Pereira, Pernambuco University, Brazil.)

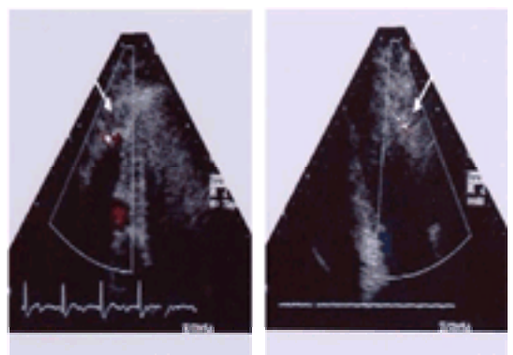

FIGURE 38.4 Patient with stab wound to the chest and right ventricle perforation. Perforation was repaired but on follow-up echocardiogram there was a very small pseudoaneurysm with some flow (*arrows*). Patient was conservatively managed without any complications.

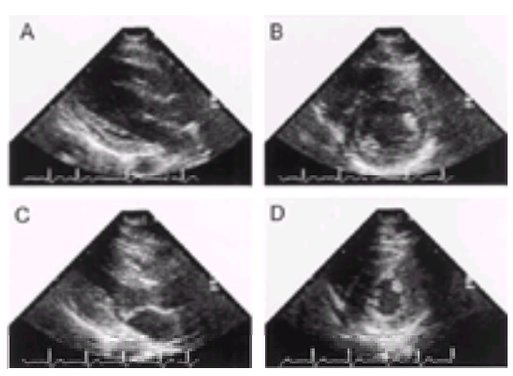

FIGURE 38.5 Patient with pneumatic staple gun injury to chest. Emergent echo in the emergency room initially did not demonstrate any pericardial effusion **(A,B)**, but while echocardiography was being performed (within 5 minutes), pericardial fluid accumulated **(C,D)**. (Courtesy of Dr. Riyad Karmy-Jones and Eric Sisk, University of Washington, Seattle.)

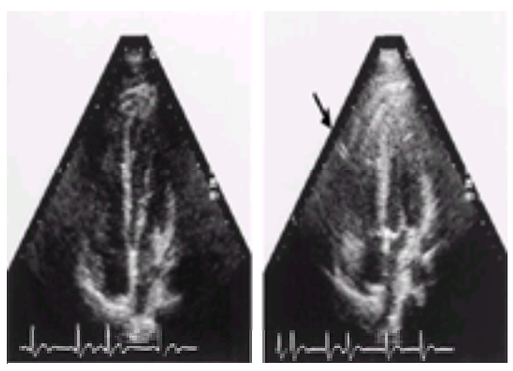

FIGURE 38.6 In the same patient, apical view showing increasing blood in the pericardium with a presence of staple in pericardium (*arrow*). Patient underwent emergent surgery. The needle was removed, and the right ventricle was successfully repaired.

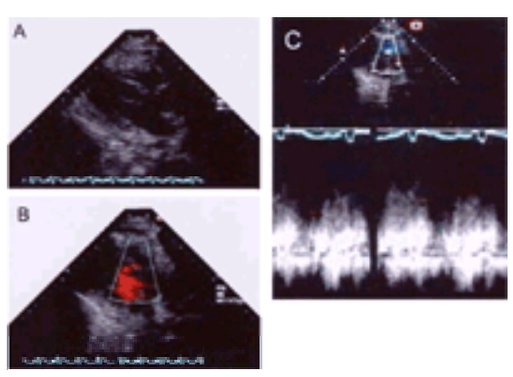

FIGURE 38.7 Patient with stab wound to chest with transsection of mid–left anterior descending artery (LAD) at the bifurcation and injury to the left ventricle. The patient had an emergency-room thoracotomy with ligation of LAD and diagonal branch. The left ventricle was successfully repaired in the operating room, and an intraaortic balloon pump was placed. There was mid and distal anteroseptal wall motion abnormality **(A)**. Abnormal flow was detected from the interventricular septum into the right ventricle **(B,C)**, which was diagnosed to be a coronary fistula (via a septal perforator) to right ventricular fistula by coronary angiography. (Courtesy of Dr. Riyad Karmy-Jones and Eric Sisk, University of Washington, Seattle.)

It is important to note that the ECG is not helpful in evaluating penetrating injury. It inconsistently shows injury pattern and if negative does not rule out significant injury (38,52). The chest x-ray may help by identifying patients with hemothorax who are difficult to image with ultrasound. But, other findings, such as an enlarged cardiac shadow or pneumopericardium, are infrequently present (53). Pericardiocentesis is not indicated for diagnosis in stable patients and can actually be harmful (54).

Prognosis

Various indices to categorize patients with penetrating cardiac trauma are available. Trauma indices describing anatomic severity, such as the Penetrating Cardiac Trauma Index, the Penetrating Thoracic Trauma Index, the Penetrating Trauma Index, the Cardiovascular-Respiratory Score component of trauma score, and the Injury Severity Score, are good predictors of outcome. However, the general condition of the patient plays a significant role in determining the prognosis of cardiac trauma. For this reason, a general condition index such as the Physiologic Index can be combined with anatomic indices to better categorize a patient. One such method is shown in *e*Table 38.0.1 (55). A unified index to objectively compare results among different institutions is not available (56).

***e*TABLE 38.0.1** INJURY SEVERITY OF PENETRATING CARDIAC INJURY

Anatomic: organ risk factor × injury severity estimate	
Organ risk factor	5
Injury severity estimate	
Tangential, involving pericardium or wall up to but not through the endocardium	1
Single right-sided chamber	2
Comminuted tears of a single chamber	3
Multiple chambers, isolated left atrial, or ventricular injury	4
Coronary vessel injury or major intracardiac defects	5
Physiologic (physiologic index)	
Stable	5
Systolic blood pressure <80 mm Hg, conscious	10
Semiconscious, thready pulse, gasping respiration, no measurable blood pressure	15
Unconscious, no vital signs, no respiratory efforts, no physical activity but had signs of life on transit to hospital	20

Patients who reach the operating room without requiring ER thoracotomy have a favorable outcome (57,58). Overall, patients with stab wounds have a better prognosis than those with gunshot wounds (59). Single-chamber injury to the heart with hemodynamic stability, shorter duration of CPR before arriving at the hospital, successful intubation, and younger age are all factors associated with better outcome (60). Presence of pericardial tamponade is thought to be a favorable predictor, as it possibly prevents exsanguination (61). Various late sequelae have been reported, including aneurysm formation, shunts, fistulas, and valvular regurgitation (*e*Table 38.0.2) (62,63). Surveillance for these anatomic sequelae with echocardiography is recommended (*e*Fig. 38.7.1) (18,64).

Video 38.1 Aortography showing an aneurysm of the ascending aorta with 3+ aortic regurgitation. The aortogram in this patient with cystic medial necrosis shows a maximum dimension of 5.4 cm. The dilation is confined to the ascending aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

***e*TABLE 38.0.2** LATE SEQUELAE OF PENETRATING CARDIAC INJURY

Pericardium	Constrictive pericarditis
Myocardium	Aneurysm
	Pseudoaneurysm
	Shunts (arterial septal defect, ventricular septal defect)
Coronary arteries	Fistula
	Aneurysm
	Pseudoaneurysm
Valves	Regurgitation
Conduction system	Conduction block
	Arrhythmia

Blunt Cardiac Injury

In civilian life, the most common cause of blunt cardiac injury is a motor vehicular collision. Falls from heights, falling objects, direct trauma from assault, and blast injury are other less common causes. Injury patterns in motor vehicular collision are governed by the location of the individual in the vehicle and the direction of impact. In a front impact, abrupt deceleration against the steering wheel is the most common cause of cardiovascular trauma. Side impact generates a high shearing force, more commonly causing an aortic injury. Seat belts and air bags also play a major role in determining the injury patterns. For unrestrained drivers, cardiac and aortic injury each occurs in approximately 20% of cases (65). Even in restrained drivers, significant thoracic injuries can still occur from contact with the steering wheel and from deceleration, but the number of deaths from thoracic injuries is significantly lower (66). The air bag has been associated with rupture of the right atrium (67).

Myocardial Contusion

Historical Perspective

Myocardial contusion was first noted by Burch in 1676 in an 8-year-old boy. In 1859, Schnabel noted hematoma with right atrial tear in a 49-year-old man who died several hours after the blunt injury. In 1954 Burchell aptly observed “and always with heart contusion, arise both doubt and much confusion” (68). The confusion is still prevalent in literature, as myocardial contusion is a pathologic diagnosis without an accurate clinical counterpart (69). It implies a bruise to a segment of myocardium that reveals subepicardial and intramyocardial hemorrhage, disruption of myocardial fibers, cellular infiltration, and interstitial edema on histologic examination. The definition by some includes the presence of myocardial necrosis with or without bleeding into the myocardium (70). In strict pathologic terms, contusion should not include necrosis as its integral part. Therefore, *myocardial contusion* is considered a less favorable term to describe this injury pattern (71). *Commotio cordis* is a term used to describe fatal cardiac arrest without detectable structural damage to the heart as a result of blunt impact to chest (72). Various mechanisms, including ventricular fibrillation, have been proposed to explain this phenomenon (73).

Anatomic Considerations

The anterior right ventricular wall is most commonly involved in myocardial contusion. The anterior interventricular septum and anterior-apical left ventricle are next in

frequency. Blunt injury can also damage the conduction system of the heart, manifesting as a right bundle branch block (74).

Pathophysiology

Autopsy studies of patients who died of blunt cardiac injury show subendocardial and interstitial hemorrhage, large surrounding areas of focal myocardial edema, myofibrillar degeneration, myocytolysis, and infiltration with polymorphonuclear cells. In essence, it resembles myocardial infarction (MI). The few distinguishing features of blunt injury are the more abrupt demarcation between normal and abnormal, more hemorrhage, and more frequent cellular laceration (75,76). Functionally, these changes present with a decrease in myocardial contractility and cardiac output (77). Right ventricular ejection fraction is more commonly decreased, probably due to its anterior location and the acutely altered loading condition of the ventricle (78). At times, patients with mild injury present with regional wall motion abnormalities but negative chemical markers of myocardial necrosis. The term *cardiac concussion* has been used to describe this. The mechanism is not known, but local factors that impair cardiac contractility, such as hematoma and focal inflammation, are considered to be responsible. These patients have excellent short-and long-term prognoses.

Clinical Profile

Cardiac contusion presents with a wide spectrum of severity. Patients with contusion can be hemodynamically unstable or stable. Pericardial tamponade and valvular regurgitation are important cardiac reasons for decompensation. Coronary artery injury, most typically right coronary artery injury, can present with acute MI. Arrhythmias are not infrequent, but their significance remains unclear. Atrial fibrillation, but not premature ventricular contractions and nonsustained ventricular tachycardia, has been associated with a worse outcome (77).

Hemodynamically unstable patients should be evaluated for the cardiac and noncardiac causes of hypotension. Noncardiac causes include hypovolemia and associated vascular injuries. Fluid challenge helps to identify significant hypovolemia. For vascular injuries, blood pressure and pulses in both upper and lower extremities should be carefully checked for discrepancies. The cardiac cause of hypotension in this group is pericardial tamponade. Clinical signs of pericardial tamponade should be evaluated carefully. Muffled heart sounds and pulsus paradoxus are not specific for tamponade and are absent in a significant number of patients. Neck veins may not be distended due to associated bleeding and hypovolemia. Other mechanical causes of cardiac decompensation are valvular regurgitation and shunts. Any murmur, especially pansystolic or continuous, should point to one of these complications. Left or right ventricular failure can lead to hypotension and would manifest with a third heart sound, rales, and increased jugular venous pressure. Coronary artery injury presents with chest pain similar to MI, but in the presence of trauma it may be difficult to ascertain the quality of chest pain. In hemodynamically stable patients, special attention should be given to complaints of chest pain, new murmur, early signs of pericardial tamponade, and heart failure.

Management

For hemodynamically unstable patients arriving after blunt chest trauma, echocardiography should be performed quickly. If echocardiography suggests a mechanical cause for hypotension, rapid appropriate surgical correction is mandatory. If there is severe ventricular dysfunction without myocardial rupture or PE, right heart catheterization may be useful to manage fluids and inotropes. Intraaortic balloon pump counterpulsation, after ruling out aortic injury, has been effectively used in this situation (79). For the more stable group, various diagnostic tests, including ECG, cardiac enzymes, and other imaging modalities, are available to quantify cardiac damage. The goal of these investigations is to identify patients at risk of immediate and future cardiac complications, but no test is considered a “gold standard.” A normal ECG helps to identify a very low-risk population, but ECG changes are neither specific nor sensitive to identify presence of wall motion abnormalities. Although echocardiography can identify these wall motion abnormalities, its role in management of stable patients after chest trauma has been questioned because the presence of wall motion abnormality does not signify a worse outcome in patients with normal ECG and enzymes (80). Cardiac enzymes, especially creatine kinase (CK) and isoenzyme of creatine kinase with muscle and brain subunits (CK-MB), are difficult to interpret in the presence of other injuries. Elevated levels of troponin T and I, although more specific, do not predict worse late clinical outcomes. The need to measure these enzymes in blunt injury patients is controversial (81,82).

Electrocardiogram. Approximately two-thirds of patients presenting with significant chest trauma have an abnormal ECG (83). Approximately half of these patients have specific ECG changes suggestive of cardiac contusion, which include conduction abnormalities, ST depression or elevation of 1 mm, and T-wave inversion in two consecutive leads (84). However, these criteria are only 47% sensitive and 79% specific in identifying the presence of wall motion abnormalities (85). Even adding right-sided ECG leads does not improve the sensitivity (86). Despite this lack of sensitivity, ECG has a very high negative predictive value for cardiac complications (87,88).

Cardiac Enzymes. Levels of CK and CK-MB are elevated in patients with blunt cardiac trauma. Elevation of CK level in blunt injury is commonly caused by skeletal muscle damage and does not help in diagnosing cardiac injury. Normal CK levels, on the other hand, do not eliminate cardiac damage, as wall motion abnormalities may still be present in two-thirds of patients with normal CK levels (89,90). The small amount of CK-MB released from the heart is diluted in the large amount of CK from other tissues. This can be overcome by use of absolute CK-MB. As CK-MB isoenzyme is found in skeletal muscle, pancreas, lung, colon, liver, stomach, and small bowel, injury to these organs can also cause some elevation of the CK-MB level (91). To improve the specificity of CK-MB, a concentration of more than 200 mg per dL has been used (87). With this high cutoff, sensitivity decreases considerably. Even different CK–to–CK-MB ratios (3% to 8%) for determining myocardial damage have not been very useful (70,92,93). This makes routine use of cardiac enzymes questionable (94).

Cardiac troponin T and I (cTn-T and cTn-I) are contractile proteins unique to cardiac muscle and can be differentiated by immunologic methods from their skeletal-muscle isoforms. These enzyme levels are elevated in a few hours after the onset of myocardial damage and remain increased for several days. There is some experimental evidence that the accuracy of cTn-I in detecting the extent of myocardial injury with contusion is higher compared with cTn-T and CK (95). Although improved specificity of cTn-I and cTn-T compared with conventional markers, the main problem with cTn-I and cTn-T is low sensitivity as well as low predictive values in diagnosing myocardial contusion. cTn-I and cTn-T measurement is currently not an improved method in diagnosing blunt cardiac injury in hemodynamically stable patients. Moreover, there is no association of postmyocardial contusion cell injury and late outcome in these patients when cTn-I and cTn-T and other conventional markers are considered (96,97).

Radionuclear Studies. Technetium pyrophosphate scan can label hydroxyapatite in the infarcted myocardium and can be useful for diagnosis of myocardial necrosis in blunt trauma. Sensitivity to identify nontransmural damage and right ventricular damage is low due to the masking effect of the large left ventricle. Specificity suffers because it cannot distinguish sternal fracture or chest wall injury from right ventricular contusion (98). First-pass biventricular radionuclide angiography with segmental wall motion analysis performed at the bedside can accurately estimate right and left ventricular ejection fraction. This is a sensitive way to diagnose cardiac abnormalities, but the positive predictive value for cardiac events is still low (77). Thallium with single-photon emission CT scan has been used for the diagnosis of myocardial damage, but the right ventricle cannot be adequately studied with this technique (99). Although presence of single-photon emission CT abnormalities is associated with a higher incidence of arrhythmia (100), it is clinically of limited use because abnormal ECG can identify this group of patients (101).

Echocardiography. Contused myocardium is identified by its increased echogenicity, increased end diastolic thickness, and impaired systolic function (102). The most common echocardiographic finding is right ventricular wall motion abnormality with some dilatation (103). However, the presence of wall motion abnormality does not signify a worse outcome if the patient has a normal ECG and enzymes (80). In patients with thoracic wall trauma, TEE is preferred over TTE because it allows a detailed study of the great vessels (84,104,105). However, safety of this procedure in trauma victims is still not well-established (106). Contrast echocardiography has been reported to help in making accurate diagnosis in some difficult cases (107).

Approach to patients with blunt trauma has to be individualized according to hemodynamic stability and other injuries. In a hemodynamically stable patient, if no abnormalities are detected on initial detailed physical examination, ECG, and chest x-ray, the patient can be observed in the ER for 12 hours and then discharged. If the ECG shows nonspecific changes, 24 hours of observation with serial enzyme assay is advisable. If enzymes are negative after the period of observation the patient can be discharged without further investigations. If, on initial ECG, there are specific abnormalities or if the chest x-ray is abnormal, echocardiography should be performed to further assess cardiac injury. If the patient with suspected cardiac contusion has to be operated on for other injuries under general anesthesia, preoperative echocardiography and/or intraoperative invasive monitoring are recommended.

Prognosis

Late complications such as arrhythmia, aneurysm, pseudoaneurysm, heart failure, valvular regurgitation, and shunts have been reported but are rare. Although similarities are drawn between MI and cardiac contusion, there are significant differences that affect the outcome. Typically the trauma victims are younger and in good general health. Also, the underlying cause of myocardial damage (trauma) is episodic and not an ongoing process (atherosclerosis). So, the prognosis in these patients is much better than in those with MI (108).

Myocardial Rupture

Rupture of the cardiac chamber, the most severe form of blunt cardiac injury, is a common finding in the patients with fatal nonpenetrating cardiac trauma (76). The right-sided chambers rupture more frequently than the left-sided chambers. Atria are more commonly involved than the ventricles (76,109). Interventricular septal rupture, an uncommon event, involves the apical part of the muscular septum more than the membranous interventricular septum (110). Interatrial septal rupture occurs rarely (111). Rarely, patients with isolated interventricular septal defect can present late with heart failure and a holosystolic murmur (112). A small muscular interventricular septal defect can be treated expectantly and repaired after 6 to 8 weeks, depending on the size of the shunt and intracardiac pressures. Myocardial rupture results in sudden cardiovascular collapse in most patients (113). On physical examination of rare survivors of free wall rupture, a sound resembling a splashing mill wheel (*bruit de moulin*) has been described. Rapid recognition of cardiac rupture with immediate thoracotomy can be lifesaving (114).

Pericardial Injury

Blunt trauma can lead to pericardial tears along with myocardial tears. These tears occur most commonly on the left side, parallel to the phrenic nerve. Other sites include the diaphragmatic surface of the pericardium, the right pleuropericardium, and the anterior pericardium (112). Irrespective of the site of the tear, cardiac herniation and strangulation can occur (115). With diaphragmatic tear, abdominal viscera can herniate into the pericardial space (116).

With pericardial tear, patients are unstable due to concomitant myocardial tear. Diagnosis is made at the time of thoracotomy. Intrapericardial diaphragmatic hernia presents with epigastric pain, gastric distention, palpitations, and shortness of breath. Gurgling sounds in the chest with muffled heart sounds and air bubbles in the pericardium on chest x-ray help in the diagnosis. Blunt trauma can lead to pericarditis without a tear. Depending on the size of the effusion, cardiac tamponade can develop. Some patients can develop late PE due to the “postpericardiotomy syndrome.”

Pericardial tamponade. Low QRS voltage and electrical alternans are characteristic findings of tamponade.

Patients with hemodynamic instability should undergo thoracotomy. Myocardial tears are repaired, leaving the pericardium open. In the presence of significant hemopericardium, surgical drainage is recommended. With a small effusion, conservative management with echocardiographic follow-up is recommended. Rarely, constrictive pericarditis may develop within 6 months to a year.

Valve Injury

Valves are involved less commonly with blunt injury. Commonly involved valves are the aortic, mitral, and tricuspid, in that order. The pulmonary valve is rarely involved. Many patients have an underlying valvular pathology that predisposes them to rupture. The aortic valve is most vulnerable in the isovolumetric relaxation phase and the mitral valve in the isovolumetric contraction phase. Injury to the tricuspid valve occurs due to a sudden increase in hydrostatic pressure on the right side of the heart from venous compression (117). With blunt trauma, the aortic valve tears at the leading edge of the cusp, more commonly near the commissures (Fig. 38.8). Bioprosthetic valves are particularly at risk (118). Mitral valve injury includes rupture or avulsion of a papillary muscle (most common), rupture of chordae, or, rarely, a tear of the valve leaflets. Tricuspid injury leads to regurgitation from rupture of the anterior papillary muscle, tear in the anterior leaflet, or, rarely, tear of the septal leaflet (119,120 and 121).

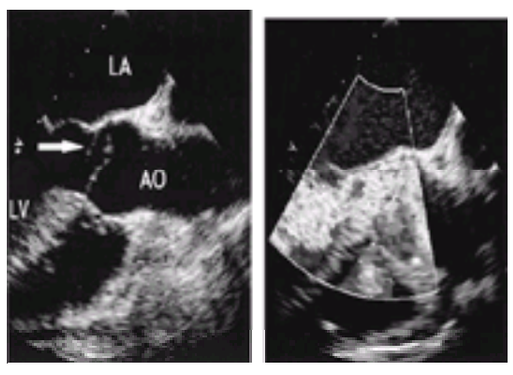

FIGURE 38.8 Aortic valve rupture from blunt injury due to a motor vehicle collision. The intraoperative transthoracic echocardiogram in long axis shows the flail left coronary cusp (*white arrow*) resulting in severe acute aortic regurgitation. AO, aorta; LA, left atrium; LV, left ventricle. (Courtesy of Dr. Ellen Mayer and Dr. Joseph Sabik, The Cleveland Clinic Foundation.)

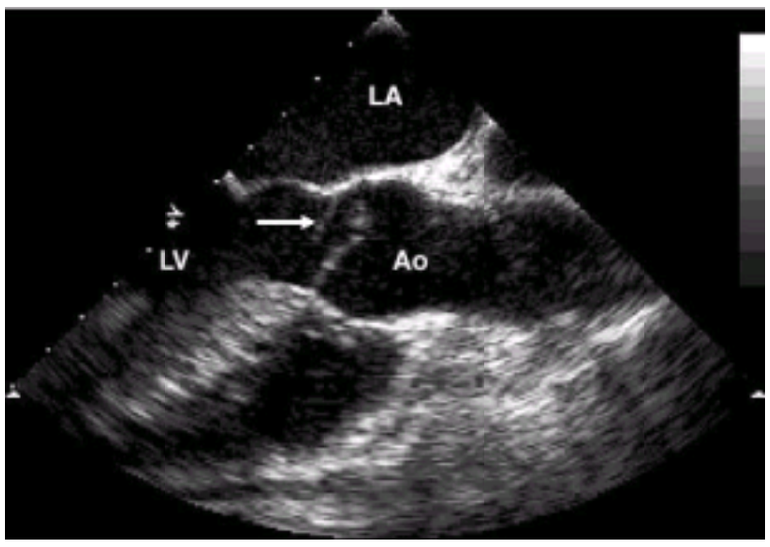
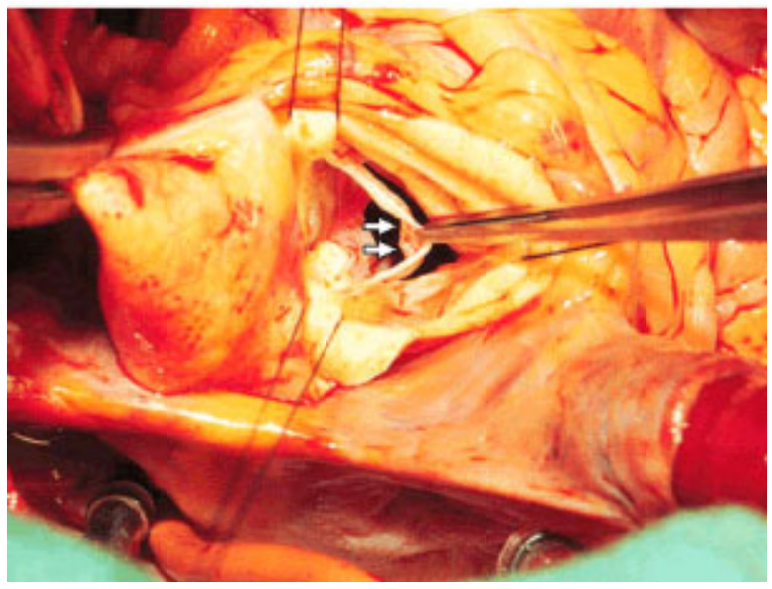


Traumatic left coronary cusp flail (*arrow*) of the aortic valve due to blunt trauma. There was resulting 4+ anteriorly directed aortic insufficiency.



Surgical field demonstrating a ruptured left coronary cusp of an aortic valve (ruptured at leaflet base) in a patient who sustained blunt trauma to the chest wall. The free edge of the left cusp is unharmed. The arrows demarcate the tear.

Valvular injuries present with acute regurgitation. Acute aortic regurgitation can present with left ventricular failure without signs of wide pulse pressure. In mitral regurgitation, harsh pansystolic murmur radiating to the base rather than the axilla with an apical systolic thrill can be present (122). Tricuspid regurgitation presents with hypotension and signs of right heart failure. TEE helps to delineate the mechanism and severity of valvular regurgitation. Acute severe valvular regurgitation requires surgical reconstruction (119). For mild to moderate regurgitation, follow-up with rest or stress echocardiography is recommended (123). Endocarditis prophylaxis is recommended in all cases.

Coronary Artery Injury

Coronary artery injury is rare in patients who die of blunt injury (76,124). If a patient presents with clinical signs of acute MI, cardiac catheterization should be considered (125,126). If coronary artery thrombosis is identified, percutaneous intervention or surgery should be considered depending on the clinical situation (127). Posttraumatic arteriovenous and arteriocameral fistulae have been reported.

Electrical Injury

Historical Perspective

In 1750, Benjamin Franklin showed by flying a wired kite during a thunderstorm that electric charge could be passed from the cloud to the primitive accumulator, the Leyden jar. This led to the discovery of the Franklin rod, a device designed to safely conduct atmospheric electricity to earth. Every day, 50,000 lightning bolts are estimated to hit the earth. The flash lasts 0.2 to 1.0 seconds, with an amplitude of 25,000 to 500,000 amp and voltage of more than 1,000 kV. Most of these enter the earth without destruction, and only unprotected people or structures are sometimes involved. In the United States, lightning injuries are more common on the Eastern Seaboard than on the West. Wyoming, due to heavy outdoor activity, has the highest incidence of fatal lightning strikes in the country. Men are more involved with lightning strikes than women (4:1). But, interestingly, when a bolt comes through the telephone system, women are more likely to be the victims (128,129). In the United States, 100 to 300 persons die annually due to lightning injury. Accidental exposure to household alternating current (AC) leads to approximately 1,000 deaths annually in the country (130).

Pathophysiology

There are major differences between injuries from AC and direct current (DC). AC changes the polarity of cells and depolarizes them. This results in acetylcholine release at the neuromuscular junction and subsequently tetanic spasm of the muscles. This leads to prolonged contact with the source, as the flexors of the hand are more powerful than the extensors. The current also causes tetanic spasms of the blood vessels, leading to ischemia in the distal bed. In the heart it causes direct tissue damage with contraction band necrosis. Conduction abnormalities are common, as conduction tissue is sensitive to the AC. The lower domestic frequency (50 Hz in Europe and 60 Hz in the United States) of AC induces ventricular fibrillation. Higher-frequency AC, as used in diathermy, is thought to be relatively safe and causes only local tissue damage. DC causes less direct tissue damage compared with similar-energy AC. DC, as in lightning stroke, can lead to ventricular fibrillation or uniform depolarization of the left ventricle, causing asystole. Sometimes cardiac automaticity can be restored spontaneously after asystole. However, concomitant respiratory arrest may continue, and hypoxic cardiac arrest may occur. The path of AC or DC through the body is also important in determining the severity of injury. Transthoracic current flow (e.g., hand-to-hand pathway) is more likely to be fatal from respiratory and cardiac arrest than a vertical- or straddle-current path (131). However, vertical path can also cause significant myocardial injury due to the direct effect of the current on the heart and due to coronary vasospasm (132,133).

Clinical Profile

Electrical injuries present with ventricular fibrillation, ventricular asystole, conduction system disturbances, transient myocardial ischemia, and myocardial damage. Cardiac arrest can be a primary ventricular fibrillation or secondary to prolonged respiratory center arrest or muscle paralysis. Electrical injury has a predilection for the conduction system for unclear reasons. It presents with sinoatrial or atrioventricular node dysfunction. MI can result from coronary artery spasm because angiography is frequently normal in these patients (130). It presents with increased enzyme levels and wall motion abnormalities. The ECG may show typical ST elevations, and Q waves can develop with evolution. QT prolongation has been noted in patients with electrical injury. This may be due to the direct effect of the current on myocardium or due to indirect effect from injury to the central nervous system.

Management

If the patient is in cardiopulmonary arrest, he or she should be resuscitated with standard advanced cardiac life support protocol. Due to low metabolic rate, survival after prolonged arrest is better in patients with electrical injury, especially from lightning, than from other causes (134). Lightning victims who do not suffer cardiac arrest have an excellent chance of recovery because subsequent arrest is uncommon. Therefore, when multiple victims are struck simultaneously with lightning, usual triage priorities should be reversed. Rescuers should give highest priority to patients in respiratory or cardiac arrest. Patients who regain their vitals after resuscitation have high survival rates (135).

After resuscitation, patients should be monitored for arrhythmia. They may develop significant tachycardia and hypertension due to catecholamine surge that may require beta-blocker therapy. Serial enzymes and echocardiography may help to estimate the extent of myocardial injury. Patients with significant myocardial damage should be monitored closely for complications. Treatment of post-MI complications is similar to that from other causes (136).

After AC shock, if the patients are stable and have a normal ECG, cardiac monitoring is not necessary (137). However, for patients struck by lightning, overnight monitoring is recommended, even if they are stable and have a normal ECG. If admission ECG is not normal (one-third of victims of electrical injury), irrespective of the cause of injury, echocardiographic assessment of left ventricular function and serial CK estimation are indicated (138).

Prognosis

The mortality with lightning injury is 20% to 30% (135). The mortality with domestic AC electrocution is difficult to estimate due to variability in severity of the shock. For every three significant injuries there is approximately one death (139). This amounts to 1,000 annual deaths in the United States (130). ECG abnormalities usually resolve in a few weeks (140). Ventricular dysfunction also improves in most patients (141). Patients tend to have a good long-term prognosis, but they should be monitored periodically for at least 1 year (137).

Radiation Injury

The heart was thought to be resistant to radiation injury in the first half of the twentieth century (142). High-dose radiation was delivered without proper cardiac shielding. Many reports of radiation-induced cardiac abnormalities changed the perception of safety of radiation to the heart. Radiation, when used in the treatment of mediastinal tumors, primarily Hodgkin's and non–Hodgkin's lymphoma, and spinal irradiation can cause cardiac abnormality in as many as 40% of patients (143). This awareness and the availability of better radiation techniques in the last decade have led to careful use of high-dose radiation to the chest with proper cardiac shielding. More than 30 Gy to the chest is usually not used. Therefore, the long-term effects of modern radiation may be less severe than before (144). However, due to better long-term survival of patients who received radiation in the past and delayed manifestation of cardiac effects, we are likely to continue to encounter these problems (145). The injuries due to radiation involve various cardiac structures and can cause acute or delayed manifestations.

Pericardium

Acute pericarditis due to radiation is rare (approximately 2% of total population undergoing chest radiation). Over the years, approximately one-half of the patients develop echocardiographically demonstrable abnormalities, and approximately 5% develop clinically significant pericardial disease (146,147). Clinical manifestations and management of radiation pericarditis are discussed in detail in Chapter 26.

Myocardium

Radiation causes progressive fibrin deposition and capillary destruction, leading to fibrosis in the myocardium (148). This leads to mild left ventricular dysfunction not requiring specific treatment (147,149). Coronary artery disease should be ruled out when significant systolic dysfunction of the left ventricle is identified. Restrictive cardiomyopathy has also been described from radiation treatment (150,151).

Valves

Valvular thickening is present in many patients after radiation treatment, but significant valvular disease is an infrequent sequela (147). The mean time from radiation to clinically recognizable valvular disease is approximately 10 years, and the symptoms develop approximately 5 years after that. Aortic and mitral replacement from radiation-induced sclerosis with significant aortic stenosis or mitral regurgitation has been reported (152). Pulmonary and tricuspid valve disease is even less common (153,154 and 155).

Conduction System

Nodal and infranodal conduction abnormalities occur with radiation injury. Although right bundle branch block is most common, complete heart block has been reported (150,154,156). Management of these abnormalities is similar to that from other causes.

Coronary Arteries

External radiation injury involves the proximal portion of coronary arteries (157,158,159 and 160). Left and right coronary ostia and proximal left anterior descending and left circumflex are involved in most cases. The lesions have an increased number of plasma cells with paucity of lipids (161). Large, bizarre fibroblasts are also present (162). Coronary disease commonly presents approximately 5 years after radiation but can present as late as 29 years (160). Predisposing factors other than the total dose of radiation are not clearly identified. Patients can present with any ischemic complication, such as angina, MI, arrhythmia, or heart failure. Children treated with chest radiation have a higher risk of MI (163). For significant left main stenosis, coronary artery bypass grafting with left internal mammary artery conduit is recommended, although surgery can be technically difficult due to excessive scarring. For other focal lesions, percutaneous transluminal coronary angioplasty can be useful. Intracoronary radiation is now used to treat recurring in-stent restenosis. The long-term effects of this type of therapy remain unknown (164,165).

Iatrogenic Cardiac Injury

With rapid increase in percutaneous interventions and devices, many procedural complications that lead to cardiac injury have been recognized. CPR can infrequently lead to cardiac trauma.

Procedural Complications

Procedural complications are described in detail with individual procedures. In the catheterization lab, with myocardial biopsy or diagnostic catheterizations, significant vascular injuries, valve injuries, and myocardial injuries have been reported (166,167). With percutaneous coronary interventions, coronary artery perforation and accompanied complications have been well-recognized (168,169). Cardiac perforation is a recognized complication of transseptal valvuloplasty (170). Central line–related cardiac injuries have been frequently reported (171,172 and 173). Pericardiocentesis can be complicated by ventricular perforation (174). In the electrophysiology lab, with transvenous pacemakers, defibrillators, and radiofrequency ablation catheters, ventricular perforation is encountered (175). Timely recognition of these complications is the key to appropriate management and better outcome.

Injuries during Cardiopulmonary Resuscitation

Closed-chest cardiac resuscitation is safe and not commonly associated with significant physical trauma to the heart. Rib fractures can occur despite proper CPR technique. Complications such as fracture of the sternum, separation of the ribs from the sternum, pneumothorax, hemothorax, lung contusions, laceration of the liver and spleen, and fat emboli can be avoided with careful attention to the details (176). CPR can cause mild elevation of CK and CK-MB levels, even in patients with normal coronary arteries (177). In rare instances, right ventricular papillary muscle rupture, rupture of atria, rupture of aorta, and coronary artery dissection have been reported (178,179). In some patients with MI who had CPR, left ventricular rupture can be found on autopsy. This is more likely to be the cause rather than the effect of CPR.

INJURY TO THE GREAT VESSELS

Penetrating Injury

Thoracic great vessel injuries cause immediate death in a significant number of patients with penetrating injury. Gunshot wounds and knife wounds are the common causes of injury (180). Iatrogenic injuries to intrathoracic vessels can result from percutaneous placement of jugular venous lines, overinflation of Swan-Ganz catheter balloon, or intraaortic balloon pump (181). These injuries can manifest with simple lacerations, pseudoaneurysm, or an arteriovenous fistula. A high suspicion for injury is warranted while evaluating all penetrating thoracic wounds, as clinical signs of pulse deficit or murmur may be absent despite significant vascular injury (182). The chest x-ray may show hemothorax, widened mediastinum, and cervical or supraclavicular widening. In stable patients, aortography and CT scan may help to decide further management. In unstable patients, surgical exploration with thoracotomy is indicated. Follow-up of these patients is recommended, as some of them may develop late complications such as distal ischemia, edema, and pseudoaneurysms.

Blunt Injury

Anatomic Considerations

Motor vehicular accidents are responsible for the majority of cases of aortic rupture (178). As the blood vessels are fixed by their branches to the chest wall, the

direction of the pull determines the site of the tear. Aorta is fixed superiorly to the thoracic outlet and posteriorly to the chest wall. Vertical deceleration pulls the heart down and to the left, which causes shear on the right side, leading to a tear at the origin of the innominate artery. Horizontal deceleration causes shear at the aortic isthmus, the junction between the relatively mobile arch and the fixed descending aorta (183). Aortic injury can result in rupture, medial tear, and intramural hematoma or only intimal disruption. Rupture of the thoracic aorta causes immediate death in 75% to 90% of patients. Patients with contained ruptures have an unpredictable course, with up to 30% mortality in the first 24 hours (76,184). Patients with intimal flap or mural hematomas have a benign course.

Clinical Profile

Aortic rupture alone does not cause shock, as it quickly leads to exsanguination and death. Patients who arrive at the ER have sealed their defect with a clot. These patients may have reverse coarctation due to injury to the origin of subclavian artery, acute pseudocoarctation with upper-extremity hypertension, and increased pulse amplitude (182). Injury to the branches of the aortic arch can cause cerebral ischemia, but limb ischemia is rare due to a rich collateral supply (see Chapter 109) (185).

Management

In unstable patients with suspected aortic injury, the cause of bleeding should be ascertained and treated before aortic surgery (184,186). In stable patients with aortic rupture, chest x-ray can show mediastinal widening (8 cm or more), blurred aortic knob, shift of trachea or nasogastric tube when present, depressed left main bronchus of more than 40 degrees, presence of apical cap sign, obliteration of aortopulmonary window, and multiple rib or sternal fractures (187). These signs are present in 70% to 95% of cases (188). If the chest x-ray is abnormal, TEE is performed to confirm the diagnosis. TEE is sensitive and specific for the diagnosis of aortic intimal disruption, medial tear, and perivascular hematoma. The advantages over aortography are the bedside availability, the noninvasive nature of the study, and the ability to simultaneously evaluate the heart. However, its limitations are an occasional inability to pass the probe in patients with cervical injury, “blind spot” (this is the 3- to 5-cm portion of upper ascending aorta that is blinded by trachea) of ascending aorta, and operator variability (189). If TEE shows no abnormality, the patient should be observed, and chest x-ray should be repeated in 6 hours. If TEE shows rupture of the aorta, surgery is indicated. In patients with a small intramural hematoma or a small intimal flap, conservative medical management with close follow-up is justified. If TEE is nondiagnostic, other imaging modalities are used. Magnetic resonance imaging is useful in this situation, as it gives an excellent definition of anatomy, including the arch vessels. Biplane aortogram is no longer considered to be the gold standard, as, depending on the plane of projection, tears and perivascular hematomas can be missed. It is an invasive procedure with occasional serious complications. CT scan has a high sensitivity for screening purposes and is a very useful imaging tool that is complementary to TEE (190,191 and 192). If the initial chest x-ray does not show any signs of aortic injury, further management should be guided by clinical judgment (193). TEE should be performed in patients older than 65 years with significant other injuries and comorbid factors.

In stable patients, nonoperative management of an intimal tear of the thoracic aorta or delayed operative management of full-thickness tear in patients with multiple injuries is favored. Use of beta-blockers to medically control shear stress by controlling heart rate and blood pressure appears to be effective in these patients.

Prognosis

Patients treated for thoracic aortic rupture with surgery have risk for paraplegia (4% to 10%) (194,195 and 196). Brain ischemia, MI, and other end-organ damage have been reported. Overall mortality is 10% to 25% when patients reach the hospital alive.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The role of echocardiography is becoming clearer in the management of stable patients with penetrating cardiac injuries. TEE has proven to be useful in management of suspected great vessel injuries and is also useful in difficult situations to complement TTE. In the management of blunt trauma with stable hemodynamics, the role of echocardiography remains less clear, but it is extremely useful when structural problems need to be ruled out. Percutaneous interventions with stent grafts may find its role in management of a subgroup of patients with thoracic great vessel injuries. Coronary interventions have been successfully used in some cases of blunt trauma–related coronary thrombosis and closure. Thoracoscopy is also being more frequently used to assess the extent of injury in stable patients.

THE FUTURE

Improvement in emergency services with a special effort for rapid patient transport to a well-equipped trauma center can save patients with serious cardiovascular trauma. TEE has significantly changed some of the protocols for evaluation of stable patients with thoracic injury, but more prospective studies are needed to better define its role. A consensus for the clinical definition of cardiac contusion is needed to avoid discrepancies in literature. Similarly, for better comparison of data from various institutions, a unified injury index should be used. Endovascular stent grafts may help in management of some injuries to thoracic great vessels.

OVERVIEW

Primary cardiac tumors involving the heart may be either benign or malignant. Most of the benign tumors are myxomas, which are most commonly located in the left atrium. Primary malignant neoplasms usually involve the myocardium and the interior of the cardiac cavities, whereas metastatic neoplasms to the heart most commonly involve the pericardium, and pericardial effusion and constriction are the most common consequences. Computed tomography (CT) and magnetic resonance imaging (MRI) are becoming the most useful instruments of precision to diagnose cardiac tumors. A number of nonneoplastic conditions in the heart or pericardium are frequently mistaken for cardiac neoplasms, including pericardial cysts, teratoma, lipomatous hypertrophy of the atrial septum, papillary fibroelastoma, thrombi, and sarcoid. There are a number of cardiac consequences of malignancy, including radiation heart disease, cardiac hemorrhages, cardiac infection, and cardiac adiposity of the corticosteroid-treated heart, cardiac hemosiderosis, and anthracycline chemotherapy. Carcinoid heart disease is a unique type of heart disease associated with a unique type of cancer.

HISTORICAL PERSPECTIVE

In the last 40 years, cardiac neoplasms have progressed from clinical curiosities described primarily in numerous case reports, with diagnosis mainly at autopsy, to fairly rapid antemortem diagnosis and frequent curative operative therapy. Diagnosis has been greatly facilitated by two-dimensional echocardiography and, in select cases, the use of MRI or CT.

CLASSIFICATION

There is no perfect classification for cardiac neoplasms. Like any organ or tissue, neoplasms involving the heart may be primary or secondary. The primary ones may be benign or malignant, and the secondary or metastatic ones are, by definition, malignant. The metastatic neoplasms are far more frequent than are the primary neoplasms by at least a 30:1 ratio (1,2). The various frequencies of the primary benign and primary malignant tumors vary from report to report, approximately 0.1% to 0.3% in most autopsy series. A list of primary benign neoplasms gathered by investigators at the Armed Forces Institute of Pathology is presented in Table 39.1; primary malignant tumors encountered are listed in Table 39.2 (3). The frequencies of the metastatic neoplasms also vary from report to report, but nearly all studies have listed carcinoma of the lung as the most commonly encountered metastatic tumor at autopsy, with cancer of the breast, followed by lymphoma and leukemia, as the next leading causes (Table 39.3). The order of frequency of metastases is different, however, if the frequency of each different type of tumor with metastasis to the heart is determined. For example, Table 39.4 lists the frequencies of metastases to the heart in each of 100 cases of 20 separate tumors: Melanoma has the highest frequency of metastases to the heart followed by malignant germ cell tumor, leukemia, lymphoma, cancer of the lung, and then the various sarcomas (3).

Tumor*	Total	Surgical	Autopsy	Age (%) at diagnosis
Myxoma	114	102	12	4
Rhabdomyoma	20	6	14	20
Fibroma	20	18	2	10
Hemangioma	17	10	7	2
Atrioventricular nodal	10	0	10	2
Granular cell	4	0	4	0
Lipoma	2	2	0	0
Paraganglioma	2	2	0	0
Myocyte hamartoma	2	2	0	0
Histiocytoid cardiomyopathy	2	0	2	2
Inflammatory pseudotumor	2	2	0	1
Fibrous histiocytoma	1	0	1	0
Epithelioid hemangioendothelioma	1	1	0	0
Bronchogenic cyst	1	1	0	0
Teratoma	1	0	1	1
Totals	199	146 (73%)	53 (27%)	45 (23%)

*Excludes papillary fibroelastoma and lipomatous hypertrophy of the atrial septum.

23. Miscellaneous	245	0
Totals	6,240	653 (10)

Numbers in parentheses are percentages.
Modified from Burke and Virmani, who combined studies of McAllister HA and Fenoglio JJ Jr. Tumors of the cardiovascular system. Atlas of tumor pathology. Washington, DC: Armed Forces Institute of Pathology; 1978:111–119; and Mikuni K, Shimizu T, Tomonaga K, et al. The incidence of secondary tumors of the heart and pericardium: a 10-year study. Jpn J Clin Oncol 1988;18:195–201.

TABLE 39.3 METASTATIC NEOPLASMS IN THE HEART AT NECROPSY IN THE ORDER OF FREQUENCY OF CANCERS ENCOUNTERED

Primary tumor	Number of autopsies	Percent with metastases to heart
1. Melanoma	100	46
2. Germ cell	100	38
3. Leukemia	100	33
4. Lymphoma	100	17
5. Lung	100	17
6. Sarcoma	100	15
7. Esophagus	100	13
8. Kidney	100	11
9. Breast	100	10
10. Mouth and tongue	100	9
11. Thyroid gland	100	9
12. Uterus	100	8
13. Urinary bladder	100	6
14. Stomach	100	5
15. Colon and rectum	100	5
16. Prostate gland	100	4
17. Pancreas	100	3
18. Nose (interior)	100	3
19. Ovary	100	1
20. Pharynx	100	1
21. Miscellaneous	100	0

These percentages were obtained by combining studies by McAllister HA and Fenoglio JJ Jr. Tumors of the cardiovascular system. Atlas of tumor pathology. Washington, DC: Armed Forces Institute of Pathology; 1978:111–119; and Mikuni K, Shimizu T, Tomonaga K, et al. The incidence of secondary tumors of the heart and pericardium: a 10-year study. Jpn J Clin Oncol 1988;18:195–201.

TABLE 39.4 METASTATIC NEOPLASMS IN THE HEART AT NECROPSY: ORDER OF FREQUENCY OF METASTASES OF EACH DIFFERENT PRIMARY TUMOR

LOCATION OF CARDIAC NEOPLASMS

Cardiac neoplasms may involve only the endocardium, only the myocardium, only the epicardium, or various combinations (Fig. 39.1). By far, the most common location of metastatic cardiac neoplasm is the epicardium. Neoplasms limited to parietal pericardium without extension into the epicardium are not considered cardiac neoplasms. The epicardial tumor deposits may be multifocal or single, or they may be extensive and essentially diffuse or nearly so. Likewise, the intramyocardial masses may be focal or multifocal. The most common locations for intramyocardial masses are the left ventricular free wall and the ventricular septum, the portions of the heart, of course, with the greatest myocardial mass. The endocardial neoplasms are the intracavitary ones. They may involve a single cardiac cavity or more than one. They may be limited to either the right or left side of the heart, or they may involve both. Intracavitary tumors produce obstruction to inflow into the heart or into a ventricular cavity or outflow from a ventricular cavity. The intracavitary neoplasms are the ones that may partially dislodge and produce either pulmonary or systemic emboli or both. The intracavitary deposits have the potential of producing the triad of obstruction, embolization, and constitutional symptoms.

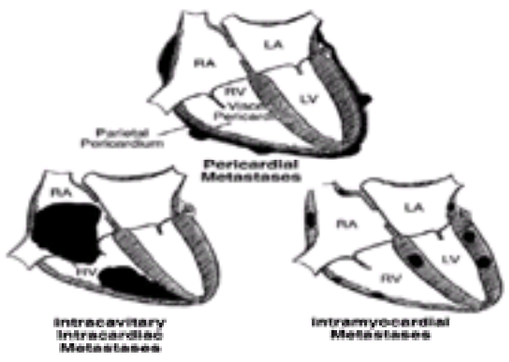

FIGURE 39.1 Diagram showing various locations of cardiac neoplasms involving the heart. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

TECHNIQUES FOR DIAGNOSING CARDIAC NEOPLASMS

Symptoms and Physical Signs

The signs and symptoms produced by the various cardiac neoplasms are determined primarily by the tumor's location in the heart. Physical examination is rarely diagnostic (4,5,6 and 7). Pericardial (specifically epicardial) involvement is the most common type of involvement by metastatic neoplasms to the heart (7). Neoplastic pericardial disease is usually asymptomatic and detected only as an incidental finding at autopsy. Signs of cardiac tamponade may be the initial or later manifestation of neoplastic pericardial disease. In patients with epicardial constriction by neoplasm, dyspnea is most commonly followed by chest pain, cough, orthopnea, and hepatomegaly. Distal cardiac sounds and a pericardial friction rub are infrequent.

Intramyocardial neoplasms are usually clinically silent. Occasionally, there are disturbances of conduction or rhythm, and both of these disturbances are determined primarily by the actual location of the tumor. The sudden development of complete heart block or high degrees of atrioventricular block or asystole are suggestive of myocardial involvement. A wide range of arrhythmias may be produced, including atrial fibrillation or flutter, paroxysmal atrial tachycardia with or without block, nodal rhythm, ventricular premature complexes, ventricular tachycardia, and ventricular fibrillation. On occasion, intramyocardial tumors impair ventricular function, resulting in confusion with restrictive cardiomyopathy or hypertrophic cardiomyopathy.

Left atrial cavitary neoplasms may produce signs and symptoms often mimicking those of mitral valve disease, especially mitral stenosis, including dyspnea, orthopnea,

paroxysmal nocturnal dyspnea, pulmonary edema, cough, hemoptysis, chest pain, peripheral edema, and fatigue. Additionally, some patients—particularly those with left atrial myxoma—may lose weight, become pale, faint, and have cardiac arrest. Left atrial tumors may produce symptoms suddenly or intermittently; sometimes, they come and go depending on body position. Although most symptoms produced by left atrial tumors are nonspecific, the occurrence of paroxysmal symptoms that occur characteristically in a particular body position and are out of proportion to the clinical findings should raise suspicion of a left atrial myxoma.

Right atrial cavitary neoplasms, if large enough, produce signs and symptoms of right-sided heart failure, including peripheral edema, ascites, hepatomegaly, and prominent ‘a’ waves in the jugular venous pulse. It may take years from the symptomatic presentation to the correct diagnosis. The development of right-sided heart failure may be rapidly progressive and is often associated with new systolic or diastolic precordial murmurs or both. The murmurs generally are the result of obstruction to the tricuspid valve orifice by the neoplasm, tricuspid regurgitation caused by the tumor’s interference with valve closure, or direct destruction of the tricuspid valve leaflets by the tumor’s movement in the tricuspid valve orifice. Signs of pulmonary embolism and pulmonary hypertension may occur. If the right atrial pressure increases to levels greater than that of the left atrium and if the foramen ovale is patent (15% of population), a right-to-left shunt may be the consequence, and systemic hypoxia, cyanosis, clubbing, and polycythemia may result. Evidence of superior or inferior vena caval obstruction, hepatomegaly, and ascites may be found. An early diastolic rumbling murmur alone or in combination with a holosystolic murmur, which increases with inspiration, usually indicates tricuspid regurgitation. A protodiastolic “tumor plop” also may occur with right atrial tumors. The jugular venous pressure may be elevated, and the ‘a’ wave within the venous system may be quite prominent.

Right ventricular cavitary neoplasms often present with right-sided heart failure as a result of an obstruction to right ventricular filling or outflow, and the consequences include peripheral edema, hepatomegaly, ascites, dyspnea, syncope, and cardiac arrest. A systolic ejection murmur at the left sternal border is usually present. Neoplastic emboli to peripheral pulmonary arteries may cause pulmonary hypertension. If the neoplasm extends into the pulmonary trunk, it may interfere with pulmonic valve closure, resulting in pulmonic regurgitation. The jugular veins are frequently distended with a prominent ‘a’ wave and a Kussmaul’s sign.

Left ventricular cavitary neoplasms are probably most frequently located at the apex of this chamber and, as a consequence, are usually clinically silent. Those in the left ventricular outflow tract may lead to obstruction to outflow, producing syncope or evidence of heart failure. Chest pain also may occur. A neoplasm in the left ventricular outflow tract may cause a precordial systolic murmur. The intensity of the murmur and the level of the blood pressure may vary with position.

Electrocardiography

The electrocardiogram (ECG) result is usually nonspecific (8,9), but it could be far more useful than has been appreciated in the past. The problem has been that the ECG may be recorded when diagnosis is first considered, but subsequent ECGs are not taken frequently toward the end of the patient’s life. One study (8) compared findings on ECG in patients with malignant lymphoma who had cardiac lymphoma to another group of patients with lymphoma who did not have cardiac involvement. The percentage with abnormal tracings (62%) was similar in each of the two groups. Fewer than one-half of the patients had more than one ECG during the entire illness. Findings included sinus tachycardia, low-voltage, ectopic tachycardia (including atrial fibrillation), atrial flutter, atrial tachycardia, atrial ventricular block (including prolonged PR interval), second- and third-degree block, premature ventricular complexes, right- or left-axis deviation, right bundle branch block, T-wave abnormalities, and ST-T–wave changes of usually nonspecific nature. The sudden development of some of these ECG findings in a patient who previously lacked these changes suggests cardiac involvement.

Radiography

The chest radiograph may be helpful, particularly when an epicardial neoplasm is present (10). Enlargement of the cardiac silhouette, mediastinal widening, a hilar mass, or an irregular contour of the cardiac silhouette may suggest pericardial involvement. Calcium within an intracardiac neoplasm can be seen, on occasion, by chest radiography or fluoroscopy. The lung fields may have a paucity of pulmonary markings in patients with large right atrial or right ventricular neoplasms. Patients with neoplasms in the left atrium may have pulmonary changes similar to those in mitral stenosis. Likewise, left ventricular neoplasms causing obstruction to left ventricular inflow or outflow may produce similar pulmonary arterial vascular changes.

Echocardiography

More cardiac tumors today are diagnosed by echocardiography (Table 39.5), at least initially, than by any other instrument of precision. Diagnosis of left atrial myxoma has been one of the principal uses of echocardiography since the introduction of the technique (11,12,13,14 and 15). The classic left atrial myxoma is a mobile echogenic mass that is in the body of the left atrium in ventricular systole and passes into the mitral orifice in ventricular diastole. Occasionally, echocardiography detects a left atrial myxoma that is small or not close to the mitral orifice; therefore, it is clinically silent. Although it is usually possible to detect intracardiac tumors with transthoracic echocardiography, the transesophageal examination produces, as a rule, spectacular images and makes diagnosis, particularly of atrial masses, relatively easy (16,17). The transesophageal examination not only offers a higher sensitivity for detecting left atrial tumors, for example, but also permits a clearer picture of the attachment or stalk of the tumor and more precise characterization of the size, shape, and location of the mass. A major advantage of echocardiography is its ability to provide serial studies. Thus, by this technique, one may see progressive increase in size of a neoplasm or detect recurrence once the initial tumor is excised. The echocardiogram also has been useful in detecting intracardiac tumors other than myxomas, including rhabdomyomas and rhabdomyosarcomas, neoplasms that occur primarily in infants and are located usually in the ventricles. The echocardiogram is also helpful in detecting metastases to the heart. This is particularly true in neoplasms that migrate up the inferior vena cava into the right side of the heart, such as renal cell carcinoma or adrenal cell carcinoma. Echocardiography, particularly transesophageal, has been extremely helpful in detecting mediastinal or extracardiac masses, which may compress the cardiac structure.

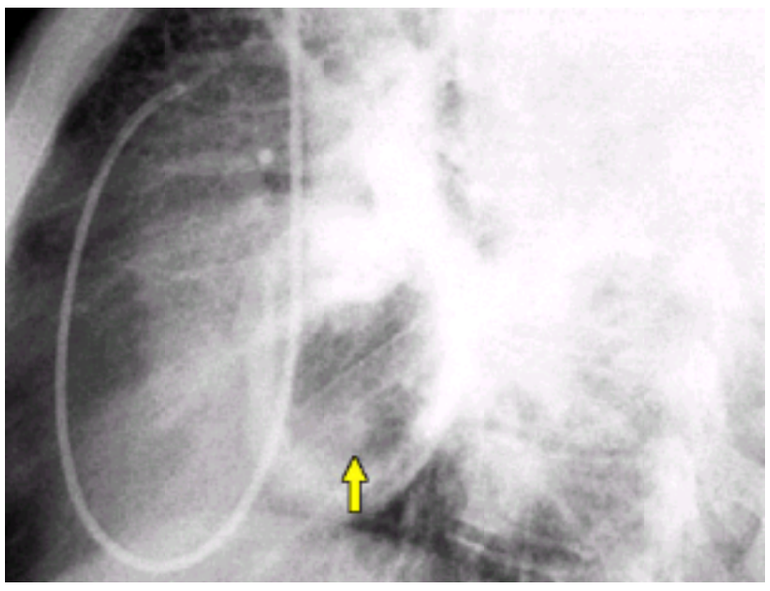
TABLE 39.5 IMAGING TECHNIQUES FOR THE DIAGNOSIS OF CARDIAC TUMORS



Left atrial myxoma. This left anterior oblique projection depicts the left atrial filling phase of a pulmonary angiogram performed via a pulmonary artery catheter inserted into the right jugular vein. A large contrast free space (*yellow arrow*) depicts a space occupying mass within the left atrial cavity, which

surgical pathology confirmed to be a myxoma.

Atrial myxoma. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Computed Tomography

CT is useful in diagnosing cardiac tumors (18,19); it may be especially useful in defining the degree of intramyocardial extension or the lack thereof and whether the tumor is present in adjacent extracardiac structures. Ultrafast CT appears to be particularly well suited for assessing intracardiac masses.

Magnetic Resonance Imaging

Compared with CT, MRI appears to be of greater value in delineating cardiac tumors (20). It may be able to depict the size, shape, and surface characteristics of the tumor more clearly than CT. This technique also can provide information regarding tissue composition that can help to differentiate neoplasms from thrombi.

Video 39.1 Atrial myxoma (long-axis). A myxoma attached to the interatrial septum is seen. During diastole, the myxoma moves through the mitral orifice into the left ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Angiography

A cardiac catheterization and selective angiography are no longer necessary in all patients with cardiac neoplasms because adequate preoperative information can usually be obtained by echocardiography, CT, or MRI. For cases in which the latter three techniques have not fully defined the location and attachment of the neoplasm, in which all four chambers of the heart have not been well delineated, or in which another type of cardiac condition is suspected (such as coronary arterial narrowing), then cardiac catheterization with angiography might be necessary. Angiography in patients with cardiac neoplasms is particularly useful in detecting compression or displacement of cardiac cavities or large masses and the magnitude of the intracavitary filling defects. The most frequent angiographic findings are intracavitary filling defects, which may be either fixed or mobile, lobulated or smooth, and attached over a broad base or by a narrow stalk. Coronary angiography is sometimes helpful in visualizing the vascular supply of the neoplasm and the relation of the neoplasm to the coronary arteries. The vascular pattern is not helpful, however, in differentiating benign from malignant tumors. In contrast to the other diagnostic techniques, cardiac catheterization can be a bit risky in patients with intracardiac neoplasms, because the catheter may dislodge a fragment of the tumor with resulting embolus. Thus, the noninvasive techniques are preferred before cardiac catheterization in a patient suspected of having an intracardiac mass. The transseptal approach to the left atrium is not advised if a left atrial tumor is suspected, because the stalk of the left atrial myxoma is usually attached to the fossa ovale membrane, where the transseptal catheter courses.

Video 39.2 Identification of intercardiac mass by negative contrast effect. Left atrium contrast injection showing negative contrast of tumor. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 39.3 An 80-year-old male patient with weight loss, fever, and dyspnea for 2 months. Angiography revealed vascular tumor, which received blood supply from the right coronary artery. Echocardiograph confirmed location of the tumor in the left atrium with appearance consistent with myxoma. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

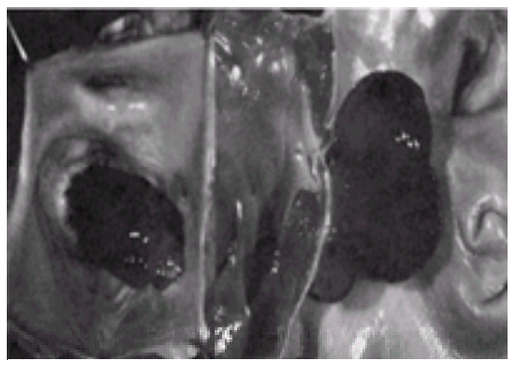
SPECIFIC BENIGN PRIMARY CARDIAC NEOPLASMS

Myxoma

Myxomas are by far the most common type of primary cardiac tumor; 75% of them are located in the left atrial cavity (eFig. 39.1.1), approximately 23% in the right atrial cavity (Fig. 39.2), and approximately 2% in a ventricular cavity (21,22,23,24,25,26,27,28,29,30,31,32 and 33). On rare occasion, the tumor is present in more than one cavity. Generally, when located in the left atrium, the neoplasm produces symptoms when it reaches approximately 7 cm in size. Those in the right atrium that produce symptoms are usually approximately twice as large and sometimes several-fold larger. The cell of origin of the myxoma is still unclear (22,34,35 and 36). How fast atrial myxomas grow has never been clarified. An attempt to answer this question was provided by a study that examined the size of recurrent myxomas and divided that size in grams by the interval between the first and second operations (37). It was estimated that recurrent left atrial myxomas grow an average of 0.15 cm per month or 1.80 cm per year, or an average of 1.2 g per month or 14.0 g per year. Whatever the exact growth rate may be, both recurrent and initial left atrial myxomas appear to grow rather rapidly (38,39). Morphologic diagnosis of myxoma is readily made by gross inspection, and their appearance is clearly different from thrombi. The surface is smooth but irregular, shiny, and usually multicolored. Although there are exceptions (29,30,31 and 32,40,41,42 and 43), attachment is nearly always to the atrial septum if the tumor is in the left atrium, and the stalk is most commonly much smaller than the maximal diameter of the mass. On occasion, the site of attachment to the atrial septum is broad. The mean age of patients with sporadic myxoma is 56 years, and at least 75% are women. During the last 10 years at Baylor University Medical Center in Dallas, 15 left atrial myxomas have been excised—14 were in women.

Video 39.4 Myxoma tumor blush from left circumflex artery. Contrast injection of left coronary showing perfusion of the tumor. *This video must be viewed with*

QuickTime. If you do not have QuickTime you may download it here.



***e*FIGURE 39.1.1** Left atrial myxoma in a 60-year-old woman (A69-275) who died of metastatic carcinoid and never had clinical evidence of heart disease. The myxoma was not large enough to prolapse through the mitral orifice during ventricular diastole. *Left*: View of left atrium cephalad. *Right*: Longitudinal view showing attachment of the myxoma to the atrial septum by a relatively broad base.

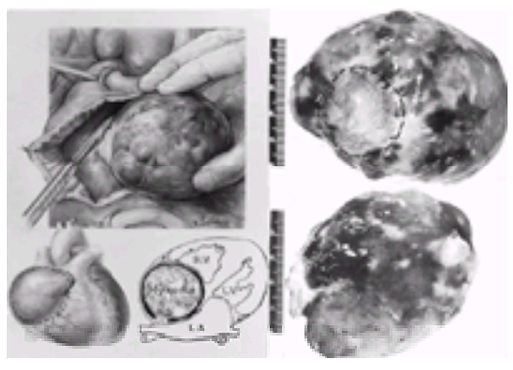


FIGURE 39.2 Myxoma excised from the right atrium of a 46-year-old man (S61-980) who had had evidence of cardiac dysfunction for 12 years. The tumor was attached to the atrial septum by a relatively small stalk (surrounded by dashed circle, *upper right*). The myxoma weighed 142 g, and its largest diameter was 8 cm. A view of the cut section of the tumor is shown in the lower right. LA, left atrium; LV, left ventricle; RV, right ventricle.

Familial cardiac myxomas constitute approximately 10% of all myxomas, and they appear to have an autosomal dominant transmission (44). These occur in younger patients (mean age, 25) and have less female gender predominance. The myxomas in the familial syndrome are much more liable (50% of the time) to be multiple and to have a ventricular cavity location (13% as compared with <1% in the nonfamilial or sporadic patients with myxomas). These patients typically have exterior facial freckling; they have noncardiac myxomas (breast or skin) and also endocrine neoplasms. Both the NAME (nevi, atrial myxoma, neurofibromata, ephelides) and the LAMB (lentigines, atrial myxoma, and balloon nevi) syndromes are associated with the familial variety of cardiac myxoma. Chromosomal abnormalities for atrial myxoma on chromosome 2 (Carney's) and chromosome 12 (*Ki-ras* genes) have been described.

Myxomas probably present the most varied clinical picture of all primary cardiac neoplasms (4,5 and 6,23,25,26,45). Several major syndromes have been observed, including presentation with signs of emboli, obstruction to blood flow, and various constitutional syndromes. Fragments of tumor located in the right side of the heart may embolize to the lungs, and of those in the left side of the heart, of course, to various systemic organs. Diagnosis may be made, on occasion, by finding typical myxomatous endothelial-like cells, which are elongated and spindle shaped with round or oval nuclei and prominent nucleoli, in surgically removed emboli.

Obstruction to blood flow may occur at the orifice of any valve, most commonly of course, the mitral valve. Interference with flow through the mitral orifice may mimic signs of mitral stenosis, including signs of pulmonary congestion, diastolic apical rumble, opening snap, and accentuated first heart sounds. A murmur of mitral regurgitation may also be present as a result of chronic damage to the valve leaflets or to interference with proper closure of the valve by tumor. Differentiation between left atrial tumor and primary mitral stenosis is suggested by the influence of position on symptoms and on the intensity of the precordial murmurs and the opening snap.

HEART SOUNDS

Audio 39.5 Moderate mitral valve stenosis. Auscultation in a 42-year-old female patient with moderate mitral stenosis with peak and mean gradients of 13 and 6 mm Hg, respectively. Mitral valve area by continuity equation is 1.5 cm^2. Note the opening snap after the second heart sound. The diastolic rumbling murmur is soft and there is slight presystolic accentuation of the first heart sound. Right upper sternal border (*first clip*); left lower sternal border (*second clip*); apex, supine (*third clip*); apex, left lateral (*fourth clip*). The constitutional symptoms associated with atrial myxomas include fever, weight loss, Raynaud's phenomenon, digital clubbing, anemia, elevated erythrocyte sedimentation rate, elevated leukocyte count, decreased platelet count, positive seroreactive protein, and abnormal serum proteins (usually increased gamma globulins). These constitutional symptoms may mimic infective endocarditis, collagen vascular disease, or occult malignancy. A myxoma also may become infected (46).

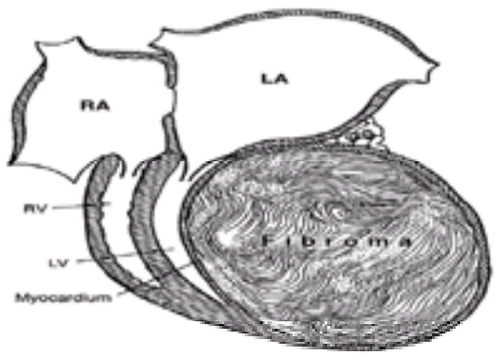
The proper treatment of myxoma in any cavity of the heart is operative resection, because no medicine is known to shrink myxomas or to prevent their continued growth (21,27,33). Some surgeons advise a biatrial approach for full visualization of both sides of the heart and then complete removal of a left or right atrial myxoma, excising the full thickness of the atrial septum if the neoplasm is attached to the region of the fossa ovalis. If a large portion of the atrial septum is removed, a patch must be used to close the defect. Because fragmentation and embolization of the tumor are ever-present threats, vigorous palpation and other manipulations of the heart should be avoided until cardiopulmonary bypass is initiated. Most surgeons induce ventricular standstill with cardioplegia solution before manipulating the heart to reduce the possibility of fragmentation of portions of the tumor. Left atrial myxomas have been removed successfully during pregnancy. On occasion, an atrioventricular valve has been so traumatized by the tumor prolapsing through it during ventricular diastole that valve excision and replacement are necessary. Fortunately, recurrences of atrial myxomas are rare, and if they do recur, it is usually within a 4-year period (38,39).

Rhabdomyoma

The most common cardiac neoplasm in infants and children is rhabdomyoma (47). There is some question about whether this particular tumor is a true neoplasm or a hamartoma. These neoplasms are usually multiple, most often involve the ventricular myocardium, and project into the cavity or move freely as a pedunculated mass (48,49 and 50). Associated tuberous sclerosis is present in approximately one-third of the patients. The diagnosis is suggested by the presence of yellow-brown angiofibromas (adenoma sebaceum) on the face, sublingual fibromas around the fingernails, café au lait spots, and subcutaneous nodules. Presenting symptoms may be caused by obstruction to inflow to or outflow from the ventricles, arrhythmias, atrioventricular block, pericardial effusion, and even sudden death (51). These neoplasms may mimic pulmonic valve stenosis and produce hypoxic spells, resembling those seen in tetralogy of Fallot. These neoplasms are usually readily diagnosed by echocardiography, angiography, or MRI. Prenatal detection of intracardiac rhabdomyoma by intrauterine echocardiography has been reported. The occurrence of more than one tumor does not prevent operative intervention. On rare occasions, these tumors have produced ventricular tachycardia in infants, and this arrhythmia has disappeared following successful operative removal.

Fibroma

Fibromas are usually within a ventricular wall (intramural) (3,52) (*e*Fig. 39.2.1). Most also occur in infants and children. Calcific deposits may be present within the neoplasm. Sudden death has occurred in approximately one-third of the patients, presumably the result of a conduction defect, arrhythmia, or obstruction to outflow from a ventricle. Left axis deviation has been seen on ECG. Total or partial resection of the neoplasm may relieve obstruction with an excellent probability of long-term survival.



***e*FIGURE 39.2.1** Diagram of an intramyocardial fibroma seen at necropsy in a 5-month-old boy (A07-92) who was found dead in his crib. The neoplasm had been diagnosed by biopsy during the child's first few days of life. It was considered nonresectable. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Lipoma

Lipomas involving the heart may be extremely small and represent incidental necropsy findings or they may be massive (53,54,55 and 56). The largest cardiac

neoplasm ever reported apparently was an intrapericardial lipoma. They may be mistaken for pericardial cysts, cause pericardial effusion, or they may be asymptomatic and suggested by a widened mediastinum on chest radiography. Intramyocardial lipomas are encapsulated and usually small. Lipomas also have been located on cardiac valves, where they may simulate vegetations or myxomas (55). MRI permits preoperative identification of these fatty tumors.

Hemangioma

Hemangiomas are best diagnosed by coronary angiography, which yields a characteristic “tumor blush.” Spontaneous resolution without treatment has been reported. Total excision usually is not possible.

Video 39.12 Transesophageal view demonstrating the right atrium with the inferior vena cava off to the left of the screens, the superior vena cava to the right, and the left atrium at the top, with the interatrial septum in the middle. This view shows a hemangioma in the interatrial septum found incidentally at the time of preoperative transesophageal echo for mitral valve replacement for severe mitral regurgitation. Intraoperatively, the mass was highly vascular as expected and was resected. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 39.13 Transesophageal four-chamber view showing an encapsulated mass in the interatrial septum that has a heterogenous appearance centrally. This was a hemangioma of the septum. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

SPECIFIC MALIGNANT PRIMARY CARDIAC NEOPLASMS

Angiosarcoma

Nearly all primary malignant cardiac neoplasms are sarcomas; the most frequent is angiosarcoma (57,58,59,60,61 and 62), which characteristically originates from the right atrium or from the epicardium of the right atrium. The large quantity of vascular channels within these tumors and the subsequent large quantity of blood flowing through them may produce a continuous precordial murmur. Approximately 25% of all angiosarcomas are, at least in part, intracavitary with valvular obstruction and cause right-sided heart failure and pericardial tamponade with a hemorrhagic-type fluid. The course is rapid, with widespread metastases, and operative intervention is usually unsuccessful.

Rhabdomyosarcoma

Rhabdomyosarcoma is the second most frequent primary sarcoma of the heart, and, like angiosarcoma, it is most common in male subjects (63,64 and 65). In contrast to angiosarcoma, however, no single cardiac chamber has a predilection for this neoplasm. Indeed, the neoplasm may be in all four cardiac chambers, or at least in more than one, and obstruction may occur in one or more valve orifices. Again, prognosis is poor, survival is short, and operative intervention is usually futile.

Miscellaneous Neoplasms

Fibrosarcoma, liposarcoma, primary malignant lymphoma, and occasional sarcomas of other cell types constitute the remaining but infrequent primary malignant coronary neoplasms (66,67,68 and 69) (Fig. 39.3, *e*Fig. 39.3.1, and Fig. 39.4). All of these neoplasms may obstruct valvular orifices or obliterate chambers, produce peripheral emboli, or both (70). Hypertrophic cardiomyopathy has been suggested by heavy tumorous infiltrations of the ventricular septum (71).

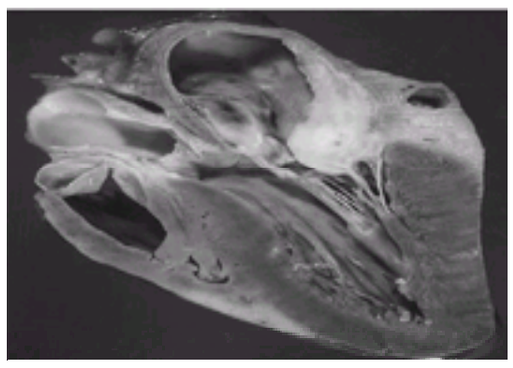


FIGURE 39.3 Primary cardiac sarcoma, undifferentiated type, causing mitral stenosis in a 46-year-old woman (A90-2) who had been well until 8 months before death. Cardiac catheterization disclosed a 20 mm Hg mean diastolic gradient between the pulmonary artery wedge position and the left ventricle. The right ventricular pressure was 105/18 mm Hg. The neoplasm was located in the walls of the left atrium and in both arteries and posterior mitral leaflets. (From Domanski MJ, Delaney TF, Kleiner DE Jr, et al. Primary sarcoma of the heart causing mitral stenosis. *Am J Cardiol* 1990;66:893–895, with permission.)

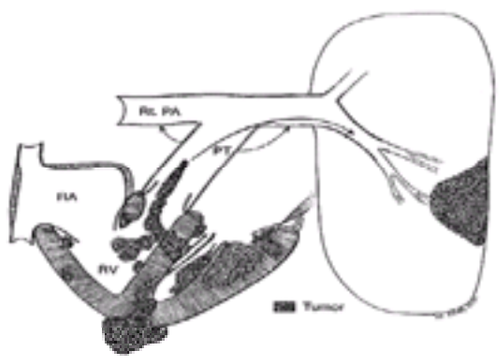

***e*FIGURE 39.3.1** Primary cardiac sarcoma, undifferentiated type, with neoplastic emboli to lung and other organs in a 26-year-old man (A69-149) who had been well until 3 months before death. PA, pulmonary artery; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

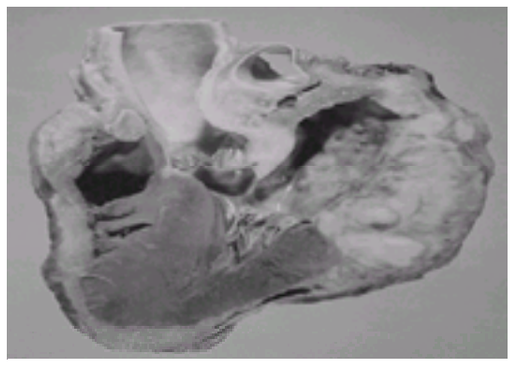

FIGURE 39.4 Cardiac histiocytic lymphoma in a 64-year-old woman (A77-172) who had had evidence of congestive heart failure for 7 months. The cause of the heart failure was not apparent until necropsy. The wall of the left atrium is massively thickened by the neoplasm. (From Roberts CS, Gottdiener JS, Roberts WC. Clinically undetected cardiac lymphoma causing congestive heart failure. *Am Heart J* 1990;120:1239–1242, with permission.)

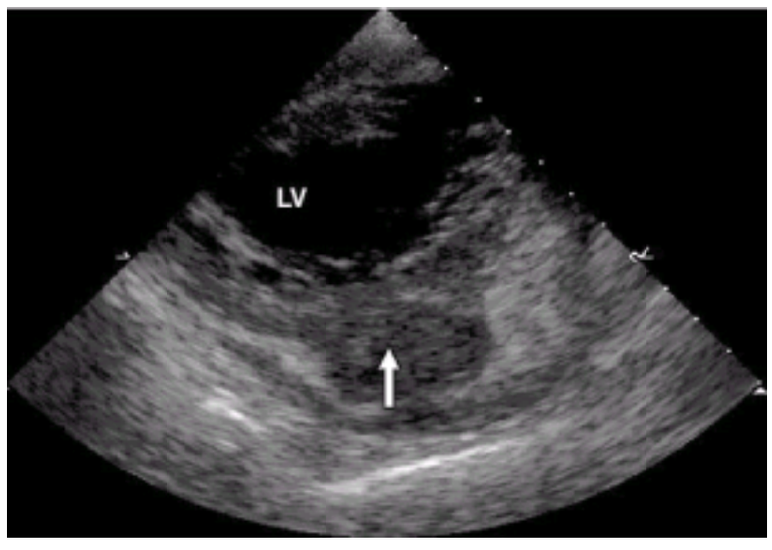


Transgastric long-axis view of a metastatic sarcoma within the anterior wall of the left ventricle at the bottom of the screen (designated by the arrow).

VIDEO

Video 39.14 Transgastric 90-degree long-axis transesophageal echo view of a patient with a sarcoma metastatic to his left ventricular anterior wall. Note the invasion of the myocardium by this large mass. Additionally, there is severe hypokinesis of the anterior wall. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

METASTATIC NEOPLASMS TO THE HEART

Metastatic or secondary tumors of the heart with a primary in another body organ or tissue are far more frequent than are primary tumors of the heart (72). The secondary tumors are far more commonly carcinomas than sarcomas, simply because carcinomas are far more common. Diagnosis can be suspected whenever cardiac manifestations occur in a patient diagnosed with a primary tumor in an organ or tissue other than the heart. The development of cardiac enlargement, tachycardia, arrhythmias, or heart failure in the presence of neoplasm elsewhere in the body is highly suggestive of cardiac metastases. Only rarely is metastatic tumor limited to the heart. Thus, the presence of metastatic tumor in the heart usually indicates widespread metastases in a number of body organs. On rare occasion, cardiac involvement may be the first or only expression of a noncardiac primary neoplasm. The most common sign is tamponade (73). Direct invasion of the heart via the vena cava or pulmonary veins may lead to obstruction of an atrioventricular valve, as well as to pulmonary or systemic emboli or both (74,75 and 76).

VIDEO

Video 39.15 Transesophageal echo of a large mobile mass seen in the right atrium, entering from the inferior vena cava. This patient had renal cell cancer that invaded the inferior vena cava. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

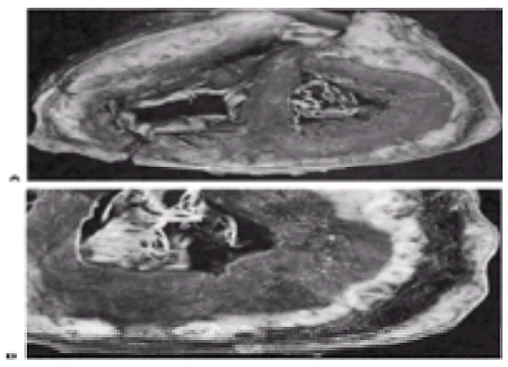
Carcinoma of the lung and carcinoma of the breast tend to invade the parietal pericardium and then the visceral pericardium, leading to myocardial constriction, pericardial effusion, or both (eFig. 39.4.1). Another common presentation of cancer of the lung is invasion of the pulmonary veins within the lung, with spread of the cancer within the lumen of the pulmonary veins into the left atrium. From there, the cancer in turn can continue into the mitral orifice, sometimes causing obstruction of that orifice (77,78) (Fig. 39.5). Metastatic cancer from the lung to the adrenal gland also may extend into the inferior vena cava and then into the right side of the heart (Fig. 39.6), just as primary adrenal gland or renal cancer can (79). Cancer of the lung or breast surrounding the main right or left pulmonary artery can lead to pulmonary arterial obstruction (80).

VIDEO

Video 39.16 Subcostal short-axis view demonstrating the left ventricle surrounded by an organized pericardial effusion, which is adjacent to highly organized pleural effusion in a patient with metastatic lung cancer. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 39.17 Apical four-chamber view (transthoracic) in a patient with metastatic lung cancer demonstrating a moderate to large pericardial effusion and a very large, highly organized pleural effusion encasing the heart. (Pleural effusion is towards the right of the screen.) Note the extensive fibrinous network in the pleural effusion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



***e*FIGURE 39.4.1** Metastatic squamous cell carcinoma of the lung in a 61-year-old man (67A-531). Cardiac tamponade was the immediate cause of death. The entire heart and great vessels were encased in tumor as shown in **(A)**. A close-up view of the tumor encasing the left ventricle is shown in **(B)**. (From Roberts WC, Spray TL. Pericardial heart disease. *Curr Prob Cardiol* 1977;2:1–71, with permission.)

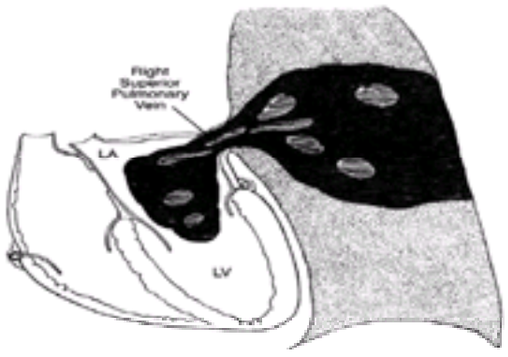


FIGURE 39.5 Sarcoma, undifferentiated type, in lung (primary uncertain, possibly in pulmonary vein) in a 29-year-old woman (A21-83) in whom echocardiography disclosed the tumor in the left atrium moving about “like a yo-yo.” The left lung and its left atrial extension were operatively excised. LA, left atrium; LV, left ventricle.

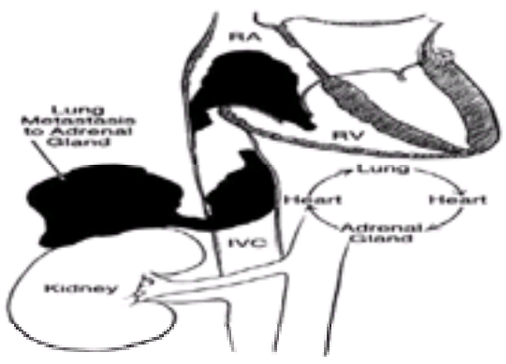

FIGURE 39.6 Diagram of metastatic cancer of the lung to the right adrenal gland with extension into the inferior vena cava (IVC) and then into the right side of the heart in a 57-year-old man (DCVAH 84A-121). Echocardiography showed the right atrial mass, which prolapsed through the tricuspid valve in atrial systole. RA, right atrium; RV, right ventricle.

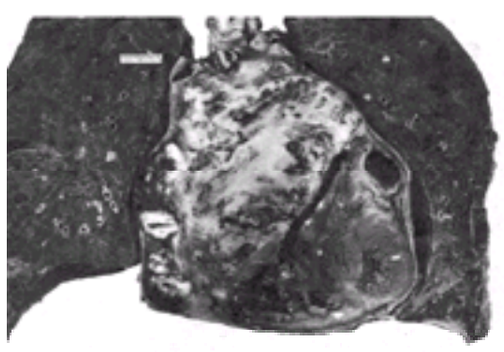
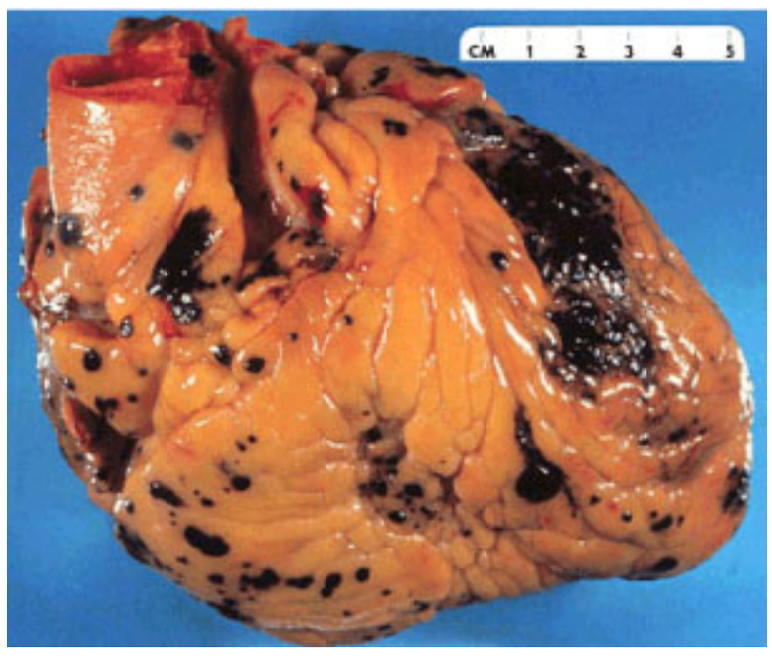
Melanoma has the highest frequency of metastases to the heart per 100 cases of any neoplasm (81,82). The metastases may be anywhere in the heart; usually, melanotic metastases invade the walls of all four cardiac chambers, the epicardium, and the endocardium (*e*Fig. 39.6.1). The cancers in these patients are in so many organs that the presence of the neoplasm in the heart is almost incidental. Resection of an intracardiac melanoma has been accomplished (83).



***e*FIGURE 39.6.1** Metastatic melanoma to the heart in a 53-year-old man (A75-41). During life, a pericardial friction rub was audible, and the neck veins were quite distended. The parietal pericardium is everywhere adherent to the epicardium. The superior vena cava, right atrium, right ventricle, and pulmonary trunk are severely compressed by the tumor. (From Roberts WC, Spray TL. Pericardial heart disease. *Curr Prob Cardiol* 1977;2:1–71, with permission.)

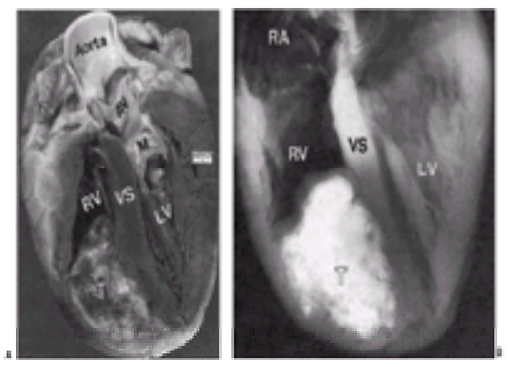


Metastatic malignant melanoma on the epicardial surface. The black deposits represent metastatic melanoma deposits.

Leukemia commonly invades the heart (84). In the days before platelet transfusions, extensive hemorrhages into the myocardial walls and into the endocardium and epicardium were commonly found in patients with fatal leukemia of various types. Histologically, leukemic infiltration between myocardial cells is quite common, and sometimes gross deposits of leukemic cells are visible within the heart. A few patients with leukemia present with pericardial effusion, which is usually hemorrhagic. Large calcific deposits in the right side of the heart have been reported (85).

Lymphoma also has a high frequency of metastases to the heart (86,87,88 and 89). Nearly 25% of patients with lymphomas of various types have lymphoma involving the epicardium, myocardium, or endocardium, or combinations. In contrast to leukemic involvement, the lymphomatous deposits are usually grossly discernible.

Some cancers, like osteogenic sarcoma, may have calcium within them (90,91 and 92) (eFig. 39.6.2).



***e*FIGURE 39.6.2** Osteogenic sarcoma to the heart in a 39-year-old woman (A80-81) with a large calcified tumor (T) in the right ventricle (RV). This patient, who was ill for 20 months, had episodic ventricular tachycardia during her last 10 months. **A:** View of both ventricles showing the tumor in the right ventricle. **B:** Radiograph of the heart at autopsy showing calcium in the right ventricular neoplasm. AV, aortic valve; LV, left ventricle; M, mitral leaflet; RA, right atrium; VS, ventricular septum. (From Seibert KA, Rettenmier CW, Waller BF, et al. Osteogenic sarcoma metastatic to the heart. *Am J Med* 1982;73:136–141, with permission.)

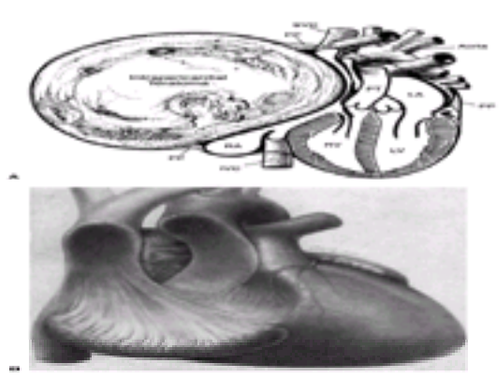
CONDITIONS MISTAKEN FOR CARDIAC NEOPLASMS

Pericardial Cyst

Pericardial or mesothelial cysts are the most frequent benign “tumors” of the pericardium. These cysts are generally asymptomatic and found on routine chest radiography (93). Approximately one-fourth of the patients, however, develop various symptoms including chest pain, dyspnea, cough, and tachycardia, as a consequence of a pericardial cyst. The cysts are usually outside the pericardial cavity and, therefore, they really should not be considered cardiac tumors.

Teratoma

Teratomas are actually extracardiac in at least 99% of the cases but still within the pericardial cavity (94,95 and 96) (eFig. 39.6.3). They arise and receive their blood supply from the ascending aorta or pulmonary trunk, presumably through the vasa vasorum. Most are found in infants and children and primarily in female subjects. Recurrent serous pericardial effusion in children should suggest intrapericardial teratoma. Because these tumors may become quite large, they may cause compression of various cardiac chambers and resulting symptoms.



***e*FIGURE 39.6.3** Intrapericardial teratoma in a stillborn. The infant’s heart weighed 8 g, and the tumor, which greatly compressed the heart, weighed 20 g. **A:** Diagram showing comparative size of the intrapericardial teratoma and the heart. **B:** Drawing showing compression of the superior vena cava, right atrium (RA), and aorta by the tumor. IVC, inferior vena cava; LA, left atrium; LV, left ventricle; M, mitral leaflet; PP, parietal pericardium; PT, pulmonary trunk; RV, right ventricle; SVC, superior vena cava. Lipomatous Hypertrophy of the Atrial Septum

Massive fatty infiltration of the atrial septum is an extremely common condition occurring almost exclusively in persons over 50 years of age and usually over 65 years of age (97) (Fig. 39.7). These lesions are essentially limited to obese people, and they are always associated with enormous quantities of subepicardial adipose tissue, particularly enormous amounts of adipose tissue in the atrioventricular sulci. These hearts are almost always so fat that they float in water (98). Normally, the atrial septum is less than 1 cm in thickness. In patients with lipomatous hypertrophy of the atrial septum, the atrial septum cephalad to the fossa ovale may be as thick as 7 cm, and the portion of atrial septum caudal to the fossa ovale may be as thick as 4 cm. Enormous infiltration of fat into the atrial septum may be associated with atrial arrhythmias. The importance of lipomatous hypertrophy of the atrial septum in the context of cardiac tumors is that these patients should not be operated on to remove fat from the atrial septum. The treatment is simply weight loss. These fatty deposits may be diagnosed by echocardiography, CT, or MRI (99,100). Fat in the subepicardial adipose tissue has been confused by echocardiography with pericardial effusion (101).

Papillary Fibroelastomas

Papillary fibroelastomas are small avascular growths with multiple papillary fronds usually limited to cardiac valves (mainly the aortic and mitral valves), and they are common in older persons (102). They consist of fibrous tissue covered by an elastic membrane, which in turn is covered by endocardium. Occasionally (approximately 15% of cases), they also occur on left ventricular or ventricular septal mural endocardium (103,104,105,106,107,108,109,110,111 and 112), particularly in patients with small or relatively small ventricular cavities, such as in patients with hypertrophic cardiomyopathy (103,109) or mitral stenosis with or without aortic valve stenosis (107,110,111). When located on the aortic valve, papillary fibroelastomas are usually found on the ventricular aspects of the cusps in the more central portions. They also occur on the aortic aspects of these cusps, usually near the margins (113,114,115 and 116). On the mitral valve leaflets, they are usually on the atrial aspects near the margins (117,118,119,120,121,122,123 and 124). In patients with hypertrophic cardiomyopathy or mitral stenosis, they may be on the ventricular aspects of the anterior mitral leaflet and sometimes on mural endocardium, particularly over the papillary muscles. These lesions may be the result of contact of one valve leaflet with another or one mural endocardial surface with another.

Papillary fibroelastoma removed from the aortic valve. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

A number of patients have been reported with papillary fibroelastomas and stroke (115,116,117 and 118,122,123,125,126,127,128 and 129). Whether the stroke was truly connected with the cardiac fibroelastomas is debatable. Some patients have been in their 20s or 30s without other predisposing features or findings commonly associated with cerebral infarction, and the occurrence of stroke in the younger age group is suggestive of a connection. In contrast to myxoma, in which myxomatous material has been seen in systemic emboli, however, histologic findings of papillary fibroelastomas have not been observed in a cerebral artery in a patient with stroke and cardiac papillary fibroelastomas. Furthermore, the papillary fibroelastomas are firmly attached to valvular or mural endocardium, and dislodgement of a fibroelastoma therefore would appear unlikely. Thrombus, however, is occasionally superimposed on papillary fibroelastomas, and it may be that the thrombus is the material that is dislodged and responsible for the stroke.

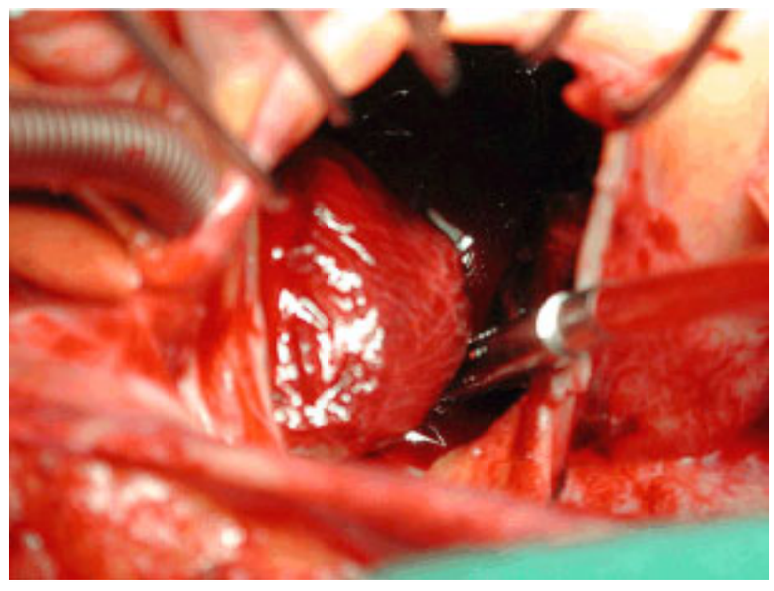
Additionally, angina pectoris (129), acute myocardial infarction (130,131,132,133 and 134), and sudden death (130,135) have been observed in patients with cardiac papillary fibroelastomas, mainly on the aortic valve. These papillary growths may obstruct an aortic ostium of a coronary artery (136,137). On rare occasion, papillary fibroelastomas have been observed on the right side of the heart, mainly the tricuspid valve (138,139,140 and 141).

Papillary fibroelastomas have been operatively excised from the cardiac valve, mural endocardium, or both in patients with evidence of stroke or other peripheral events, and a few patients have had cardiac valve replacement (107,109,111,112,115,116,118,119 and 120,125,126,133,137,139,141). When papillary fibroelastomas are detected by echocardiography in asymptomatic patients, operative excision rarely appears warranted.

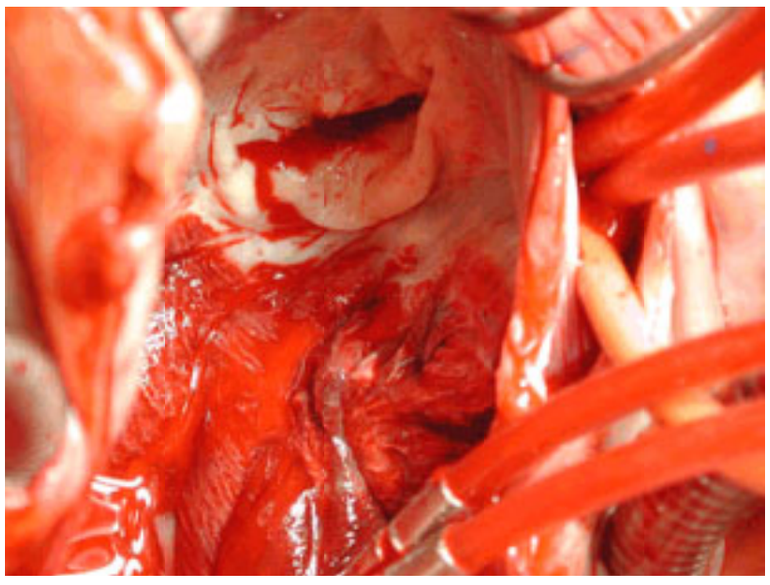
Thrombi

Thrombi within an intracardiac cavity may be indistinguishable from neoplasm by echocardiography or radiography. Grossly, however, they are very different.

Video 39.18 Subcostal view of a patient with severe left ventricular dysfunction and multiple mobile thrombi within the left ventricular cavity. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Intraoperative field looking into the left atrium of a patient with severe mitral stenosis who developed extensive clot within the left atrium. Notice the large mass in the center of the field, to the left of the opening within the left atrium. This is the largest portion of the left atrial thrombosis.



Intraoperative field looking into the left atrium after the large left atrial thrombus was resected demonstrating the rheumatic mitral valve at the top of the screen. Note the scarred, thickened, restricted mitral leaflets. This patient had severe mitral stenosis with a mean pressure gradient of 20 mm Hg across the valve and a mitral valve area of 0.7 cm^2.

Surgical specimen of the large left atrial mass explanted at the time of surgery. Note its somewhat pale, glistening surface, suggesting that the thrombus is not fresh and possibly endothelialized.

Sarcoid

When located in myocardium, sarcoid granuloma may grossly resemble neoplasm (142,143 and 144).

Sarcoidosis. Skin plaques with purple, raised lesions seen in sarcoidosis (*arrows*).

CONSEQUENCES OF THERAPY FOR NEOPLASMS IN THE HEART OR MEDIASTINUM

Radiation Heart Disease

Radiation heart disease was first recognized after radiation therapy for Hodgkin's disease (145,146,147 and 148). Some of the earlier patients with Hodgkin's disease

received 8,000 rad, which adversely affected the pericardium, myocardium, and endocardium. The most common manifestation of radiation heart disease is pericardial effusion. Fibrin deposits occur on both the visceral and parietal aspects of the pericardia. Because coronary arteries are located in subepicardial adipose tissue, they often receive the effects of radiation. Many patients have been reported to have coronary arterial narrowing at a very young age after radiation therapy, particularly patients with Hodgkin's disease. The intimal plaques resulting from radiation heart disease cannot be distinguished from plaques occurring from typical atherosclerosis. The distinguishing feature of radiation heart disease involving the coronary arteries is extensive fibrous thickening of the adventitia, and also loss, focally or diffusely, of internal and external elastic membranes, particularly the latter. Narrowing of coronary ostia also is common in radiation heart disease. In addition, radiation can cause considerable scarring within the subepicardial adipose tissue. The second most common manifestation of radiation heart disease is mural endocardial thickening, most commonly of the right atrium and ventricle, but focally also in the left ventricle. The third most common manifestation of radiation heart disease is interstitial fibrosis; depending on the portal of entry, it usually involves the anterior wall of the right ventricle more than any other portion of the heart.

Cardiac Hemorrhages

Thrombocytopenia, particularly if persistent, often results in focal epicardial, myocardial, and mural endocardial hemorrhages. If the hemorrhages are located in conduction tissue, various degrees of heart block or arrhythmias may be the consequence.

Cardiac Infection

The most common cardiac infections today in cancer patients are myocardial abscesses and mural endocardial and epicardial abscesses. These are particularly prevalent in patients with prolonged leukopenia (149,150). Patients having unsuccessful bone marrow transplantation are particularly prone to these infections, which usually are produced by fungi, not bacteria. Gas gangrene may involve the heart as well as most other body organs and tissues (151).

Cardiac Adiposity or the Corticosteroid-Treated Heart

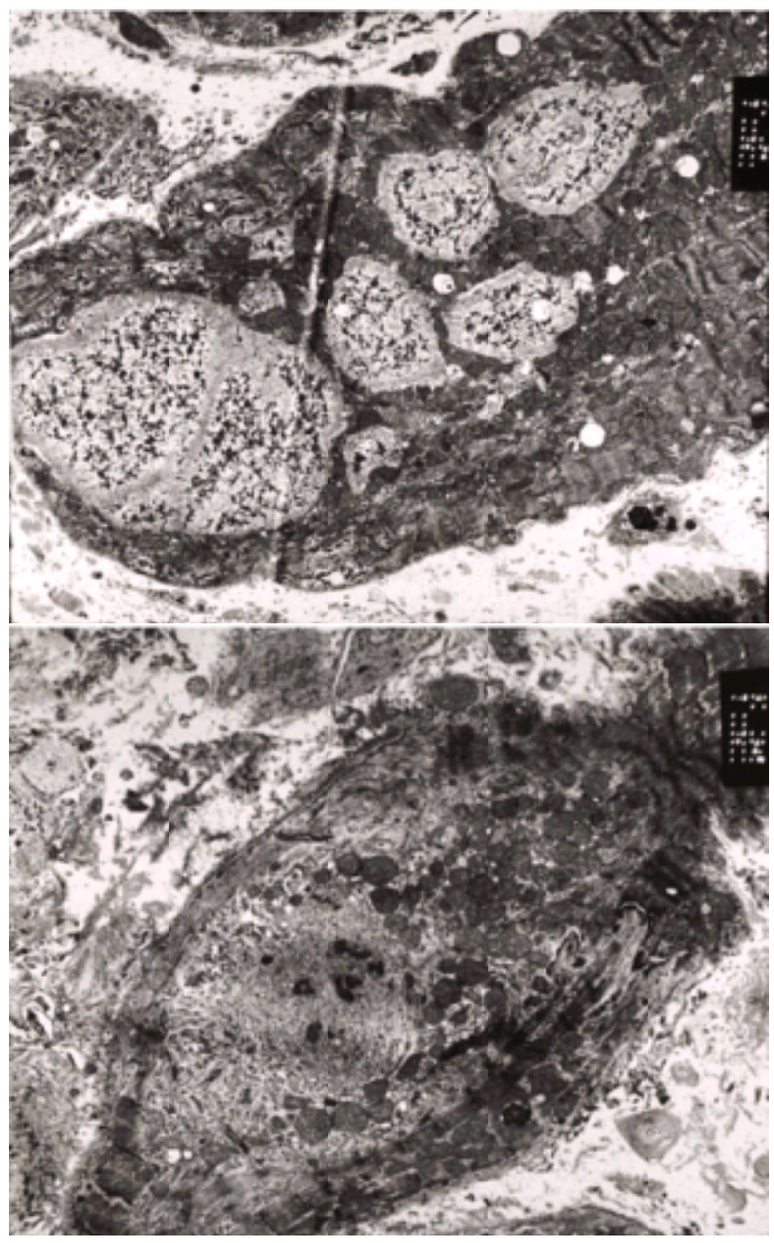
Patients with various types of cancers, particularly those with leukemia and lymphoma, and those developing cancer after transplantation of one or more body organs, usually receive corticosteroid therapy for prolonged periods. The consequence is excessive deposition of fat in the heart, mainly in the subepicardial areas (152). These hearts may become so fatty that they float in water (buffalo hump of the heart), and this excessive subepicardial adipose tissue may simulate pericardial effusion.

Cardiac Hemosiderosis

Normally, the human body contains approximately 4 g of iron. If the deposits increase to approximately 25 g, iron deposits are then usually found within myocardial cells. Patients who receive 100 units of blood without associated bleeding diatheses can acquire approximately 25 g of iron within the body organs and tissues. This situation may exist in some patients with cancer, particularly leukemia, and the result is cardiac hemosiderosis (153). These patients may be asymptomatic, or they may develop features of dilated cardiomyopathy with heart failure. At times, ventricular arrhythmias may be a consequence. Myocardial restriction as a result of myocardial ironic deposits has occurred, but dilatation is far more common (154).

Anthracycline Chemotherapy (Doxorubicin and Daunorubicin)

Cardiac toxicity is a well-recognized complication of doxorubicin and daunorubicin therapy and is frequently the dose-limiting factor in their administration (155,156 and 157). Clinical toxicity is usually manifested by evidence of impaired left ventricular systolic function. Morphologic signs of toxicity may be present when clinical signs of toxicity are absent.



Electron microgram of 3+ doxorubicin (Adriamycin) toxicity (A,B). (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

A UNIQUE HEART DISEASE ASSOCIATED WITH A UNIQUE CANCER: CARCINOID HEART DISEASE

Carcinoid tumors are never primary in the heart, and they rarely metastasize to the heart (158). Nevertheless, patients with ileal, bronchial, or ovarian carcinoid, when hepatic metastases are present, often develop distinctive lesions in the heart, particularly in the right side (159,160,161,162 and 163) (Fig. 39.8). The distinctive lesions consist of deposits of fibrous tissue devoid of elastic fibers on the ventricular aspect of the tricuspid valve leaflets and on the arterial aspect of the pulmonic valve leaflets. Occasionally, deposits also are seen on the ventricular aspects of the mitral leaflets and, rarely and usually to a small extent, on the aortic aspects of the aortic valve cusps. These lesions may result in tricuspid regurgitation and stenosis and pulmonic valve stenosis and regurgitation. Surprisingly, patients with carcinoid heart disease, compared with patients with metastatic carcinoid disease without carcinoid heart disease, have similar life spans after diagnosis of the carcinoid syndrome. The syndrome is diagnosed primarily by the presence of facial flushing and diarrhea.

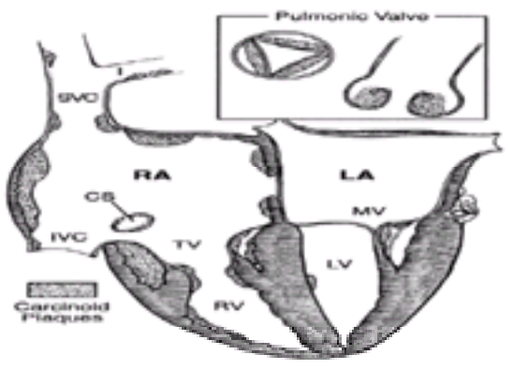


FIGURE 39.8 Diagram showing location of carcinoid fibrous plaques in carcinoid heart disease. CS, coronary sinus ostium; I, innominate vein; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; MV, mitral valve; RA, right atrium; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve. (From Ross EM, Roberts WC. The carcinoid syndrome: comparison of 21 necropsy subjects with carcinoid heart disease to 15 necropsy subjects without carcinoid heart disease. *Am J Med* 1986;79:339–354, with permission.)

Ross and Roberts (162) studied at necropsy 36 patients with metastatic carcinoid: 21 (57%) with and 15 (43%) without carcinoid heart disease. The two groups were similar in mean age (54 vs. 55 years), duration of clinical illness (4.7 vs. 6.3 years), body weight (50 vs. 52 kg), systemic blood pressure (117/77 vs. 128/77 mm Hg), blood hematocrit levels (37% vs. 36%), total serum protein levels (6.0 g per dL), and serum albumin levels (2.2 vs. 2.6 g per dL). The two groups differed in the frequency of the presence of precordial murmurs consistent with tricuspid regurgitation, pulmonic stenosis, or both (95% vs. 13%); cardiomegaly by chest radiography (38% vs. 0%); low voltage on ECG (47% vs. 0%); and location of the primary site of the carcinoid tumor. Total ECG 12-lead QRS voltage was similar in each group (105 vs. 132 mm; 10 mm = 1 mV). Of the patients with carcinoid heart disease, 43% died of cardiac causes; none of those without carcinoid heart disease died of cardiac causes. Of the 21 subjects with carcinoid heart disease, seven had left-sided cardiac involvement, but in none was it of functional significance. Thus, although carcinoid heart disease frequently is the cause of death in patients with the carcinoid syndrome, the development of carcinoid heart disease is not related to the duration of symptoms of the carcinoid syndrome.

All of the 21 patients with carcinoid heart disease studied by Ross and Roberts (162) had involvement of both tricuspid and pulmonic valves by carcinoid plaques, and 19 also had carcinoid plaques on the mural endocardium of the right atrium and usually also on the mural endocardium of the right ventricle. The number of subjects with right-sided valvular dysfunction as a consequence of the carcinoid plaques on the valvular leaflets is less certain because of the relative difficulty in diagnosing by auscultation mild degrees of tricuspid and pulmonic valve dysfunction. In 2 of the 21 subjects with right-sided carcinoid heart disease, the degree of morphologic involvement of both valves was minimal, and valvular function clearly was not affected. Of the remaining 19 subjects, 18 had precordial systolic, diastolic, or both kinds of murmurs of grade 2/6 or greater intensity.

Although the composition and location of the carcinoid plaques on both right-sided cardiac valves are similar, the functional consequences of the carcinoid plaques are different. The deposits occur nearly entirely on the downstream side of the valvular leaflets (i.e., on the ventricular aspects of the septal and posterior tricuspid leaflets and on the pulmonary arterial side of the pulmonic valve cusps). On the anterior tricuspid valve leaflet, the deposits can be on both sides. The consequence of the “downstream” deposition is an adherence of the leaflet to the underlying mural endocardium (tricuspid septal and posterior leaflets) or to the underlying pulmonary arterial endothelium (pulmonic valve) via the carcinoid plaques. The fibrous tissue of the carcinoid plaque acts as a constricting substance such that the “ring” of both right-sided cardiac valves is made smaller than normal; at the same time, leaflet mobility is diminished. The consequence is tricuspid regurgitation with or without some degree of stenosis. Nearly all patients with pure tricuspid regurgitation (no element of stenosis) have dilated valve rings, but patients with some degree of stenosis in addition to regurgitation do not have dilated annuli. Patients with carcinoid heart disease follow this principle. Thus, patients with carcinoid heart disease have much more tricuspid regurgitation than stenosis, but usually there is some degree of stenosis, albeit small.

In contrast to the tricuspid valve, the dominant functional pulmonic valve lesion is stenosis, although all patients with stenosis have some degree of pulmonic regurgitation. The reason for the difference from the tricuspid valve is that the orifice of the normal pulmonic valve is much smaller initially than the orifice of the tricuspid valve. Thus, the constriction by deposition of carcinoid plaques within the pulmonic sinuses causes constriction of the pulmonic root with the production of pulmonic stenosis. Because the distal portions of the pulmonic cusps are inverted toward the sinuses and the mobility of the cusps is lost, some degree of regurgitation is inevitable in patients who have any degree of pulmonic stenosis.

Although combined lesions of both mitral and aortic valves are fairly common as a consequence of rheumatic heart disease, infective endocarditis, or both, combined lesions of tricuspid and pulmonic valves are rare, and carcinoid heart disease is the only condition in which uniformly both right-sided valves are involved, not just one. The two dominant functional consequences of right-sided carcinoid heart disease are pulmonic stenosis and tricuspid regurgitation. These two lesions in the same patient are particularly unfavorable because pulmonic stenosis increases the degree of tricuspid regurgitation. A commonly employed method of producing chronic congestive heart failure in experimental animals is by banding the pulmonary trunk to create pulmonic stenosis and excising or destroying one or more tricuspid valve cusps to make the valve purely regurgitant. Thus, right-sided carcinoid heart disease, in essence, creates this experimental model. If a patient with carcinoid heart disease had only dysfunction of the pulmonic or the tricuspid valve, the functional consequence probably would be insignificant. The combination of both right-sided valvular lesions, namely pulmonic stenosis and tricuspid regurgitation, has the potential of being devastating.

Clinical diagnosis of carcinoid heart disease can usually be established by noninvasive means. Auscultation, of course, is the first clue. In Ross and Roberts’ study (162), 20 (95%) of 21 subjects with carcinoid heart disease and 5 (33%) of 15 subjects without carcinoid heart disease had one or more precordial murmurs. Of the 20 subjects with precordial murmurs and carcinoid heart disease, 8 had both systolic and diastolic murmurs and 12 had only systolic murmurs; of the 5 subjects with precordial murmurs but without carcinoid heart disease, all the murmurs were systolic only. Thus, nearly all patients with carcinoid heart disease have precordial murmurs, and when the murmur has a diastolic component, diagnosis of carcinoid heart disease can be made with confidence.

The systemic arterial blood pressure is not helpful in either diagnosing carcinoid syndrome or distinguishing those with from those without carcinoid heart disease. Only 3 of the 36 subjects studied by Ross and Roberts (162) had indirect systolic systemic arterial pressures of more than 140 mm Hg, diastolic arterial pressures of more than 90 mm Hg, or both: 1 of the 21 with carcinoid heart disease and 2 of the 15 without it. The average peak systolic pressure was 117 mm Hg in the 21 subjects with carcinoid heart disease and 128 mm Hg in the 15 subjects without it. The average diastolic pressure in both groups was 77 mm Hg.

Chest radiography is helpful in diagnosing carcinoid heart disease. The cardiothoracic ratio was more than 0.50 in 8 (38%) of the 21 subjects with carcinoid heart disease and in none of 15 subjects without it. Thus, the cardiothoracic ratio is not a very sensitive test for carcinoid heart disease, but it is specific.

The resting ECG is somewhat useful in distinguishing subjects with and without carcinoid heart disease. In Ross and Roberts’ study (162), the sum of the QRS voltage in leads 1, 2, and 3 was 15 mm or less in 9 of the 21 subjects with carcinoid heart disease and in none of the 15 subjects without the disease. The sum of the total 12-lead QRS voltages ranged from 58 to 227 mm in 34 subjects, and the mean values did not differ significantly between the two groups (105 vs. 132 mm). Evidence of right ventricular hypertrophy was rare. The R wave was greater than the S wave in either lead V_1 or V_2 in only 4 of the 21 subjects with carcinoid heart disease and in none of the 15 subjects without it. Despite right atrial dilatation in most of the subjects with carcinoid heart disease, all 21 with and all 15 without carcinoid heart disease had sinus rhythm. The RR interval was normal (0.20 sec or less) in 18 of 21 subjects with the disease and in 14 of 15 subjects without it. The width of the QRS complex was normal (0.12 sec or less) in all subjects, irrespective of whether they had carcinoid heart disease. Thus, other than the higher frequency of low voltage in the subjects with carcinoid heart disease, ECG was not helpful in distinguishing between subjects with and without carcinoid heart disease.

Echocardiography, particularly cross-sectional, is helpful in diagnosing carcinoid heart disease (164,165). Callahan and associates (164) described retrospectively echocardiographic features in 20 patients with the carcinoid syndrome. By physical examination, 15 patients had a diagnosis of carcinoid heart disease and the other five did not. Both M-mode and cross-sectional examinations in the latter five patients disclosed no abnormal findings. Of the 15 patients with auscultatory evidence of carcinoid heart disease, five had normal M-mode and cross-sectional echocardiographic findings. The other ten, all of whom had tricuspid regurgitation by physical examination, had dilated right ventricular cavities, abnormal motion of the ventricular septum, and of the nine in whom the tricuspid valve leaflets were visualized by cross-sectional echocardiography, strikingly abnormal tricuspid leaflets (thickened and retracted with fixed orifice). The pulmonic valve cusps were not visualized in any patient by M-mode echocardiography, but in the four in whom they were visualized by cross-sectional echocardiography, the pulmonic valve cusps were abnormal in each.

Howard and associates (165) prospectively examined by cross-sectional echocardiography 14 patients with the carcinoid syndrome, and eight had definite abnormalities of one or both right-sided cardiac valves. Clinically, five had auscultatory evidence of tricuspid regurgitation, and all five had diffusely thickened and retracted tricuspid valve leaflets; the other nine patients had normal tricuspid valves by echocardiography. Four patients by auscultation had evidence of pulmonic

stenosis with or without pulmonic regurgitation. The pulmonic valve cusps were visualized by echocardiography in seven patients: Two had retracted pulmonic cusps with decreased systolic motion (one of whom had pulmonic stenosis by auscultation), and five had normal cusps (none of whom had auscultatory evidence of pulmonic stenosis).

Right-sided cardiac valve excision with or without valve replacement or valve commissurotomy or annuloplasty has been carried out in some patients with carcinoid heart disease. The interval from onset of symptoms and signs of congestive heart failure to cardiac valve operation in 15 patients collected from published reports by Ross and Roberts (162) ranged from 3 to 60 months (mean, 14) and the interval from onset of symptoms of the carcinoid syndrome to cardiac valve operation ranged from 0.5 to 33.0 years (mean, 10). Preoperatively, at least 12 of the 15 patients had hemodynamic evidence of tricuspid valve stenosis with mean diastolic pressure gradients between right atrium and right ventricle ranging from 4 to 24 mm Hg (mean, 9). Of 15 patients, 14 had tricuspid regurgitation, which was graded as severe at angiography in at least seven patients. Pullback pressures between pulmonary artery and right ventricle were recorded in 14 patients, 12 of whom had peak systolic pressure gradients ranging from 3 to 50 mm Hg (average, 29). The presence or absence of pulmonic regurgitation as determined by pulmonary angiography was noted in 12 patients, and only two apparently had regurgitation into the right ventricle during ventricular diastole. Of the 15 patients, 14 had tricuspid valve procedures: replacement in 13 and annuloplasty in one. Ten patients had pulmonic valve procedures: commissurotomy in six, replacement in three, and excision only in one. Of the 15 patients, eight had died at the time of the report: four within 2 months of operation, and one each 4, 8, 24, and 72 months after the operation. The other seven patients were alive 4 to 132 months (median, 23) after the operation.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Benign cardiac tumors should constantly be kept in mind because so many of them are entirely curable by operative therapy. It is not bad to overlook metastatic cancer to the heart, because virtually no cancers metastasize to the heart without metastasizing to other body organs and usually multiple other body organs. Cardiac tumors, whether primary or secondary, can simulate more common types of cardiac disease, and this fact should always be kept in mind.

THE FUTURE

Improvement of chemotherapy will almost certainly improve outcome of primary and metastatic cancer involving the heart.

OVERVIEW

Currently available cardiovascular agents are often limited by side effects and the potential for exacerbating the condition being treated. In addition, therapy is complicated by altered disposition of drugs as a result of concomitant disease processes, active metabolites, drug interactions, and poorly defined therapeutic ranges with great interpatient variability. The considerations presented here can serve only as a first approximation in determining a suitable drug or dosage regimen. Clinical observation then allows at least some appreciation of how a particular patient responds to a drug. With an understanding of basic pharmacologic principles, the patient's response to and disposition of drug at other doses can then be predicted. A grasp of such principles is invaluable in the choice of drug, its dosage, and the establishment of an optimal risk-benefit ratio for the patient.

DRUG ACTION

Receptors

At the beginning of the twentieth century, it was generally accepted that the response to a drug is mediated by interaction of the drug with specific cellular-binding sites called *receptors*. Technologic advances, notably affinity chromatography, photoaffinity labeling, and modern molecular biologic techniques, have allowed characterization of the receptor macromolecules themselves and the steps involved from initial recognition and interaction between a ligand and receptor (drug or endogenous substance) to the expression of effect. Ligand-binding studies have also aided our current understanding of receptor localization, specificity, structure–activity relationships, and receptor dynamics. Drug–receptor interactions may alter a process directly or act by an allosteric mechanism to produce graded increases or decreases in sensitivity to endogenous ligands.

Receptors are heterogeneous, ranging from enzymes (digitalis glycosides bind to Na^+-K^+-adenosine triphosphatase) to nucleic acids (with which many antineoplastic agents interact). Ligand–receptor interactions, however, generally result in changes either in ion permeability or in some biochemical function (second messengers) such as activation of a cyclic nucleotide-dependent protein kinase, or both.

Signal Transduction

The ligand–receptor activation process can be modeled to various degrees of sophistication; the simplest model is an equilibrium between two receptor states: resting and activated. One theory proposes that the relative affinity of a ligand for these two receptor states determines its biologic activity. For example, agonists (agents that elicit a response) shift the equilibrium in favor of the activated state (i.e., they promote the interaction of the receptor with the coupling protein), whereas antagonists (agents that prevent a response to the agonist) show equal affinity for both receptor states and do not alter their equilibrium. The formation of the antagonist–receptor complex prevents agonists from binding that would normally have the ability to shift the equilibrium and increase the amount of receptor in the activated states. A partial antagonist (e.g., a beta-blocker with intrinsic sympathomimetic activity) may be thought of as having an only somewhat greater affinity for the activated state. Thus, it causes only a slight shift of the equilibrium in favor of the activated state.

An important concept is that the receptor population is not fixed, and the number of receptors self-regulates in response to the degree of stimulation. Thus, phenomena related to an attenuated or augmented response (tolerance, tachyphylaxis, desensitization, or increased sensitivity to the drug) can be wholly or in part due to changes in receptor density. For example, beta-adrenergic receptor density increases (upregulation) during chronic treatment with propranolol. The effect appears to persist as long as propranolol is administered and for some time after discontinuation, providing a possible explanation for the delayed supersensitivity to beta-adrenergic stimulation seen after stopping propranolol therapy (1). Clinically, this may be manifest as increased heart rate, increased blood pressure, worsened angina, or arrhythmias. Chronic receptor stimulation (e.g., the use of sympathomimetics in the treatment of asthma) may lead to a reduction (downregulation) in receptor density and therefore to a loss of efficacy.

Another mechanism of receptor sensitivity control may be modification of receptor coupling to a regulatory protein, so that ligand–receptor binding is divorced from the sequence of events leading to effect. Such a mechanism may be important in instances of acute desensitization to the agonist. In more recent years, it has become apparent that inherited differences in the amino acid sequences of receptors (i.e., receptor polymorphisms) are responsible for some medical disorders (e.g., asthma, obesity) and are probably responsible for variability in response to drugs. This exciting new area of molecular pharmacology holds the potential of much more specific and targeted drug therapy. In many cases, specificity of action extends to steric requirements. Thus, only the L-optical isomer of norepinephrine, and not the D-isomer, elevates blood pressure; the L-enantiomer of verapamil has more potent hypotensive and negative chronotropic effects than the D-verapamil (2).

Not all drugs interact with specific receptors, however. For example, by generating a nitric oxide free radical, nitrate vasodilators may initiate vascular smooth muscle

relaxation mediated by increases in cyclic guanosine monophosphate (3). Osmotic diuretics depend on their physical properties for therapeutic benefit.

Structure-Activity Relationships

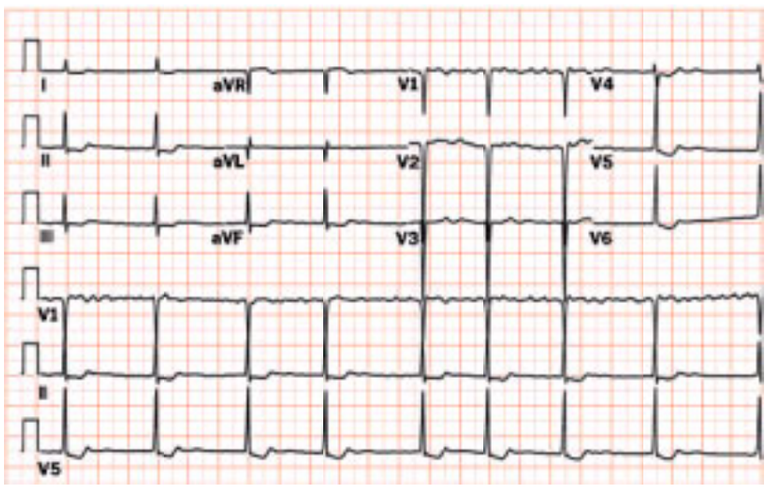
The therapeutic usefulness of most drugs depends on their specificity, which in turn implies interaction with a receptor. The ability of a drug to interact with a receptor depends on its having the correct physical, chemical, and spatial configuration. Minor modifications in structure can yield compounds with widely differing potencies or loss of efficacy. The screening of a series of chemical compounds related in structure to a known active compound not only can produce information on chemical relationships crucial to pharmacologic activity, but also can provide clues to receptor configuration.

The specificity of a drug for a particular receptor also determines the scope of its biologic activity. For example, terfenadine and its active metabolite, fexofenadine, are commercially available antihistamines. Although fexofenadine differs only slightly in structure, the drugs have very different pharmacologic actions. Both drugs block histamine receptors, but only terfenadine blocks cardiac potassium ion channels (55). The extent to which these two agents interact with the receptors involved in transducing these effects determines their relative potencies and, in this case, their safety. Terfenadine's ability to block cardiac potassium channels has been associated with rare but serious reports of torsades de pointes, a potentially life-threatening ventricular arrhythmia. Fexofenadine, although differing only slightly in structure, lacks this risk.

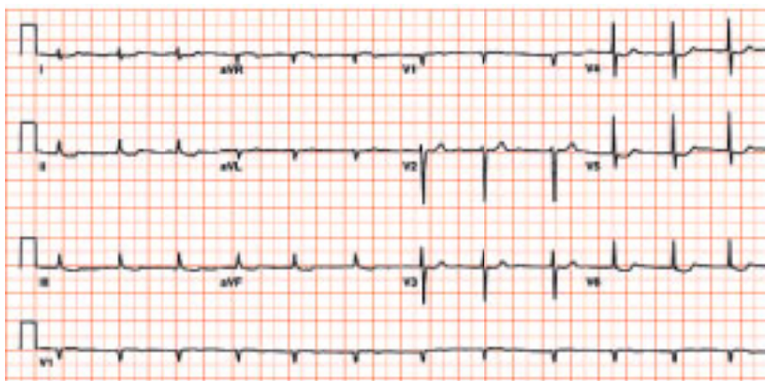
Dose Response Relationships and the Therapeutic Window

The therapeutic window for a drug encompasses the range of doses (or plasma concentrations when there is a reliable correlation with pharmacologic effect) that elicits a therapeutic effect in the majority of patients, with adverse effects occurring in only a few. At some appropriately chosen low dose, most patients do not respond at all. Increasing doses result in more and more patients showing a desired therapeutic response, and this is most likely paralleled by an increasing number of patients who develop unwanted adverse effects. The wider the margin between the concentrations that produce efficacy and those associated with side effects, the more leeway there is in dosing, and the wider the therapeutic window. Conversely, a narrow therapeutic window requires careful dose adjustment to avoid toxic effects. The therapeutic window also depends on the definition of efficacy. For example, the therapeutic window for slowing of atrial fibrillation with digoxin is probably wider than that for improving heart failure.

Heparin complication. Extensive purpura from heparin treatment.



Digitalis effect. Note controlled ventricular rate with short, scooped ST segments in the lateral leads.



A 74-year-old male patient with accelerated junctional rhythm secondary to digitalis toxicity and retrograde P waves.

One aim of understanding pharmacokinetics is to assist in the achievement and maintenance of plasma concentrations within the therapeutic window. This is especially important when dealing with cardiovascular agents because their *therapeutic ratio* (the plasma concentration that produces a desired therapeutic effect compared with the concentration that elicits toxic effects) is usually low.

Active Drug Metabolites

In numerous cases, the drug administered is a prodrug (i.e., it is converted in the body to a metabolite that is responsible for the pharmacologic actions of the drug). In many cases, the action is the desired action. The 5-hydroxy metabolite of propafenone is active and likely contributes to the antiarrhythmic activity of the parent drug (4). The *O*-desmethyl metabolite of the potent sodium channel blocking drug, encainide, is more active than encainide and is most likely responsible for excess conduction delay and induction of new arrhythmias in some individuals (5). In addition, the metabolites of drugs can be chemically reactive and bind to tissues, causing damage, as in the case of acetaminophen.

PHARMACOKINETIC PRINCIPLES

Absorption

Following administration of most drugs (aside from intravenous injection), the agent first must be absorbed from the gut, oral mucosa, muscle, skin, or subcutaneous tissue and must enter the systemic circulation before it can reach its site of action. Several factors influence the rate and extent of absorption from these sites, including the physicochemical properties of the drug, the surface area available for absorption, and regional blood flow. In general, lipid-soluble drugs penetrate cell membranes more readily than hydrophilic agents; a nonionized drug permeates more readily than an ionized drug. Because many drugs are either weak acids or weak bases, differences in the pH of the gastrointestinal tract (strongly acid stomach, nearly neutral small intestine) determine the extent of ionization and thus the rate of absorption following oral administration. For practical purposes, however, the greatest amount of absorption occurs in the small intestine by virtue of the large surface area available.

Gastrointestinal pathology can influence the amount of drug absorbed. Diarrhea or extensive small bowel resection, both of which reduce intestinal transit time, can result in markedly diminished absorption, especially of sustained release preparations that are designed to allow prolonged absorption.

The same principles apply to other routes of administration. For example, following intramuscular injection, absorption is more rapid from deltoid rather than gluteal muscle because the former has a higher blood flow. Drugs that are insoluble at tissue pH, or those in an oily vehicle or microcrystalline suspension, form a depot, releasing the drug slowly, which may allow less frequent injections.

Bioavailability

Bioavailability is the proportion of an administered dose that reaches the systemic circulation. By definition, following intravenous injection, a drug is 100% bioavailable. Thus, bioavailability after oral administration is determined by comparison of the area under the plasma concentration–time curves following oral and intravenous dosing. Bioavailability can be lowered by incomplete absorption because of problems in the drug's formulation or the presence or absence of food, or by concomitant administration of agents that alter gastric pH (e.g., antacids) or motility (e.g., narcotic analgesics and atropine-like drugs that slow gastric emptying, or metoclopramide, which speeds it). Efficient presystemic extraction by the gut wall or the liver (first-pass effect) also lowers systemic availability.

The time course of absorption may also be important in instances in which rapid attainment of a therapeutic plasma concentration is desirable following the initial (or single) dose. Although either rapid absorption or slow absorption can result in the same amount of drug becoming available systemically (equal areas under the concentration-time curves), therapeutic concentrations are achieved sooner if absorption is rapid. It has become apparent that the bioavailability of many drugs can be influenced by the food or drink accompanying their oral administration. Likewise, the time of day at which the drug is administered can influence the bioavailability of some drugs (e.g., theophylline).

Volume of Distribution Estimates

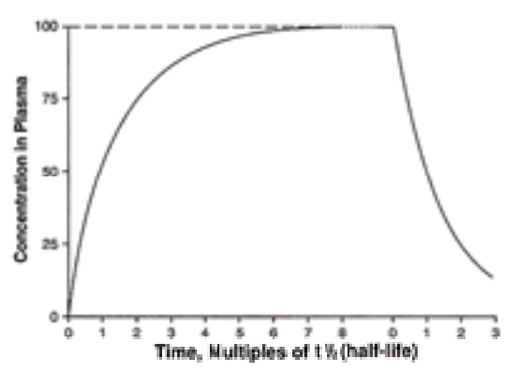
Having entered the systemic circulation, the drug distributes throughout the body, carried by the extracellular (vascular and interstitial) water in which it is dissolved. As in the case of absorption from the site of administration, the drug's passage into various body tissues depends on the lipid solubility of the drug, its degree of ionization, the vascularity of the tissue, and the size of the drug molecule, or drug–protein complex when the drug is bound to plasma protein. Lipid-soluble drugs readily diffuse across capillaries and all biologic membranes (including the blood–brain and blood–cerebrospinal fluid barriers), whereas hydrophilic drugs depend on the permeability characteristics of the capillaries to allow access to extravascular sites. The capillaries in the liver and kidney are particularly permeable to all but highly protein-bound drugs, whereas those of the brain are virtually impermeable to water-soluble molecules of any size. In more recent years it has become apparent that access to the brain and some intracellular spaces is tightly regulated by the activity of membrane pumps that exclude many drugs (6). Because quantification of the amount of drug in the various body spaces is not readily feasible, the plasma concentration usually serves as a surrogate and a guide to the rate of drug disposition.

The *volume of distribution* (V_D) is a parameter often used to describe what happens to a drug once it is in the body. It is a useful but often misunderstood term. It is obtained by measuring the plasma concentration after a dose of known magnitude has been given; if one assumes instantaneous mixing and extrapolates the measured concentrations back to the time of drug injection, that concentration is determined by the volume into which the drug is dissolved. At any time following administration, the drug concentration in plasma is defined by the amount of drug in the body and all of the volumes in which it is distributed. If we place 100 g of drug into the body and it distributes in 100 L of fluid, the concentration in that fluid will be 1 g per L. However, this rarely is the plasma concentration. Intracellular protein binding or tissue sequestration results in only a small amount of drug being left in the extracellular water. Thus, the plasma concentration is low. On the other hand, the calculated variable, the (apparent) volume of distribution, will be large, because estimation of the volume of distribution is by comparison of the amount of drug administered with the plasma concentration. Obviously, the smaller the fraction in plasma, the larger the calculated volume of distribution. Thus, the apparent volume of distribution should not be ascribed to actual anatomic volumes. For instance, the volume of distribution of mexiletine is approximately 600 to 700 L (7), far in excess of total body water. The usual reason for such a large value is extensive tissue binding, leaving little drug in the plasma.

Some substances, however, are confined to certain physiologic volumes and may be used as reference materials in pharmacokinetic studies. For example, certain dyes such as methylene blue remain confined to plasma, inulin distributes throughout the extracellular water, and antipyrine distributes throughout total body water. Their apparent volumes of distribution for a 70-kg individual are 3, 13 to 16, and 40 to 46 L, respectively. In general, however, the calculated volume of distribution of most drugs relates to the extent of tissue localization or metabolism of a drug rather than to any actual physiologic volume.

Metabolism and Elimination

Even before a drug enters the circulation, it is available for elimination. Enzymes in the intestinal wall rapidly destroy many drugs. Once in the plasma, elimination usually occurs either by metabolic modification of the drug or by excretion via the kidneys. The rate of removal of a drug is termed *clearance* and is expressed as the volume of plasma from which a drug is completely removed per unit time (e.g., milliliters per minute). *Total body clearance* is the sum of clearance at all sites of elimination. Another important term, *half-life*, is the time for any process to change to one-half of its original value. It can be used to describe a decrease or increase in the amount of drug in the body. A half-life of *elimination* is the time required for one-half of the drug in the body to be eliminated or for the plasma concentration to fall to one-half of its original level (eFig. 40.0.1).



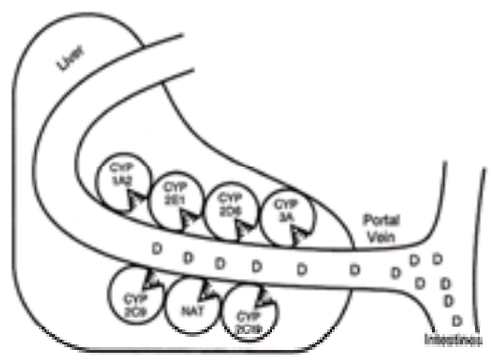
***e*FIGURE 40.0.1** Accumulation and elimination as a function of half-life.

Metabolic Pathways: Pharmacogenetics of P450 Enzymes

Most lipophilic drugs are extensively metabolized by oxidative enzyme products that can then be conjugated with acetate, glucuronic acid, or mercapturate, forming highly water- soluble compounds that are almost always pharmacologically inactive and readily excreted in the bile or urine. The oxidative step in this process is performed by enzymes belonging to a superfamily called *cytochrome P450* (CYP). The name cytochrome comes from the bright red color that the enzymes impart to the tissue and the characteristic wavelength (450 ^{l}) for absorption of ultraviolet light when exposed to carbon monoxide. A standardized designation has been developed for specific genes and enzymes in this superfamily based on their DNA homology. For example, *CYP2D6* specifies that the enzyme is in the cytochrome P450 superfamily, 2 family, D subfamily, and 6 gene.

As shown in eFigure 40.0.2, these enzymes form a potential barrier to protect the individual from foreign substances in the environment. These enzymes are found in

especially high amounts in the appropriate sites to prevent entry into the body (i.e., the gastrointestinal mucosa, liver, and lungs). They are also found in many other tissues, such as the brain, where their function is less clear. Some research indicates that they may function to regulate the levels of intracellular substances responsible for controlling ion channel permeability. In the gastrointestinal mucosa and liver, they are a formidable barrier to many of the orally administered drugs. As shown in *e*Table 40.0.1, many families of P450 have different but sometimes overlapping specificity for metabolism of certain cardiovascular drugs. *e*Table 40.0.1 lists the drugs for which a specific P450 is the major enzyme responsible for its metabolism, and it also lists drugs or agents that induce the synthesis of the P450s and agents that are inhibitors of the enzymes. Notice that some agents have relative selectivity for a given P450, whereas others are more general in their ability to inhibit or induce P450s. The cardiovascular drugs are predominantly metabolized by CYP3A and CYP2D6. Knowledge of the specific P450 involved in the metabolism of drugs has become of clinical value in more recent years. For example, if it is known which P450 is responsible, it is possible to predict the extent of variability of metabolism in the population at large. It will also be possible to predict which drugs are likely to inhibit or induce the metabolic clearance of the drug. In the relatively near future, it is likely that knowledge of the genetic inheritance of an individual will allow the physician to predict the degree of P450 enzyme expression in an individual and adjust therapy appropriately.



***e*FIGURE 40.0.2** A drug (D) absorbed from the intestines passes to the liver via the hepatica vein. As it passes through the liver, the drug may be metabolized by one or more of the phase 1 P450 enzymes (e.g., CYP3A, 2C19, 2D6, 2E1, 1A2, 2C9). The oxidized product may then be conjugated by phase 2 enzymes such as *N*-acetyltransferase (NAT), glutathione-*S*-transferase, or others before being excreted into the bile or passing into the hepatic vein and ultimately into the systemic circulation.

***e*TABLE 40.0.1** OXIDATIVE DRUG METABOLISM

CYP1A2	2C19	2C9	2D6	2E1y	3A3,4,5
Drugs					
Theophylline	S-mephenytoin	Tolbutamide	Propafenone	Acetaminophen	Erythromycin
R-warfarin	Phenytoin	Phenytoin Y4-OH	Flecainide	Theophylline	Clarithromycin
Caffeine	Diazepam	S-warfarin	S-mexiletine	Ethanol	Quinidine
Acetaminophen	Omeprazole	Losartan	Lidocaine (in part)	Ondansetron	Lidocaine
Amiodarone	Lansoprazole	Fluconazole	S-metoprolol	Halothane	Cyclosporine
Cimetidine	R-warfarin	Isoniazid	Propranolol	Enflurane	FK506
Mexiletine	Propranolol (in part)	Amiodarone	Timolol	Sevoflurane	Terfenadine
Propranolol	Imipramine		Carvedilol	Methoxyflurane	Astemizole
Estradiol	Amitriptyline (in part)		Phenytoin	Isoflurane	Verapamil
Verapamil	Indomethacin		Guanoxan		Nifedipine
			Clomipramine		Diltiazem
			Imipramine		Felodipine/nisoldipine
			Haloperidol		Lovastatin
			Dexfenfluramine		
Inhibitors					
Cimetidine	Ketoconazole	Fluconazole	Haloperidol	Disulfiram	Ketoconazole
Amiodarone	Cimetidine	Isoniazid	Quinidine		Itraconazole
Fluoroquinolones	Omeprazole	Amiodarone	Fluoxetine		Fluconazole
	Lansoprazole		Cimetidine		Erythromycin

Hepatic Clearance

For many drugs, the liver is the major site of drug-metabolizing activity in the body. Hepatic extraction may include biotransformation (metabolism), biliary excretion, and drug binding to intracellular proteins. Hepatic clearance is influenced by two independent variables: the activity of drug-metabolizing enzymes and liver blood flow. The relative importance of these two factors depends on the particular drug. For a drug with a low hepatic extraction ratio, increases in enzyme activity result in important changes in pharmacokinetic variables (increases in clearance and a shortened elimination half-life). On the other hand, for a drug with a high extraction ratio, increased metabolizing activity has little effect. Conversely, changes in hepatic blood flow affect high-extraction drugs, but not low-extraction drugs. Thus, changes in liver blood flow do not alter the disposition of phenytoin (a low-extraction drug), whereas enzyme induction does not have a large effect on the disposition of lidocaine or propranolol (high-extraction drugs).

Some drugs are so extensively cleared by the liver after absorption by the gut and before entering the general circulation (the first-pass effect) that oral use is not feasible. One example is lidocaine, which is well absorbed, but only approximately 35% is systemically bioavailable after oral administration. Increasing the oral dose to attain therapeutic plasma levels results in a corresponding increase in the levels of lidocaine's metabolites. These metabolites, however, result in unacceptable central nervous system (CNS) side effects, precluding the use of large oral doses of lidocaine.

Enzyme Induction and Inhibition

Certain agents (enzyme inducers) can promote synthesis of microsomal enzymes, resulting in increased drug-metabolizing activity. In some cases, the increased activity results in more rapid destruction of the drug itself, and tolerance to the drug develops as a consequence. Some drugs, however, are able to induce enzymes for which they themselves are not substrates. Concomitantly administered agents, which happen to be substrates for the induced enzyme, then may be subject to increased hepatic metabolism. Enzyme induction is most likely to have important consequences for the disposition of drugs with a normally low hepatic extraction ratio.

A number of agents can inhibit drug-metabolizing enzymes, increasing the systemic availability of drugs normally highly extracted by the liver. For instance, cimetidine increases the availability and prolongs the half-life of lidocaine (8) and propranolol (9). Propranolol, both by reducing hepatic blood flow and by inhibiting microsomal enzymes, decreases the clearance of lidocaine (10).

Obviously, careful patient observation is necessary whenever multiple medications are prescribed, but especially when stopping or starting a drug that alters the metabolism of other agents. Some drugs with known or proposed enzyme induction or inhibition effects in humans are listed in *e*Table 40.0.1.

Such changes in drug metabolism can result in unexpected toxicity or loss of therapeutic effect and may not be immediately apparent. For example, amiodarone covalently binds to several cytochrome P450s and noncompetitively inhibits the hepatic clearance of many drugs (11). Because the elimination half-life of amiodarone ranges from 2 weeks to 15 weeks, it may take months before the effect becomes manifest or months before normal hepatic clearance of other drugs is restored after stopping amiodarone.

Renal Clearance

Products of drug metabolism are usually more polar, and thus more water soluble, than the parent compound, facilitating excretion via the kidneys by either passive glomerular filtration or active tubular secretion. The kidneys are by far the most important routes of excretion of unchanged drug or drug metabolites. In some cases, excretion by the kidneys is the major route of elimination and the means of terminating a drug's effect. In other cases, the kidneys simply excrete a drug's inactive metabolites.

Elimination by glomerular filtration is a passive process, dependent on the extent of plasma protein binding. Because only free drug can pass the glomerular membrane, a highly protein-bound drug that is not actively secreted into the urine is eliminated slowly. If this is the main route of elimination and the volume of distribution is large (i.e., little drug in plasma), a prolonged half-life can result. For example, diazoxide is 90% bound to albumin and eliminated by glomerular filtration with a half-life of approximately 30 hours. Changes in protein binding that result in an increase in free drug concentration also increase renal elimination and shorten the elimination half-life.

Although glomerular filtration is a passive process, tubular secretion is an active process and may or may not occur, depending on the particular drug. When renal clearance exceeds clearance by filtration, tubular secretion can be inferred. As free drug is carried into the tubular lumen, more free drug dissociates from the protein–drug complex to replace the "lost" drug. Protein binding, therefore, does not limit tubular secretion as it does glomerular filtration.

Tubular reabsorption can also be important in reducing the renal clearance of drugs. Because the nonionized form of a weak acid or base can diffuse readily from the tubular urine back across the tubule cells into plasma, an alkaline urine promotes excretion and prevents reabsorption of a weak acid, whereas an acidic urine diminishes excretion and favors reabsorption. The opposite relationship is true for weak bases. For example, the half-life of mexiletine, a weak base, is approximately 9 hours when the urine is alkaline, and 3 hours when the urine is acidic (12).

Protein Binding

In plasma, most drugs are reversibly bound to plasma proteins, including albumin, alpha-1-acid glycoprotein (AAG), lipoproteins, and gamma globulins. Although the most abundant protein, albumin, avidly binds acidic drugs, many cardiovascular agents are basic and bind to AAG (13). AAG is an acute-phase protein whose concentration increases dramatically in response to stresses such as myocardial infarction, burns, or surgery. Increased levels have also been reported in chronic inflammatory diseases such as rheumatoid arthritis, inflammatory diseases, and Crohn's disease.

The degree of protein binding has implications for both drug disposition and drug effect. Only the unbound free drug is able to cross cell membranes or bind to receptor sites, thereby eliciting a pharmacologic effect. A decrease in protein binding, as a result of disease or displacement by another drug, increases the free fraction, which in turn increases the amount of drug available for equilibration with extravascular sites. This increases the volume of distribution and may alter clearance as described here.

Changes in protein binding are most likely to be clinically important for drugs that are highly protein bound. For example, for a drug that is 98% bound to plasma protein, a decrease in binding to 96% doubles the free fraction from 2% to 4%. For a drug that is 60% bound, a similar decrease in binding results in only an increase of one-twentieth (from 40% to 42%) in the free fraction. In the latter case, clinically important consequences of the change in protein binding are unlikely. In the former case, the clinical significance depends on the total amount of drug present in the plasma and whether the increase in free fraction results in a corresponding increase in free drug concentration. This, in turn, depends on whether the increase in free fraction is accompanied by an increase in clearance. For most protein-binding displacement interactions, so-called bumping reactions, the *transient* increase in free drug is not clinically relevant because the drug rapidly distributes into tissues, is metabolized, or both. In the rare cases in which displacement of drug from plasma proteins is clinically relevant, a concomitant inhibition of drug metabolism is usually responsible for accumulation of excess drug (14).

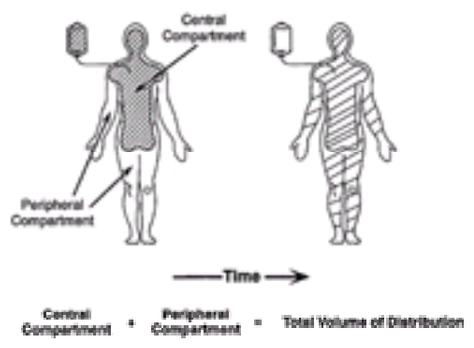
Plasma protein binding can serve as a drug storage site, "protecting" drug from passive elimination processes in the liver and kidneys, or it can act as a delivery system for drugs that are highly cleared by the liver or kidneys as a result of active transfer processes.

For most drugs, the fraction of drug bound to protein, at least for doses in the therapeutic range and well beyond, remains constant. Some drugs (e.g., disopyramide), however, show nonlinear saturable protein binding in the range of concentrations attained during routine clinical use. Thus, as the total plasma concentration increases, so does the free fraction. For example, doubling the total disopyramide concentration from 2 to 4 µg per mL may increase the free disopyramide concentration by as much as sixfold (15). The use of a slow-release formulation of disopyramide causes downward peaks on the impact of saturable protein binding.

CLINICAL PHARMACOKINETICS

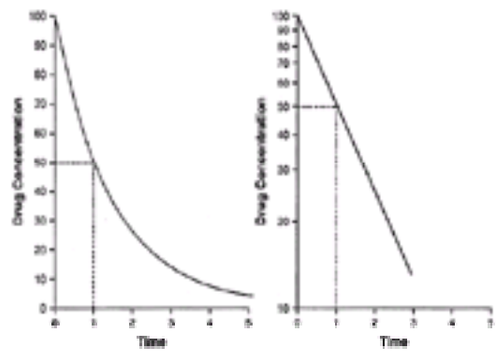
Pharmacokinetics describes the relationship of the processes of absorption, distribution, and elimination of a drug with time. The application of pharmacokinetics principles in the practice of medicine can improve dosage selection, resulting in improved clinical benefits and reduced toxicity (16,17). The fate of a drug in the body can be approximated by mathematical models fit to plasma concentration data that, in turn, allow prediction of dosing schedules.

The various spaces into which the drug distributes can be viewed as theoretical "compartments" or volumes containing a certain mass of drug, with rate constants for entry and exit of drug from each of these compartments. Entry and exit of drug occur from a central compartment, which in practical terms may be thought of as the plasma (and perhaps highly perfused tissues such as brain, lung, heart, and kidneys, depending on the rapidity of distribution to these tissues relative to others). The drug may distribute more slowly into various tissues that can then be regarded as peripheral compartments, with rate constants of entry to and exit from the central compartment (*e*Fig. 40.0.3). Although the postulated compartments may correspond to drug distribution and elimination from discrete tissue groups, such physiologic processes cannot be reliably inferred from the model. It is important to recognize that the purpose of partitioning a drug into compartments is simply to allow convenient mathematical description of the time course of drug disposition and to use knowledge of this time course to determine optional dosing regimens.



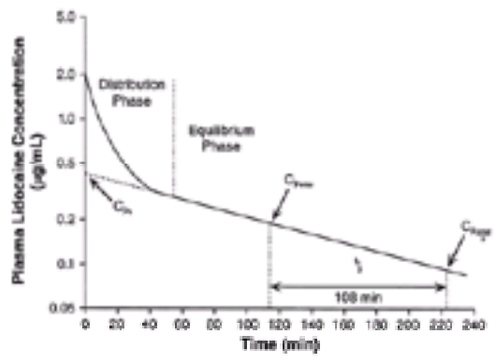
***e*FIGURE 40.0.3** Two-compartment model of drug distribution. A drug administered intravenously produces a high concentration in the central compartment; this concentration dilutes as the drug distributes into a larger peripheral compartment.

The simplest case is that of rapid, intravenous injection of a drug that is not distributed to other compartments. In this case, a semilogarithmic plot of plasma concentration against time yields a straight line (*e*Fig. 40.0.4). Such a linear relationship describes a first-order process (i.e., a process dependent on only one parameter). The amount of drug cleared from the plasma depends, at any instant, on one parameter, the amount of drug remaining in the plasma. Thus, plasma concentration decreases by a constant fraction with each unit of time. The most useful unit of time is that required for the plasma concentration to decrease by half and is the *elimination half-life*.



***e*FIGURE 40.0.4** Drug concentration with time during first-order elimination for a single compartment plotted on an arithmetic scale **(left)** and on a semilog scale **(right)**.

Following intravenous administration of a drug such as lidocaine, a plot of log plasma concentration against time (semilog plot) often shows an initial curvature. This departure from linearity represents the initial dilution of drug within the plasma and its distribution to other tissues. Once distribution is complete, drug in both the central and peripheral compartments is in equilibrium. The curve can be dissected into two straight lines rather than one; the first represents the *distribution* half-life (8 minutes for lidocaine), and the second already is familiar as describing the *terminal elimination* half-life (108 minutes for lidocaine) (eFig. 40.0.5).

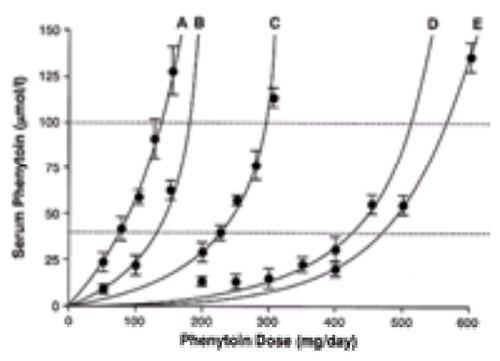


***e*FIGURE 40.0.5** Semilogarithmic plot of drug concentration against time, two-compartment model. The initial rapid decrease in plasma concentration (C_p) primarily reflects distribution.

This concept of mass action compartments wherein drug is distributed can be extended to multicompartment models. The semilog plot of plasma concentration with time following a single intravenous dose may then be described by a polyexponential equation, with rate constants for entry to and exit from each compartment. With the aid of computers to fit the data to an equation, however, most drugs can be modeled to one or two compartments. It is unusual to require more complex considerations such as a three-compartment model. A prominent example of such complexity is amiodarone, which usually requires three or more exponents to describe its disposition.

A drug administered by a route other than an intravenous one first must be absorbed into the circulation. A semilog plot of plasma concentration against time shows an initial increase in concentration as drug is absorbed, followed by equilibration of drug between central and peripheral compartments, and a linear elimination phase with a slope identical to that evidenced with intravenous administration. Absorption, like elimination, is usually a first-order process; a constant fraction of the total drug present is absorbed per unit of time. As the amount of drug remaining to be absorbed diminishes, so does the rate of absorption. Sustained release preparations, in which drug slowly dissolves out of a wax or polymer matrix, are designed to be roughly analogous to a constant-rate infusion. This may be zero-order (independent of the total amount of drug) absorption (i.e., a constant amount of drug is absorbed per unit of time). Zero-order absorption is the case whenever a reservoir of drug is available to replace the amount absorbed.

Pathways of elimination (e.g., biotransformation, renal tubular secretion) may become saturated at high doses of drug, and elimination may change from a first-order to a zero-order process. This is the case for elimination of propranolol (18), phenytoin (19), and possibly diltiazem (20), which exhibit first-order elimination at low doses and zero-order elimination at high doses, leading to disproportionately large increases in plasma concentration with increasing dose (eFig. 40.0.6).

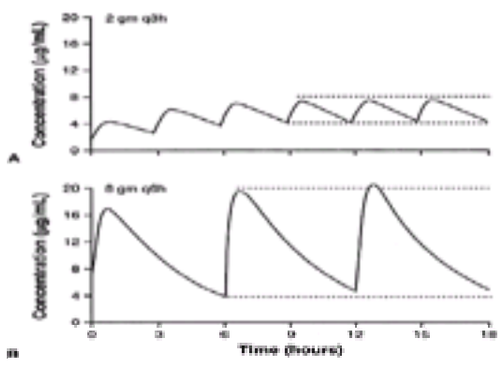


***e*FIGURE 40.0.6** Effect of increasing phenytoin dose on plasma phenytoin concentration. Dashed lines indicate therapeutic window. At low doses, increasing the dosage produces a proportional increase in plasma concentration. At high doses, as elimination pathways become saturated, increased dosage produces a disproportionately large increase in plasma concentration. (From Richens A, Dunlop A. Serum phenytoin levels in the management of epilepsy. *Lancet* 1975;2:247, with permission.)

The mathematical relationships describing the previously mentioned processes provide the basis for constructing dosing schedules and are of practical utility in understanding and interpreting plasma drug concentration information (21,22).

Drug Accumulation

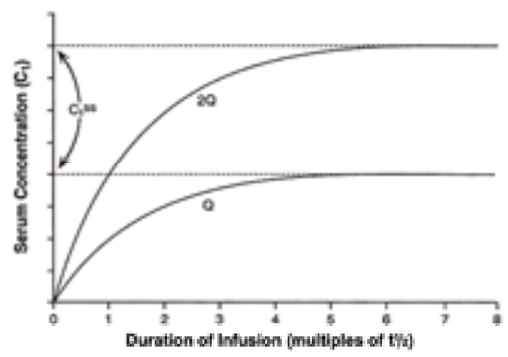
Most drugs are given as multiple doses to maintain an effective plasma concentration. In practice, there is fluctuation about a mean plasma concentration between doses. The degree of thefluctuation depends on the length of the dosing interval relative to the elimination half-life. If the dosing interval is short relative to the half-life, the fluctuation will be small, but the degree of accumulation will be large. Conversely, a long dosing interval combined with a short half-life results in wide fluctuation but little accumulation. By definition, the plasma concentration of a drug administered at intervals corresponding to its half-life shows a twofold fluctuation between minimum and maximum plasma concentration. The acceptability of a dosage regimen depends more on the width of the therapeutic window than on the half-life (eFig. 40.0.7); in fact, few drugs are administered every half-life (23).



***e*FIGURE 40.0.7** Relationship among the elimination half-life, the width of the therapeutic window, and the frequency of dosing for a rapidly absorbed and eliminated drug (in this case, procainamide). These computer simulations of plasma concentrations show that frequent dosing is required when the therapeutic window is narrowing (4 to 8 µg per mL) **(A)** to avoid excessively high or low values. If the therapeutic window were wider (e.g., 4 to 20 µg per mL) **(B)**, larger doses could be given less frequently. Because the elimination half-life (139 minutes) is not changed, the time to reach steady-state conditions is the same. (From Roden DM, Woosley RL. Application of pharmacologic principles in the evaluation of new antiarrhythmic agents. In: Morganroth J, Moore EN, eds. *Sudden cardiac death and congestive heart failure: diagnosis and treatment*. Amsterdam: Martinus Nijhoff, 1983:13, with permission.)

Steady State

By definition, following multiple dosing or continuous infusion, a drug reaches *steady state* when the rate of entry into the body equals the rate of elimination (i.e., true equilibrium). An important concept is that the time taken to reach steady state or to eliminate the drug completely depends only on the elimination half-life of the drug or active metabolites, if these accumulate. *e*Figure 40.0.1 illustrates the relationship between half-life and drug accumulation or elimination. It is evident that after approximately five half-lives, either process is virtually complete. Neither increasing the dose nor increasing the rate of administration hastens the achievement of the plasma concentration plateau; such maneuvers simply increase the final plasma concentration achieved (*e*Fig. 40.0.8). Loading doses (see Loading Dose Calculations, later in this chapter) may allow one to reach an effective concentration sooner, but do not alter the time ultimately required to reach true steady state.



***e*FIGURE 40.0.8** Plasma concentration against time for constant infusion at rates Q and 2Q. Note that plateau concentration is reached at the same time, independent of Q, but that the plateau concentration achieved depends on Q. C_1^{SS} is the concentration at steady state for each of the two infusion rates.

It also follows that factors influencing the elimination half-life also affect the time taken to reach steady state. For instance, a reduction in liver blood flow due to diminished cardiac output or treatment with beta-blockers or cimetidine can prolong the half-life of drugs that are extensively metabolized in the liver. Renal dysfunction can slow clearance and thus prolong the half-life of drugs eliminated by the kidneys. In either case, it will take correspondingly longer to reach steady state, so that premature dose escalation based on the usual time taken to achieve plateau plasma levels would lead to excessive accumulation of drug. Chronic administration of drug can also be associated with changes in elimination kinetics, especially for drugs eliminated mainly by the liver and for those with hemodynamic effects that reduce splanchnic blood flow. For example, the elimination half-life of verapamil is approximately twice as long during long-term oral therapy (24), so that less frequent dosing is required to prevent toxicity.

Initial Dose Calculations

The selection of an initial dose of a drug must take into account the pharmacokinetics of the drug and the clinical objectives of therapy. In most cases, the drug accumulates to some degree during chronic therapy. Unless the patient requires urgent treatment, it is often preferable to allow the drug to accumulate to steady state without the use of a loading dose (see following section). The initial dose should be one that is likely to be safe and well tolerated when steady state is reached. If one has an estimate of the volume of distribution of the drug and a target plasma concentration, it is a simple matter to estimate the initial dosage that will produce that concentration. As shown in *e*Figure 40.0.7, it is essentially the definition of the word *concentration*. Concentration = mass/volume or, stated more appropriately,

$$\text{Target concentration} = \frac{\text{Dosage of drug}}{\text{Volume of distribution}}$$

Loading Dose Calculations

In many instances, it is not feasible to wait four to five half-lives before effective plasma concentrations are attained. In such cases, a loading dose can be employed to attain an initial rapid increase in plasma concentration followed by maintenance doses to keep the plasma concentration within the therapeutic range. It always takes five half-lives to achieve steady-state concentration, but an effective plasma concentration may be attained sooner. The price paid is an increased risk of attaining toxic plasma levels after an initial large dose. Loading doses may not be feasible if a drug has an active metabolite that accumulates slowly and is required for optimal clinical response. In addition, should the maintenance dose be too high or too low, side effects or loss of efficacy, respectively, will develop after an apparently calculated beneficial response to the loading dose. For these reasons, reassessment of a patient's response at true steady state is always essential.

In cardiology, one of the most common applications of loading dosages is in the treatment of ventricular arrhythmias with drugs such as lidocaine. In this clinical situation, it is desirable to produce an antiarrhythmic effect rapidly. The relatively long half-life of lidocaine (approximately 2 hours) means that it will be several hours before lidocaine accumulates to effective concentrations if a patient were simply placed on a maintenance infusion. The following is a general discussion of how the principles of a loading dosage can be applied to the use of lidocaine.

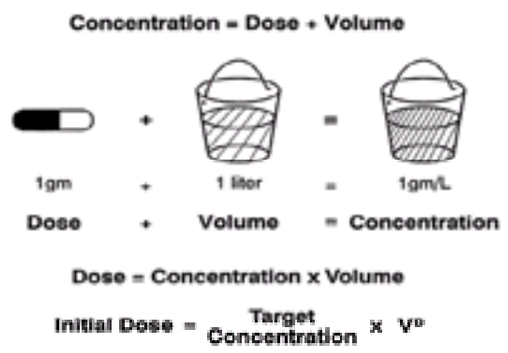
A loading dose ideally would be adequate to produce a concentration in the middle of the therapeutic window (3 µg per mL) when the drug has totally distributed throughout the body. For a 75-kg person with normal hemodynamics and organ function, however, the total volume of distribution of lidocaine at steady state averages 100 L. *e*Table 40.0.2 and *e*Figure 40.0.9 describe the concepts and the equation to calculate the magnitude of a loading dose when the volume of distribution and the desired concentration are known. However, calculation of the loading dose for the volume of distribution at steady state would result in a loading dose of 300 mg of lidocaine, a dose that would be extremely toxic if given at one time. We know that lidocaine, when administered intravenously, behaves according to the kinetics of a linear two-compartment model system. Initial concentrations after a rapid injection indicate that the volume of the central compartment is approximately 33 L, approximately one-third of the total volume of distribution. Administering one-third of the total loading dose should produce a plasma level of 3 µg per mL in the central compartment, which then declines with a distribution half-life of 8 minutes. After 8 minutes, the level should fall to 1.5 µg per mL because half of the initial dose (50 mg) has distributed into the peripheral compartment and replacement with a 50-mg injection should return the concentration to 3 µg per mL. If no additional loading dose is given at this time, the plasma concentration continues to fall below the usual therapeutic range. The maintenance dose should accumulate to reach the therapeutic range in several hours. During this period, however, the patient's arrhythmia may recur, and the patient may be mistakenly labeled "refractory" to lidocaine. As shown in *e*Figure 40.0.10, a series of loading injections every 8 minutes prevents the plasma concentration from falling below the therapeutic window and thereby prevents the

patient from becoming vulnerable to the development of lethal arrhythmias. eTable 40.0.3 displays a simplified version that is easy to remember and appropriate for most male or female patients of average size (approximately 70 kg). Both tables list the reduction in loading doses necessary for patients with heart failure in whom the volume of distribution is usually reduced to 50% of normal.

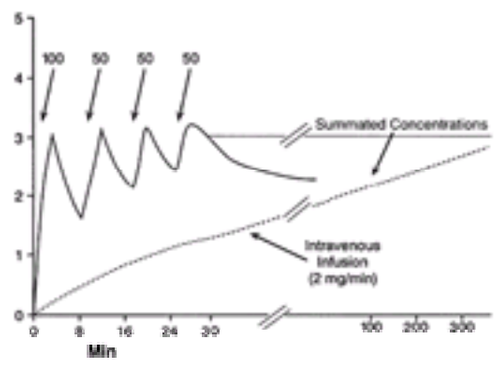
***e*TABLE 40.0.2** PROTOCOL FOR RAPIDLY PROVIDING PLASMA LIDOCAINE CONCENTRATIONS OF 3 µG PER ML[a]

			Load by body weight (mg/kg)	
Time	**Dose**		**Healthy patient**	**Patient with heart failure**
0	First bolus	Loads central compartment	1.5	0.9
8 min	Second bolus	Replaces loss in first half-life	0.8	0.4
16 min	Third bolus	Replaces loss in second half-life	0.8	0.4
24 min	Fourth bolus	Replaces loss in third half-life	0.8	0.4
		Total body load	3.9	2.1

[a]Protocol is based on loading dose = volume of distribution × desired plasma concentration = 1.32 L/kg × 3 µg/mL = 3.9 mg/kg. The patient should be monitored carefully and evaluated before each bolus injection (see text).



***e*FIGURE 40.0.9** The volume of distribution is based on the definition of the term *concentration*. Knowledge of the dose and the final concentration allows one to calculate the theoretical volume of distribution. Also, the initial dose can be calculated by multiplying the target concentration by the volume of distribution (V^D).



***e*FIGURE 40.0.10** Lidocaine loading regimen. An intravenous bolus of 100 mg reached 3 mg per mL (the target) but rapidly distributed to subtherapeutic levels (less than 1.5 mg per mL). To maintain concentrations in the therapeutic range, a series of replacement boluses should be given unless the patient has side effects (e.g., persistent tinnitus, heart block, hypotension, lethargy, slurred speech, seizures).

***e*TABLE 40.0.3** LIDOCAINE LOAD FOR AVERAGE PATIENT (MG)[a]

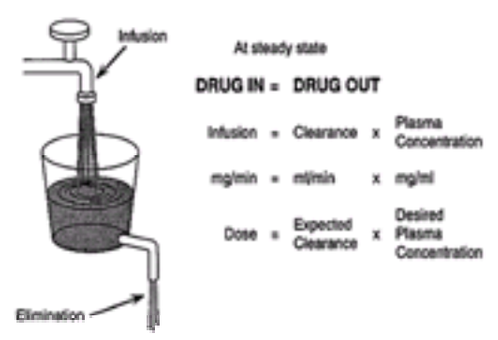
	Time (min)			
Patient type	**0**	**8**	**16**	**24**
Normal	100	50	50	50
With congestive heart failure	50	25	25	25

[a]Stop load for central nervous system symptoms, hypotension, heart block, and bradycardia (see text).

It must be emphasized that these guidelines are based on average values, and there is a large variance in the pharmacokinetic data for lidocaine. For example, the volume of the central compartment has been found to vary from 33 to 60 L. This means that the peak plasma concentration after a bolus injection varies up to twofold in healthy individuals. For this reason, one should choose the lower value of 33 L to calculate the initial loading bolus dose. Awareness of this variability is essential and requires that the patient be evaluated continuously while receiving lidocaine. During the loading process, the patient's electrocardiogram, blood pressure, and mental status should be monitored; at the first sign of excessive lidocaine administration, the loading process should be stopped.

Maintenance Dose Calculations

The selection of a maintenance dose is based on the concept that at steady state the amount of drug cleared from the body must be replaced. If the volume of plasma cleared of drug per unit of time (clearance) and the target concentration are known, multiplying these values yields the mass of drug cleared per unit of volume. eFigure 40.0.11 and eTable 40.0.4 and eTable 40.0.5 demonstrate how this calculation can guide the selection of an infusion rate that can be individualized for patients with heart failure or liver disease. eTable 40.0.4 lists the calculated dosages based on body weight in kilograms, and eTable 40.0.5 gives a simplified dosing regimen estimated for an average 75-kg adult.



***e*FIGURE 40.0.11** Calculation of a maintenance dose based on the principle that, at steady-state equilibrium, the amount of drug administered must equal what is eliminated.

***e*TABLE 40.0.4** PROTOCOL FOR MAINTAINING PLASMA LIDOCAINE CONCENTRATION OF 3 µG PER ML[a]

Patient	**Infusion rate (µg/kg/min)**
Normal (clearance = 10 mL/min/kg)	30
Heart failure (clearance = 6 mL/min/kg)	18

[a]Protocol based on dose = desired plasma concentration × clearance (e.g., = 3 µg/mL × 10 mL/min/kg = 30 µg/kg/min).

***e*TABLE 40.0.5** LIDOCAINE MAINTENANCE THERAPY FOR AVERAGE PATIENTS

Healthy patients	2–3 mg/min or 30 µg/kg/min
Heart failure	1–3 mg/min or 19 µg/kg/min
Liver disease	0.5–1.0 mg/min or 10 µg/kg/min

Again, it must be emphasized that these are first approximations of dosage, and all patients must be monitored to detect individuals who fall at the extremes of the normal distribution. Because some patients have a half-life of elimination of 4 to 5 hours, accumulation may occur for up to 24 hours. Late development of CNS side effects, disorientation, or lethargy should prompt the suspicion of lidocaine toxicity, which can be easily verified with a lidocaine plasma assay. Any patient who develops late CNS symptoms while receiving lidocaine is a likely candidate for lidocaine toxicity. The utility of plasma concentration monitoring in this and other situations is discussed in the following sections.

CAUSES OF VARIABILITY IN DRUG RESPONSE

Liver Disease

Chronic liver disease has the greatest effect on drugs that are normally highly cleared by the liver. Both drug-metabolizing activity and hepatic blood flow may be reduced, with portosystemic shunting diverting portal blood (and unchanged drug) directly to the systemic circulation. These changes reduce hepatic clearance and thus raise plasma concentrations of unchanged drug. For most drugs, reduction in dosage or dosage interval is necessary to avoid toxicity. For a drug with active metabolites, the net effect would depend on the pharmacokinetics and pharmacodynamics of the metabolites compared with the parent drug. In cases in which therapeutic benefit is largely derived from active metabolites, another agent, not subject to hepatic metabolism, should be considered. Aside from changes in drug disposition, there is some evidence of pharmacodynamic change for certain drugs in patients with hepatic disease. For example, the CNS effects of benzodiazepines are exaggerated in such patients, particularly in the presence of hepatic encephalopathy.

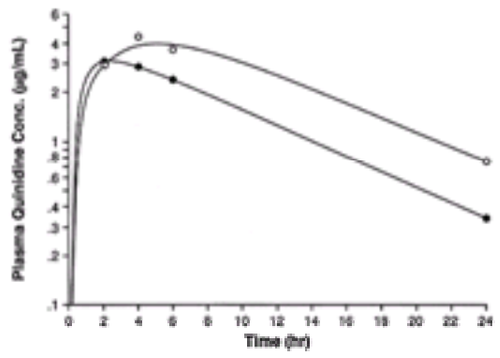
Renal Disease

Obviously, renal disease has the greatest effect on those drugs eliminated mainly by the kidneys. Renal disease can also affect protein binding (25) (hypoalbuminemia; presence of binding inhibitors or altered affinity of protein for drug), drug metabolism (diminished activity of some enzyme systems including *N*-acetyltransferase), and urinary pH (alkalinization can alter tubular reabsorption of drugs and the degree of ionization of weak bases, resulting in diminished excretion).

It is difficult to predict the interplay and relative contribution of these various effects to changes in drug disposition. For drugs that are mainly eliminated by renal excretion, one can expect decreased clearance and prolongation of elimination half-life, often in direct proportion to the decrease in creatinine clearance. For example, the half-life of digitoxin, elimination of which involves mainly extrarenal pathways, does not change in renal failure, whereas the half-life of digoxin, which is largely eliminated by the kidneys, increases with severe renal failure from 36 hours to approximately 4 days. Sotalol and the active metabolite of procainamide, *N*-acetylprocainamide (NAPA), are eliminated by the kidneys and can accumulate to toxic levels in renal failure (26,27). Obviously, if accumulation to toxic levels is to be avoided, less drug must be administered, by either increasing the dosing interval or decreasing the dose administered.

Cardiac Failure

Decreased cardiac output and increased sympathetic tone in patients with congestive heart failure result in diminished blood supply to the gut, liver, and kidneys, and in poor peripheral perfusion. These changes have implications for drug absorption, distribution, and elimination. Delayed and incomplete absorption of drugs in patients with cardiac failure can be expected. For instance, cardiac patients may absorb approximately half as much quinidine as healthy subjects and take twice as long to reach peak plasma concentration (28). Because of the reduced volume of distribution, however, plasma concentrations attained by cardiac patients may be higher than those in control subjects (*e*Fig. 40.0.12).



***e*FIGURE 40.0.12** Plasma quinidine concentrations in healthy subjects (*closed circles*) and in congestive heart failure patients (*open circles*) following oral administration of 600 mg of quinidine sulfate. The data points are the mean levels in ten subjects. (From Crouthamel WG. The effect of congestive heart failure on quinidine pharmacokinetics. *Am Heart J* 1975;90:335, with permission.)

A decreased volume of distribution in cardiac failure has also been described for disopyramide (29) and lidocaine (30). It is important to recognize that, even in patients with fluid retention and “volume excess,” the volume of drug distribution can be *reduced*, increasing plasma concentrations and resulting in excess drug action. Cardiac failure may also result in significant changes in drug clearance, both for drugs with a clearance dependent mainly on organ blood flow and for those with a clearance determined by drug-metabolizing enzyme activity. Cardiac failure decreases perfusion of the liver and kidneys, and a decrease in drug-metabolizing enzyme activity has been found in liver biopsy specimens from patients with congestive cardiomyopathy. A direct relationship between plasma clearance of lidocaine and cardiac output has been described, with a mean 39% decrease in lidocaine clearance among heart failure patients compared with healthy subjects (30).

Depending on the relative magnitude of changes in clearance and volume of distribution, the elimination half-life may be unaffected or prolonged. Despite changes in clearance, the mean elimination half-life of lidocaine (30), procainamide (31), and quinidine (28) appear similar in patients with and without heart failure, whereas those of disopyramide (29) and mexiletine (32) appear to be prolonged in patients with heart failure and require a proportionately longer time to reach steady state. It is important to recognize that, although half-life may not be prolonged in congestive heart failure, clearance is usually reduced and total dosage must be reduced proportionately.

Clearly, drug therapy in patients with cardiac failure requires initial low doses with escalation under careful supervision. Prolongation of elimination half-life may also warrant less frequent dosing and less frequent changes of dose because the length of time to reach steady-state plasma concentration is increased.

Acute Myocardial Infarction

The patient with acute myocardial infarction presents a special challenge with respect to drug therapy. Altered hemodynamics and increased levels of AAG can markedly affect the disposition of any drug administered following myocardial infarction.

Lidocaine is one of the most frequently administered and probably the most extensively studied drug in the setting of acute myocardial infarction. Administration of lidocaine to patients suspected of having sustained an infarction results in a broad range of plasma levels with accumulation of lidocaine in plasma during a constant infusion in patients with confirmed infarction. These changes can be largely explained by an increase in plasma protein binding as a result of increased levels of AAG (33). Although the total plasma concentration increases in parallel to AAG concentration, the free fraction declines, and free lidocaine concentration remains fairly constant. Therefore, higher than usual plasma concentrations may be well tolerated in acute myocardial infarction (concentrations of 6 to 12 µg per mL, normally considered toxic, have been reported to be well tolerated several days after myocardial infarction) and indeed may be necessary to maintain adequate free lidocaine levels for antiarrhythmic effect. Similarly high plasma concentrations of drug when administered to patients with myocardial infarction have been reported for quinidine (34) and disopyramide (35). In addition to increased total plasma concentration of drugs binding to AAG, the changes in drug disposition described for lowered cardiac

output and renal impairment may also apply following myocardial infarction.

A further consideration in drug therapy following myocardial infarction is that the usual temporal relationship between drug administration and effect may be altered. The heart is normally a highly perfused organ so that most drugs in plasma rapidly equilibrate with myocardial tissue. In infarction, however, the areas of poorly perfused myocardium appear to accumulate (and eliminate) drug far more slowly than does the rest of the heart (36). Thus, such areas function as peripheral, rather than central, pharmacokinetic compartments and, depending on the drug's effector site, there may be a corresponding delay between drug administration and pharmacologic effect.

Age

Drug disposition in both the elderly and the very young can vary widely from that in the young adult population in which it is usually defined during drug development. Deterioration or immaturity of renal and hepatic function can result in significant changes in the pharmacokinetic variables. For example, elderly patients have a reduced response to beta-receptor agonists and antagonists, probably because the number of beta-receptors declines with age (37). On the other hand, elderly patients show an increased sensitivity to benzodiazepines (38) and coumarin anticoagulants (39). However, many drugs have not been systematically evaluated in either the very young or the elderly, and information has often been gained through anecdotes or adverse clinical experiences, sometimes at considerable human expense.

Biologic Sex

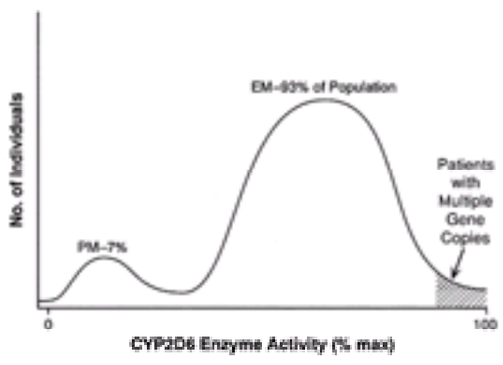
In more recent years, we have become aware of the importance of examining the importance of sex in determining drug response. However, there are still limited data comparing drug response in men and women. Numerous studies have demonstrated pharmacokinetic differences between men and women, mainly for drugs metabolized by CYP3A4. However, none of the differences is large enough to be clinically relevant.

On the other hand, Makkar et al. (52) called attention to the greater risk of torsades de pointes in women treated with antiarrhythmic drugs. This retrospective metaanalysis was supported by two clinical studies in which the investigators demonstrated a greater sensitivity of the QT interval in female than male subjects to ibutilide (52a) or quinidine (53). Drici et al. (54) have observed that treatment with dihydrotestosterone can reduce the QT response to quinidine in isolated perfused rabbit hearts. These studies have demonstrated, for the first time, clear sex differences in myocardial response to drugs and point out the need for further studies with other drugs, especially those affecting cardiac repolarization.

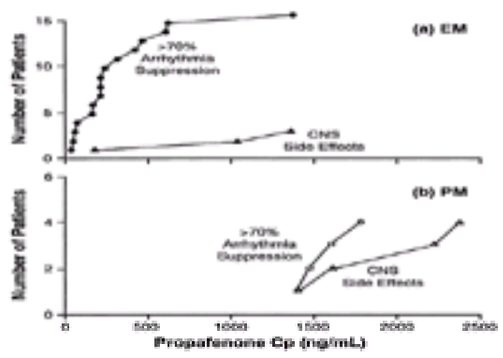
Metabolic Polymorphism

Although in most cases drugs are metabolized to compounds with little or clinically inconsequential pharmacologic activity, in some instances metabolites can contribute significantly to the efficacy or toxicity observed after administration of the parent drug. For instance, the monoethylglycine xylidide metabolite (MEGX) of lidocaine possesses some antiarrhythmic activity, and the glycine xylidide metabolite potentiates the convulsant properties of both lidocaine and MEGX (40). Certain metabolites of quinidine may be antiarrhythmic and may contribute to QT prolongation seen during therapy (41). NAPA, the major metabolite of procainamide, can be antiarrhythmic in its own right, with electrophysiologic and clinical effects distinct from procainamide. Therefore, NAPA may or may not contribute to the antiarrhythmic actions of procainamide. However, high concentrations of NAPA can certainly contribute to toxicity, including torsades de pointes, a syndrome of polymorphic ventricular tachycardia occurring in a setting of marked prolongation of the QT interval. Acetylator phenotype, which markedly influences the response to drugs that are substrates for *N*-acetyltransferase, is genetically determined and bimodally distributed. In white and black populations, the distribution between slow and fast acetylators is approximately equal, whereas Asian populations are predominantly (90%) rapid acetylators. Procainamide-induced lupus occurs more frequently and earlier in slow acetylators. However, there is no readily available way of predicting acetylator phenotype without administering a drug. Therefore, one should monitor both parent drug and metabolite levels on at least one sample in patients receiving these drugs. A NAPA to procainamide ratio greater than unity when dosing is at steady state (and renal failure is absent) indicates a rapid acetylator phenotype (42). The clinician should be aware that the patient may be responding to parent drug, metabolite, or both.

Bimodal distribution of enzymes involved in oxidative metabolism has been described for debrisoquine (43), propranolol (44), flecainide, timolol, metoprolol (45), carvedilol (46), and propafenone (*e*Fig. 40.0.13) (4). As described previously, 7% of the population lack the major enzyme responsible for biotransformation of these drugs, CYP2D6. The clinical implications in these poor metabolizers depend on the relative potencies and pharmacokinetics of the arent drug and metabolites. For example, in CYP2D6 extensive metabolizers, the oral bioavailability of propafenone (a drug with sodium channel and beta-blocking actions) is approximately 25% to 35% as a result of extensive presystemic metabolism; the elimination half-life of propafenone in these individuals is approximately 5.5 ± 2.0 hours (range, 2 to 10 hours) (4). Apparent elimination half-lives of 5-hydroxy propafenone, a metabolite with sodium channel blocking activity but little potency as a beta-blocker, on the other hand, are considerably longer (9.0 ± 1.5 hours) (47). In contrast, in poor metabolizers (7% of the population), oral bioavailability is approximately 90% to 95%, with a propafenone elimination half-life of 17 ± 8 hours. These differences result in a distinct plasma drug-concentration profile and pharmacodynamic consequences in poor metabolizers (eFig. 40.0.14), because certain metabolites of propafenone have antiarrhythmic activity equal to that of propafenone.



***e*FIGURE 40.0.13** The graph displays the distribution pattern for the activity of the CYP2D6 enzyme activity in a white population. Most patients are either homozygous for the normal (wild-type) alleles or are heterozygous and have one mutant allele. These are termed *extensive metabolizers* (EM). Ninety-three percent of the population are extensive metabolizers with two wild-type alleles, but 7% express the highest activity because they have multiple copies of the CYP2D6 gene. Seven percent of the population inherit two alleles for one or more of the seven known mutations that result in low or absent levels of enzyme activity and are termed *poor metabolizers* (PM). In African-American or Asian populations, the PM incidence is 1% to 2%.



***e*FIGURE 40.0.14** Predose plasma concentration (Cp) of propafenone versus cumulative frequency of antiarrhythmic response and central nervous system (CNS) side effects in patients with the CYP2D6 extensive metabolizer (EM) phenotype **(a)** and poor metabolizer (PM) phenotype **(b)**.

Receptor Polymorphism

In more recent years, it has become apparent that some of the variability in response to drugs is caused by inherited differences in the structure of the receptors for drugs. Polymorphisms in the beta-receptor have been associated with the development of tolerance to beta-agonists in asthma (54a). Mutations in the serotonin transporter are thought to be responsible for depression in Parkinson's patients (54b). In these cases, the response to a given drug depends on whether it has the same action at the mutated receptor as at the wild-type receptor. This is an active area of research and one that has a great deal of potential to reduce much of the empiricism now such a great part of therapeutics.

Drug Interactions

Drug interactions can generally be classified as either pharmacokinetic or pharmacodynamic. Pharmacokinetic interactions are the result of processes that lead to a change in the disposition of one or more drugs and result in a change in clinical response. The most common form of a pharmacokinetic interaction is when one drug induces or inhibits the metabolism, elimination, or both of another, and the steady-state concentration of a drug is lowered or raised. Pharmacodynamic interactions result when drugs have separate actions that are either augmented or antagonized when the drugs are used together. A common example is when drugs that block beta-receptors and calcium channels are given together and produce excessive slowing of atrioventricular nodal conduction and heart block. It is important to note, however, that not all drug interactions are detrimental. Many times in medicine, pharmacokinetic interactions are used to reap a therapeutic advantage. The best example again involves beta-blockers and calcium channel blockers used synergistically to treat angina pectoris or hypertension.

ROLE OF THERAPEUTIC DRUG MONITORING

The usefulness of drug plasma concentrations as a means of guiding therapy presupposes a correlation between pharmacologic effect and plasma concentration of a drug. Although there generally is a correlation, plasma concentration can be misleading in some instances. For example, a pharmacologic effect may persist even after drug has been eliminated from plasma. Often, this may be accounted for by the presence of an active metabolite (e.g., NAPA) or some irreversible action of the drug that requires physiologic regeneration for termination of effect (e.g., depletion of catecholamine stores by reserpine). In some cases, a temporal delay between plasma concentration and effect may be the result of the drug's receptor site residing in a poorly perfused tissue or in a tissue into which drug diffuses slowly.

Further complications are poorly defined therapeutic ranges [the usually quoted therapeutic range for quinidine is derived using a nonspecific assay and is based mainly on 30-year-old data on conversion of atrial fibrillation (48)] and great interpatient variability in response. Part of this variability is explained by the fact that the free unbound drug is considered pharmacologically active, whereas most therapeutic ranges are based on total plasma concentration of the drug (free drug plus that quantity bound to plasma protein). The extent of binding to plasma protein varies considerably. A range of 51% to 87% among healthy subjects has been quoted for quinidine (49); it is likely that variability among patients is greater. The situation could be improved by monitoring free drug rather than total plasma drug concentration, because the amount of free drug should correlate better with pharmacologic effect. For example, acute electrocardiographic changes caused by intravenous quinidine (50) and disopyramide (51) correlated well with free, but not total, drug levels. However, free levels of drug are rarely measured, partly because they are often too low for accurate measurement by conventional methods. It also should be mentioned that drug concentrations in whole blood or serum are not equivalent to plasma concentration. The ratio of blood to plasma concentration is related to the hematocrit, the affinity of the drug for blood cells, and the protein binding. Determination in serum carries the potential of loss of drug adsorbed to clots.

The specificity of the drug assay also should be taken into consideration when interpreting drug-level data. Is the assay specific for unchanged drug, or does it also include metabolites that may themselves possess pharmacologic activity and distinct pharmacokinetics Newer, more specific assays that measure parent drug alone may not correlate well with a therapeutic range based on older nonspecific assays.

Drug-level data can be useful only if accompanied by some knowledge of the dosing history, when the sample was obtained relative to the time of dosing, concomitant medication, and other disease processes. Only then can the measured concentration be evaluated in a meaningful way. Finally, drug levels are no substitute for clinical judgment. Some patients respond (or even develop side effects) at low concentrations, whereas others may require high concentrations or tolerate them without side effects.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Therapeutic clinical trials have led to major advances in the treatment of cardiovascular disease, but none has had a more dramatic influence on the overall practice of medicine and the science of clinical trial methodology than the Cardiac Arrhythmia Suppression Trial (CAST). CAST demonstrated the potential error of extrapolating results in one population to another without confirmation of overall clinical benefit (i.e., drugs effective in suppression of life-threatening ventricular arrhythmias were found to increase mortality in a lower risk population). The results of CAST have made regulatory agencies reluctant to assume drugs are safe and effective unless tested in the relevant population. For example, aspirin prevents recurrent strokes and heart attacks, but is it safe and effective for primary prevention? The other obvious message from CAST emphasizes the value of having a placebo group. A therapy may not be effective even if the results are better than historical controls. Subsequently, the negative results seen with potassium channel blockers in the Survival with Oral d-Sotalol Study and the modest response, at best, to amiodarone in large clinical trials, have reinforced the lessons we learned in CAST. Another lesson from these trials is that drugs should not be developed to block normal ion channels. The targets for drug development should be selected based on an understanding of the mechanism of the disease. We do not yet understand the mechanism of sudden cardiac death at the cellular or metabolic level. Only with that knowledge will we be successful in designing new effective therapies.

But are therapeutics being practiced optimally? Fewer than one-half of the patients with heart failure who are candidates for beta-blockers or ACE inhibitors are prescribed these potentially life-saving drugs. Over 50% of post–myocardial infarction patients fail to receive potentially life-saving beta-blocker therapy, but an equal number receive potentially harmful calcium channel blockers. Twenty-three percent of prescriptions for the elderly have been judged inappropriate or dangerous. The second most common cause of malpractice suits is a prescription error. The data indicate that there is a serious need for better understanding of the drugs being prescribed, yet the changes in medical care today discourage this. Managed care organizations and insurers confront physicians with formularies that demand that their patients receive the lowest-bid drugs in each class. Physicians trying to prescribe the drug that they know best in a class are coerced to change their patients to the drug preferred by their insurers because it costs less. Physicians must master the needed information about therapeutics and stand firm as advocates for their patients.

THE FUTURE

The ability to determine the genetic basis of disease and genetic predictors of response to drugs is beginning to yield strategies that will reduce the current level of empiricism that complicates therapeutics. Today, we treat hypertension by empirically suggesting salt restriction and diuretic therapy. The only logic in the decision-making process is that certain populations (e.g., the elderly, African-Americans, whites) respond to a given class of drug. With improved understanding about the molecular mechanism for hypertension, it should be feasible to target therapy more specifically. As the molecular mechanisms of diseases are determined, more specific therapy will surely result.

It is currently possible to use polymerase chain reaction–based techniques to identify mutations responsible for common polymorphisms of cytochrome P450, CYP2D6, and CYP2C19. This knowledge can predict individuals at risk for flecainide toxicity; excessive beta-blockade with timolol, propranolol, or metoprolol; and unexpected responses to many other potent cardiac and neurologic drugs. The routine availability of P450 genotyping should enable physicians to choose drugs and dosages more intelligently, reducing the number of titrations necessary to obtain an optimal response and reducing the incidence of excessive drug effects. This will undoubtedly become routine in future therapeutics.

The basic principles of pharmacology will change dramatically as we are able to identify the genetic factors responsible for the variability in response to drugs. Genetic polymorphisms will be identified and drugs will be selected to act on genetically defined components of physiology or pathology.

OVERVIEW

The relationship between generalists and specialists and the role that each has in the overall care of patients has become an increasingly important issue in health care delivery and is undergoing dramatic changes. *Consultation* is the act of seeking advice regarding diagnosis and management, and *referral* is transferal of the patient to another physician for a specific therapy or management of a particular medical problem while the primary (or referring physician) provides general care. Consultation may be a major component of a cardiologist's practice, but a consultant's good clinical judgment only has an impact on a patient's care if recommendations are communicated effectively.

During consultation, ideally, there should be an exchange of information between the primary physician and the cardiology consultant, as well as coordination of care that ensures that patients receive care from the physician who is most likely to be able to provide a favorable outcome at the lowest cost. The consultant should determine whether the clinical situation is an emergency or whether it is urgent or elective. Emergency or urgent consultations should be discussed with the primary physician. It is important for the consultant to verify all information communicated by the physician. The most important component of successful cardiology consultation is effective communication with patients and primary physicians. The consultant should provide contingency plans and remember that follow-up increases compliance with recommendations.

Preoperative risk assessment is a frequent reason for cardiac consultation. As morbidity and mortality related to noncardiac surgery steadily decrease, cardiovascular management strategies that are known to improve long-term outcomes should guide decision making in the perioperative setting. Several factors may limit the predictive value of the clinical indices. There is extensive published data on the role of radionuclide perfusion imaging for preoperative risk stratification. Stress echocardiography is also evolving as a valuable tool for identifying high-risk patients. Risk reduction is the cornerstone of preoperative evaluation and management. Medical treatment and coronary revascularization procedures, when used appropriately, may significantly reduce perioperative cardiac events.

The preoperative cardiac consultation also represents an opportunity to initiate or modify cardiac care, including primary and secondary preventive measures. A stepwise approach to perioperative cardiac risk assessment, as set forth by recent joint American College of Cardiology (ACC) and American Heart Association (AHA) guidelines, should be used.

HISTORICAL PERSPECTIVE

Physicians have collaborated in the care of patients since antiquity. Hippocratic writings dating back to 400 BC refer to the importance of consultation in challenging medical cases (1). In 1927 (for the first edition of his textbook), Cecil explained why the work required more than one author:

"The rapid growth of medical science during the last few years has made it almost impossible for a single individual to master the entire field. In Internal Medicine, as in other branches of human knowledge, the age of specialism has of necessity arrived, and some of our ablest practitioners even devote themselves in great measure to one disease . . ." (2)

In 1940, approximately 1,000 American physicians considered themselves to be heart specialists, but few of them had received formal training in cardiology (3). Earlier in the twentieth century, possession of an electrocardiograph (ECG) defined a physician as a cardiovascular specialist. With the trend toward specialization, the number of cardiovascular specialists has increased substantially. Today, cardiologists still fill the traditional roles of teachers, researchers, and care providers, but the field has diversified to include endeavors from molecular biology to disease prevention to cardiac imaging to coronary intervention (3). In 1965, the number of self-designated cardiologists was 1,901. The ACC on its fiftieth anniversary reported 25,214 members, including 34 masters and 20,525 fellows (4). In 1999 and 2000, there were 190 cardiology training programs and 2,164 trainees (5). Burgeoning numbers of cardiovascular specialists have contributed to substantial advances in cardiovascular knowledge and patient care.

Foot and associates (6) studied the effects of the changing demographics of the U.S. population on the cardiology workforce. They estimated that the U.S. population would reach 275 million in 2000, 297 million in 2010, and 397 million in 2030. As a result of the World War II baby boom, the population is aging, and the number of senior citizens (age >65 years) will increase from 12.6% to 20.0% of the population between 2000 and 2030. Due to the increasing prevalence of heart disease, deaths from heart disease are projected to increase by 128% between 2000 and 2050 (6). This suggests that demand for cardiovascular specialists in the future will increase. Unless a revolutionary breakthrough in the management of cardiovascular diseases occurs, this demand will be evident in the next 5 to 10 years and will continue until at least 2030.

Although consultation can be a major component of a cardiologist's practice, the skills necessary to provide coordinated patient care are generally learned by trial and error. Primary care providers may seek some consultants, but other consultants may have difficulty converting knowledge gained through years of specialty training and practice into cost-effective cardiovascular consultation (7). The hallmark of successful cardiology consultation is effective communication with referring physicians. A consultant's good clinical judgment only has an impact on a patient's care if recommendations are communicated effectively (8). This chapter focuses on the goals and components of clinical assessment, the context in which such assessment occurs, and the function and elements of effective consultation.

RELATIONSHIP TO REFERRING PHYSICIANS

Generalists and surgeons usually have some knowledge and experience in treating patients with cardiovascular diseases, and therefore thresholds for referral to a cardiologist will vary. Referral may be influenced by a practitioner's level of diagnostic certainty (9), the availability of consultants (10), and the accessibility of diagnostic tests (11). Ongoing changes in the American health care system are likely to influence the route by which patients reach the care of a cardiovascular specialist, and self-referral by patients likely will be dramatically reduced if development of managed care continues to its logical conclusion. The Physician Workforce Advisory Committee of the ACC performed a membership survey to quantify the amount of cardiovascular care provided by noncardiologist primary care physicians. Figure 41.1 summarizes the type of cardiovascular procedures performed by the primary care physicians. The most commonly performed procedure was ECG; 44% of internists performed exercise stress tests, compared with less than 18% of family practitioners. Primary care physicians indicated that 29% to 52% of their patients with cardiovascular disease or cardiovascular risk factors also saw a cardiologist (*e*Fig. 41.1.1). On the other hand, cardiologists perform a significant amount of the primary care. Cardiologists indicated that they were the primary care source for 30% of their patients and primary care providers for 13% of patients not seen for cardiac diagnoses (12).

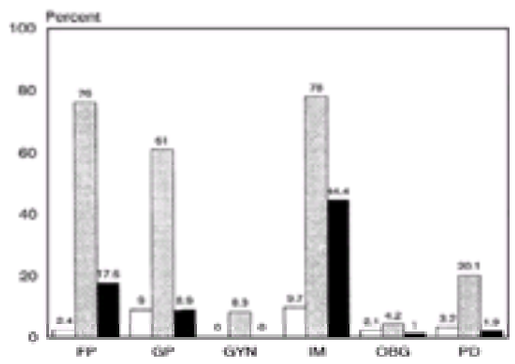

FIGURE 41.1 Frequency with which noninvasive cardiovascular procedures are performed by primary care specialists. Crosshatched bars, electrocardiography; solid bars, exercise stress tests; open bars, echocardiography. FP, family practitioner; GP, general practitioner; GYN, gynecologist; IM, internal medicine; OBG, obstetrician-gynecologist; PD, pediatrician. (From Vetrovec GW, Gardin JM, Gregory JJ, et al. Adult cardiovascular physician resources and needs assessment. *J Am Coll Cardiol* 1995;26:1125–1132, with permission.)

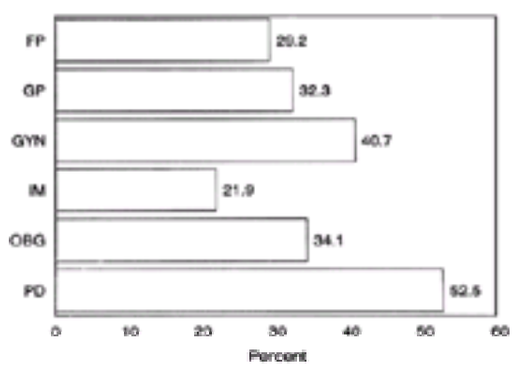
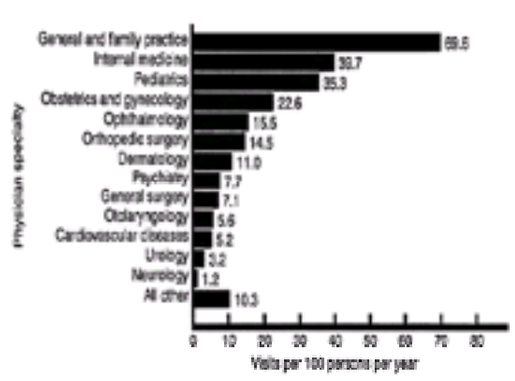


***e*FIGURE 41.1.1** Percentage of patients with cardiovascular disease who see a cardiovascular specialist, as reported by indicated practitioners. FP, family practitioner; GP, general practitioner; GYN, gynecologist; IM, internal medicine; OBG, obstetrician-gynecologist; PD, pediatrician. (From Vetrovec GW, Gardin JM, Gregory JJ, et al. Adult cardiovascular physician resources and needs assessment. *J Am Coll Cardiol* 1995;26:1125–1132, with permission.)

The ACC defines a cardiologist as a "physician with special training and skills in finding, treating, and preventing diseases of the heart and blood vessels in adults." A board-certified cardiologist is a physician who has completed training and certification in cardiovascular medicine after completion of training in internal medicine. Thus, the cardiologist has general competence in general internal medicine, in addition to the skills required to perform and interpret cardiovascular tests and procedures. Cardiologists have expertise in diagnostic and therapeutic procedures including echocardiography, nuclear cardiology, electrophysiology, angiography, and cardiovascular interventions (13).

According to the National Ambulatory Medical Care Survey (1995–1996), 2.1% of office visits (5.2 visits per 100 persons per year) are to specialists in cardiovascular diseases (13). The distribution of visits to cardiologists, general and family practitioners, internists, and other physicians is shown in eFigure 41.1.2. In another survey (1989–1990), cardiologists provided 35.3% of all physician visits for angina, 32.8% for cardiac dysrhythmias, 23.9% for other forms of chronic ischemic heart diseases, and 5.2% for essential hypertension. Consultation accounts for approximately 40% of a cardiologist's work week, whereas diagnostic tests and procedures account for less than 20% (14).



***e*FIGURE 41.1.2** Annual rate for office visits by physician specialty, United States, 1995–1996. (From Schappert SM, Nelson C. National ambulatory medical survey. *Vital Health Stat 13* 1999;142:1–14, with permission.)

Although it may be in society's best interest for generalists to provide cardiologic care to whatever extent safety and effectiveness allow, the optimal divisions of care between cardiologists and noncardiologists are unclear. The ability of residents in internal medicine to recognize common heart murmurs is less than expected (15,16). Less is known about the abilities and clinical judgment of general practitioners. Based on the content of certifying examinations of the American Board of Internal Medicine, internists are expected to have sufficient knowledge to manage a wide range of common cardiologic problems in hospitalized patients. However, subspecialists do significantly better than general internists on items pertaining to their area of specialization on examination for recertification (17), and in a survey of perceived causes of family physicians' errors, 49% of participating physicians reported lack of knowledge about the medical aspects of a case and reaching beyond capabilities as contributing to errors (18).

Whether the additional training and experience of cardiologists translate to improved cardiovascular outcomes has not been firmly established. We know that for a controlled population, specialists use more resources than do primary care providers (19). An important question is whether the increased cost of care incurred by specialists translates into improved outcomes. Schreiber and colleagues (20) reviewed a prospective cohort of 890 consecutive patients discharged with a diagnosis-related group diagnosis of unstable angina from William Beaumont Hospital (Royal Oak, Michigan). They compared 225 patients treated by internists with

665 patients treated by cardiologists with regard to patterns of use of established pharmacotherapies for unstable angina, diagnostic testing, and clinical outcome. Patients treated by internists had a prior cardiac history less frequently (53% vs. 80%, $p < .001$). Cardiologists were more likely to use aspirin (78% vs. 68%, $p = .032$), heparin (84% vs. 67%, $p < .001$), and beta-adrenergic blocking agents (30% vs. 18%, $p < .004$) in initial management. Exercise tests were undergone less frequently by cardiologist-treated patients (22% vs. 37%, $p < .001$), but catheterization (61% vs. 27%, $p < .0001$) and angioplasty (40% vs. 7%, $p < .0001$) were undergone more frequently. Patients with unstable angina whose care was directed by internists experienced a trend toward increased hospital mortality (4.0% vs. 1.8%, $p = .06$), although the incidence of myocardial infarction (MI), length of stay, and hospital charges were similar (20).

These observations support a previous study by Greenfield and coworkers (19) that indicated that cardiologists tend to use more expensive diagnostic techniques. Interestingly, patients of cardiologists were older, had worse functional status and well-being scores, and had more chronic diagnoses than patients of general internists (21). In another investigation, Greenfield and colleagues (22) found no evidence that specialists achieved better long-term outcomes than generalists for patients with non–insulin-dependent diabetes mellitus or hypertension. It is possible that this may be the result of the very common nature of these illnesses and of good dissemination of information related to optimal care of these conditions.

Improved dissemination of information from clinical trials was advocated by Ayanian and coauthors (23), based on the finding that internists and family practitioners are less aware of or less certain about important advances in the treatment of MI. They surveyed 1,211 cardiologists, internists, and family practitioners in two states about four treatments demonstrated by randomized clinical trials to improve survival after MI (thrombolytic therapy, immediate and long-term use of aspirin, and long-term use of beta-blockers) and two treatments for which such evidence is lacking (diltiazem for patients with pulmonary congestion and prophylactic lidocaine). They asked physicians about the effect of each treatment on survival and the likelihood that they would prescribe each class of drugs. Cardiologists believed more strongly than internists and family physicians that survival was improved by the four beneficial treatments and were more likely to prescribe these drugs ($p < .001$). With regard to thrombolytic agents, for example, 94% of cardiologists said they were very likely to use these medications to treat an acute MI, compared with 82% of internists and 77% of family practitioners. On the other hand, cardiologists were less likely than internists and family practitioners to believe there was benefit associated with the two treatments for which the trials showed no survival benefit. Cardiologists were significantly less likely to prescribe these drugs ($p < .001$); only approximately 5% of cardiologists reported that they were very likely to use prophylactic lidocaine, compared with 13% of internists and more than 16% of family practitioners.

These findings may help to explain those of Jollis and associates (24), who examined mortality according to admitting physician specialty among 8,241 Medicare patients admitted for acute MI in four states during a 7-month interval in 1992. Patients admitted by cardiologists were more likely to have had a previous MI or coronary artery bypass graft surgery (CABG), to have an anterior MI, and to have lower blood pressure on admission, whereas patients admitted by primary care physicians had lower rates of inferior MI and presentation as Killip class I. Primary care physicians' patients also had higher rates of diabetes mellitus and cerebrovascular disease. The investigators found that cardiologists had higher rates of use of cardiac procedures and medications associated with improved survival, such as thrombolytic agents and beta-blockers. They also found that patients who were admitted to the hospital by a cardiologist for treatment of acute MI were 12% less likely to die within 1 year than those admitted by a primary care physician ($p < .001$). Thus, although health care strategies that shift the care of patients with acute MI from cardiologists to primary care physicians may result in lower resource use at potentially lower costs, such a shift may cause decreased survival (24).

In a retrospective study of 327 patients with MI, management of hyperlipidemia for secondary prevention of coronary disease was shown to vary by physician specialty. Only 30% of patients with LDL levels greater than 130 mg per dL who were followed in a general internal medicine clinic received a cholesterol-lowering agent, compared with 55% of patients who were followed in a cardiology clinic ($p < .008$). This Veterans Affairs Health Care System–based study, in which access to drug treatment was equal among all patients, implies that patients observed by cardiologists are likely to have better outcomes, in part as a result of better secondary prevention (25). More recently, Stafford and Blumenthal (26) examined specialty differences in cardiovascular disease prevention practices. Using a national survey of office visits, they analyzed 30,929 adult visits to 1,521 physicians selected at random. When analysis was controlled for patient and visit characteristics, the likelihood that preventive services would be provided was higher for cardiologists than for general internists [adjusted odds ratio (OR), 1.65; 95% confidence interval (CI), 1.44 to 1.89].

Currently, there is a paucity of empirical evidence to support guidelines with regard to indications for and timing of cardiovascular consultations. This suggests that more research is needed that documents outcomes for patients with many types of medical problems who are treated by generalists and specialists in various systems of care. Cardiologists should take an active role in fostering research that evaluates patient outcomes for a variety of cardiovascular conditions. Cardiologists can also educate referring physicians and should make themselves available to discuss clinical situations with referring physicians. Such a process may facilitate patient care and allow primary care physicians to appreciate nuances of patient presentations that justify referral, even in the presence of guidelines that suggest that the role of the cardiologist in patient care is limited.

Conversely, the cardiologist is a subspecialist with training in internal medicine. The cardiologist might seek the assistance of a generalist or other specialist for care beyond the cardiologist's usual practice. This interchange may be an important educational opportunity for both physicians: The generalist or other medical specialist may gain insight into cardiologic problems and management, and the cardiologist has an opportunity to learn about new approaches in other specialties (8).

REASONS FOR REFERRAL AND CONSULTATION

Although the terms "consultation" and "referral" are often used interchangeably, their definitions are distinct. *Consultation* is the act of seeking advice regarding diagnosis and/or management (14). Such an exchange between the primary physician and the consultant may be formal (an appointment for an outpatient visit is made or an order for an inpatient consultation is written in the medical record) or informal (the "curbside consult," consisting of conversation regarding a patient between two physicians either in the hallway or by phone). A patient, a patient's family, or an insurance company may also seek a "second opinion." These are usually alluded to as "confirmatory consults." *Referral* represents transferal of the patient to another physician for a specific therapy or management of a particular medical problem while the primary (or referring physician) provides general care (14).

In cardiology practice, it is quite common for primary physicians to cede the care of the patient to the cardiologist when cardiovascular problems predominate. This represents *transferal of care*, which makes the cardiologist responsible for a patient's overall care during that hospitalization. In this situation, it is prudent for the primary care physician to continue observing the patient to remain abreast of clinical developments during the hospitalization. This maintains continuity of care and helps provide guidance regarding noncardiac problems and complex medicosocial decisions such as end-of-life issues. Finally, on discharge, the cardiologist should ideally send a letter to the primary care provider describing the patient's hospital course and a cardiac management plan as well as outstanding medical issues.

Referral and consultation rates vary widely, even for family physicians and nurse practitioners within the same practice. The rate at which a practitioner orders consultation in a specialty area increases in relation to the diagnostic certainty at the time of the consultation (9). Diagnostic certainty may be related to a referring practitioner's knowledge in a specialty field (implying that greater knowledge in a specialty leads to more consultations in that field). Studies have shown that referral rates range from 1.5% to 11% of patient visits in the family practice setting (27,28,29 and 30). In the managed care era, we can expect an increase in research evaluating the costs and effectiveness of calling on different types of physicians, with special focus on comparisons between generalists and specialists (31). Kaiser Permanente, a large health maintenance organization that provides health care services to 25% of the total population in northern California, has reported declines in consultation request rates with the introduction of the hospitalist system (32). Little information is available regarding referral to specific specialties. However, 10% of referrals from the University of Missouri–Columbia Department of Family and Community Medicine (14) and 6.8% of referrals from general internal medicine at University Hospital in Boston (33) were for cardiology services, and 11.9% of patients at Family Medical Center at the University Hospital in Seattle were referred to cardiology (34).

Consultation with a cardiologist may be sought to establish or confirm a diagnosis, to review or suggest specific management options for a known medical problem, to perform or interpret diagnostic tests, to perform a therapeutic procedure, or to clarify prognosis or cardiovascular risk associated with noncardiac tests and procedures. Depending on the severity of the patient's of illness and the urgency of the questions being asked of the consultant, patients may be evaluated in the outpatient setting (e.g., office, preadmission testing clinic, emergency department, or free-standing diagnostic imaging center) or inpatient setting (e.g., ward or specialized care or intensive care unit). The expectation is that the patient-physician relationship will terminate when the service requested by the primary care physician is complete. However, consultation may require multiple patient visits over an extended period of time, depending on the nature of the medical problem (35). Alternatively, a primary care physician may not feel that formal consultation is required and may desire only to confirm impressions or plans that have already been formulated. This type of informal consultation occurs frequently and involves a brief telephone call, e-mail, or hallway conversation.

ROLE OF THE CARDIOLOGY CONSULTANT

The opinions and reports of the Judicial Council of the American Medical Association, published in 1960 (36), contain one of the most comprehensive lists of the responsibilities of a consultant. This document lists nine ethical principles of consultation, six pertaining to the role of the consultant:

- The attending physician has the overall responsibility for the patient's treatment.
- The consultant should not assume the primary care of the patient without consent of the referring physician.
- The consultation should be done punctually.
- Discussions during consultation should be with the referring physician and only with the patient by prior consent of the referring physician.

- Conflicts of opinion should be resolved by second consultation or withdrawal of the consultant; however, the consultant has the right to render an opinion to the patient in the presence of the referring physician.

More than 40 years later, these tenets remain the guiding principles for the conduct of a successful consultant.

Evaluation

The first tasks for the cardiology consultant are to establish what question the primary physician would like to have answered and to establish the urgency of the consultation (37). Frequently, the question has not been clearly communicated by the primary care physician, and at other times, the consultant may overlook the question. If the issue prompting consultation is not clear, direct contact with the primary care physician can help to avoid consultations that do not meet the primary care physician's needs. Whether a scheduled patient is to be seen in the office or in the hospital, the consultant should determine whether the clinical situation is an emergency or whether it is urgent or elective.

The consultant's evaluation of a patient begins with a detailed medical history, physical examination, and review of data that may have already been obtained by the referring physician. It is important to "look for yourself" (37). Consultations are rarely requested to obtain assistance in interpreting already available data (38), but a careful review of the patient's chart is imperative for a complete consultation. This review should include obtaining outside records, pursuing unreturned laboratory workups, and personally reviewing ECGs, echocardiograms, and radiographs. Previous angiographic and hemodynamic data should also be reviewed personally. The New York Heart Association has classified the components of a complete cardiovascular evaluation and diagnosis of disease into the following categories: etiology, anatomy, physiology, cardiac status and prognosis, and specific recommendations (39). A complete cardiac diagnosis will likely include one or more of these categories. Based on this evaluation, tests may occasionally be repeated or new tests recommended.

Not every patient requires every test. The consultant should be mindful of test characteristics and the influence of pretest likelihood (prior probability) on posttest likelihood (predictive value). *Sensitivity* is the frequency of a positive test result in a population of patients with a particular disease. *Specificity* is the frequency of a negative test result in a cohort of patients without a certain disease. The *positive predictive value* of a test is the proportion of patients with a specific disease in a group of patients with a positive test result. The *negative predictive value* is the proportion of patients without a specific disease in a group of patients with a negative test result. The overall *diagnostic accuracy* of a test is the percentage of patients correctly classified by the test. *Bayes' theorem* states that the predictive value of a test result is a function of the prevalence of disease in the population being evaluated. The *posttest likelihood* of a disease is equal to the pretest likelihood multiplied by the probability that the test result is a true one. Therefore, a false-negative test is most likely to occur when the test is applied to a member of a patient group in which the particular disease is very common; conversely, a false-positive test is most likely to occur when the test is applied to a member of a patient group in which the particular disease is very uncommon. Posttest probability can be calculated from the disease prevalence and diagnostic test sensitivity and specificity (eTable 41.0.1). With these principles in mind, Patterson and Horowitz (40) have suggested a clinical approach to the use of diagnostic tests (eTable 41.0.2).

***e*TABLE 41.0.1** CHARACTERISTICS OF DIAGNOSTIC TESTS
Sensitivity: $TP/(TP + FN)$
Specificity: $TN/(TN + FP)$
Positive predictive value: $TP/(TP + FP)$
Negative predictive value: $TN/(TN + FN)$
Overall accuracy: $TP + TN$/total number of tests
Bayes' theorem:
Probability of disease with a positive test =

$$\frac{\text{sensitivity} \times \text{prevalence}}{(\text{sensitivity} \times \text{prevalence}) + [(1 - \text{specificity}) \times (1 - \text{prevalence})]}$$

Probability of disease with a negative test =

$$\frac{(1 - \text{sensitivity}) \times \text{prevalence}}{(1 - \text{sensitivity} \times \text{prevalence})\ [\text{specificity} \times (1 - \text{prevalence})]}$$

FN, false negative (negative result in a patient with disease); FP, false positive (positive result in a patient without disease); TN, true negative (negative result in a patient without disease); TP, true positive (positive result in a patient with disease).

***e*TABLE 41.0.2** CLINICAL APPROACH TO USE OF DIAGNOSTIC TESTS
1. Make a clinical estimate of the probability of disease based on the patient's history, physical examination, and preliminary laboratory tests.
2. Formulate options in further management.
3. Define the specific question that needs to be answered to decide among management options.
4. Define performance of tests available to answer the specific question (sensitivity and specificity).
5. Synthesize test results with preliminary clinical estimate to give the best answer to the specific question (predictive value and error).
6. Determine which further tests or therapies are needed on the basis of clinical data and initial test results.
7. Review whether the testing strategy used was optimal for each individual patient.

From Patterson RE, Horowitz SF. Importance of epidemiology and biostatistics in deciding clinical strategies for using diagnostic tests: a simplified approach using examples from coronary artery disease. *J Am Coll Cardiol* 1989;13:1653–1665, with permission.

Another important application of cardiovascular testing is in establishing prognosis. Knowledge of prognosis potentially affects decisions regarding medical management of a wide range of cardiovascular and noncardiovascular problems, as well as patient decisions regarding lifestyle and medical therapy. For example, physicians frequently use exercise testing to establish a prognosis in patients with stable coronary artery disease (CAD) or recent MI (41). Results may assist the physician in selecting patients who may be treated medically or should undergo further noninvasive or invasive evaluation (42).

Communication

A patient may be confused about the various doctors involved in his or her care. The following information should be discussed with the patient at the beginning of the consultant's visit: the consultant's name, the fact that the consultant is providing a service at the request of the patient's primary physician, the specialty that consultant represents, and the reason for consultation (37). If more than one person from the consulting service is involved (e.g., a student or a fellow), this should be explained to the patient, as should each person's role (36).

After the initial patient evaluation and the formulation of a management plan, the cardiology consultant must record his or her findings in the medical chart and communicate an assessment and recommendations to the primary physician who requested the consultation or referred the patient to the cardiologist. Opinions should be expressed in as brief a manner as appropriate. When writing in the hospital chart, it may be sufficient to merely note the history already provided and add components not already documented (38). This preliminary note may serve to communicate the initial assessment and recommendations to the medical team and to supplement a conversation between the consultant and primary physician. However, this brief note may be inadequate from the standpoint of medicolegal documentation and for documentation reimbursement purposes (see Documentation Compliance with Federal Health Programs). Although a long list of possible diagnoses with references to the medical literature may be of academic interest, lengthy intellectual discussions are unlikely to be read. Nevertheless, a copy of one or two key references, preferably from top-tier subspecialty journals, left at the front of the chart may be greatly appreciated. The cardiology consultant should share expertise with brevity, clarity, and lack of condescension (eFig. 41.1.3). Also, whether the consultant or the primary physician will execute the recommendations or arrange the pertinent tests should be either clearly stated in the note or verbally communicated. Specific recommendations should be made, with contingency plans (37). The primary physician should be able to copy recommendations directly to the order sheet if he or she is in agreement. By anticipating potential problems, contingencies allow for brief management strategies to be in place if a patient's status changes (8).

***e*FIGURE 41.1.3** Sample inpatient preoperative cardiology consultation. BP, blood pressure; CHF, congestive heart failure; CXR, chest x-ray; ECG, electrocardiogram; LAD, left anterior descending artery; LVEF, left ventricular ejection fraction; MI, myocardial infarction; PTCA, percutaneous transluminal coronary angioplasty.

The consultative process represents an exchange of information between the primary physician, who may be a generalist, surgeon, or other medical subspecialist, and the cardiology consultant. As such, consultation provides a unique opportunity for the consultant to learn about state-of-the-art therapies provided by other medical specialties (8).

Documentation Compliance with Federal Health Programs

In its February 1999 Comprehensive Plan for Program Integrity, the federal agency that administers Medicare and Medicaid, the Health Care Financing Administration (HCFA), stated that “Our program integrity goal is straightforward . . . to pay the right amount, to a legitimate provider, for covered, reasonable and necessary services, provided to an eligible beneficiary . . .” (43). Accurate and complete medical records are absolutely essential to ensure high-quality patient care and an efficient and smooth process for the submission and reimbursement of claims. One of the most important principles is to verify that the current procedure terminology codes indicating the services provided match the services rendered and that *ICD-9* (*International Classification of Diseases, Ninth Revision*) codes indicating diagnosis support the services provided. The consultant must also be able to prove the scope of medical history covered, the extent of the physical examination, and the complexity of the decision making. HCFA’s evaluation and management documentation guidelines define exactly how much documentation must be provided for each type of encounter. Detailed description of these guidelines is beyond the scope of this text and is available through the American College of Physicians or can be found as part of Medicare billing rules (44).

Extensive documentation is also supposed to improve patient care. However, HCFA’s complex evaluation and management requirements may also result in omission of critical information from the patient’s chart while the physician attempts to document trivial details (45). However, the reality is that a consultant must comply with HCFA’s burdensome evaluation and management rules or risk the consequences.

Effective Consultation

Certain aspects of a consultant’s role may influence whether recommendations are carried out by the requesting physician. Literature on this subject is limited and is available primarily from academic institutions. One measure of consultative quality is compliance with the consultant’s recommendations. In one study, compliance with the consultant’s advice ranged from 54% to 77% in academic centers (36). A study in a military teaching center reported that 90% of the recommendations were followed, implying higher compliance in nonacademic institutions (46).

Most research on the consultative process confirms the importance of good communication. In one study, disagreement occurred between the primary physician and the consultant on the issues of a consultation in 14% of cases (37). No specific question may be asked in 24% of preoperative consultations, and consultants may ignore explicit questions in 12% of cases (47). Direct contact between the consultant and the physician ordering the consultation can clarify misperceptions and has been associated with increased compliance with recommendations (46).

Compliance with recommendations decreases as the number of suggestions increases. Sears and Charlson (48) found that compliance was highest in their series of 202 general medicine consultations when five or fewer recommendations were made, regardless of the severity of the illness. The inverse relationship between number of recommendations and compliance has been observed in other studies (46,49). Identifying essential recommendations leads to greater compliance. Pupa and colleagues (46) found that labeling recommendations as “crucial” led to more than 90% compliance, even when the recommendations were contained in a long list of other suggestions. Verbal communication of high-priority recommendations is extremely effective. Recommendations should be as specific as possible so that physicians less familiar with cardiovascular tests and medications can copy suggestions directly to the order sheet in the chart (37). Horwitz and associates (50) found 100% compliance with recommendations for pharmacologic therapy when dose and duration were included in the consultant’s note; compliance fell to 85% when only dose or duration was specified and to 65% when neither was stated ($p < .001$).

Thus, when composing a consultative note in the chart, one might consider listing the impression and plan at the top to gain greater attention. Brief bullets are often more effective than long sentences. Recommendations may be divided into those aimed at making a diagnosis and those used for further management or therapy.

An effective consultant may also benefit from an organized referral evaluation team. The structure of this team greatly varies according to the size of the referral base and the consultant’s practice. For example, a single cardiologist in a multispecialty group may have nurse practitioners and physician assistants as a part of his referral team compared to multiple cardiologists in a single specialty group. Another variation in the practice of cardiology pertains to physicians being on staff at an academic medical center where medical housestaff and cardiology fellows may play an important role in accepting, evaluating, and treating a patient. One of the most important elements of providing consultative services, regardless of the structure of the team, is appropriate acceptance followed by expedited evaluation and cohesive management. This can be achieved by providing easy access to the referring physician and delegating responsibility among the members of the referral evaluation team.

Follow-Up and Prevention

Many cardiovascular conditions require follow-up, which allows the cardiologist to adjust medications and assess response to therapy. Examples include management of severe hypertension and hyperlipidemia, cardiomyopathy, and inoperable CAD. Several studies have shown the importance of follow-up in gaining greater compliance with recommendations (47,51). Horwitz and colleagues (50) found that when more than one follow-up note was written, consultation had an effect on diagnosis in 92% of cases and an effect on management in 84% of cases. When one or no follow-up note was written, effects on diagnosis were noted in only 74% of cases ($p < .001$), and effects on management were observed in only 56% of cases ($p < .001$). A final job for the consultant is to ensure continuity of the patient’s care for cardiac problems after discharge. A letter to the primary physician is often indicated to better coordinate the long-term management plan (36).

Just as follow-up improves compliance with recommendations in the hospital, continued communication with a referring physician facilitates fine-tuning and monitoring of medical therapy by the primary physician between patient visits to the cardiologist. Conversely, after treatment for acute cardiovascular disease, follow-up in some circumstances is best performed by the primary physician, and the patient should be promptly sent back to the referring physician. Greenfield and colleagues (52) investigated “reverse referrals” (i.e., referrals from subspecialists to generalists) and found that such patients had more diagnoses, complaints outside of the subspecialty, and total clinic visits, including increased visits to different types of clinics, than retained patients. The referring generalist may best manage patients with complex psychosocial issues or those who have a long-standing relationship with the primary care physician. However, referral back to the primary physician should occur only after a clear management plan has been established.

PREOPERATIVE EVALUATION

Advances in surgical and anesthetic techniques and an aging patient population have resulted in more complex procedures being performed in greater numbers of patients with higher likelihood of significant cardiovascular disease. Consultation may be sought for a history of cardiovascular disease, hypertension, or chest pain, or in the presence of a murmur, arrhythmia, or abnormal ECG results (51,52 and 53). Preoperative cardiac consultations are also frequently obtained for patients who have high pretest likelihood of CAD or in patients undergoing a high-risk noncardiac surgery.

Although consultation may occur in the office, on the ward, or in the postanesthesia care unit, recent greater emphasis on outpatient surgery or admission of patients on the morning of the planned surgical procedure has led to more frequent evaluations in a preadmission testing clinic (53). After noncardiac surgery, patients with

cardiovascular disease require surveillance for cardiac complications, particularly for the first 48 hours after surgery, although the risk of MI may persist for at least 5 to 6 days after surgery (54). Particular attention to good consultative techniques is warranted, because it has been suggested that compliance with consultant recommendations is lower for preoperative consultation than for consultations performed in other settings (55).

Cardiology consultants have sought to identify the patients at highest risk for perioperative cardiac complications and to intervene to reduce risk. Risk stratification has been achieved with clinical criteria (56,57), screening ECG (58), results of cardiac evaluations using exercise testing (59,60 and 61), thallium scanning (62,63 and 64), stress echocardiography (65,66), and coronary angiography (67,68), as well as the combination of clinical criteria and noninvasive testing (69). Coronary revascularization in selected patients may reduce the risk of noncardiac surgery (70,71), but bypass surgery and coronary angioplasty also have risks. The evidence on which decisions are made regarding use of these tests and procedures comes largely from retrospective studies, because the necessary clinical trials require large numbers of patients and have not been performed (72).

Perhaps partially due to the lack of results of clinical trials to guide decision making, there is significant variation in practice with regard to risk stratification (73). Furthermore, stress testing all patients who undergo high-risk procedures may not be effective (74), and therefore selective screening of high-risk patients is preferable. The process of risk assessment is costly, estimated to be $3.7 billion annually (73), and the vast majority of patients will not die or sustain a postoperative MI.

Epidemiology of Postoperative Myocardial Infarction

Of the 27 million men and women who have surgery each year in the United States, 1 million have perioperative cardiac complications, which result in approximately $20 billion in costs of in-hospital and long-term care (75). Over the course of the next 25 years, it is estimated that 37 million patients will undergo an operation, and 12 million of those will be older than 65 years. As a result, perioperative mortality will increase substantially, resulting in an approximate cost of $40 billion by the year 2018 (76).

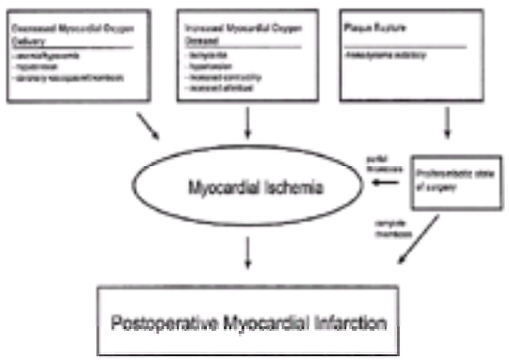
The overall risk of postoperative MI is low overall (<1%) (77,78). A history of MI increases the chance of sustaining a recurrent perioperative MI to approximately 6% (79). The risk of MI peaks within the first 3 postoperative days. Von Knorring (80) prospectively analyzed a cohort of surgical patients and found that 87% of perioperative MIs occur within the first 3 postoperative days, with peak incidence on postoperative day 2. Most postoperative MIs are non–Q-wave MIs and are usually detected in the first 24 hours after the operation, probably as a result of increased surveillance using frequent ECG and measurement of cardiac enzymes (81,82 and 83).

Because atherosclerosis is a diffuse process, patients with peripheral vascular disease often have CAD. In a study seeking to define the relationship between CAD and peripheral vascular disease, 1,000 patients undergoing peripheral vascular reconstruction at The Cleveland Clinic underwent preoperative coronary angiography; only 14% had normal coronary arteries (68). Several other studies have correlated coronary angiographic findings with different types of vascular diseases. The incidence of severe CAD among patients with abdominal aortic aneurysms is 52% to 82%, and the incidence among patients with peripheral occlusive disease is 47% to 60% (84). In a random sample of 6,895 Medicare patients undergoing major vascular surgery, perioperative mortality was 7.3% for aortic surgery and 5.8% for infrainguinal vascular surgery (85). Eagle and coworkers (86) identified 3,368 patients from the Coronary Artery Survival Study (CASS) registry who underwent noncardiac surgery, after a mean follow-up of 4.1 years. In patients with CAD who have not undergone revascularization, abdominal, vascular, thoracic, and head and neck surgery each had a combined rate of death and MI of more than 4%, with the highest event rate in vascular surgery patients (rate of perioperative MI, 8.5%; mortality rate, 2.8%). Therefore, the substantially higher cardiac morbidity and mortality among patients with nonrevascularized CAD who are undergoing vascular surgery mandates the need for an aggressive risk stratification strategy.

The presentation of postoperative MI is often silent or subtle because of residual effects of anesthesia or the presence of narcotics and sedatives. Nonspecific symptoms, such as new or worsening congestive heart failure (CHF), hypotension, nausea, altered mental status, or arrhythmias, may be the only clinical indications of infarction (87). For these reasons, and because the average mortality associated with postoperative MI may be as high as 50% (57,77,78,87), close perioperative surveillance with prompt initiation of therapy if infarction is suspected is warranted. Some procedures incur a higher risk because of associated blood loss, higher risk of hypotension, intravascular fluid shifts, or tendency for older, debilitated patients to require the procedure. Conversely, procedures performed under local anesthesia are usually associated with very low risk. For example, ophthalmologic procedures and herniorrhaphies have been performed soon after MI (88,89).

Pathophysiology

Alterations in the balance of clotting and fibrinolytic systems, varying as a function of the magnitude of the surgery, create a “prothrombotic milieu” (*e*Fig. 41.1.4) in the postoperative period that predisposes the patient to thrombotic complications such as deep vein thrombosis, stroke, and MI (91). The stress response is a physiologic measure of the magnitude of the surgery and surgical factors such as urgency, blood loss, and perioperative fluid shifts, which have been shown to influence perioperative cardiac events (90).



***e*FIGURE 41.1.4** Pathophysiology of perioperative myocardial infarction. In the setting of a coronary stenosis, the normal ability of vasculature to adjust flow and meet an increase in myocardial oxygen demand is limited. Even if demand is steady, acute decreases in oxygen supply can occur. The combination of these conditions may lead to myocardial ischemia, although an alternative hypothesis implicates plaque rupture and thrombus formation at a noncritical stenosis. (From Beattie C, Fleisher LA. Perioperative myocardial ischemia and infarction. *Int Anesth Clin* 1992;30, with permission.)

To date, very few studies have attempted to elucidate the pathophysiologic mechanism of postoperative MI. Traditionally, oxygen supply–demand mismatch has been invoked as the pathophysiologic mechanism of postoperative MI. However, plaque rupture followed by intracoronary thrombosis may also be a causative mechanism in patients who experience fatal MI. Cohen and Aretz (91) identified 26 patients who had sustained a fatal postoperative MI out of a total of 1,841 autopsies. They found that plaque rupture was present in almost one-half (46%) of the patients. In another study, Dawood and associates (92) found evidence of plaque rupture in 23 (55%) of 42 patients who died after noncardiac surgery. Therefore, in addition to oxygen supply-demand mismatch, plaque rupture followed by coronary thrombosis may also be an important pathophysiologic mechanism, and multiple strategies likely are required to lower the risk of postoperative MI.

Clinical Prediction

Several groups have stratified surgical risk based on patient characteristics. First, Dripps and colleagues (93) assigned a physical status class to patients, before administration of anesthesia, over a 10-year period (1947–1957). This physical status index is still used by the American Society of Anesthesiologists (ASA; *e*Table 41.0.3) (94) and has been validated in a large cohort of patients (95). However, the index is subjective and may be less predictive in some subsets of patients, such as elderly patients, obese patients, and patients with prior MI or mild systemic disease (96). Goldman and coworkers (57) developed a multifactorial index to assess the cardiac risk of noncardiac surgery in 1,001 consecutive general surgery patients (57) (*e*Table 41.0.4). To adjust risk estimates for a specific planned surgical procedure, Detsky and colleagues (97) developed a modified index of perioperative cardiac risk. They altered several features of Goldman’s original index, based on the authors’ clinical experiences (*e*Table 41.0.5).

***e*TABLE 41.0.3** DRIPPS’ MODIFICATION OF THE INDEX OF PHYSICAL STATUS, AMERICAN SOCIETY OF ANESTHESIOLOGISTS
1. A healthy patient.
2. A patient with mild systemic disease.
3. A patient with a severe systemic disease that limits activity, but is not incapacitating.
4. A patient with an incapacitating systemic disease that is a constant threat to life.

5. A moribund patient who is not expected to survive 24 hours with or without an operation.

Note: In the event of an emergency operation, precede the number with an E.

Canadian Cardiovascular Society angina	
Class 3	10
Class 4	20
Unstable angina within past 3 mo	10
Alveolar pulmonary edema	
Within 1 wk	10
Ever	5
Valvular disease	
Suspected critical aortic stenosis	20
Arrhythmias	
Sinus plus APDs or rhythm other than sinus on last preoperative ECG	5
>5 ventricular premature depolarizations at any time before surgery	5
Poor general medical status[a]	5
Age >70 yr	5
Emergency operation	10

APDs, action potential durations; ECG, electrocardiogram.

[a]PO_2 <60 mm Hg; PCO_2 >50 mm Hg; serum K^+ <3.0 mmol/L; serum $^-HCO_3$ <20 mmol/L; blood urea nitrogen ³18 mmol/L; serum creatinine >260 mmol/L; abnormal aspartate aminotransferase level; signs of chronic liver disease; and/or patient bedridden because of noncardiac causes.

Reprinted from Detsky AS, Abrams HB, McLaughlin JR, et al. Predicting cardiac complications in patients undergoing noncardiac surgery. *J Gen Intern Med* 1986;1:211–219, with permission.

The Goldman risk index has been tested prospectively (98) and demonstrated an incremental increase in cardiac risk according to preoperative classification in a broad group of patients presenting for a variety of surgical procedures. The applicability of the Goldman index for more specific patient subsets and types of surgery has been questioned. For example, Gerson and coworkers (99) evaluated the predictive value of patient history, physical examination, and rest and exercise radionuclide ventriculography (RVG) to risk-stratify 155 geriatric patients presenting for nonemergency abdominal, thoracic, or aortic surgical procedures. No clinical predictor, including the Dripps-ASA and Goldman indices, provided any additional independent predictive information. In another study, Jeffrey and colleagues (100) prospectively evaluated the Goldman risk index for 99 consecutive patients who presented for elective abdominal aortic surgery. The risk of serious cardiovascular complications was significantly higher than predicted among Goldman class I patients (7%) and insignificantly higher among class II and class III patients. The authors concluded that the Goldman risk index was not as accurate in predicting cardiac risk among patients undergoing elective aortic surgery. More recently, Gilbert and coauthors (101) prospectively compared the ASA index, Goldman's index, Detsky's index, and the Canadian Cardiovascular Society index for angina level in 2,035 patients scheduled for urgent or elective surgery. To determine the overall accuracy of the stratification systems, they calculated the area under the receiver operating characteristic curve for each index. All the cardiac risk indices provided a significant degree of risk stratification (p <.001); however, the difference among areas under the receiver operating characteristic curves for various indices was not statistically significant (p >.05).

Several factors may limit the predictive value of these clinical indices. When estimating surgical risk, relevant factors (patient-specific, institution-specific, and procedure-specific) must be considered. These considerations, as well as the desire to increase predictive accuracy, have led to investigation of noninvasive tests to help assess preoperative risk to the patients in an incremental fashion.

Stress Testing and Assessment of Left Ventricular Function

One of the first noninvasive technologies used in preoperative cardiac risk stratification was exercise treadmill testing, because poor functional capacity in patients with CAD is associated with an increased incidence of subsequent cardiac events. The positive predictive value for postoperative death and MI of abnormal results of an exercise stress test ranges from 5% to 25%. The negative predictive value of normal results of a maximal study exceeds 90% (102). An important limitation of exercise testing in preoperative evaluation of noncardiac surgery is patients' inability to perform optimal level of exercise in 30% to 50% of cases (102). This does not preclude obtaining important functional information, and estimates of perioperative risk can be determined in patients who can exercise. Numerous studies have examined the usefulness of exercise stress testing as a preoperative diagnostic tool in men, and the results may not be reliable when applied to women (75). Exercise stress testing has a lower overall accuracy among women compared with that among men because of the higher prevalence of ECG changes with hyperventilation or position change among women. Table 41.1, from the ACC/AHA guidelines, illustrates selected studies of preoperative exercise testing before major noncardiac surgery (103).

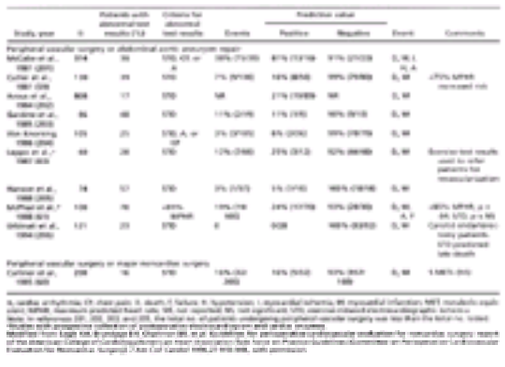

TABLE 41.1 SUMMARY OF STUDIES EXAMINING THE VALUE OF PREOPERATIVE EXERCISE TESTING BEFORE MAJOR NONCARDIAC SURGERY

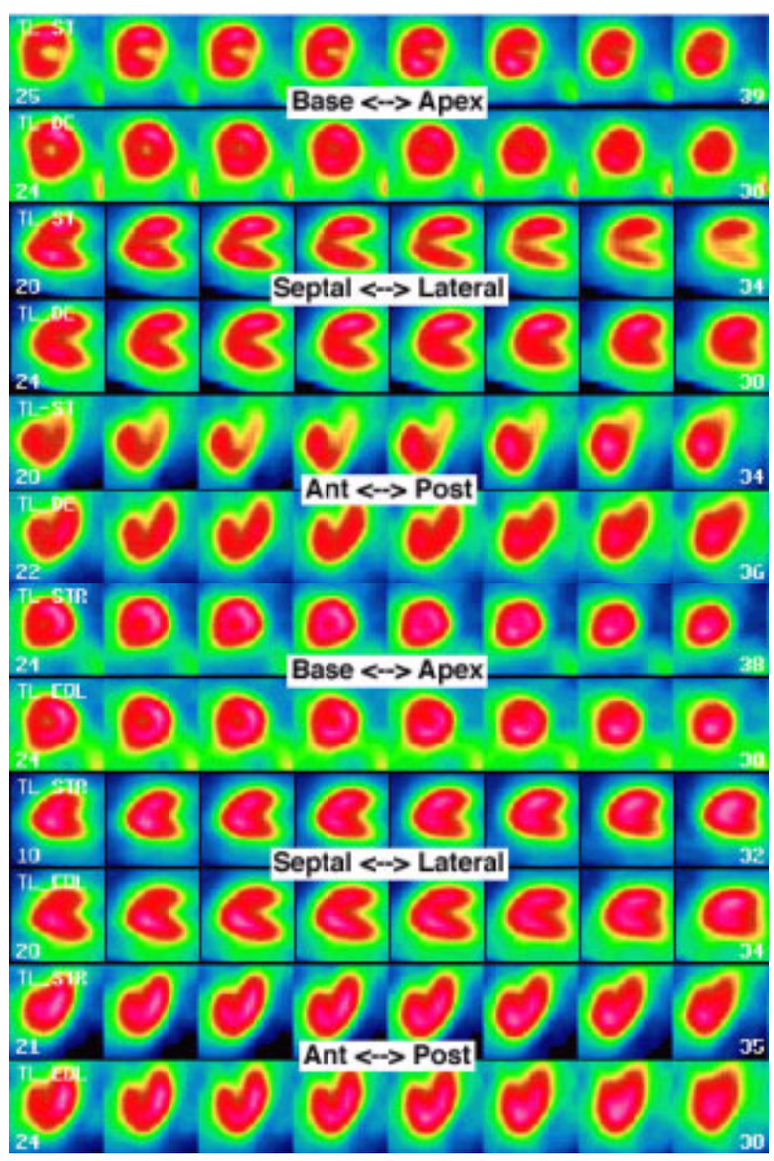
Several studies suggest that inability to perform even modest levels of exercise identifies a high-risk subset of patients (61,101,102). McPhail and associates (61) demonstrated that patients who achieved greater than 85% predicted maximal heart rate during exercise testing had a postoperative cardiac complication rate (cardiac death, MI, CHF, malignant ventricular ectopic activity) of 6%, whereas patients who achieved less than 85% of their predicted maximal heart rate had a complication rate of 24%. In addition, Gerson and colleagues (104) showed that inability to perform 2 minutes of supine bicycle exercise to raise the heart rate above 99 beats/min was a good predictor of perioperative pulmonary, cardiac, and combined cardiopulmonary complications (104).

Investigators have also assessed resting and exercise left ventricular function using RVG and echocardiography. Initial studies showed a relationship between decreased left ventricular systolic function and adverse cardiac events (105,106,107,108,109,110 and 111). However, subsequent studies (112,113,114,115 and 116) failed to show a statistically significant relationship between resting left ventricular ejection fraction (LVEF) and the development of perioperative adverse cardiac events. Thus, taken together, the data indicate that resting LVEF is a relatively insensitive and nonspecific marker for postoperative MI and cardiac death, however poorly left ventricular systolic function or diastolic dysfunction may predict postoperative CHF. Similar findings have been reported with echocardiography, although results have not been uniform across studies (117). More recently, Rhode and coauthors (118) studied the incremental value of transthoracic echocardiography after consideration of clinical data for prediction of cardiac complications after a major noncardiac surgery in 570 patients. In univariate analyses, preoperative systolic function was associated with postoperative MIs (OR, 2.8; 95% CI, 1.1 to 7.0). In logistic regression analysis, models with echocardiographic variables predicted major cardiac complications much better than those that included only clinical variables. Studies of exercise LVEF (104,119) also have indicated that resting LVEF and exercise-induced wall motion abnormalities are insensitive predictors of postoperative MI and cardiac death.

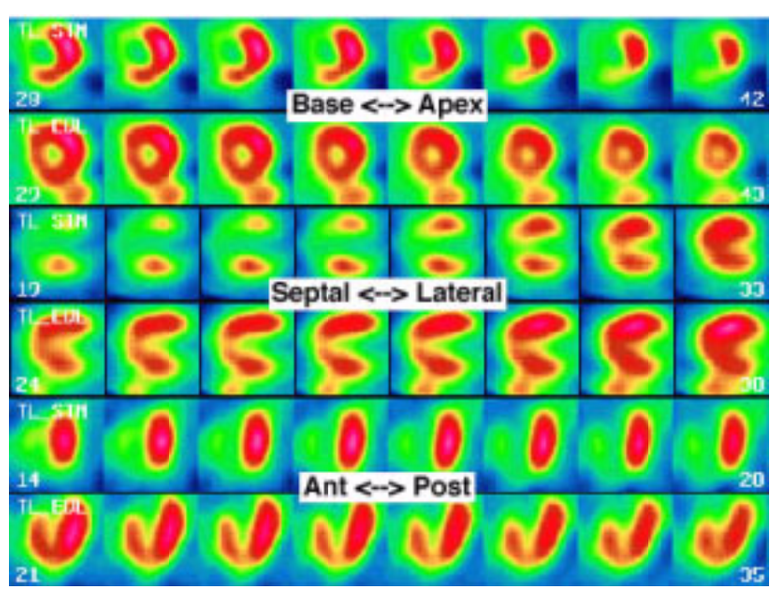
Perfusion Imaging

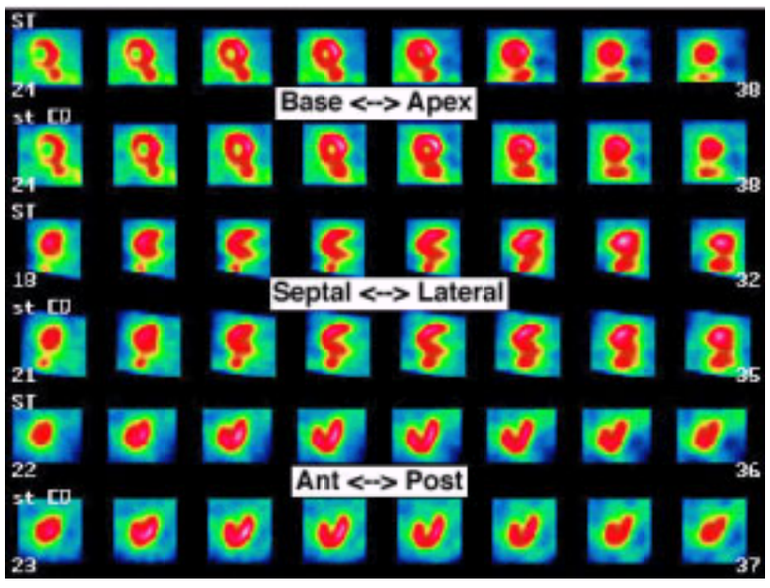
Although functional capacity appears to be a strong determinant of overall prognosis, as well as a significant predictor of perioperative cardiac risk, there are many patients who have a limited ability to exercise. Thus, exercise testing has limited prognostic value (120,121 and 122) in many patients who are scheduled to undergo vascular, orthopedic, or neurosurgical procedures. Preoperative patients with amputation, claudication, morbid obesity, or advanced age are frequently studied under pharmacologic stress, using agents such as dipyridamole, adenosine, or dobutamine (102).

The first study to demonstrate the usefulness of dipyridamole-thallium scanning for preoperative cardiac risk assessment in patients who are unable to exercise was carried out by Boucher and coworkers (62). Of the 48 patients (89%) who underwent vascular surgery without coronary angiography, 16 patients had thallium redistribution on preoperative dipyridamole-thallium scintigraphy. Eight perioperative ischemic cardiac events (unstable angina, MI, or cardiac death) occurred. All eight events occurred in the group of 16 patients who had preoperative thallium redistribution. No adverse postoperative cardiac events were seen in the 20 patients for whom results of dipyridamole-thallium scanning were normal or in the 12 patients who had persistent thallium defects only. All six patients who underwent coronary angiography before surgery had multivessel coronary disease; four patients underwent CABG, followed by peripheral vascular surgery, without postoperative cardiac ischemic events. The results of this landmark study have been confirmed by many subsequent studies (61,62 and 63,68). Leppo and colleagues (63) progressed to the next logical step by comparing dipyridamole stress with exercise stress ECG. Multivariate analysis revealed that thallium redistribution was the best predictor of perioperative cardiac events; 14 (33%) of 42 patients with thallium redistribution defects suffered MI or perioperative death (63). Waters and colleagues (123) demonstrated a significant correlation between reversible perfusion defects and intraoperative development of new wall motion abnormalities, confirming the relationship between jeopardized myocardium and preoperative perfusion abnormalities during noncardiac surgery.

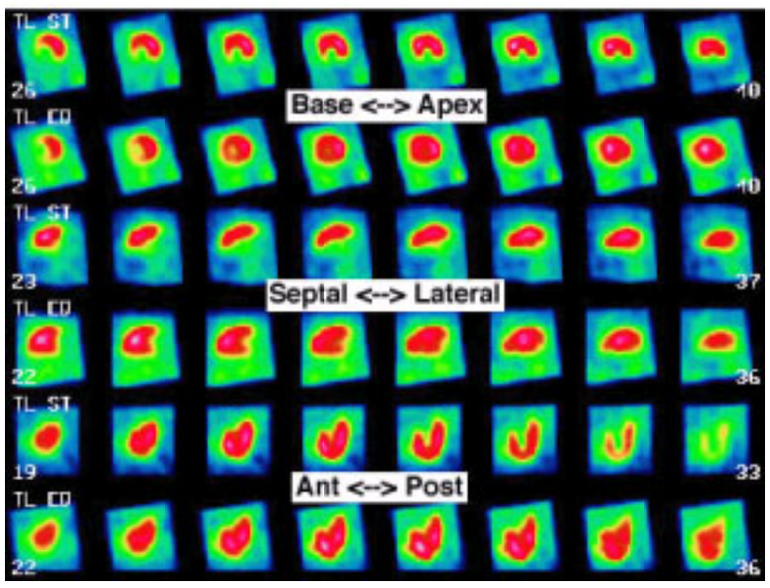


Thallium-201 single-photon emission computed tomography stress and delayed images (A). Transverse, sagittal, and coronal plane images demonstrating lateral wall ischemia in a patient with severe proximal left circumflex artery stenosis. Thallium-201 single-photon emission computed tomography stress and equilibrium images (B). Transverse, sagittal, and coronal plane images obtained from a patient after successful intervention for severe proximal left circumflex artery stenosis (normal study).





Thallium-201 single-photon emission computed tomography stress and equilibrium images. A: Transverse, sagittal, and coronal plane images demonstrating anterior, septal, apical, and distal inferior ischemia in a patient with a severe proximal left anterior descending (LAD) artery stenosis in whom the LAD wraps around the left ventricular apex. B: Transverse, sagittal, and coronal plane images from the same patient as A after intervention for severe proximal LAD artery stenosis (normal study).



Thallium-201 single-photon emission computed tomography stress and equilibrium images. Transverse, sagittal, and coronal plane images demonstrating inferior and posterior wall ischemia in a patient with a severe proximal stenosis in a dominant right coronary artery.

The concept that risk of cardiac events is not simply related to the presence or absence of jeopardized viable myocardium and is directly proportional to the extent of myocardium at risk has also been demonstrated (124). Lane and colleagues (64) found that perioperative cardiac risk was related to the number of reversible thallium defects on planar imaging; five or more transient defects were associated with 44% probability of a cardiac event, compared with 14% among patients with one or more transient defects (p <.01). Lette and coworkers (125) defined semiquantitative indices of the extent and severity of reversible thallium abnormalities. There was a strong correlation between the indices of severity and extent of thallium redistribution and postoperative cardiac death or MI. Reversible left ventricular cavity dilation was also a significant predictor of postoperative cardiac complications. Similarly, Levinson and coauthors (126) showed that patients with redistribution in four or more myocardial segments were more likely to experience a perioperative ischemic cardiac event than patients with three or fewer such segments (38% vs. 12%; p = .03). Patients with dipyridamole-thallium redistribution in two or three coronary artery territories were significantly more likely than patients with redistribution in only one coronary artery territory to have a perioperative cardiac complication (43% vs. 13%; p = .007). Multivariate analysis identified thallium redistribution in more than one view (p <.001) as the strongest predictor of perioperative cardiac complications. Therefore, assessment of perioperative risk must take into consideration the extent of ischemia. Patients who have only a small amount of jeopardized viable myocardium appear to be at low risk for cardiac events and probably do not need preoperative coronary revascularization (124).

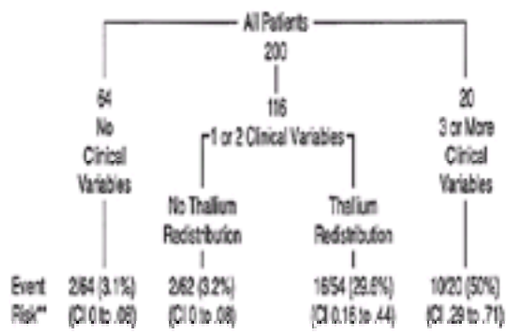
Although thallium redistribution appears to be quite sensitive for predicting postoperative ischemic cardiac events, specificity is low. However, applying the test in a higher-risk cohort and not performing the test in low-risk subsets could improve specificity. Stratification of patients into groups of those who should and should not have further noninvasive cardiac assessment was the focus of two studies by Eagle and colleagues (69,127). In the first study, the authors evaluated the predictive value of dipyridamole-thallium imaging for postoperative cardiac events in 61 patients referred for elective aortic surgery (abdominal aortic aneurysm resection or aorto-iliac reconstruction) (69). Thallium redistribution predicted postoperative ischemic events (unstable angina, ischemic pulmonary edema, MI, or cardiac death). Several clinical variables, including Q waves on ECG, history of CHF, and possibly presence of diabetes, also had predictive value. The absence of these variables was considered, along with the history of MI or angina, to attempt to identify a clinically low-risk subset of patients who could proceed directly to vascular surgery without further noninvasive testing. Only 1 (3.4%) of 29 low-risk patients (defined by absence of all five clinical markers) experienced a perioperative ischemic event (unstable angina), whereas seven (22%) higher-risk patients (defined by the presence of one or more of the five clinical markers) experienced a perioperative ischemic event. The stratification instrument was then prospectively validated in 50 patients undergoing vascular procedures. There were 23 low-risk patients, among whom no ischemic events occurred. Among the 27 patients with one or more clinical markers, the event rate was 37%, including three cardiac deaths. Thallium redistribution had been seen on preoperative dipyridamole-thallium scintigraphy for each patient who died.

These investigators later extended their observations by retrospectively analyzing 200 consecutive patients referred for vascular surgery (aorto-iliac or aortofemoral bypass grafting in 67 patients, abdominal aortic aneurysm resection in 71 patients, and peripheral vascular procedures such as femoral popliteal bypass or carotid endarterectomy in 62 patients) (69). In multivariate analysis, Q waves on the preoperative ECG, history of angina, history of ventricular ectopic activity requiring treatment, diabetes requiring pharmacologic therapy, and age older than 70 years were independent clinical predictors of postoperative ischemic events. The two independent dipyridamole-thallium scanning predictors of ischemic events were thallium redistribution and ischemic ECG changes during or after dipyridamole infusion (p <.01). Three logistic regression models were created to predict postoperative cardiac ischemic events: (a) clinical variables alone, (b) dipyridamole-thallium scanning results alone, and (c) both clinical and dipyridamole-thallium test variables. The sensitivities and specificities of these three models were compared.

Thallium redistribution was the most sensitive predictor, but it was less specific than several of the clinical variables, particularly the appearance of Q waves on the preoperative ECG. The model in which both clinical markers and dipyridamole-thallium test results were used achieved significantly higher specificity, at equivalent sensitivity levels, than models using either clinical variables alone or dipyridamole-thallium test results alone (eFig. 41.1.5). Of 64 patients with none of the five clinical variables, only two patients (3.1%; 95% CI, 0% to 8%) suffered postoperative cardiac ischemic events, compared to 10 (50%; 95% CI, 29% to 71%) of 20 patients who had three or more clinical markers. Patients with either one or two clinical variables had an intermediate risk; 18 ischemic events were seen in 116 patients (15.5%; 95% CI, 7% to 21%). The presence or absence of thallium redistribution further delineated the intermediate-risk group into low- and high-risk categories; only 2 (3.2%; 95% CI, 0% to 8%) of the 62 patients in the intermediate-risk subgroup without thallium redistribution experienced events, compared to 16 events (29.6%; 95% CI, 16% to 44%) among the 54 patients with thallium redistribution. Collectively, these studies indicate that the specificity of preoperative dipyridamole-thallium scintigraphy is improved by considering clinical variables. Such variables may be used to identify clinically low- and high-risk subsets of vascular surgery patients, while reserving dipyridamole-thallium imaging for further risk stratification of intermediate-risk patients.



***e*FIGURE 41.1.5** Clinical markers of risk (Q waves on electrocardiography, age >70 years, history of angina, history of ventricular ectopic activity requiring treatment, and diabetes requiring treatment) and thallium redistribution. **Unstable angina, ischemic pulmonary edema, myocardial infarction, or death. CI, confidence interval. (From Eagle KA, Coley CM, Newell JB, et al. Combining clinical and thallium data optimizes preoperative assessment of cardiac risk before major vascular surgery. *Ann Intern Med* 1989;110:859–866, with permission.)

Baron and coworkers (74) prospectively evaluated 457 consecutive patients undergoing elective abdominal aortic aneurysm surgery with dipyridamole-thallium single-photon emission computed tomography (SPECT) and RVG. The cardiac event rate was 19% (prolonged myocardial ischemia in 61 patients, MI in 22, CHF in 20, severe ventricular tachyarrhythmia in two, and death from any cause in 20). Clinical evidence of CAD (OR, 2.6; 95% CI, 1.6 to 4.3) and age older than 65 years (OR, 2.3; 95% CI, 1.4 to 3.6) were better predictors of adverse outcome than thallium redistribution (OR, 1.1; 95% CI, 0.6 to 2.0). LVEF measured by RVG predicted only postoperative CHF. The authors concluded that the routine use of dipyridamole-thallium SPECT and RVG for preoperative cardiac risk assessment before abdominal aortic surgery might not be justified. Zarich and colleagues (128) prospectively evaluated 93 diabetic patients with quantitative planar thallium scintigraphy before noncardiac surgery. They divided the patient population into two groups: those with and those without clinical markers of significant CAD. Overall, adverse cardiac events occurred in nine patients, with MI in six patients and death in three patients. No adverse cardiac event occurred in diabetic patients who did not have the clinical markers (angina, CHF, MI, or pathologic Q waves), despite a 58% prevalence of abnormal thallium scans, signifying a low positive predictive value. They concluded that preoperative myocardial perfusion imaging might add little to cardiovascular risk assessment in asymptomatic diabetic patients who did not have other markers of significant CAD.

In a multicenter study that sought to develop and validate a Bayesian risk prediction model for vascular surgery candidates, L'Italien and coworkers (129) developed a prediction model involving 567 patients from two centers based on clinical variables (age older than 70 years, angina, history of MI, diabetes mellitus, history of CHF, and prior coronary revascularization). A second model was developed from dipyridamole-thallium scanning results (i.e., perfusion abnormalities and ST-segment changes). Model performance, alone and in combination, was evaluated using ROC analysis. The models were then validated in a separate cohort of 514 patients from three centers. The observed and predicted cardiac event rates were comparable for both sets. The addition of dipyridamole-thallium scan data reclassified more than 80% of intermediate-risk patients into low-risk (3% event rate) and high-risk (19% event rate) categories (p <.0001) but provided no stratification for patients classified as low risk or high risk by the clinical model. The authors concluded that clinical markers, weighted according to prognostic impact, reliably stratify risk for patients who are candidates for dipyridamole-thallium scintigraphy, obviating the need for more expensive testing.

Because of the association between CAD and peripheral vascular disease and a higher event rate in this population, most investigations have evaluated noninvasive testing in the population of patients undergoing vascular surgery. However, preoperative noninvasive cardiac risk assessment has also been evaluated in patients undergoing other noncardiac surgery, with similar results. Patients undergoing renal allograft surgery, like those in the vascular surgery cohort, are at an increased risk of coronary disease and ischemic complications. Brown and colleagues (130) studied this cohort preoperatively, using dipyridamole-thallium scintigraphy and RVG. Multivariate regression analysis revealed that a reversible thallium defect and LVEF were the only significant predictors of death or MI. Studies involving other groups of patients have demonstrated a positive predictive value of 8% to 27% and a negative predictive value of 98% to 100% for MI or death (131,132,133,134,135 and 136). Two general principles apply to risk stratification for nonvascular noncardiac surgery. First, risk stratification should be considered when the surgical procedure being undertaken is associated with substantial perioperative cardiac complications. Second, myocardial perfusion imaging is more helpful when it is applied in a population with a high prevalence of CAD (e.g., prior MI or history of angina). Because the prevalence of significant CAD is much lower among patients who do not have vascular disease, it may be more appropriate to use clinical evidence of coronary disease to determine whether to proceed with myocardial perfusion imaging for further risk stratification (124).

Newer imaging agents and modalities are now in common use. Technetium-99m sestamibi (MIBI), an agent with higher energy than thallium, produces superior image quality and may also have utility in preoperative coronary risk assessment (133,134,137). Two studies (138,139) described the value of dobutamine stress myocardial perfusion imaging in assessing cardiac risk associated with vascular surgery. Both studies (involving 126 and 142 patients) found a significantly increased risk of perioperative cardiac events among patients with reversible perfusion defects (50% vs. 5% and 19% vs. 3%, respectively) (140).

The ACC and the AHA task force summarized current knowledge regarding preoperative myocardial perfusion imaging methods (eTable 41.1.1) (103). The task force report noted that the predictive value of thallium redistribution for MI or death ranged from 4% to 20% in selected reports that included more than 100 patients. The positive predictive value has decreased over the course of time, a change that likely is related to use of thallium imaging results for therapeutic interventions such as coronary revascularization or intensive medical therapy before noncardiac surgery. Furthermore, the results of myocardial perfusion imaging may lead to the performance of less extensive procedures or cancellation of surgery. Nevertheless, the negative predictive value has remained high (approximately 99%), and the prognosis associated with normal results of scanning is excellent (103).

***e*TABLE 41.1.1** SUMMARY OF STUDIES EXAMINING THE VALUE OF DIPYRIDAMOLE-THALLIUM IMAGING FOR PREOPERATIVE ASSESSMENT OF CARDIAC RISK

Study, year	*N*[a]	No. (%) of patients with ischemia by TI-RD imaging	Events,[b] no.	Perioperative events: RD scan Positive predictive value	Perioperative events: Normal scan Negative predictive value	Comments

Long-Term Prognostic Value of Perfusion Imaging

Because the prevalence of CAD is high among patients with peripheral vascular disease, patients undergoing peripheral vascular surgery remain at increased risk of cardiac events in subsequent years, even if they remain event-free during the immediate postoperative period (127). Hendel and colleagues (141) evaluated 360 patients, of whom 327 patients underwent vascular surgery. Operative death and nonfatal MI occurred in 4.9% and 6.7%, respectively. A cardiac event (nonfatal MI or cardiac death) occurred in 14.4% of patients with a transient thallium defect, compared to 1% among patients with normal results of scanning (p <.001). Multivariate analysis revealed that the best predictor of perioperative events was the presence of a reversible thallium defect. Late cardiac events occurred in 53 (15.2%) surgical survivors or nonsurgically treated patients who were followed for a mean of 31 months. Patients with a fixed perfusion abnormality had a 24% late-event rate, compared with 4.9% among patients with normal results of the dipyridamole-thallium study (p <.01). Cox regression analysis showed that a fixed thallium defect was the most powerful predictor of late events and increased the relative risk by almost fivefold. A history of CHF was the only significant clinical variable that contributed additional value to knowledge of the presence of a fixed defect. Life-table analysis confirmed the strong relationship between fixed defects and cardiac event–free survival (p <.0001).

Younis and coworkers (142) also evaluated late outcomes among 131 patients scheduled for peripheral vascular surgery. Two years after surgery, the actuarial event-free survival rate for patients with thallium redistribution was approximately 50%. Urbinati and colleagues (207) evaluated early and late cardiac events among 106 patients with neither history nor symptoms of CAD who underwent exercise thallium myocardial perfusion imaging before carotid endarterectomy. No cardiac deaths or MIs occurred within 30 days of surgery. However, actuarial survival without coronary events was 51% among patients with positive results of stress test and thallium redistribution, compared with 98% among patients without such results (p <.01) by 7 years (Fig. 41.2).

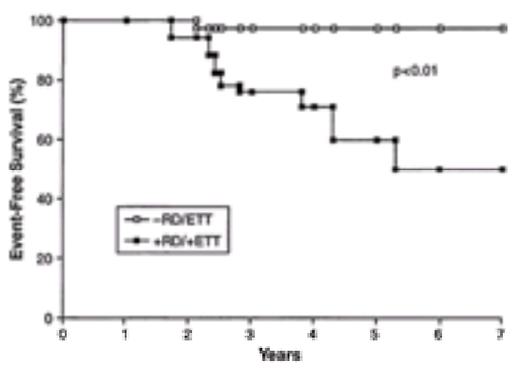

FIGURE 41.2 Long-term follow-up in patients undergoing exercise thallium-201 imaging before carotid endarterectomy. p <.01. ETT, positive stress electrocardiogram; RD, reversible defects.

Among 172 patients who were followed for a mean of 21 ± 14 months after elective vascular surgery, event-free survival was significantly less for patients with abnormal MIBI scans than for those with normal scan results (74% vs. 96%; p <.0001). After controlling for other clinical factors using Cox proportional hazards models, abnormal results of an MIBI study (relative risk, 3.7; 95% CI, 1.2 to 11.4) and MIBI-detected ischemia (relative risk, 2.7; 95% CI, 1.2 to 6.1) remained significant predictors of increased risk of late cardiac events (143). More recently, Cohen and associates (144) reported long-term prognostic significance of preoperative dipyridamole technetium-99m MIBI scanning in vascular surgery patients. They followed 153 patients for as long as 4 years after the dipyridamole MIBI scan to determine nuclear imaging predictors of death and MI. The only statistically significant predictor of death and MI visible on dipyridamole MIBI scanning was abnormality in the left anterior descending artery territory (adjusted relative risk, 2.9; 95% CI, 1.2 to 7.3).

Stress Echocardiography

Several reports have evaluated the accuracy of pharmacologic stress echocardiography in identifying patients who are at risk for postoperative cardiac events (65,66,145,146,147,148,149 and 150) (Table 41.2). Most studies have used dobutamine, although dipyridamole has also been used. The populations examined predominantly have been patients undergoing vascular surgery. Only one study has blinded clinicians to the echocardiographic results (147). In the other studies, results affected management, including decisions about whether to perform preoperative coronary angiography and coronary revascularization. Among the studies of preoperative dobutamine echocardiography, the positive predictive value for MI and death ranged from 7% to 23%; the negative predictive value was 100% in all but one study. The severity of wall motion changes at low-dose dobutamine infusion may be especially important. Furthermore, Poldermans and coworkers (151) have shown that stress-induced ischemia on dobutamine echocardiography is predictive of late cardiac events after vascular surgery. Recently, Ballal and coauthors (152) reported long-term cardiac outcome in 233 vascular surgery patients who underwent preoperative dobutamine stress echocardiography. Late events occurred in 36 patients after a mean follow-up of 28 months. New or worsening regional wall motion abnormality was predictive of these events, even after the analysis was adjusted for clinical variables and left ventricular dysfunction (relative risk, 3.3; p = .001).

TABLE 41.2 SUMMARY OF STUDIES EXAMINING THE VALUE OF DOBUTAMINE STRESS ECHOCARDIOGRAPHY (ECG) FOR PREOPERATIVE RISK ASSESSMENT

A metaanalysis of published reports on preoperative pharmacologic stress risk stratification identified ten reports on dipyridamole–thallium-201 scintigraphy and five on dobutamine stress echocardiography (153). Random effect models were used to calculate the summary OR and 95% CIs. The summary OR for death or MI and secondary cardiac end points were greater for dobutamine-induced echocardiographic dyssynergy (14-to 24-fold) than for dipyridamole-thallium defect redistribution (fourfold). However, wide CIs were noted with dobutamine echocardiography (Fig. 41.3). Therefore, the published experience with stress echocardiography is not as extensive as that with radionuclide perfusion imaging, but the literature to date suggests that dobutamine stress echocardiography is a valuable risk stratification modality.

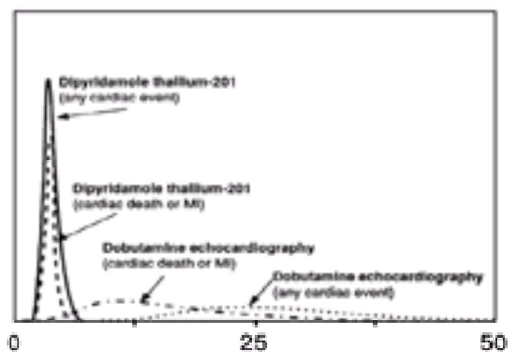

FIGURE 41.3 Summary odds ratio and 95% confidence intervals for risk stratification of patients undergoing pharmacologic stress perfusion and echocardiographic imaging, as determined by metaanalytic confidence profile method. Because of larger sample sizes, narrower confidence profiles are seen for dipyridamole–thallium-201 perfusion imaging than for dobutamine stress echocardiography, although point estimates for the summary odds ratio are greater using echocardiography. MI, myocardial infarction. [From Shaw LJ, Eagle KA, Gersh BJ, et al. Meta-analysis of intravenous dipyridamole–thallium-201 (1985–1994) for risk stratification before vascular surgical candidates. *J Am Coll Cardiol* 1996;27:787–798, with permission.]

Alternative Methods of Risk Stratification

The predictive value of ambulatory ECG monitoring for 24 to 48 hours preoperatively has been reported by several investigators who studied patients undergoing vascular and other types of noncardiac surgeries (81,107,154,155,156,157,158 and 159). Although some of these reports have suggested favorable utility, preoperative ST-segment monitoring has several significant limitations, including a low positive predictive value (10%) (102). Finally, other imaging modalities may have limited utility. Coronary calcification on computed tomographic scans performed before noncardiac thoracic surgery has been shown to be predictive of postoperative cardiac morbidity (160). Stress magnetic resonance imaging or ultrafast cine computed tomography theoretically should identify patients at risk. However, less expensive and more widely available technologies exist.

Perioperative Evaluation of Other Cardiac Conditions

To this point, we have considered the evaluation of the patient only in terms of the presence or absence of significant CAD and the implications for prognosis. However, preoperative cardiac consultation is sought for a variety of indications, including CHF, murmurs, and arrhythmias (51,52 and 53).

CHF is an important harbinger of poor postoperative outcome (64,65,161). Therefore, great effort should be made to identify and treat unsuspected heart failure by performing a careful history and physical examination. It is important to identify the mechanism of CHF, because systolic dysfunction, diastolic dysfunction, and valvular abnormalities all can cause this syndrome, and management of each of these disease entities is significantly different. Determination of etiology may have prognostic implications (103).

Cardiac murmurs are common. The cardiology consultant must determine etiology and distinguish significant murmurs from those that are not clinically important. Severe aortic stenosis conveys high risk (57) and may justify postponement or cancellation of surgery. Rarely, percutaneous balloon aortic valvuloplasty may be justified in a patient who is not a candidate for aortic valve replacement, which is the preferred treatment before noncardiac surgery (103). Mild or moderate mitral stenosis requires monitoring to maintain reasonable control of heart rate to reduce the risk of pulmonary congestion associated with a decreased diastolic filling period. Patients with severe mitral stenosis may benefit from balloon mitral valvuloplasty or open surgical repair before high-risk noncardiac surgery (103). Patients with regurgitant lesions may benefit from heart-rate control, antibiotic prophylaxis, or afterload reduction, depending on the etiology and severity of the lesions. Patients with prosthetic valves should receive appropriate antibiotic prophylaxis for endocarditis (162). In addition, patients with mechanical prosthetic valves require careful management of coagulation and may need a short course of intravenous heparin therapy.

Cardiac arrhythmias and conduction disturbances are common in the perioperative period (56,86,163). Although both supraventricular and ventricular arrhythmias have been associated with increased risk of adverse postoperative cardiac events, they are probably markers for underlying cardiopulmonary disease that places a patient at higher risk. Perioperative atrial fibrillation is a common arrhythmia, especially after intrathoracic surgical procedures; direct atrial irritation may be the operative mechanism. Because of the increased catecholamine state that occurs in the immediate postoperative period, it may not be possible to maintain sinus rhythm, and therapy should be directed at heart-rate control and anticoagulation, if indicated (164). Cardioversion is usually reserved for hemodynamically compromising atrial fibrillation. Most arrhythmias are not malignant, but their presence can expose underlying disease that may compromise the patient (e.g., new atrial fibrillation with rapid ventricular response that precipitates ischemia and subsequent CHF). Patients with conduction disease and no history of high-grade atrioventricular block generally do well. However, high-grade atrioventricular block may require insertion of a temporary pacing wire. Transcutaneous pacing allows rapid response to sudden and hemodynamically significant heart block (106).

For patients with pulmonary vascular disease, the risk associated with noncardiac surgery is higher. Abnormal pulmonary vasoreactivity may make these patients prone to further increases in pulmonary vascular resistance during periods of perioperative hypoxia (164). Corrected and uncorrected congenital heart disease, sometimes associated with pulmonary vascular disease, may be accompanied by lower cardiac reserve, increasing perioperative risk (164). However, pulmonary hypertension has not been extensively studied as an independent perioperative risk factor for noncardiac surgery.

The cardiology consultant may also play an important role in patient care during recovery from surgery. Postoperative arrhythmias, hypotension, and hypertension may occur in the postanesthesia care unit. The consultant should evaluate the patient's volume status to prevent hypotension and CHF in the first 48 hours (54). Because of the risk of ischemic events in patients with CAD, the cardiology consultant should check the ECG immediately after surgery. The consultant should also check the ECG daily and follow the patient for at least 3 days after the operation if the patient remains in the hospital.

Risk Reduction

Risk reduction is the cornerstone of preoperative evaluation and management. Generally, interventions aimed at reducing perioperative cardiac risk can be classified as perioperative monitoring, medical therapy, or preoperative revascularization. In preoperative monitoring, the role of pulmonary artery catheters has been studied, although not extensively. The effect of various medical therapies, including beta-blockers, alpha-adrenergic agents, and calcium channel blockers has been reported. Preoperative coronary revascularization to decrease cardiac risk has also been studied, but most of the data have been observational.

There is some evidence that optimization of preoperative hemodynamics may be beneficial (165), and careful perioperative hemodynamic monitoring may decrease cardiac morbidity (166). However, Bender and associates (167) randomly assigned 104 patients to one of two groups: a group in which all patients received a pulmonary artery catheter and a group in which only patients with accepted indications for pulmonary artery catheterization received such a catheter. The authors demonstrated no significant difference in rates of intraoperative and postoperative complications or mortality between the two groups. Valentine and colleagues (168) reported a randomized trial studying the routine use of pulmonary artery catheters in 120 patients undergoing aortic surgery. They found no significant reduction in morbidity and a higher rate of intraoperative cardiac events among patients who had a pulmonary artery catheter. Overall, the routine use of pulmonary arterial catheters in the initial care of surgical patients has been discouraged (167,168,169 and 170). Consultants should be aware that insertion of a pulmonary artery catheter, by itself, does not constitute a cure. It is only by obtaining vital information that is used to guide therapy and interpreting that information correctly that the pulmonary artery catheter may prove useful (170). Furthermore, a retrospective analysis of data for patients who underwent abdominal aortic surgery revealed that risk of cardiac arrest was higher when no daily rounds were made by an intensive care unit physician (OR, 2.9; 95% CI, 1.2 to 7.0) (171). Therefore, careful postoperative management of critical patients by an intensivist and sound decision making based on clinical and procedural data are the only monitoring strategies that may be recommended.

Several studies suggest that beta-blockade may be beneficial in the perioperative period and long term in patients who have undergone noncardiac surgery (172,173 and 174). The first well-designed trial randomly assigned 200 patients undergoing noncardiac surgery to receive atenolol or placebo. Atenolol was used intravenously before and immediately after surgery and orally thereafter for the duration of the hospitalization. No difference was noted in the perioperative MI or death, but the overall mortality after discharge from the hospital was significantly reduced among patients who received atenolol (0% vs. 8% at 6 months; p <.001; 3% vs. 14% at 1 year; p = .005; 10% vs. 21% at 2 years) (172). However, the placebo group had a higher risk profile as a result of unequally distributed risk factors. More recently, Poldermans and coworkers (174) performed a randomized trial involving 173 high-risk patients in whom inducible regional wall motion abnormalities were seen on dobutamine stress echocardiography to assess the effect of perioperative bisoprolol on the incidence of cardiac events within 30 days after a major vascular surgery. The primary end point of cardiac death and MI occurred in two patients (3.4%) in the bisoprolol group versus 18 patients (34%) in the group of patients who received standard care without beta-blockers (p <.001). This dramatic reduction in events may be partly attributed to selection bias; the study was performed in a high-risk cohort in which an exceptionally high event rate was seen in the placebo group.

Administration of nitroglycerin in the perioperative period may decrease the incidence of intraoperative myocardial ischemia, but reduction in the incidence of MI or cardiac death has not been demonstrated (175,176). One small study evaluated the efficacy of use of intravenous diltiazem in patients undergoing vascular surgery. A lower incidence of myocardial ischemia was noted among patients who were receiving diltiazem. However, the study was too small for it to be possible to draw conclusions about the effect of diltiazem on MI or death (177). Perioperative use of $alpha_2$-agonists has also been studied in few small randomized trials that failed to demonstrate a significant reduction in postoperative events (178,179). In a European multicenter trial, 2,801 patients with known CAD who were undergoing noncardiac surgery were assigned to receive intravenous mivazerol (an $alpha_2$-agonist that reduces postganglionic noradrenaline availability and sympathetic efferent output) or placebo. Mivazerol failed to reduce the overall rate of death and MI. However, among a preselected cohort of patients with known CAD who were undergoing vascular

surgery, a reduced risk of death and MI was seen in the mivazerol group (relative risk, 0.67; 95% CI, 0.45 to 0.98) (180). Further study of the alpha-adrenergic agents may, therefore, be warranted. Presumably, these medical interventions could prevent postoperative adverse cardiac events that are preceded by tachycardia and ECG evidence of ischemia (181,182).

Interventions aimed at increasing oxygen supply through increased oxygen delivery (183) or improved blood flow via intraaortic balloon counterpulsation (IABP) may reduce postoperative cardiac morbidity and mortality (183,184 and 185). Arafa and associates (186) analyzed 344 patients undergoing cardiac operations who required perioperative use of IABP, with a mean follow-up of 7.45 years. On regression analysis, timing of IABP insertion was identified as an independent predictor of early (30-day) mortality (p <.05) and late death (p <.05). Survival analysis demonstrated significantly improved survival among patients who received an IABP preoperatively (p <.02). These studies may justify allowing preoperative IABP a more liberal role in treatment of high-risk patients undergoing cardiac surgery.

There are no randomized trials to evaluate the protective role of percutaneous coronary revascularization before noncardiac surgery. Studies by Golden and colleagues (187) and Younis and coworkers (136) suggest that coronary intervention in patients identified as high risk by myocardial perfusion scintigraphy may improve cardiac outcomes. Retrospective analysis of data regarding the role of use of percutaneous transluminal coronary angioplasty (PTCA) for preoperative revascularization has been reported (188,189 and 190). All three studies reported a low incidence of perioperative cardiac events after noncardiac surgery. However, these studies did not define a clear indication for PTCA, and they also lacked a control arm, making interpretation of the results difficult. A recent study that used an administrative database of patients who underwent noncardiac surgery revealed that PTCA was associated with significant reduction in perioperative cardiac events (191). Interestingly, the percutaneous revascularization procedure reduced risk only if it was performed more than 90 days before surgery. This finding suggests that PTCA immediately before surgery may not confer protection against perioperative cardiac events, and that the immediate postprocedure period is probably not the optimal time for noncardiac surgery. Coronary stenting before noncardiac surgery presents a unique clinical dilemma because of the risk of acute stent thrombosis and bleeding complications associated with postprocedure anticoagulation. Kaluza and colleagues (192) studied 40 patients who underwent noncardiac surgery less than 6 weeks after coronary stent placement. Seven MIs and eight deaths occurred, all in patients who underwent surgery fewer than 14 days after coronary stenting. Judging by ECG and by enzymatic and angiographic evidence, stent thrombosis accounted for most of the fatal events. Therefore, postponing elective noncardiac surgery for at least 4 weeks after coronary stenting should allow completion of a mandatory antiplatelet regimen, thereby reducing the risk of postoperative cardiac events.

Studies have shown that patients who have undergone recent CABG before noncardiac surgery have postoperative cardiac morbidity and mortality rates that are similar to those among patients who have no clinical evidence of CAD (193,194 and 195). Manske and colleagues (196) performed a randomized trial in which patients with coronary disease who were scheduled to undergo renal transplantation were assigned to receive medical therapy or CABG. Although a 57% reduction in cumulative probability of unstable angina, MI, or death at 12 months was observed among patients who underwent revascularization compared with that among medically treated patients and the study was terminated early, loss to follow-up and small size limit the study's usefulness. A similar randomized trial involving patients who had peripheral vascular disease has not been performed. However, the CASS registry provided a unique opportunity to evaluate the outcome of patients with CAD who were either medically managed or had undergone CABG and subsequently underwent noncardiac surgery. Eagle and colleagues (86) evaluated 3,368 patients, of whom 1,546 were undergoing abdominal, vascular, or head and neck surgeries. Among the patients who underwent these high-risk procedures, a dramatic reduction in event rates and fewer deaths (1.7% vs. 3.3%; p = .03) and MI (0.8% vs. 2.7%; p = .002) were seen in the CABG group than in the medically treated group. Rihal and associates (197) analyzed data from the CASS registry to examine the long-term outcomes of 1,834 patients undergoing noncardiac surgery. For patients treated with CABG, the Kaplan-Meier 8-year and 16-year survival rates were 72% and 41%, respectively; for the medically treated group, the corresponding survival rates were 57% and 34%, respectively (p <.0001). However, the benefits were limited to patients with three-vessel CAD and inversely related to LVEF. These data may suggest that the relatively high short-term risks of CABG may be outweighed by the long-term benefits, even though the overall long-term survival rates among patients with peripheral vascular disease remain poor. Finally, in a recently published analysis of the Bypass Angioplasty Revascularization Investigation trial, patients randomly assigned to undergo CABG or PTCA who underwent noncardiac surgery during the follow-up period were evaluated for perioperative cardiac events (198). After an average of 29 months of follow-up, low perioperative event rates were associated with both of the revascularization procedures (1.6% in each group), suggesting that coronary revascularization of either type may reduce the event rate of cardiac complications after noncardiac surgery (199).

Certain issues regarding risk reduction remain unresolved: (a) the lack of randomized trials that evaluate preoperative coronary revascularization and the optimal timing for the revascularization procedure, (b) the optimal timing and duration of perioperative beta-blocker therapy and the usefulness of beta-blockers to treat patients undergoing nonvascular surgery and low-risk patients, and (c) the role of alpha-adrenergic agents and the usefulness of their addition to perioperative beta-blocker therapy.

Stepwise Approach to Preoperative Cardiac Risk Assessment

Preoperative cardiac testing achieves both short-term and long-term risk assessment. With use of current anesthetic, surgical, and medical care techniques, it is rare for the clinician to encounter a patient in whom the noncardiac surgical risk exceeds that associated with CABG. Therefore, strategies that are known to improve long-term outcomes should guide decision making, and in this regard, the preoperative setting represents for many patients the first opportunity for coronary evaluation. Additionally, preoperative evaluation may have value other than the detection of significant CAD, including the identification of asymptomatic or minimally symptomatic valvular or myocardial disease that requires long-term management. Costs and quality of testing modalities vary locally and regionally. The cost-effectiveness of alternative modalities, such as preoperative stress echocardiography, has not been evaluated to date. Therefore, the clinician must weigh these factors in determining a risk assessment strategy that is appropriate for a specific patient.

The ACC and the AHA have jointly produced guidelines, based on current knowledge, for cardiac evaluation before noncardiac surgery. A general strategy for preoperative cardiac risk assessment is summarized in Figure 41.4. Ideally, this strategy should be applied in the outpatient setting for elective surgery. A stepwise approach to risk stratification includes the following (103):

FIGURE 41.4 American College of Cardiology/American Heart Association Guidelines flow diagram. *Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by noncardiac surgery, or intensified care. **Major clinical predictors: unstable coronary syndromes, decompensated congestive heart failure, significant arrhythmias, severe valvular disease. †Intermediate clinical predictors: mild angina pectoris, previous myocardial infarction (MI), compensated or previous congestive heart failure (CHF), diabetes mellitus. ‡Minor clinical predictors: advanced age, abnormal results of electrocardiography (ECG), rhythm other than sinus, low functional capacity, history of stroke, uncontrolled systemic hypertension. MET, metabolic equivalent.

1. Determine whether the patient has undergone coronary revascularization in the past 5 years. Prior coronary revascularization probably reduces the cardiac risk associated with noncardiac surgery (70,71).
2. Determine whether the patient has had an adequate, favorable prior cardiac evaluation in the past 2 years. If there have been no new intercurrent symptoms, it may not be necessary to repeat costly testing.
3. Determine whether the patient has an unstable coronary syndrome or a major clinical predictor of risk (e.g., decompensated heart failure, significant arrhythmias, severe valvular disease), which usually leads to cancellation or delay of surgery until the problem has been diagnosed and treated.
4. Determine whether the patient has intermediate clinical predictors of risk (e.g., prior MI recognized by history or by ECG, angina pectoris, compensated or prior heart failure, and diabetes mellitus). Consider the patient's functional capacity and surgery-specific risk.
5. Patients who have no major predictors but who have intermediate predictors of clinical risk and at least moderate functional capacity generally may undergo intermediate risk surgery with low probability of perioperative MI or death. Conversely, patients with poor functional capacity (inability to exercise at 4 metabolic equivalents) or who have multiple markers of risk and who are undergoing higher-risk surgery should undergo noninvasive evaluation to further stratify risk. If the anticipated risk of surgery is high and results of noninvasive testing show abnormalities that suggest significant CAD, coronary angiography, followed by coronary revascularization if appropriate, should be considered.
6. Noncardiac surgery is generally safe for patients with neither major nor intermediate predictors of clinical risk and at least moderate functional capacity.
7. Use results of the preoperative evaluation, including noninvasive testing in selected patients, to determine further preoperative management. Use information

gained during preoperative evaluation and careful postoperative surveillance to tailor long-term therapy and follow-up.

To date there have been no large prospective studies of preoperative cardiac risk reduction, in part because of the difficulties associated with designing and carrying out such investigations (74). Because of the lack of sufficient sound evidence, the decision to perform coronary angiography based on preoperative noninvasive cardiac testing remains difficult, controversial, and costly. The ACC/AHA guidelines for perioperative cardiovascular evaluation before noncardiac surgery do not address whether coronary angiography should be performed in response to specific test results (103). Therefore, using a modification of the *Delphi method* (a term sometimes used to describe a reiterative process by which consensus panels make recommendations), Cohen and Eagle (200) offered an expert opinion regarding the indications for preoperative coronary angiography when results of noninvasive tests are known. There was agreement that catheterization should be performed for (a) ischemia seen on exercise ECG in a patient with a blood pressure drop greater than 10 mm Hg; (b) stress perfusion scan reversibility in greater than or equal to one-half of SPECT slices; and (c) ischemia seen on stress echocardiography in more than five segments, more than two coronary artery zones, or four left anterior descending coronary artery segments. Therefore, in general, coronary angiography should be performed in the appropriate clinical context, based on results of noninvasive tests that indicate large zones of myocardial ischemia, and should not be performed for patients who have limited ischemia without other significant clinical findings.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Cardiology consultants frequently provide perioperative cardiac care. Evidence supports selective screening and efforts at cardiac risk reduction. “Universal precautions,” including intensified antiischemic medical regimens and close hemodynamic monitoring, combined with constantly improving surgical and anesthetic techniques, may make preoperative cardiac risk assessment less cost-effective. In this context, surgery may be considered just one of many potential triggers of cardiac morbidity and mortality with which a person may come in contact during daily life. The preoperative cardiac consultation may, therefore, represent an opportunity to initiate or modify cardiac care, including primary and secondary preventive measures. The consultant should assess and suggest management for risk factors for CAD (e.g., hypertension and hyperlipidemia) and heart failure. Further evaluation may be appropriate after the patient has recovered from surgery. The physician responsible for the long-term care of the patient should receive pertinent information obtained during the perioperative consultation (103). One of the most important aspects of a consultation is referral back to the primary care provider. This ensures that the physician responsible for the overall medical needs of the patient remains involved in the individual’s care. Also, the primary care provider may have the benefit of long-term follow-up, providing more insight into the social and psychological aspects of patient care. Lastly, referral back to the primary care provider helps strengthen the relationship between the consultant and the referring physician, which may result in continued referrals to the consultant’s practice.

THE FUTURE

Regardless of the political and economic environment in which medicine is practiced, successful cardiology consultation requires more than proficiency in taking histories, examination, and test interpretation. The ideal consultant “informs without patronizing, educates without lecturing, and directs without ordering. . . .” (36). Cardiology consultants might gain from the adage: “Successful consultation depends on the ‘3 A’s’: affability, availability, and ability—in that order!”

OVERVIEW

During the late 1960s and 1970s (an era that has been euphemistically termed the *open checkbook era* in health care), hospitals and doctors in the United States were paid essentially what they charged. Competition on price was nonexistent, but competition among hospitals to have the most modern, technologically up-to-date facilities was fierce. The resulting double-digit annual escalation in health care costs alarmed policy makers and private businesses and led to the first concerted efforts to control the growth of medical spending (1).

The failure of modest efforts at medical cost control during the 1970s and 1980s convinced many payers that the medical establishment would not voluntarily become fiscally accountable. In the late 1980s, the business and insurance communities began an aggressive bid for control of health care costs and increased accountability in medicine, catching the profession largely by surprise (2). Many physicians had assumed that the value of the U.S. health care system was self-evident and hence that their dominant role in it was assured. Others believed that pathophysiologic reasoning or personal experience and judgment were sufficient to justify a course of action, regardless of the cost. Still others regarded any discussion of costs as demeaning to the profession. These attitudes largely became untenable when multiple outcome studies in the 1980s demonstrated that physicians practicing in different areas of the country made remarkably different management decisions for similar patients (3,4). Other studies from this period reported that doctors across the country performed significant numbers of unnecessary surgical procedures, particularly coronary bypass surgery. Together, variability of practice and appropriateness of care studies suggested the presence of substantial waste in the medical care system and demonstrated that physicians and hospitals by themselves had no incentives to develop a more standardized and efficient mode of practice.

Managed care can trace its origins back to the 1930s, but it first gained serious national attention during the 1970s as a method of controlling escalating health care costs. It was not until the late 1980s, with costs continuing to rise unabated and the medical establishment's prestige and credibility in tatters, that managed care began its exponential growth phase. Two major factors have driven this expansion: (a) the failure of health care reform efforts during the first term of the Clinton administration and (b) the demand by large employers for their employee health care costs to start shrinking rather than growing. For a brief period in the 1990s, managed care became the *de facto* national health care reform policy in the United States. However, because it is driven by market interests rather than carefully crafted policy, it does not address many key issues (such as access to care and funding of medical research and education). Furthermore, managed care will not be successful in the long-term control of medical spending. Between 1999 and 2006, medical costs in the United States are expected to double. The pressure from payers to resist these increases is therefore likely to intensify in the next 5 years. For clinicians to be partners in shaping the future of medicine during the critical period to come, they must understand the outcomes of medical care and its costs. The purpose of this chapter is to provide a general introduction to the key concepts of medical cost analysis and to review current knowledge about the economic consequences of cardiovascular diagnostic and therapeutic technologies.

MAJOR MEDICAL COST CONCEPTS

Medical cost analysis is a hybrid field that owes as much to the discipline of accounting as to economics. Economics provides much of the theoretical framework, whereas cost accounting deals with issues of empiric measurement. This section provides an introduction to the major economic and accounting concepts of medical cost and an overview of cost terminology that clinicians are likely to encounter and then examines the issue of empiric cost measurement. The section concludes with an examination of selected methodologic issues that are relevant to studying costs in the medical arena.

Medical Cost: General Considerations

To the average person, "cost" means money. The accountant has a more detailed notion of the resources required to produce the good or service that underlies any given monetary payment (5,6). The economist, however, operates from a more theoretical position (7,8). A major economic axiom is that any societal decision to use resources in the production of goods or services is accompanied by foregone opportunities to do something else with those resources (9,10). Because each health service or program uses up some societal resources that could have been used for some other purpose, it thereby involves a cost. Economists refer to this as *opportunity cost*. When economists talk about cost, they usually have opportunity cost rather than dollars in mind.

Economics also holds as axiomatic that society's resources are finite. Hence, choices must be made among the competing goals that society has for its resources, and not all goals can be fulfilled (9,10). Economics provides a set of tools to help define alternatives and make choices. In this context, the health economist is concerned with answering three basic questions (7,8):

1. How much should be spent on health care and what health care goods and services should be produced?
2. How shall these goods and services be produced?
3. For whom shall they be produced?

Resources are typically divided into large generic categories, such as labor, land, and capital (e.g., machines, factories, and stores of materials). The application of technology allows society to convert these raw resource inputs into desired goods and services, such as medical care. To compare societal choices for potential alternative uses of resources, it is necessary to assess the opportunity cost of health care, weapons, public education, and other societal priorities in some common metric. Some societies use barter, the transformation of one good into another of equivalent value through physical exchange, to match goods and services to individual needs. In industrialized societies, however, markets are used to match buyers and sellers, and money is used as the exchange intermediary. The market price in these societies then represents the amount of money equivalent in value to the total resource inputs used in the production of each good or service. (Market prices also include a profit component that ideally is equivalent to a fair rate of return on investment.) The key concept to the economist is consumption of resources. The dollar cost is merely a convenient way of valuing all the disparate resources involved on a common scale.

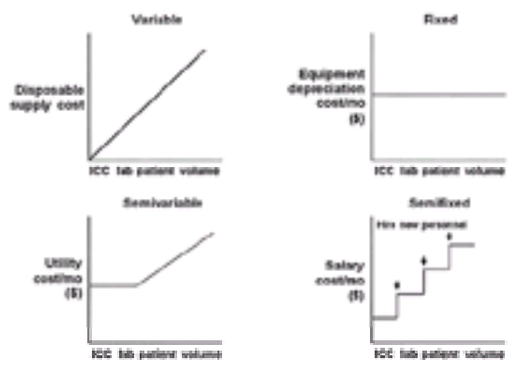
Medical Cost: Terminology

Several types of cost terms are used in the medical economics literature (*e*Table 42.0.1). One set of terms describes the behavior of cost as production volume

changes (1,5,9,10) (eFig. 42.0.1). *Variable costs* are those that change with unit changes in service volume; *fixed costs* remain unchanged as production of health care services (e.g., tests or treatments) is increased or decreased. For example, each extra balloon angioplasty catheter or coronary stent that is used in a revascularization procedure increases the cost of the procedure in a predictable fashion. These items would be counted as variable costs in a cost analysis. In contrast, the catheterization laboratory itself is a fixed cost. Whether two or ten cases are done a day in that facility has no effect on the costs that are attributable to the facility (such as depreciation of the building and the major equipment in it). (It should be noted also that a cost is fixed in relation to a finite defined period of time. With a long enough time horizon, virtually all costs become variable.)

***e*TABLE 42.0.1** MAJOR COST CONCEPTS AND TERMINOLOGY

Behavior of cost relative to health care service production
Variable costs
Fixed costs
Semifixed costs
Traceability to the production of health care services
Direct costs
Indirect costs (overhead)
Cost changes with shifts in the use of health service
Marginal costs
Incremental cost
Future cost consequent to initial health care provided
Induced costs (and savings)
Societal costs due to lost productivity
Indirect costs (productivity costs)



***e*FIGURE 42.0.1** Graphic representation of terms relating behavior of cost to production volume changes. ICC, intensive coronary care.

Many costs do not behave as either completely variable or fixed. Hence, two additional cost behavior terms are occasionally used to describe hybrid categories (1). *Semifixed costs* change with changes in output but in a step fashion rather than continuously (eFig. 42.0.1). Catheterization laboratory personnel often represent fixed costs because they are paid a certain salary per month regardless of the caseload. However, if the laboratory volume goes up past a certain threshold, the director may need to hire additional staff. The costs of running the facility would then increment up by the amount of these additional salaries. Alternatively, persistently low volume may persuade the laboratory director to downsize by reducing the staff of the facility. This would step the fixed costs down accordingly.

The other hybrid cost behavior category is *semivariable*. This type of cost typically starts with a fixed component and then becomes variable past a certain threshold (eFig. 42.0.1). For example, the electricity cost in the catheterization laboratory would be greater than zero even if no cases were done at all. Each case increases the electricity cost of the laboratory beyond this fixed threshold in a proportional or variable manner. Other utility costs tend to behave in the same fashion. Personnel costs may also behave this way if the laboratory uses a core of salaried employees and supplements them with temporary help who are paid on an hourly basis.

Another set of cost terms describes the traceability of individual costs to the production of health care services (eTable 42.0.1). *Direct costs* can be unambiguously linked to the production of a given product or service. They are also generally under the control of the health care providers. In a cardiac care unit, examples of direct costs include personnel (such as nursing time), disposable supplies (such as electrocardiographic electrodes), and medications administered. *Indirect costs*, in contrast, cannot be traced to the production of specific medical goods and services and are instead allocated arbitrarily, using one of several accounting methods available, among all goods and services produced. These costs are generally not controllable by the physicians and nurses who care for patients (although there are some exceptions). Hospital administration, depreciation on the hospital building and the major equipment in it, medical billing, and medical records are all considered indirect costs. For accountants, indirect costs are synonymous with overhead; economists use “indirect costs” differently, as discussed below. One caveat: The distinction between what is considered direct versus indirect is dependent in part on the perspective of the analyst and the sophistication of the cost-accounting data that are available. Some costs may be assigned to the overhead category for the convenience of the analyst rather than because of conceptual difficulty in tracing their relationship to the production of health care services.

In general, the direct versus indirect cost distinction has primarily been used for accounting purposes within a given health care institution to ensure that expenditures match revenues. The distinction can also be useful in a cost-finding study that is trying to define and cost out all the medical resources consumed in the production of a particular medical service. This distinction has also become relevant for clinicians who are under great pressure (often from hospital administrators—who are part of the overhead costs) to reduce the direct cost of patient care. A detailed analysis of medical services to identify all the major cost components, direct and indirect, is the first step in responsible cost reduction.

Marginal cost is a concept that is frequently referred to by economists. It is defined as the extra cost involved in producing one extra unit of good or service. For all practical purposes, it is identical to the variable costs of production described earlier. For example, if a patient with uncomplicated myocardial infarction (MI) is discharged on day 4 instead of day 5, the hospital saves the variable costs associated with the extra hospital day. If that hospital bed cannot be filled by another patient, however, the hospital still has fixed costs associated with that bed that must be paid (electricity, heating, depreciation, and possibly even idle hospital staff).

The concept of one more (or less) test or procedure is a useful construct for economic analysis. In clinical practice, however, a more pragmatic question is the cost of shifting a group of patients from one diagnostic or therapeutic strategy to an alternative. In this latter setting, many economic analysts substitute the term *incremental cost* for marginal cost (11). Incremental cost analysis addresses a key issue in health care: How much savings are available (or costs are added) by shifting from one clinical strategy to an alternative? Incremental cost analysis is a fundamental aspect of (see Cost-Effectiveness Analysis). It should be noted that some analysts use the terms *marginal* and *incremental* interchangeably (12).

Two additional cost terms are frequently used in medical economic analyses. *Induced costs* (*savings*) refers to the costs of tests or therapies added (or averted) as a consequence of some initial management decision. For example, the use of angiotensin-converting enzyme (ACE) inhibitors in patients with heart failure reduces the need for future hospitalizations. In this case, the therapy is said to have induced a cost savings equal to the cost of the hospital days avoided. In another familiar example, performance of an initial percutaneous transluminal coronary angioplasty (PTCA) is associated with a need for repeat revascularization in 20% to 25% of patients to treat restenosis. These follow-up procedures are an induced cost of the initial PTCA procedures.

Finally, the term *indirect cost* is used by economists to refer to the societal costs associated with loss of productivity due to morbidity. The term *productivity costs* has been proposed to avoid confusion with the accounting meaning of indirect costs (9). The productivity costs associated with morbidity include time lost from work or (more controversially) leisure activities. Changes in productivity due to shortened life expectancy are by convention counted as negative health benefits rather than productivity costs.

Medical Cost: Measurement

As mentioned at the outset of this chapter, “cost” means different things to different analysts and consumers of cost data. To measure cost, one must have a clear operational definition of what is to be measured. The economist’s concept of opportunity cost represents the purest definition of “true cost.” However, opportunity cost is a theoretical construct that does not have a practical measurement analog.

Accountants are more concerned with measurement than are economists and consequently make a number of important simplifications. To measure true accounting

costs all the individual resources consumed in the production of a particular medical good or service must be determined and market prices assigned to each. Although measurement of true accounting costs is possible in some restricted situations, most cost analyses incorporate a number of approximations to increase ease of measurement. Because collecting cost information itself has a cost, the cost analyst must decide how much detail is necessary to satisfy a particular cost-accounting goal.

Two general approaches can be used to assess the cost of medical care services and products, “bottom-up” and “top-down” (1) (*e*Table 42.0.2). They differ in the level of detail used to describe resource consumption and in the quality of the cost weights collected. The bottom-up methods all involve enumeration of individual resources consumed in an episode of medical care and the corresponding cost weights. The gold standard bottom-up approach (also known as *microcosting*) involves a detailed enumeration of all the resources consumed by the medical care in question, detailed cost-accounting estimates of individual resource cost weights, and assignment of appropriate cost weights to each resource (5). The sum of the resources multiplied by their unit cost yields the total cost. However, this methodology can be quite laborious and expensive and is therefore infrequently used. For a relatively simple service, such as the administration of an antibiotic or performance of a laboratory test, this type of analysis may be feasible. A microcosting analysis of a more complex hospital procedure, such as a coronary angioplasty, or an episode of hospital care, such as an admission for acute MI, is a substantially greater challenge, in part because of the greater number and variability of resource inputs involved in the analysis.

***e*TABLE 42.0.2** OPTIONS FOR COST MEASUREMENT
Bottom-up methods
Microcosting analysis (gold standard)
Hospital cost-accounting system
“Big ticket” cost analysis
Top-down methods
Charge to cost conversion (hospital bill–based, United States only)
Diagnosis-related group standard costs

In the United States, some hospitals have installed computer-based cost-accounting systems that provide a bottom-up estimate of cost for each identifiable product that the institution produces. The level of detail and accuracy of such systems can approach that of a true microcosting analysis; however, substantial variability among vendors and even among hospitals using the product of an individual vendor likely occurs, partly because these systems typically allow the user to control the level of detail and the accuracy of the cost and resource data contained in the system. At present, many institutions still do not have electronic cost-accounting systems. Furthermore, such detailed cost-accounting systems are rare outside the United States.

A simplified version of the bottom-up approach involves enumeration and costing of “big ticket items.” This method requires the identification of the subset of resources consumed that are considered the most important cost components (“the big tickets”). Use of this approach allows the analyst to concentrate on costing out only a subset of the entire resources consumed. The principal advantage of this approach is that it is less expensive. However, this approach also has several important potential limitations (*e*Table 42.0.3).

***e*TABLE 42.0.3** STRENGTHS AND LIMITATIONS OF COST MEASUREMENT METHODS

Method	Strengths	Limitations
Full microcosting analysis	Most accurate	Most expensive and time consuming
Hospital cost-accounting system	Accuracy approaches that of microcosting	Variable levels of detail used Many key assumptions invisible to end user
Big ticket cost analysis	Efficient Less expensive	Estimates average (not marginal) cost May oversimplify, miss important cost differences Presumes uniform cost weights
Hospital bill charge to cost conversion	Efficient Based on detailed resource use data Can be used for most U.S. hospitals	Estimates average cost (not marginal cost) Variable methodologies used by different hospitals
DRG reimbursement rates	Efficient Least expensive	Not sensitive to resource use variations within a DRG category Health Care Financing Administration reimbursement rates may be lower than true costs

DRG, diagnosis-related group.

The other major approach to cost estimation is the top-down approach. At least two variants of this method can be used, one based on detailed hospital billing data and the other on summary episode-of-care descriptors. The method that uses hospital billing records is suitable for use only in U.S. institutions that generate hospital bills (and analyses that involve hospitalizations). The medical charges that appear on U.S. hospital bills represent a tremendously inflated statement of the underlying true costs for the care in question (13). In the earlier (preprospective payment) era of Medicare, hospitals were reimbursed on the basis of their “reasonable and necessary” costs of providing care to patients. To define what proportion of hospital charges these reasonable costs were, Medicare developed an elaborate reporting system that required each hospital to file a cost report each year with the Health Care Financing Administration (HCFA). This report provides a set of correction factors, known as the *Medicare ratios of cost to charges*. These are used with an HCFA-defined summary billing form, the Uniform Billing Form of 1992 (UB-92), to generate an estimate of hospital costs from hospital charge data for any hospital admission at an institution that participates in the Medicare program. The major U.S. hospitals that do not generate the data necessary for these calculations include the Veterans Administration System, some other military hospitals, and some fully capitated health maintenance organizations. The strengths of this approach are severalfold (14) (*e*Table 42.0.3). Most important, it is based on a detailed enumeration of resource consumption and thus tends to provide a sensitive measure of variations in resource use. In addition, this method is suitable for use in large-scale multicenter studies involving U.S. hospitals. The top-down charge-to-cost conversion also has several limitations that should be kept in mind (15) (*e*Table 42.0.3).

Medicare diagnosis-related group (DRG) reimbursement rates provide an alternative top-down cost estimation method that does not depend on conversion of hospital charge data (1). Once the patient’s DRG is defined, it becomes a straightforward matter to assign the “hospital costs.” This methodology has a number of important limitations (*e*Table 42.0.3). Most important, it is not sensitive to variations in resource use intensity within a given type of hospitalization. Furthermore, the reimbursement rates that are set by HCFA or that are provided by private insurers are only very loosely related to the true hospital costs of providing care. For these reasons, DRG reimbursement rates are primarily used for economic analyses done from the HCFA or other payer’s perspective. They are used for other cost analyses only when more accurate and appropriate cost weights cannot be obtained or the accuracy of such estimates is not particularly important to the overall analysis. Analogous DRG-based methods are available for use in some European countries.

Assignment of costs to physician services is typically done in one of three ways (1). In the past, physician fees (charges) were used. These numbers are determined by what the physician was historically able to bill for his or her services in the fee-for-service sector rather than the true cost of the resource inputs. Thus, physician fees are a distorted and inflated measure of physician service costs analogous to hospital charges. However, unlike the situation with hospital charges, no Medicare conversion factors have been established to translate these numbers into true physician costs. Alternatively, physician services can be included in a microcosting analysis (discussed earlier), although assigning costs remains problematic with this approach.

For this reason, we prefer to use the Medicare Fee Schedule, which is based in part on a resource-based relative value scale developed by Hsiao and colleagues at Harvard (16). The underlying concept of this scale is that the price of a physician service should reflect the long-term cost of providing that service. Thus, the resulting physician fees include the variable costs of the service in question as well as a component of fixed costs reflecting practice overhead expenses (such as office staff and malpractice insurance). Medicare fees under this system are tied to the physician’s *Current Procedural Terminology* classification system developed by the American Medical Association. Thus, use of the system in a cost analysis starts with assignment of appropriate *Current Procedural Terminology* codes to the relevant physician services.

For cost analyses outside the United States, a variety of estimates of physician service cost may be available. In Canada, for example, the Provincial Health Authorities each generate their own Physician Fee Schedule that is similar in general outlines to the Medicare Fee Schedule.

Medical Cost: Methodology of Cost Studies

The performance of a medical cost study requires that consideration be given to five issues (*e*Table 42.0.4): (a) the structural framework for the cost analysis, (b) the perspective(s) of the analysis, (c) the approach to cost measurement, (d) the importance of time and the need for discounting costs in the analysis, and (e) issues related to generalizability of the findings (1).

Structural Framework

Cost studies generally fall into three major domains: observational studies, randomized controlled trials, and cost-effectiveness models. Cost effectiveness is discussed in a separate section. *Observational cost studies* include descriptive series (which are sometimes referred to as *cost-finding* or *cost-identification studies*) and more complex analyses using regression models in nonrandomized comparisons. Descriptive cost series are primarily useful in areas in which there are still few published data on costs. More complex observational studies are used to identify the major determinants of a particular treatment cost (cost drivers) or to make comparisons among providers or strategies for a particular condition. To identify the independent cost drivers in a data set, statistical multivariable models are used (see next section). In scorecarding or benchmarking applications, appropriate use of statistical adjustment techniques is critical to “level the playing field.” Understanding the major cost drivers allows the analyst to ensure that the factors most important to creating a level playing field have been accounted for.

Over the last decade, an increasing number of randomized trials have incorporated cost measurement into their design (17,18). Cost data are collected in a randomized trial primarily to answer the question, “If the intervention under study is found to be effective, as hypothesized, then what are its economic implications?” Because effectiveness is almost always the primary issue for the trial, cost is typically evaluated as a secondary end point or in an ancillary study. The method of economic data collection for a clinical trial is chosen from the options described under the previous section on cost measurement. The Duke Outcomes Group has been involved in more than a dozen multicenter randomized trials in which cost data were collected on up to 4,000 patients per trial. Our approach has been to use the top-down method with hospital billing data to estimate hospital costs and the Medicare Fee Schedule to estimate physician and outpatient care costs. Medical resource use data are ideally collected on the medical case report form, but if this is not feasible, the economic substudy must make provisions to collect the appropriate data. Whenever possible, the economic portion of the trial should be planned and conducted prospectively along with the clinical part of the trial (19). This ensures that the proper economic variables are incorporated into the case report form and that additional economic data required can be collected efficiently.

Not all randomized trials are suitable for economic analysis. In our experience, the sample size requirements to obtain a precise estimate of the difference in costs between two treatment strategies may be surprisingly large. Even in a large clinical trial, economic analysis may be problematic if the clinical protocol specifies important additional testing or treatment that distorts standard patterns of care. Generally, the best trials for economic analysis are the large simple randomized trials that attempt to mimic as closely as possible good clinical practice as it occurs in the medical community at large (20).

An intention-to-treat analysis in a randomized trial protects from unaccounted-for treatment selection biases but not other types of potential biases. Some economic analysts have been critical of the use of economic analysis in randomized trials because these analyses do not provide a picture of the economic effects of the new therapy as it will be used in the community at large. The providers and institutions in a trial are almost never representative of the medical communities in which they practice. Trial investigators may systematically steer certain eligible patients away from enrollment in the trial because they feel certain that they already know what is best for these individuals. Demographic and educational factors have been shown to affect patient willingness to be randomized in a trial. Although these biases may affect the generalizability of the economic substudy of a randomized trial, they also affect the generalizability of clinical results of that trial (21). These issues are discussed further in the section Generalizability.

Perspectives of Cost Analysis

A cost analysis always entails a perspective that is defined by who the buyers and sellers (or consumers or producers) of the medical care in question are (9). *e*Table 42.0.4 lists the most common perspectives used for cost studies. The importance of perspective (also referred to by some as the *viewpoint* for the analysis) is pragmatic: A particular medical care, good, or service may be a cost from one perspective but not from another. For example, the use of a statin agent to lower cholesterol after an MI is a cost in an analysis using the societal viewpoint but is not a cost in an analysis using a fee-for-service hospital viewpoint, because the care takes place in the outpatient setting and the drug is not provided by the hospital. Most health economists and health policy analysts recommend the routine use of the societal perspective (9). This is the broadest viewpoint, and it provides for comparability with other societal perspective cost analyses. If other viewpoints are relevant to the analyst, they can be used in addition to the societal perspective.

Resource Use and Cost Measurement

After the structure and objectives of the study have been defined and the perspective(s) has been agreed on, decisions must be made about what resources to include in the analysis and the method to be used for assigning costs to those resources. The details of cost measurement using bottom-up or top-down approaches have already been discussed.

Time Effects on Cost

Time has an important influence on medical costs that must be considered in economic studies. When medical care or its consequences take place over a period of years, there is broad agreement in the economic community that all future costs (as well as future health outcomes) should be expressed in terms of their “present value” to the decision maker (9). The mathematical procedure for calculating present value costs from a stream of costs that occur over a period of years is called *discounting*. The rationale for discounting costs can be easily illustrated. Given the choice between having $100 now and $100 five years from now, the decision maker always chooses the former option. This reflects the decision maker’s time preference for present value relative to future value. The time preference is logical because if the decision maker has the $100 now, he or she can invest it and have significantly more than $100 five years from now. Conversely, receiving $100 five years from now would be equivalent to receiving a sum of less than $100 today.

Inflation is a separate issue from discounting (9). Inflation causes the value of money to diminish over time. As a simplifying step, most medical economists tend to ignore the effects of inflation. The implicit assumption is that inflation affects all components of the costs being studied or compared equivalently. However, inflation must be taken into account when comparing the results of (historical) cost studies from different years. For example, a study done in 1985 on the cost of coronary bypass surgery would need to be adjusted for inflation to provide properly calibrated cost estimates that are relevant to 2002. The most common method for achieving this kind of inflation correction is through the use of the medical care component of the Consumer Price Index or a relevant subcomponent.

Generalizability

The methodology that we have reviewed so far relates to the assessment of the costs of medical care for a defined cohort of patients in the context of an observational study or a randomized trial. In either case, it is possible to collect empiric resource use and cost data on the patients in question and to draw conclusions about the economic effects of the given medical care from the empiric data that are available. Sometimes, however, the economic analyst is interested in a broader question: What is the economic impact of the therapy in question on an entire health system? For example, we were able to calculate the incremental costs of substituting accelerated tissue plasminogen activator (t-PA) for streptokinase in the treatment of eligible MI patients in the Global Utilization of Streptokinase and t-PA for Occluded Coronary Arteries (GUSTO) I trial using the empiric data collected from that trial (22). However, the GUSTO trial does not address the question of what the economic impact would be of adopting a policy of substitution of t-PA for streptokinase nationwide. Many policy makers and other health care decision makers are more interested in the systemwide impact of a new therapy on costs than they are in the detailed cost analysis that is typically obtained in a given clinical study. The system

in question may be a country, a state or province, a managed health care organization, or a chain of hospitals.

Clear trade-offs must be made in moving from the empiric arena to the health system or policy arena. In particular, policy or systemwide projections typically involve far greater uncertainty and consequent imprecision. We can calculate quite precisely the incremental costs of t-PA in the GUSTO study, but extrapolating to the national use of thrombolytic therapy requires detailed empiric data about how many MI patients a year in the United States are eligible and are treated with thrombolytic therapy along with relevant demographic and clinical characteristics of those patients. Such data are usually not available. Typically, one of a number of surrogate sources is used to estimate the relevant information, such as claims data or even expert opinion. When several such estimates of uncertain accuracy are used together, the result may be little more than an elegant “back of the envelope” projection.

Medical Cost: Cost Drivers

Cost drivers can be considered conceptually to fall into four major categories (Table 42.1): patient-related factors, treatment-related factors, provider-related factors, and geographic/economic factors (1). *Patient-related factors* affect cost primarily by influencing the likelihood of complications of various types and severity due to variations in the severity in the underlying disease process and the extent of comorbidity. *Treatment-related cost determinants* fall into two major categories. The first involves costs incident to management decisions made by the medical providers. Thus, an aggressive interventional management strategy for a patient with an acute coronary syndrome is associated with higher medical costs (over the short run at least) than a conservative strategy. Second, there is a more complex interaction between the management strategy selected and the patient characteristics, which may result in an increase or decrease in treatment-related complications and consequent cost. For example, timely aggressive intervention may prevent a serious complication that would have otherwise occurred as a result of disease progression. Alternatively, use of an aggressive strategy may result in a previously unsuspected comorbidity becoming clinically manifest and inducing extra medical care costs.

Patient-related factors
Age
Sex
Cardiac disease severity (e.g., ejection fraction, extent of coronary artery disease)
Cardiac comorbidity (cardiac disease other than the principal condition under study)
Noncardiac comorbidity
Treatment-related factors
Aggressive versus conservative management
Complications
Provider-related factors
Quality of care
Efficiency of care
Preferred management styles
Geographic/economic factors
Labor costs
Supply costs

TABLE 42.1 MAJOR CATEGORIES OF MEDICAL COST DRIVERS

Provider-related factors refer to quality and efficiency of care issues as well as overall preferred management styles for a particular clinical problem. Complications associated with medical care cannot be eliminated, but care that is of a very high technical quality can minimize those complications relative to care of lesser quality. Efficiency of care as it relates to a provider refers to the provision of the required care with a minimum set of necessary medical resources and, thus, the minimum amount of waste achievable. Multiple studies have shown that some practitioners have a more resource-intensive style of practice than do others; how these different styles relate to quality and efficiency of care remains controversial (23,24,25,26,27 and 28).

Even after all the preceding characteristics are accounted for, costs will still vary from one provider to the next because of *geographic/economic factors* that create true variations in the costs of the component resources required to provide the care in question. Variations in the cost of medical care labor in different geographic markets and variations in the purchase price of supplies can both affect cost in important ways. For example, low unemployment rates and a shortage of skilled registered nurses may drive up the salary rate for nurses in a particular region. Very large hospital chains or payers can negotiate discounts with medical suppliers and pharmaceutical companies that are not available to small independent providers.

Cost-Effectiveness Analysis

Cost-effectiveness analysis is a form of economic efficiency analysis (1,9,10,12). As described earlier in this chapter, economists are concerned with making decisions about the most efficient use of scarce societal resources. The principal agenda of the analysis is to define for the policy maker how to allocate finite health care dollars among the possible alternative programs. In its most general form, economic efficiency analysis attempts to help solve problems of allocation of resources across major sectors of the economy, such as education, defense, public works, and health care. It is assumed in such analyses that the decision maker desires to maximize the benefits produced for society for a given investment of resources. Consequently, these techniques are insensitive to considerations about who gains and who loses as such trade-offs are made.

Types of Analyses

Economic efficiency analysis includes three related analytic techniques: cost-effectiveness analysis, cost-utility analysis, and cost-benefit analysis (11) (*e*Table 42.1.1). These methods have several important features in common. First, all three explicitly evaluate the following decision maker’s dilemma: “In moving from a reference therapy (strategy) to a new therapy (strategy), how much will be gained in additional benefits, how much additional cost will be incurred, and will the resource (monetary) investment required to produce an extra unit of benefit with this new therapy fall into an acceptable or worthwhile range judged according to past experience or other precedents?” The general formula for all three techniques is

$$\frac{C_{\text{new}} - C_{\text{usual care}}}{E_{\text{new}} - E_{\text{usual care}}}$$

where *C* = costs and *E* = effectiveness. Second, they all use the same calculation for the incremental costs of the new strategy or therapy (*e*Table 42.1.1).

***e*TABLE 42.1.1** COST-EFFECTIVENESS, COST-UTILITY, AND COST-BENEFIT RATIOS: SAMPLE CALCULATIONS

Strategy	Treatment costs	Effectiveness (life expectancy)	Utility (QOL)	QOL-adjusted life expectancy	Benefits[a]
Rx A	$20,000	4.5 yr	0.80	3.60 QALYs	$4,000
Rx B	$10,000	3.5 yr	0.90	3.15 QALYs	$2,000

$$\text{Incremental cost-effectiveness ratio} = \frac{\$20{,}000 - \$10{,}000}{4.5\text{ yr} - 3.5\text{ yr}} = \$10{,}000 \text{ per life-yr saved}$$

$$\text{Incremental cost-utility ratio} = \frac{\$20{,}000 - \$10{,}000}{3.6\text{ QALYs} - 3.15\text{ QALYs}} = \$22{,}222 \text{ per QALY saved}$$

$$\text{Incremental cost-benefit ratio} = \frac{\$20{,}000 - \$10{,}000}{\$4{,}000 - \$2{,}000} = 5$$

QALY, quality-adjusted life-year; QOL, quality of life; Rx, treatment.

[a]Shows health benefits valued in dollars.

From Detsky AS, Naglie IG. A clinician's guide to cost-effectiveness analysis. *Ann Intern Med* 1990;113:147–154, with permission.

The three modes of economic efficiency analysis differ in the way that they evaluate incremental health benefits (11) (eTable 42.1.1). *Cost-effectiveness analysis* expresses incremental benefits in terms of natural units. Most commonly, incremental life-years are used. It is this form of the cost-effectiveness ratio for which most of the available benchmarks exist (eTable 42.1.2). However, it is legitimate to calculate cost-effectiveness ratios using other medical end points. For example, a cost-effectiveness ratio of incremental dollars required to save an additional life or to produce an additional 30-day survivor or to discover one additional patient with left main coronary disease could be calculated if such outcomes were deemed relevant to decision making. The difficulty is not in calculating such ratios but in interpreting them. The consensus is that cost-effectiveness ratios of less than $50,000 per added life-year are "economically attractive," whereas ratios above $100,000 per added life-year are "economically unattractive" (1,9). The middle zone represents an uncertain area. Some have proposed setting the economically attractive threshold as low as $20,000 per added life-year (29). No such benchmarks exist for cost-effectiveness ratios constructed with other effectiveness measures such as were cited previously. Thus, these alternative cost-effectiveness ratios cannot be used for making broad-based trade-offs among alternatives for societal investment, and they can be problematic to interpret as isolated measures of value within a given health care system.

***e*TABLE 42.1.2** EXAMPLE LEAGUE TABLE OF COST-EFFECTIVENESS RATIOS

New therapy	Comparison therapy	Patient group	Cost-effectiveness ratio
CABG	Medicine	Left main disease, severe angina	$7,000
Medical Rx	No Rx	Severe HBP	$20,000
Hemodialysis	No hemodialysis	Chronic renal failure	$35,000
Medical Rx	No Rx	Moderate HBP	$40,000
Cholesterolemia	No Rx	Cholesterol >265 in asymptomatic men aged 45–60 yr	$180,000

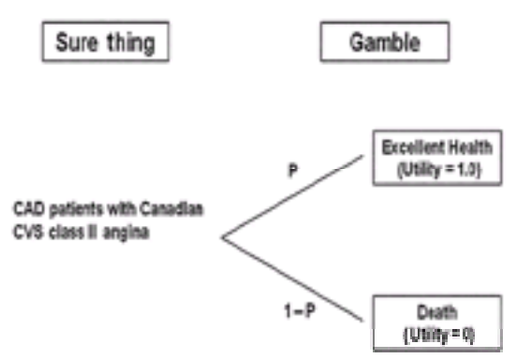
CABG, coronary artery bypass graft surgery; HBP, hypertension; Rx, treatment.

Data from Goldman L. Cost-effective strategies in cardiology. In: Braunwald E, ed. *Heart disease: a textbook of cardiovascular medicine*. Philadelphia: WB Saunders, 1992:1694–1707.

It is important for medical consumers of economic analyses to recognize that cost-effectiveness ratios are not the precise figures that they appear to be (30). Rather, they are estimates with varying (often large) degrees of uncertainty incorporated in their calculation. Furthermore, there is no single cost-effectiveness threshold that separates the "worthwhile" from the "worthless" interventions. The figures discussed in the previous paragraph for dollars per added life-year are general guidelines, not absolute benchmarks. A cost-effectiveness analysis addresses a particular decision scenario for a particular time. Its results are not absolute for all scenarios at all times. A particular intervention may be judged economically attractive in the United States but not in the United Kingdom. Similar disparities may arise in the fee-for-service versus managed-care segments of the U.S. health care system. These differences relate in part to variations in the costs of care in these different systems as well as to the different levels of willingness to spend additional dollars to buy more health care benefits.

Cost-utility analysis is a special case of cost-effectiveness analysis in which the benefit is expressed most often as a quality-adjusted life-year (QALY) (11) (eTable 42.1.1). Calculation of such a quantity assumes that patients would be willing to give up extra survival to improve quality of life. The process of equating various quality of life states to their equivalent survival durations is known as *utility assessment*. Although conceptually attractive, there are a number of important pragmatic problems in assessing utilities and incorporating them into an economic analysis. Utilities or utility weights are quantitative measures of the relative desirability of different health states. By convention, they are scored from 0 (death) to 1 (excellent health), although values of less than 0 can be used to represent health states judged worse than death. Utilities for use in economic analysis are derived by two major methods, direct assessment and use of a health utility index. Direct assessment typically involves interview- or questionnaire-based measurements using patients in a given health state of interest or, less commonly, other subjects who are asked to imagine (with the help of certain descriptive aids) being in the health state in question.

The most commonly used direct assessment methods are the standard gamble and the time trade-off (9,31). The standard gamble asks the subject to consider choosing (hypothetically) between remaining in his or her current (suboptimal) health state (the "sure thing") and a gamble. The gamble is constructed with two possible outcomes, one better than the sure thing (such as excellent health) and one worse (such as death). The probabilities of the gamble are varied systematically until the patient reports being indifferent between the sure thing and the gamble. The simple example in eFigure 42.0.2 shows the process for assessing the utility of Canadian Cardiovascular Society class II angina. The patient with this condition (or a nonpatient assessor who is provided a comprehensive description of the health state being evaluated) is asked about his or her willingness to gamble on a chance of excellent health (given the probability, p) versus immediate death (with a probability of $1 - p$). If the patient reports being indifferent, for example, between a 90% chance of excellent health (with a 10% chance of immediate death) versus class II angina, then class II angina would be assigned a utility weight of 0.9. The more unfavorable the patient's view of the sure thing, the more he or she will likely be willing to consider riskier gambles (yielding lower utility values).



***e*FIGURE 42.0.2** Simple standard gamble for assessing the utility of Canadian Cardiovascular Society (CVS) class II angina. CAD, coronary artery disease.

On theoretical grounds, many economists and decision scientists favor the standard gamble for assessment of utilities because it is most consistent with the axioms of game theory (the Von Neumann–Morgenstern axioms) that collectively define how decision makers should act in situations of uncertainty. A central premise of decision theory is that decision makers should select the option with the highest expected utility. Whether decision makers actually act in this fashion and whether empirically observed violations of the principle of utility maximization pose a threat to the validity of the standard gamble remain controversial (32,33). Investigations have shown that many individuals are inconsistent in their attitude toward risk (the gamble); specifically, they tend to overvalue a loss of certain magnitude relative to a gain of equal magnitude.

Most researchers have found the standard gamble complex to use and impractical for large-scale studies. A popular alternative is the time trade-off (34,35). In this method, the patient (rater) is asked in a series of questions how much of his (or her) life expectancy he (or she) would be willing to give up to live the remaining years in excellent health. Although simpler than the standard gamble, the time trade-off is still difficult for many patients to understand. This method also has the potentially undesirable property of valuing all future survival uniformly. In contrast, most patients tend to value their next year of life significantly higher than one that they will experience 10 years from now.

The major alternatives to the direct utility assessment techniques described previously are the health utility indexes. Each index consists of a set of discrete health states, typically defined in relatively simple generic terms, for which utility weights have been derived. Most often utility weights are obtained from the general (nondiseased) population. Seven health utility indexes are currently in use, although none has achieved widespread use in the United States (9,36).

Cost-benefit analysis requires that health benefits be converted to their monetary equivalent (11) (eTable 42.1.1). Because physicians and patients are often uncomfortable with these conversions, and because the methodology for making such equations is vulnerable to important technical and ethical criticisms, this method of analysis is infrequently used in medicine. Its principal advantage over the other forms of economic analysis is that it can be used across the entire spectrum of societal decision making, whereas cost-effectiveness and cost-utility analysis are useful only for health policy decisions in which the goal is to maximize the added life-years (or added QALYs) produced. Cost-benefit analysis directly calculates the gain or loss for society of a particular program expressed in terms of dollars invested versus the monetary value of the return on investment. The results can be expressed as a ratio (as shown in eTable 42.1.1) or (more preferably) as the net benefits of the program (the incremental benefits minus the incremental costs). If the cost-benefit ratio is greater than 1, or the net benefits are positive, the program is judged "worthwhile" from a societal perspective.

One confusing issue to many noneconomists is the distinction between incremental cost effectiveness and average cost effectiveness (11). As noted earlier, all

cost-effectiveness analysis compares a new strategy with some alternative, typically “usual care.” In incremental cost-effectiveness analysis, the new strategy and the comparison strategy are defined explicitly by the analyst. Some researchers have proposed calculating an average cost-effectiveness ratio by dividing the average effectiveness of a particular therapy or strategy into the average cost. Although this might appear to be a reasonable measure of “value” or “average bang for the buck,” this calculation actually provides an unrealistic incremental cost-effectiveness ratio in which the comparison strategy has no effectiveness (i.e., all patients die immediately) and no cost. In almost no clinical situation in medicine are these circumstances fulfilled, because even with no medical therapy there are downstream costs (such as hospitalization to treat complications) and positive health outcomes (i.e., in most cases, some of the patients survive even in the absence of any effective therapy). Thus, average cost-effectiveness ratios are misleading and should be avoided.

Standards for Economic Analysis

Economic efficiency analysis has as one of its principal goals the provision of information that is necessary to maximize the health benefits for a given population using a specific (fixed) budget. Despite the importance of this goal and the absence of competing quantitative methodologies for achieving it, cost effectiveness has never been used to make policy and allocation decisions explicitly in a health care system. Oregon attempted to use cost-effectiveness rankings to prioritize medical benefits in its Medicaid program, but after the initial effort proved extremely controversial and, in a number of cases, counterintuitive, cost effectiveness was eliminated as a ranking method in favor of effectiveness alone (37,38 and 39).

Several factors have been identified as limits on the practical use of cost effectiveness in policy making. First, many policy makers (and members of the public at large) do not accept the underlying economic model involving efficient allocation of scarce resources as the most desirable method of making health care decisions at a societal or health-system level. In particular, it has been shown that many potential decision makers place greater importance on equity considerations than is done with traditional economic analytic techniques (40). Second, there are many medical strategies for which no adequate cost-effectiveness data exist, making it difficult to use these methods for system-level allocation decisions even if desired. (The absence of adequate data is one major reason given for the failure of the Oregon Medicaid experiment with cost effectiveness.) Finally, the methodology used by different analysts to generate cost-effectiveness estimates can be so variable that even where data on cost effectiveness of different strategies exist, they may not be comparable due to methodologic differences. In addition, the absence of standard methodologies creates the impression that economic analysis is very *ad hoc* and thus quite susceptible to investigator bias.

Several national groups and one *ad hoc* group have proposed standards for cost-effectiveness analysis (9,41,42 and 43). The Panel on Cost Effectiveness in Health and Medicine convened by the U.S. Public Health Service published standards for U.S. cost-effectiveness analysis (9,44,45 and 46). Most of the standards proposed are not new. The fact that they are only intermittently used at present reflects more the limitations of the available data and the resources available to support these types of analyses than explicit decisions on the part of the analyst.

ECONOMIC STUDIES OF CARDIOVASCULAR DISEASE

Acute Coronary Syndromes

General Considerations

Acute coronary syndromes (acute MI, unstable angina) share a common pathophysiology, similar clinical manifestations, a need for hospital-based management in the vast majority of cases, and a self-limited course that typically extends 30 to 60 days from presentation (47,48). After this period, most (surviving) patients cycle back to a stabler phase of coronary disease. The economic analysis of acute coronary syndromes and their treatments therefore is primarily focused on the events during the critical initial phase of presentation and care, particularly those that occur during the initial hospitalization.

Conceptually, the cost of hospitalization for an acute coronary syndrome can be divided into four major resource/cost components (Fig. 42.1). In patients who are eligible for reperfusion therapy, the reperfusion strategy selected (i.e., either thrombolytic therapy or direct coronary angioplasty) is a major cost component. Although streptokinase is relatively inexpensive (at approximately $300 per dose), t-PA, recombinant tissue plasminogen activator (rt-PA), and TNK all cost more than $2,000 per dose, and the procedural costs of direct PTCA are even higher. A second component is the routine hospital stay that is required for the patient with an uncomplicated course. For acute MI patients in the United States, this typically includes 1 or 2 days in the intensive care unit and 3 or 4 days more in a step-down or regular hospital floor setting. For unstable angina, the course is typically shorter. The primary cost components for this type of care are the hospital room costs and the associated ancillary care costs (such as laboratory testing, medications administered, consultations obtained, radiology testing performed, and so on). A third major component is the risk stratification strategy selected. For many patients in the United States with acute coronary syndromes, diagnostic coronary angiography is the principal mode of risk stratification. Use of coronary revascularization techniques has been shown to track the use of coronary angiography with a fair degree of predictability (49). The need for revascularization is a major predictor of higher hospital costs (50). For some patients, one of several noninvasive testing strategies can be used. These may eventually lead to coronary angiography and revascularization or may permit the patient to be discharged without such testing being performed.

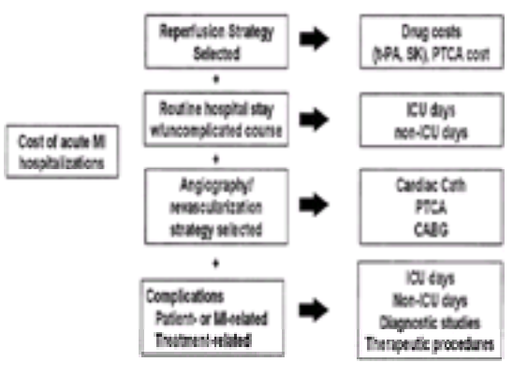


FIGURE 42.1 Cost components for an acute coronary syndrome hospitalization. CABG, coronary artery bypass graft surgery; ICU, intensive care unit; MI, myocardial infarction; PTCA, percutaneous transluminal coronary angioplasty; SK, streptokinase; t-PA, tissue plasminogen activator.

The last category of cost components for patients with acute coronary syndrome is complications. These are of several different types and have varying cost implications. The reperfusion strategy selected, for example, can induce a variety of complications, including minor bleeding (which may have no discernible cost effects) and major bleeding (which may induce a significant extra cost). Coronary angiography in the anticoagulated patient may lead to a major groin hematoma or other vascular complications, which in turn require additional days of care, testing, and consultation. Thrombolytic and anticoagulant drugs may induce gastrointestinal bleeding, sometimes because of previously undiagnosed gastrointestinal comorbidity. The acute coronary syndrome itself may produce complications (e.g., heart failure, arrhythmias, and recurrent ischemia). Costs related to complications can be substantial and are difficult to predict.

Thrombolytic Therapy

The benefits of thrombolytic therapy in acute MI are firmly established (51). Of the approximately 16 studies that have been published on the cost effectiveness of thrombolytic therapy, most are now of historical interest because of their age or because of changes in the standard of practice, or both (52). Four thrombolytic strategy comparisons are of current relevance: streptokinase versus no reperfusion therapy, t-PA versus streptokinase, t-PA versus rt-PA or TNK, and rt-PA versus rt-PA with abciximab. As of 2001, the U.S. market share for streptokinase was only approximately 4%, that for t-PA was approximately 44%, and rt-PA and TNK were equivalent at approximately 25% each. Outside of the United States, streptokinase remains the most widely used thrombolytic agent (53).

However, none of the large-scale randomized trials of streptokinase versus conservative (i.e., no reperfusion) therapy collected the empiric data on resource use or cost that are necessary to estimate the direct costs of these two strategies. Given inadequate data, we are forced to take a conservative position and assume that the improved medical outcomes (particularly survival) seen in the randomized trials of streptokinase are associated with an increased net cost relative to no reperfusion therapy, making it necessary to evaluate the drug’s cost effectiveness. One of the most useful studies in this area was conducted by Naylor et al. (54). They estimated that substitution of intravenous streptokinase for no reperfusion therapy had a cost-effectiveness ratio of approximately $2,000 to $4,000 per added life-year, assuming that each additional survivor due to streptokinase therapy had a life expectancy of approximately 10 years. These figures make streptokinase therapy an extremely economically attractive intervention, probably falling into the category of “best buy.”

Krumholz and colleagues (55) estimated the cost effectiveness of intravenous streptokinase in elderly patients (age 75 years or older). The effectiveness portion of

their analysis was based on the Gruppo Italiano Per lo Studio Della Streptokinase Nell'Infarto Miocardio (GISSI) and International Study of Infarct Survival-2 (ISIS-2) data, which indicated a 13% relative reduction in short-term mortality. The base case cost-effectiveness ratio for an 80-year-old with a projected (undiscounted) life expectancy of 2.7 years was $21,200 per added life-year (1990 dollars). For a 70-year-old with a projected life expectancy of 5.5 years, the cost-effectiveness ratio was $21,600 per added life-year.

GUSTO I clearly established that t-PA was superior to intravenous streptokinase in establishing Thrombolysis in Myocardial Infarction flow grade 3 (TIMI-3) coronary flow and in saving lives (56). Because the cost of t-PA is substantially higher than that of streptokinase, the question that directly emerged from the clinical results of GUSTO I was whether the added benefits of accelerated t-PA were sufficient to justify the added costs of this regimen. It is important to note that from a patient perspective (assuming that the patient does not bear the added cost of t-PA), the choice of thrombolytic regimen virtually always favors t-PA on medical grounds alone (i.e., additional survivors minus additional disabling strokes). On the other hand, from the fee-for-service hospital perspective, t-PA is usually a losing financial proposition, because the added costs of the therapy are often not reflected in the reimbursement received. The one added survivor per 100 generated by t-PA is a statistical survivor, and the individual patient who is actually "lost" when streptokinase is used in lieu of t-PA cannot be identified clinically and is therefore invisible to the hospital. Furthermore, most of the added life-years generated by t-PA, as is discussed below, occur after patients are discharged from the hospital.

In a detailed prospective economic analysis, the GUSTO I trial estimated that cumulative medical costs (hospital costs plus physician fees) at 1 year averaged $24,575 for streptokinase patients and $24,990 for t-PA patients exclusive of the costs of the thrombolytic agent (22). When the average wholesale drug costs for the two agents were added in, the incremental lifetime (undiscounted) costs for each patient who received t-PA was $2,845. Using the empiric 1-year GUSTO survival data, additional data from the Duke Cardiovascular Database, and statistical modeling, we projected a life expectancy for t-PA patients of 15.41 years versus 15.27 for the streptokinase patients, an undiscounted increase in life expectancy for t-PA of 0.14 years per patient. This result can be more intuitively restated as follows: The one extra patient per 100 saved with accelerated t-PA lives an average of 14 additional years.

With an increased life expectancy of 0.14 years of life per patient for t-PA patients and an increased cost of $2,845 per patient, the incremental cost-effectiveness ratio for t-PA (discounted at 5%) was $32,678 per year of life saved (22). Because the average thrombolytic drug cost to hospitals is lower than the average wholesale prices for the two drugs, we substituted a cost of $270 for the streptokinase and $2,216 for the 100 mg t-PA and repeated the calculations. These lower drug costs yielded a cost-effectiveness ratio of $27,115 per year of life saved (22).

The GUSTO III trial compared rt-PA with t-PA and found no difference in major cardiovascular events (including death, stroke, and bleeding) out to 1 year (57). The costs of these two agents are the same, and although the nursing time and ancillary costs associated with a double-bolus regimen are likely smaller than with a bolus and 90-minute infusion, inefficiencies in the care process would likely eliminate these small theoretical savings.

TNK-tPA was compared with rt-PA in 16,999 patients in the Assessment of the Safety and Efficacy of a New Thrombolytic Regimen (ASSENT) 2 Study (58). Mortality was identical in the two arms as was intracranial hemorrhage. Bleeding complications and need for blood transfusion were modestly reduced by TNK. The cost of TNK is the same as that of t-PA, and the single-bolus administration regimen is attractive to a busy emergency department, if not cost saving. A formal economic analysis of ASSENT 2 has not been performed.

The GUSTO V trial compared rt-PA with half-dose rt-PA plus full-dose abciximab in 16,588 patients (59). The combination regimen reduced nonfatal reinfarction but did not alter 30-day mortality. The rt-PA plus abciximab regimen also reduced urgent revascularization but increased bleeding, although strokes and intracranial hemorrhage rates were equivalent. A cost analysis of this trial is currently under way.

Primary Percutaneous Coronary Reperfusion

A quantitative overview of all the randomized trials conducted through 1996 showed that there was a strong possibility that direct angioplasty was superior to thrombolytic therapy in saving lives (60). Furthermore, comparison of hospital charges in the Primary Angioplasty in Myocardial Infarction I (PAMI I) study and estimated hospital costs in the Mayo Clinic Randomized Trial both suggested that direct angioplasty might also be a less expensive reperfusion strategy (61,62 and 63). However, of the ten trials included in the overview, nine were quite small. The largest, by far, was GUSTO II.

Although the small randomized trials had established that dedicated experienced operators could achieve excellent results with primary angioplasty, the GUSTO II study was meant to evaluate whether the technique was practically suited for larger-scale implementation in the cardiovascular community. GUSTO II compared accelerated t-PA and primary angioplasty. A total of 1,138 patients were enrolled (1994–1995) in the trial from 57 hospitals in nine countries (64). The 30-day results of this trial showed a statistically significant 33% reduction in the primary outcome event (the combination of death, nonfatal MI, and disabling stroke) for primary angioplasty. However, at the end of 6 months of follow-up, the 30-day benefit had attenuated by approximately 50%, and the intention-to-treat comparison was no longer statistically significant. The small differences observed in mortality and nonfatal MI, both favoring direct angioplasty, were not statistically significant. However, the study was not powered to detect such differences.

The principal resource use data from the U.S. portion of the trial showed the expected extra procedures in the direct angioplasty group (65). Importantly, the rate of diagnostic angiography was approximately 70% in the accelerated t-PA group. This is consistent with the rates observed in GUSTO I and reflects the predominant choice among U.S. GUSTO investigators in the use of angiography as a primary risk stratification tool after MI. At the end of the initial hospitalization, direct angioplasty showed a $900 cost advantage in the use of hospital resources, whereas accelerated t-PA had a $600 cost advantage in the use of physician resources, leaving a net cost advantage for direct angioplasty of approximately $300 ($p$ >.05) (65). At the end of the 6-month follow-up period, the net cost advantage of direct angioplasty had fallen to approximately $100.

One of the main limitations of the direct angioplasty reperfusion strategy is that only approximately 20% of U.S. hospitals have catheterization facilities, and many of these are not staffed 24 hours a day (66). Building new interventional catheterization laboratories, training new personnel to staff them, and providing 24-hour coverage would substantially increase the long-term per-case cost of the procedure over that calculated in the GUSTO II analysis (67).

The Myocardial Infarction Triage Intervention registry performed an observational comparison of 1,050 patients who received direct angioplasty with 2,095 patients who received thrombolytic therapy (65% t-PA, 32% streptokinase, 3% other) (68). This community-based study found no mortality benefit for angioplasty, but, in contrast to the GUSTO II economic analysis, it found that the thrombolytic group had 13% lower costs at 3 years.

More recently, the percutaneous approach to acute MI patients has been modified to include stenting and the use of glycoprotein (GP) IIb/IIIa inhibitors. Stenting versus PTCA has been compared in six randomized trials, five of which were quite small (see Chapter 18). The largest, STENT PAMI, randomized 900 patients to stent over balloon PTCA (69). Only approximately 5% of patients received a GP IIb/IIIa inhibitor. At 1 month, the stent group had a nonsignificant increase in mortality and a nonsignificant decrease in reinfarction. The major difference in outcome was a lower rate of target vessel repeat revascularization seen in the stent arm (10 per 100 fewer at 6 months). Cohen and colleagues (70) performed an economic analysis of STENT PAMI. The index hospital costs in the stent arm were approximately $2,000 higher, due primarily to the extra costs of the stents used. The decreased need for follow-up procedures saved approximately half that amount over the first year of follow-up. In addition, the avoidance of recurrent angina and repeat procedures was associated with a small utility benefit for the stent patients. Thus, with a net cost of approximately $1,000 per patient and a utility advantage of 0.02, the cost per QALY added with stenting was $65,000 using the technology available during the trial. With the current repertoire of longer stents that allow a reduction in the total number of stents placed, the equipment cost of the stent arm in STENT PAMI would have been lower and the cost per QALY would have been less than $30,000, using the assumptions of the investigators.

The benefits of adding abciximab to primary PTCA were evaluated in 483 MI patients enrolled in the ReoPro and Primary PTCA Organization and Randomized Trial (71). No significant benefit was seen for the addition of abciximab to PTCA on death or reinfarction out to 6 months. Urgent target vessel repeat revascularization was significantly reduced, but any target vessel revascularization was not. In addition, major bleeding and the need for transfusion were increased by abciximab.

The benefits of adding abciximab to primary stenting in acute MI were tested in the Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications (CADILLAC) trial. This trial enrolled 2,665 acute MI patients who were within 12 hours of symptom onset and who were deemed eligible for stenting. Randomization used a factorial design: balloon PTCA versus stent and abciximab versus no abciximab. In contrast to STENT PAMI, this trial showed a nonsignificant mortality benefit for stenting over PTCA. The addition of abciximab reduced ischemia and ischemia-driven target revascularization for stent and for PTCA patients. The Abciximab before Direct Angioplasty and Stenting in Myocardial Infarction Regarding Acute and Long-term Follow-up (ADMIRAL) trial randomized 300 acute MI patients who were undergoing acute coronary intervention with stenting to abciximab or placebo (72). At 30 days, the abciximab arm had a 49% lower mortality, a 49% lower incidence of reinfarction, and a 58% reduction in target vessel revascularization. Major bleeding was not increased by abciximab, although minor bleeding was. At 6 months, the abciximab arm had a 5.4% absolute decrease in the need for revascularization.

Neither CADILLAC nor ADMIRAL has yet reported economic data (73). Given that bolus plus 12-hour infusion therapy with abciximab adds approximately $1,400 to the cost of care, examination of resource use patterns and associated costs will be an important aspect of final interpretation of these data. At present, it appears that percutaneous revascularization is a clinically acceptable but less available and more expensive alternative to thrombolytic therapy.

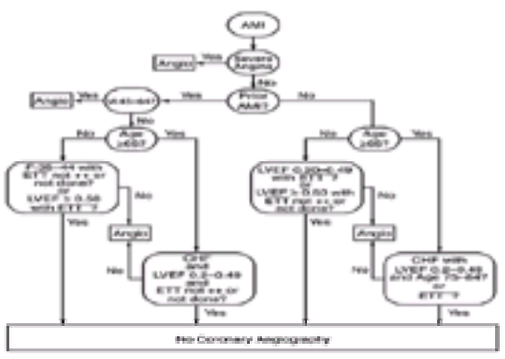
Coronary Angiography and Predischarge Risk Stratification

Several randomized trials have now compared different forms of invasive and conservative management strategies for patients with acute coronary syndromes. The TIMI IIIB trial compared these two strategies in 1,473 patients (74). Early invasive management involved routine angiography at 18 to 48 hours after presentation. Early conservative management used angiography only if certain high-risk indicators were present. At 6 weeks, the two strategies had identical rates of death and MI. Hospital stay was shortened for the invasive arm, and rehospitalization for recurrent unstable angina was also reduced in this arm. Veterans Affairs Non–Q-Wave Infarction Strategies in Hospital (VANQWISH), in contrast, found that early conservative management in 920 patients with non–Q-wave MI was associated with lower mortality at hospital discharge and at 12 months (75). In the conservative arm of TIMI IIIB and of VANQWISH, catheterization was used in approximately half of the assigned patients. In contrast, in Fragmin and Fast Revascularization during Instability in Coronary Artery Disease (FRISC) II, only 10% of patients from the conservative arm received catheterization (76). If such an extreme conservative strategy is the comparator, invasive therapy has clearly demonstrable benefits in patients with acute coronary syndrome. What is less clear is whether a policy that uses angiography approximately half the time is inferior to one that uses it almost all the time. The most recent clinical trial to address this issue is the TACTICS-TIMI 18 study (77). At 6 months, death was equivalent in the two arms and there was an approximately 2 per 100 reduction in the rate of MI in the invasive arm. A cost analysis of this trial found that the invasive arm was modestly more expensive during the index hospitalization ($14,660 vs. $12,667) but less expensive during the first 6 months of follow-up ($6,063 vs. $7,203) (78). Thus, cumulative costs at 6 months were equivalent.

Despite the absence of conclusive evidence from randomized trials favoring routine angiography in acute coronary syndromes, data from the GUSTO trials show that 70% to 80% of such patients in the United States routinely undergo coronary angiography before discharge (26,64). In 16 managed-care Kaiser hospitals, angiography rates between 1990 and 1992 were somewhat lower, ranging from 30% to 77% (79). Because coronary angiography is a diagnostic technology, it produces no direct health benefits (aside from the rare negative health benefit of a procedure-related complication). Consequently, to evaluate the cost effectiveness of this form of risk stratification relative to potential alternatives such as the use of various noninvasive tests or even clinical screening alone, a linkage must be made between the likely information provided by the tests and the subsequent management decisions by physicians that would ultimately be likely to yield improved survival or quality of life, or both. Given the difficulty in making such linkages and the lack of good empiric data with which to do so, it is not surprising that very few attempts have been made to produce a cost-effectiveness analysis of this problem.

Kuntz and colleagues (80) examined the cost effectiveness of routine coronary angiography in the convalescent phase of acute MI versus an exercise tolerance test and selective referral to angiography. Their decision model examined long-term costs and survival along with angina class and heart failure. Clinical data for the model came from pooled analyses of the literature. Where no adequate data were available, such as in estimating post-MI coronary artery bypass graft (CABG)–related survival, data were used from other patients with coronary artery disease (CAD), and the assumption was made that these results were pertinent to acute MI patients as well. Long-term survival after MI in patients who were given medical therapy was derived from the Coronary Heart Disease Policy Model, which uses data from U.S. life tables and various epidemiologic studies to simulate the long-term survival pattern of patients with coronary heart disease (CHD). Cost data were obtained from the Medicare files for 1987, with costs adjusted to 1994 dollars using the Consumer Price Index.

The base case analysis of this model showed that routine coronary angiography increased quality-adjusted life expectancy in all post-MI patient subgroups except women aged 35 to 44 years old with normal left ventricular function, no postinfarction angina, and a negative exercise treadmill test (80). When costs were considered, two factors were especially influential in creating favorable cost-effectiveness ratios for coronary angiography: inducible myocardial ischemia (either spontaneous or during a stress test) and a history of prior MI. When both these factors were present, the cost-effectiveness ratios ranged between $17,000 and $44,000 per QALY. In contrast, most patient subgroups with a negative exercise test had incremental cost-effectiveness ratios for coronary angiography in excess of $50,000 per QALY added. Some of the results of this model were counterintuitive. For example, favorable cost-effectiveness ratios were found for men aged 45 to 74 with a negative exercise treadmill test and an ejection fraction of 50% or greater but a history of prior MI. A summary flow diagram for the use of routine coronary angiography in post-MI patients based on a cost-effectiveness threshold of $50,000 per QALY added is shown in eFigure 42.1.1.



***e*FIGURE 42.1.1** Cost-effective use of diagnostic coronary angiography in acute myocardial infarction (AMI) survivors. CHF, congestive heart failure; ETT, exercise tolerance test; LVEF, left ventricular ejection fraction. (From Kuntz KM, Tsevat J, Goldman L, et al. Cost-effectiveness of routine coronary angiography after acute myocardial infarction. *Circulation* 1996;94:957–965, with permission.)

Antithrombin Therapy

Small randomized trials of heparin versus no heparin in patients with unstable angina or non–Q-wave MI have shown a reduction in short-term death and nonfatal MI. Consequently, heparin has been adopted as a standard of care for these patients in the early phase of their presentation (47).

Recent work has centered on identifying more potent antithrombin agents that would improve on the results obtained with heparin. The most promising new antithrombin at present is bivalirudin. Kong and colleagues (81) performed a metaanalysis of six trials that compared this agent with standard heparin therapy in elective percutaneous revascularization (4,603 patients) and in acute coronary syndrome (1,071 patients). Overall, at 30 days, bivalirudin reduced the risk of death or MI by 27% (p = .02). In addition, bivalirudin was associated with a 59% decrease in major bleeding. These data suggest at least equivalent effectiveness with heparin and better safety. Two ongoing large phase III trials are testing bivalirudin in percutaneous coronary revascularization and acute coronary syndromes, respectively. Both trials are including prospective economic analyses.

Several studies have been conducted using low-molecular-weight heparins in patients with acute coronary syndromes. The first such study, FRISC, reported a benefit for dalteparin but had some important design limitations that made it difficult to interpret the study for current cardiovascular practice. In the FRISC II trial, patients with acute coronary syndrome were randomized to dalteparin plus aspirin versus aspirin alone for approximately 1 month (82). At 6 days, the dalteparin arm had a significant reduction in death or MI, but these differences did not persist at the 6-month follow-up.

A second agent, enoxaparin, has been compared with unfractionated heparin in more than 7,000 patients in the Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events (ESSENCE) (3,171 patients) and TIMI IIB (3,910 patients) trials. Metaanalysis of these two trials showed a 23% reduction in death or MI at 8 days that persisted at 6 weeks (83). In the ESSENCE trial, these benefits lasted out to 1 year. The economic analysis of ESSENCE showed that the low-molecular-weight heparin strategy was associated with a drug cost of $155 per patient (2.5 days of therapy) in the United States. After taking this cost into account, the enoxaparin strategy was associated with a cost savings of $760 to $1,170 per patient shifted from standard unfractionated heparin therapy because of a reduction in use of invasive procedures and length of stay (84).

Antiplatelet Therapy

As reviewed elsewhere in this text, a number of new compounds have been developed that block the platelet GP IIb/IIIa receptor, thereby providing potent inhibition of platelet aggregation. Three compounds have been approved for clinical use in the United States: abciximab (in patients undergoing or planned for percutaneous revascularization), eptifibatide, and tirofiban. The GUSTO IV trial surprisingly failed to show a benefit of abciximab therapy in patients with non–ST-elevation acute coronary syndrome (85). Tirofiban has been tested in two trials, Platelet Receptor Inhibition in Ischemic Syndrome Management (PRISM) and Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM-PLUS).

The PRISM trial tested tirofiban without heparin and found a significant mortality reduction but no effect on MI or refractory ischemia at 30 days (86). However, the same tirofiban plus aspirin with no heparin regimen had the highest mortality in PRISM-PLUS, and this arm was stopped prematurely (87). Thus, many believe that the

mortality benefit in PRISM was not a real finding. With no mortality benefit and also no effect on MI, there is little effectiveness in PRISM to use as the basis for a cost-effectiveness analysis.

In PRISM-PLUS, investigators were “encouraged” to refer patients to coronary angiography between 48 and 96 hours after enrollment, and 90% of patients underwent catheterization. This protocol-guided care represented a substantial shift from usual practice for most of the participating sites and creates difficulties in assessing the economic impact of the tirofiban plus heparin regimen. To date, no formal cost-effectiveness analysis of the entire PRISM-PLUS trial has been performed. Based on the 1.8% absolute reduction in mortality and 2.9% absolute reduction in MI at 6 months for the tirofiban plus heparin arm and a mean infusion duration of 71 hours (total cost of tirofiban infusion is approximately $1,000 to $1,100), it is likely that a formal cost-effectiveness analysis would find this therapy to be economically attractive.

The Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT), with 10,948 patients, is the largest trial of an intravenous GP IIb/IIIa inhibitor in patients with non–ST-segment elevation acute coronary syndrome. At 30 days, the eptifibatide arm had a 1.5% absolute reduction in death or MI compared with placebo (p = .04) (88). A detailed prospective economic substudy in the 3,522 U.S. patients enrolled in PURSUIT showed two major findings (89). First, with a diagnostic catheterization rate of 85% as background, the addition of eptifibatide did not alter the use of invasive cardiac procedures or hospital length of stay. Second, with a cost for the eptifibatide regimen ranging from $1,217 (average wholesale price) to $1,014 (hospital discounted price) and an incremental increase in life expectancy of 0.11 years attributable to eptifibatide therapy in U.S. patients, the cost per year of life added was between $13,700 and $16,500. This fulfills criteria cited earlier for an economically attractive therapy.

Coronary Revascularization

In the United States, it is estimated that approximately 1.3 million diagnostic cardiac catheterizations, approximately 553,000 coronary artery bypass surgeries, and 926,000 percutaneous interventional procedures (on 528,000 patients) are performed annually (based on 1998 figures) (90). Thus, defining the clinical effectiveness, costs, and appropriate roles for these technologies has been a paramount research problem in clinical medicine over the last decade. Early outcomes research studies in cardiology found a surprising and substantial degree of variability in the use of these procedures in different geographic areas in the United States (91). More recent investigations have at least partially explained the sources of these variations. Two of the paramount determinants are the availability of cardiovascular specialists in the geographic area and the availability of angiographic and revascularization facilities (27,49). Strong correlations are also found between the use of noninvasive diagnostic testing and subsequent use of coronary angiography on the one hand and between the use of coronary angiography and subsequent revascularization procedures on the other (92). Early responses from health policy analysts to the observations about geographic variability in cardiac procedure use centered on the presumption that the high-use areas had a higher rate of inappropriate care (93). However, a number of studies using rigorous expert panel consensus guidelines for appropriate and necessary care have failed to confirm this supposition. In fact, the rate of unnecessary procedures in New York State is virtually equivalent to that in Ontario, Canada, a geographic area with approximately half the overall procedure rate of New York (94). Work by Hux and colleagues (95) in Canada has suggested that in areas of Ontario where the use of angiography and revascularization is higher, a greater proportion of patients who receive the procedures have small predicted marginal health benefits in terms of survival or angina relief. Thus, the debate about the appropriate use of invasive cardiac procedures is shifting from a focus on wasteful and unnecessary care to the balance between incremental benefits and incremental costs. However, although a number of studies have described the costs of different interventional strategies for coronary disease, very few have attempted to address their cost effectiveness. A comprehensive cost-effectiveness analysis in this area would, in fact, be quite difficult due to the complexity of the underlying clinical decisions, the difficulty in obtaining adequate outcome data, and the rapidly evolving technologies that comprise the set of currently used invasive cardiac procedures. Wong and colleagues (96) made the most recent attempt, in 1990, but their model does not include more recent data or changes in current evidence or practice patterns.

Percutaneous Coronary Revascularization

In the Evaluation of PTCA to Improve Long-Term Outcome by c7E3 GPIIb/IIIa Receptor Blockade (EPILOG) multicenter randomized trial, which involved 2,792 patients undergoing nonemergent balloon PTCA in 1995 and 1996, mean length of stay was 3.3 days; mean hospital costs were $7,600 with physician fees (from the Medicare Fee Schedule) of $1,400, yielding a total initial medical cost of $9,000 (97). Costs for follow-up hospitalizations and procedures to 6 months were $3,400, so that cumulative 6-month medical costs totaled $12,400. As noted earlier, PTCA costs can be systematically examined by separating them into four categories (Table 42.1). Patient characteristics can alter the costs of coronary angioplasty through their effects on the complexity of the procedure, the likelihood of success, and the rate of complications, early (e.g., abrupt closure) and late (e.g., restenosis). Patients with American College of Cardiology/American Heart Association type B2 or C lesions, for example, tend to have higher procedure-related costs because the procedure is less often successful, and, even when it is initially successful, the results are less often durable (98). In the Duke database, costs for angioplasty were lowest for one-vessel disease, intermediate for two-vessel disease, and highest for three-vessel disease (99). The Bypass Angioplasty Revascularization Investigation (BARI) study confirmed these findings and also reported that costs associated with an angioplasty strategy in diabetic patients were substantially higher than those for nondiabetics ($9,500 more for diabetics with 2-vessel disease vs. nondiabetics, more than $40,000 more for 3-vessel disease after 5 years of follow-up) (100). In a consecutive series of 1,258 patients who underwent percutaneous revascularization at The Cleveland Clinic between November 1992 and June 1993, the strongest clinical predictors of increased cost were admission for acute MI (91% increase), recent MI (17% increase), more complex lesion morphology based on the American College of Cardiology/American Heart Association classification (³12% increase), diabetes (12% increase), and the number of diseased vessels (9% increase per vessel) (101).

In a private insurance claims database, Topol and coworkers (102) found that hospital charges for PTCA were higher in older patients, in women, and in individuals with a history of prior MI. In summary, the most consistent patient-related predictors of higher initial hospital costs for percutaneous coronary intervention (PCI) are acuity of presentation, complexity of treated lesions, presence of diabetes, more extensive coronary disease, and older age. Some of these predictors, in turn (e.g., age, diabetes), may be surrogates for unmeasured aspects of disease severity or lesion complexity.

Treatment-related factors can also have a large effect on PCI costs. Ellis and colleagues (101) found that decision delay (delay between admission and diagnostic angiography or between diagnostic angiography and revascularization) was associated with an 86% increase in hospital costs and that weekend delay (postponed procedure due to a weekend) was related to a 61% increase. In a separate analysis, combined angiography and PTCA increased hospital costs by $850 versus separate procedures (98). Reeder and coworkers at the Mayo Clinic found that failed PTCA more than doubled hospital charges (due primarily to referral for CABG) relative to initially successful procedures (103,104). Use of adjunctive procedures and pharmacologic agents has a substantial influence on the cost picture of PTCA. In The Cleveland Clinic study, urgent CABG increased costs 83% and intraaortic balloon pump use increased costs by 42% (101). Costs were also increased with the use of transluminal extraction catheter atherectomy (40% increase), Rotablator (25% increase), stents (25% increase), perfusion balloons (12% increase), directional coronary angioplasty (10% increase), and laser (7% increase). In the EPILOG randomized trial, use of abciximab (with low-dose heparin) increased index hospital costs by a net of approximately $600 (97). Average cost for the drug itself was approximately $1,450 per patient, and reduced complications offset some, but not all, of that initial cost. In the Evaluation of Platelet IIb/IIIa Inhibitor for Stenting Trial (EPISTENT), the cost of stenting added approximately $2,200 to the hospital costs (not counting professional fees), and stenting with abciximab added $3,600 (105). Thus, the main procedural determinants of PCI costs are related primarily to extra therapies that are used to prevent or treat complications.

With regard to provider-related factors, care at a teaching hospital was associated with lower charges for PCI in one study (102). The physician who performed the procedure was a major cost driver in 250 consecutive patients treated at the University of California at San Francisco, with a $4,400 cost increase from lowest-cost to highest-cost physician (98). This difference appeared to reflect a behavioral pattern by the more expensive operators of using more catheterization laboratory resources. No differences were found with lower-cost operators in patient characteristics, lesion characteristics, success rate, or complications. Shook and colleagues (106) found that high-volume operators (³50 cases/year) averaged slightly lower hospital costs compared with low-volume operators ($7,977 vs. $8,278, p = .07) despite greater complexity and risk of procedures done by the high-volume operators. Geographic factors have also been identified as an important source of cost variability, with the western region of the United States having the highest charges and the Midwest having the lowest for balloon PTCA (102).

Coronary Artery Bypass Graft Surgery

The costs of CABG surgery have been studied for approximately two decades. During this time, the technical aspects of the procedure as well the postprocedure care and the long-term outcomes have changed substantially. Therefore, only the more recent literature is of relevance to current practice. The most recent national cost figures for bypass surgery come from an analysis by Cowper and coworkers (107) at Duke Medical Center of the 1990 Medicare database. At that time, the average hospital costs for an admission for bypass surgery were $23,000. With an additional $10,000 in physician fees (i.e., charges), the total cost of an isolated bypass surgery was approximately $30,000. In 2001 figures, this equates to a cost of approximately $41,000. The distribution of costs for the initial hospitalization included 37% for intensive care unit and regular care rooms, 21% for operating room, and 42% for laboratory/supply/pharmacy and other departments.

A number of studies have evaluated the determinants of the cost of CABG. Patient characteristics typically account for no more than 25% of the total variance in hospital costs for this procedure. In an analysis of 604 patients treated at Duke, factors identified as predictive of higher costs included older age (p <.0001), female gender (p <.005), black race (p <.19), lower ejection fraction (p <.0001), prior bypass surgery (p <.0001), more extensive coronary disease (p <.01), prior CABG (p <.0001), and diabetes (p <.03) (108). In 807 patients treated at Emory University, patient predictors of higher cost included higher angina class (p = .02), previous MI (p = .03), older age (p = .0001), heart failure (p = .001), and a higher number of diseased vessels (p = .0001) (109). Diabetes was a marginally significant predictor of higher costs (p = .07). However, in the BARI study, diabetic patients who underwent CABG had 5-year costs that were $15,000 higher than those of their nondiabetic

counterparts (100). In contrast, there was no difference in cost between patients with two- and three-vessel disease who were undergoing CABG in BARI.

Two procedural factors have been associated with higher CABG costs: need for additional invasive procedures, such as valvular surgery or coronary angiography, and use of internal mammary artery grafts (107). Perioperative complications are a major source of increased hospital costs for CABG. Complications identified as important cost drivers in the Emory study included adult respiratory distress syndrome, pneumonia, septicemia, major arrhythmias, neurologic events, and bleeding that required reexploration (109). Patients with no complications had a mean hospital cost of $16,776 (1990 dollars). Patients with one of the above complications had hospital costs of $17,794, patients with three complications had costs of $23,624, and patients with five complications had costs of $50,609.

Analysis of the national Medicare data has indicated that hospital-level provider-related factors account for approximately 17% of the total variation in bypass surgery costs, independent of patient-level factors (107). Analysis of determinants of CABG costs at Duke Medical Center showed that the attending surgeon was the single most important determinant of cost (108). Median hospital cost for the most expensive surgeon was $15,000, whereas the corresponding figure for the least expensive surgeon was $10,800.

As with coronary angioplasty, the costs for coronary bypass surgery are a moving target. Nationally, length of stay for this procedure has decreased substantially over the last decade, in part because of the pressures of managed care. Progress with minimally invasive coronary artery bypass surgery (MICAB) has raised the possibility of further reductions in cost (110). Investigators from Johns Hopkins University reported length-of-stay and cost figures for MICAB that are comparable to those of percutaneous interventional procedures ($7,803 for PTCA, $13,415 for stent, $11,623 for MICAB) (111). However, the technology is still in its developmental phase, and its true role in the panoply of revascularization options will likely not be defined for at least several more years.

Two trials have compared medical therapy with percutaneous revascularization. The Angioplasty Compared to Medical Therapy (ACME) trial found a very modest improvement among 212 patients with single-vessel disease in exercise treadmill time and physical functioning in the PTCA arm (112). A preliminary economic analysis of ACME was conducted but has not yet been published. The second Randomized Intervention Treatment of Angina (RITA-2) trial found that PTCA improved angina and exercise test performance but had a slight excess of procedure-related MIs. Quality of life was significantly better for the PTCA arm at 1 year, but these benefits attenuated by 3 years (113). At least part of this attenuation appears due to late revascularization procedures in the medical arm. An economic analysis of RITA-2 has not yet been published.

The Asymptomatic Ischemia Pilot randomized 558 patients with clinically stable coronary disease and documented ischemia to one of three treatment strategies: angina-guided medical care, ischemia-guided medical care, and revascularization. The ischemia-guided therapy was adjusted on the basis of repeated ambulatory monitoring studies. The principal medical regimens used in this pilot study were either atenolol-nifedipine or diltiazem-isosorbide. Patients who were randomized to revascularization received either PTCA or CABG at the discretion of the principal investigator. Although an economic analysis was not initially planned for this study, we performed a *post hoc* analysis using the available resource use data along with cost estimates taken from the GUSTO I analysis (114). At the end of 3 months, the average costs for the revascularization patients were $13,400, compared with $1,500 for the angina-guided patients and $900 for the ischemia-guided patients. However, between 3 months and 2 years, the costs for the medical arms significantly exceeded those for the revascularization arm, primarily because of an increased need for revascularization procedures and rehospitalizations. At the end of 2 years, the cumulative costs for the angina-guided strategy were $7,735, those for the ischemia-guided strategy were $8,575, and those for the revascularization strategy were $16,782. No empiric data were collected past 2 years in the Asymptomatic Ischemia Pilot. However, taking the second-year costs as the best estimate of annual costs for each treatment arm, a simple linear extrapolation (discounting future costs at a 3% rate) suggested that at 10 years the medical arms would have cumulative costs of approximately $23,500 and the revascularization arm would average $25,300. However, good empiric data on resource use patterns after 5 years in a modern cohort of CAD patients does not exist.

Two randomized trials have compared the costs of coronary angioplasty and coronary bypass surgery in patients with multivessel coronary disease in the United States. The clinical outcomes from these trials are reviewed in Chapter 16. The Emory Angioplasty Surgery Trial (EAST) enrolled 392 patients between 1987 and 1990 (115). Patients were followed every 6 months for 3 years. Hospital costs were estimated from hospital bills, with charges converted to costs using department-level cost-charge ratios (116). Physician fees for care at Emory were obtained from physician bills (i.e., charges). Hospital cost data were not collected for outside (i.e., non-Emory) hospitalization. Instead, Emory costs were applied to the follow-up hospitalizations reported on follow-up contacts. Costs were all deflated to 1987 dollars. For the initial hospitalization, hospital costs were $11,684 (median, $10,290) for PTCA and $14,579 (median, $13,991) for CABG ($p$ <.0001) (116). With physician fees added in, total initial costs were $16,223 for PTCA and $24,005 for CABG ($p$ <.0001) (Fig. 42.2). At the end of 3 years, cumulative costs for the PTCA arm were $23,734 versus $25,310 for CABG ($p$ <.0001) (Fig. 42.3). Thus, PTCA costs initially constituted 68% of CABG costs but after 3 years had risen to 94% of these costs (116). In multiple regression analysis, the major correlates of initial medical costs were randomization to CABG, heart failure, and male gender (Table 42.2). Regression analysis of 3-year costs identified ejection fraction, hypertension, and male gender as the major cost correlates. Assignment to CABG was no longer an independent predictor. Between 3 and 8 years, the CABG patients had $2,700 of extra medical costs versus $4,700 for the PTCA arm. With 8 years of follow-up, total costs were $46,348 for the CABG arm and $44,491 for the PTCA arm (p = .37) (117).

TABLE 42.2 MAJOR COST CORRELATES IN EMORY ANGIOPLASTY SURGERY TRIAL

BARI enrolled 1,829 patients with multivessel CAD between 1988 and 1991 in 18 centers (118). The BARI Substudy of Economics and Quality of Life was conducted in 7 of the 18 enrolling sites and collected cost data on 934 of the 1,829 total patients randomized in the trial (100). Detailed cost data were collected on all hospitalizations (regardless of diagnosis) as well as outpatient visits to ten different types of health care providers and outpatient cardiac tests and procedures. Medication use was also collected in this trial. Initial length of stay was 9 days for the PTCA arm and 13.3 days for the CABG arm. Hospital costs were $14,415 versus $21,534, and physician fees were $6,698 versus $10,813 (100) (Fig. 42.4). In follow-up, PTCA patients averaged 3.1 readmissions versus 2.7 for CABG patients. Total inpatient follow-up costs (hospital plus physician) were $27,439 for PTCA and $19,529 for CABG. Number of outpatient visits was equivalent for the two therapies, as were outpatient costs ($1,656 vs. $1,617). The PTCA patients took an average of 4.1 cardiac medicines at a cumulative 5-year cost of $4,948. The CABG patients averaged 4.0 cardiac medicines at a cost of $3,670. Outpatient diagnostic testing was equivalent in the two treatments, but CABG patients had a slightly higher rate of nursing home admission (3.2% vs. 2.6%) with higher associated costs ($1,027 vs. $265). After 5 years of follow-up, total discounted costs in the CABG arm were 5% greater than those for PTCA ($58,889 vs. $56,225) (Fig. 42.4). In subgroup analyses, patients with two-vessel disease had significantly lower costs with angioplasty ($52,390 vs. $58,498 for CABG), whereas angioplasty costs were actually higher than those of bypass surgery in patients with three-vessel disease ($60,918 vs. $59,430).

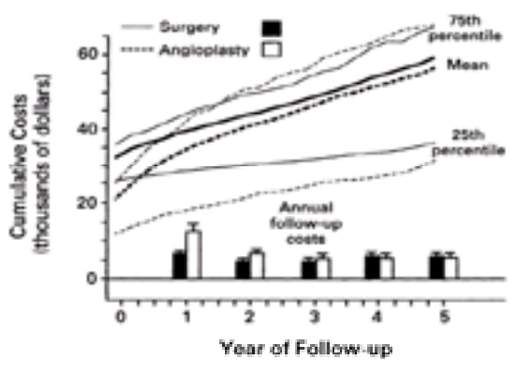

FIGURE 42.4 Cumulative cost at quarterly intervals for patients in Bypass Angioplasty Revascularization Investigation Substudy of Economics and Quality of Life. The thick lines indicate mean cumulative costs. The lighter lines represent twenty-fifth and seventy-fifth percentiles of the cumulative costs. The bars at the bottom show the mean (±2 standard error) follow-up costs accrued over the prior year. (From Hlatky MA, Rogers WJ, Johnstone I, et al. Medical care costs and quality of life after randomization to coronary angioplasty or coronary bypass surgery. *N Engl J Med* 1997;336:92–99, with permission.)

Cost analysis of the British Randomized Intervention Treatment of Angina trial of 1,011 patients confirmed the findings of EAST and BARI (119). The initial costs (estimated in British pounds) of treating with PTCA were approximately 52% those of CABG, but at the end of 2 years PTCA costs were 80% those of CABG. Follow-up in this trial out to 10 years is planned.

Coronary Stents

Coronary artery stents have undergone an exponential increase in usage since 1994. Data from 18 high-volume interventional programs participating in the National Cardiovascular Network showed that 6% of interventional cases at these institutions involved stents in 1994; by 1996, that proportion had risen to 39%, and current usage averages more than 70% (120).

To date, five randomized trials have compared a strategy of primary stenting versus conventional balloon PTCA (with stent backup if necessary) in stable patients with lesions of 20 mm or less in large target vessels (³3.0 mm): the Stent Restenosis Study I (STRESS I), Belgian Netherlands Stent Study (BENESTENT) I, BENESTENT II, the Optimum Percutaneous Transluminal Coronary Angioplasty Compared with Routine Stent Strategy (OPUS) trial, and the Doppler Endpoint Stenting International Investigation (121,122,123,124 and 125). The clinical data from these trials are reviewed in Chapter 80. Most important, these trials did not show any significant differences between initial stent and initial PTCA strategies in mortality, nonfatal MI, stroke, or anginal symptoms. The principal benefit of stenting that emerged from these trials was a reduction in repeat revascularization rates. In BENESTENT II, which used a heparin-coated Palmaz-Schatz stent and a ticlopidine-aspirin antithrombotic regimen in lieu of the earlier aspirin-warfarin regimen, 14% of PTCA patients and 9% of stent patients required a repeat revascularization procedure out to 6 months (125). These results are important not only because of the substantial reduction in clinical restenoses achieved in the stent arm but also because of the very substantial improvement in outcomes reflected in the PTCA arm statistics relative to earlier trial results.

Sukin and coworkers (126) compared 1995 practice in 78 patients who underwent coronary stenting at the Beth Israel Hospital with earlier data from the STRESS I trial (1991–1993). The major temporal trends observed in the use of coronary stenting included use of more stents and more adjunctive balloons per patient to achieve “optimal stent deployment.” The associated catheterization laboratory costs rose from $3,012 in STRESS I to $5,209, a $2,197 increase. Stenting of large lesions or multiple lesions increased catheterization laboratory costs by an additional $2,000 relative to single-lesion stenting.

Peterson and colleagues (127) compared hospital costs of stenting with those of balloon PTCA at Duke Hospital from 1995 to 1996 (Table 42.3). Compared with PTCA, stenting costs were $3,600 more per case in catheterization laboratory resources and $3,300 higher in total hospital costs (127). Over the next 6 months, however, stent patients were rehospitalized less often (22% vs. 34%) and had less frequent need for repeat revascularization (9% vs. 26%). Thus, at 6 months, the costs for the two strategies were equal ($19,600 vs. $19,800), and this economic parity was maintained out to 1 year.

Cost category	Stent, 5/95–6/96 (n = 384)	PTCA, 5/95–6/96 (n = 159)	p Value
Catheter laboratory			
Balloons	$1,759	$1,479	<.001
Stents	$3,629	$199	<.001
Abciximab	$661	$817	.15
Guide catheter/wire	$481	$490	.54
Dye	$516	$504	.34
Other costs	$2,694	$2,765	.82
Total	$8,780	$6,224	<.001
Rooms			
Routine	$1,309	$1,479	.88
Step-down/intensive care unit	$1,368	$1,402	.79
Pharmacy	$302	$289	.89
Laboratory	$285	$345	.31
Emergency room	$287	$756	.35
Catheter laboratory	$8,780	$6,224	<.001
Other	$871	$1,100	.30
In-hospital costs	$14,802	$11,534	<.001
Professional fee	$1,863	$1,816	<.001
Total in-hospital costs	$16,665	$13,350	<.001

TABLE 42.3 COMPARISON OF STENT AND PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY (PTCA) COSTS AT DUKE HOSPITAL

The OPUS-1 trial tested whether routine coronary stenting was superior to optimum PTCA with provisional stenting in 479 patients with one-vessel disease (123). In the routine stenting arm, patients averaged 1.2 stents, whereas in the optimum PTCA arm they averaged 0.5 stents, and 37% of patients in this arm required stent implantation. Use of abciximab was low in both arms (13% to 14%). Index hospital length of stay was similar in the two arms (2.5 to 2.6 days). The procedural costs were higher for routine stenting ($5,455 vs. $4,219, p <.001), and total initial hospital costs were correspondingly higher for the stent arm: $9,234 versus $8,434 ($p$ <.001). Follow-up cardiac events out to 6 months were higher in the PTCA arm (123). In particular, target vessel repeat revascularization occurred in 10% for the PTCA arm versus 3% for stenting and any repeat revascularization procedure in 15% of the PTCA arm versus 5% of the stent arm. Hospital readmissions were twice as frequent for PTCA-arm patients. These follow-up costs offset the extra initial costs of routine stenting so that at 6 months, the stent group had slightly lower cumulative costs ($10,206 vs. $10,490 for PTCA). A bootstrap simulation yielded a net 6-month cost savings for routine stenting in 69% of 1,000 replications, with a mean savings of $268.

Comparisons of PTCA with stenting must also be interpreted in the larger context of a comparison of percutaneous revascularization (including stenting and PTCA) versus CABG and medicine. Several trials have compared a percutaneous revascularization strategy with routine stenting to CABG. The Arterial Revascularization Therapies Study randomized 1,205 patients with multivessel CAD to stent versus CABG (128). At 1 year, there was no significant difference in mortality, stroke, or MI. Repeat revascularization occurred in 16.8% of stent patients versus 3.5% of CABG patients. Initial procedural costs (based on European practices and prices and converted to U.S. dollars) were lower in the stent arm ($6,400 vs. $10,700). At 1 year, these differences had narrowed somewhat because of the extra repeat procedures in the stent arm: $10,700 for the stent arm versus $13,600 for the CABG arm (p <.001). The relevance of these cost data for U.S. practice is uncertain given the unexpectedly low cost estimates for CABG. The Canadian/European Surgery or Stent study has been reported in abstract form, and an economic analysis of this trial is anticipated. The ongoing Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial is comparing optimal medical therapy with a strategy of PCI, and an economic analysis of this trial is planned.

Heart Failure

Approximately 4.7 million Americans carry a diagnosis of heart failure, and more than 550,000 new cases are identified each year (90). Approximately 70% of cases are due to coronary disease, with hypertension the next most common underlying disorder (129). The annual hospitalization volume for heart failure now approaches 1 million (1998 figure), with an associated annual cost in excess of $3.7 billion. The prevalence of heart failure rises with increasing age, and it is the single most frequent cause of hospitalization in the Medicare population (age ³65) (90). After a first admission for heart failure, Medicare patients have a 44% chance of being readmitted at least once within 6 months (130).

Costs of Medical Care of Heart Failure

To analyze the costs of heart failure and their determinants, it is useful to look at three cost components (Fig. 42.5): maintenance care, care for episodes of decompensation, and procedures to reverse the heart failure state. Maintenance care includes the use of medications and routine medical follow-up for the patient with a stable, well-compensated course. The goals of maintenance therapy are to reduce symptoms and improve functional status to the extent possible, to improve survival, and to decrease the need for repeat hospitalizations. Periodically, patients with heart failure enter a state of decompensation; this may occur gradually as a result of progressive myocardial dysfunction or more abruptly (e.g., because of complicating arrhythmias, excess intake of dietary sodium, infection, or inappropriate cessation or reduction of medical therapy). The three most common causes of need for hospitalization in patients with congestive heart failure (CHF) are uncontrolled ischemia, uncontrolled atrial fibrillation, and increasing pulmonary or peripheral edema. Although not all hospitalizations for CHF can be eliminated without reversing the underlying heart failure state, some interventions have been proven to reduce the need for such admissions. Whether the efficiency of admissions for heart failure can also be improved (with a consequent reduction in costs) remains largely undefined. Finally, there are a growing number of nonpharmacologic interventions whose goal is to stabilize or even reverse the heart failure state. These include cardiac transplantation, use of various mechanical assistive devices, and CABG (with or without left ventricular reconstruction).

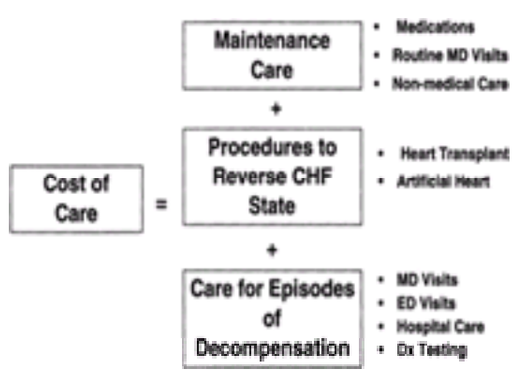

FIGURE 42.5 Cost components for heart failure care. CHF, congestive heart failure; Dx, diagnosis; ED, emergency department; MD, doctor of medicine.

The costs of care for a typical group of patients with heart failure consist of a mix of costs due to maintenance care and costs for treatment of decompensation. Only very small numbers of patients (2,360 in 2000) undergo cardiac transplantation (90). No “natural history” cost studies of heart failure have been done, and therefore it is difficult to define the cost of the disorder independently of the interventions used to treat it. Overall annual costs for patients with advanced heart failure, including inpatient and outpatient care and outpatient medications (including ACE inhibitor therapy), averaged $22,500 in the Fosinopril Efficacy/Safety Trial (FIRST) study and $21,100 in the Washington University trial (131,132). Patients with New York Heart Association (NYHA) class IV had higher costs than those with class III; costs were also increased for patients with renal insufficiency and with diabetes (131).

Digoxin

Digoxin is one of the oldest pharmacologic interventions in cardiovascular medicine, but its clinical effectiveness remains controversial. The National Institutes of Health DIG trial found no survival benefit for digoxin but a significant 6% reduction in the need for hospitalization (133). Using DRG-based Medicare reimbursement rates, Eisenstein and colleagues (133) performed a cost analysis of the DIG trial. Digoxin patients averaged fewer all-cause (1.9 vs. 2.0, p = .01) and heart-failure (0.6 vs. 0.8, p = .001) hospitalizations. Digoxin patients had higher total medical costs ($12,648 vs. $12,362, p = .001). Heart-failure costs were lower ($3,122 vs. $4,130, p = .001), but non–heart-failure costs were higher. PTCAs were more frequent in the digoxin arm, suggesting that these patients improved enough clinically to be treated more aggressively for their CAD. The average cost of the digoxin therapy over a mean of 37 months was $163. A cost-effectiveness analysis of this trial is planned.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitor therapy is recognized as one of the foundations of modern medical therapy for heart failure (134). A number of large-scale clinical trials have clearly demonstrated that ACE inhibitors prolong survival in patients with heart failure due to systolic dysfunction. However, none of these trials included prospective measurement of costs. Two U.S. studies have used decision analysis models to estimate the cost effectiveness of this form of therapy (135,136).

Glick and colleagues (135) used primary data to form the Studies of Left Ventricular Dysfunction (SOLVD) treatment trial (mild to moderate heart failure and ejection fraction <35%) to model the cost effectiveness of enalapril therapy. The model evaluated 48-month outcomes (from the available empiric data) and projected lifetime outcomes. Analysis was done from a societal perspective, and costs were expressed in 1992 U.S. dollars. On the health-benefit side, this study estimated that patients who were randomized to enalapril gained 0.14 discounted years of life and 0.11 discounted quality-adjusted years of life during the 4-year follow-up of the trial. The life expectancy of these patients was estimated at 6.5 to 7.0 years, and over this period enalapril was projected to add 0.30 discounted years and 0.21 discounted QALYs.

On the cost side, enalapril patients averaged $11,840 in discounted costs of hospitalization, enalapril therapy, and outpatient visits during the 4 years of the study. The corresponding cost for the placebo patients was $12,560. Thus, during the trial period, enalapril saved $720 per patient (135). Importantly, these savings occurred during the first 18 months of the trial, and costs after this point were similar. Over the projected life expectancy of the study cohort, enalapril patients had discounted costs of $22,000 and placebo patients had costs of $21,975. The lifetime incremental cost of enalapril therapy was therefore projected to be $25 per patient.

During the 4 years of the trial, enalapril improved survival and reduced medical costs. Projecting these data out to a lifetime cost-effectiveness perspective, enalapril saved an added life-year for $80 and an added QALY for $115 (135). These data demonstrate that, at a minimum, ACE inhibitor therapy with enalapril in mild to

moderate CHF is in the “best buy” category of cost effectiveness. For several reasons, it is likely that in this population ACE inhibitor therapy is actually cost saving over the patient’s lifetime. First, sensitivity analysis on the long-term effects of enalapril shows that if the drug continued to reduce hospitalizations after 18 months it would be cost saving (135). Second, the average wholesale price for a year’s supply of enalapril, 20 mg per day, is $475. The advent of generic captopril makes an ACE inhibitor available for a substantially lower cost and would, therefore, make the therapy cost saving over a lifetime. Finally, the cost assigned to follow-up hospitalizations was based on HCFA DRG reimbursement rates and may have, therefore, underestimated the fair cost of such an event (and, hence, the value of preventing it).

Paul and colleagues (136) created a decision model of ACE inhibitor therapy using published data from SOLVD treatment and Veterans Administration Heart Failure Trials I and II. Because they did not have access to primary patient-level data, they were not able to evaluate the cost-saving potential of enalapril. This analysis assigned a cost of $6,750 (1992 U.S. dollars) to each heart failure hospitalization and a cost of $959 for a year of 20 mg per day enalapril therapy (based on a telephone survey of ten retail pharmacies in Boston). In this analysis, enalapril was projected to increase life expectancy from 4.36 years to 4.65 years at an incremental cost of $2,569. The cost-effectiveness ratio for enalapril was $9,700 per life-year. Although less favorable than the SOLVD analysis, this study confirms that ACE inhibitor therapy is economically in the “best buy” category of therapies. Several economic analyses of ACE inhibitor therapy for heart failure have been conducted in Europe (137). Using data from the Munich Mild Heart Failure Trial, Kleber (138) found that ACE inhibitor therapy recouped approximately 75% of the cost of medication by reducing the need for hospitalization in patients with progressive heart failure. The Institute for Medical Technology Assessment in the Netherlands found that survival was increased and costs were decreased by first-line ACE inhibitor use in heart failure (139). A third model was based on published SOLVD treatment trial outcomes and U.K. costs (140). This model evaluated the importance of different modes of initiation of ACE inhibitors (hospitalization for various durations vs. outpatient initiation). Hospital initiation (3-day hospital stay) was cost effective, and outpatient initiation made the therapy cost saving overall.

Beta-Blocking Agents

Two important randomized trials reported that beta-blocker therapy in heart failure produces a clinically important and statistically significant reduction in mortality and hospitalization. The Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) randomized 3,991 patients with class II or greater heart failure and an ejection fraction of 0.40 or less to metoprolol CR/XL or placebo (141). With an average follow-up of 1 year, metoprolol reduced death or heart transplantation by 32%. All-cause hospitalization was reduced from 33% to 29% (p = .004), and days in hospital were reduced from 6.1 to 5.1 per patient (p = .004). The discounted retail cost of metoprolol XL/CR therapy ranges from $20 per month for the 50-mg dosage ($240 per year) to $54 per month for the 200-mg dosage ($650 per year). Although a formal cost analysis of MERIT-HF has not yet been reported, the cost of metoprolol therapy should be largely offset by the approximate 1-day average reduction in hospital stay.

The Cardiac Insufficiency Bisoprolol Study II (CIBIS II) enrolled 2,647 patients with heart failure in class III or IV with an ejection fraction of 35% or less (142). All-cause mortality was reduced 34% by bisoprolol (p <.001). All-cause hospitalization was reduced 20% from 34% to 33% (p <.001). An economic analysis of CIBIS II is planned. In contrast, the Beta-Blocker Evaluation of Survival Trial randomized 2,708 class III or IV heart failure patients to bucindolol or placebo (143). At an average of 2 years, there was no significant effect on mortality overall, although nonblack patients had a survival advantage. Hospitalization was reduced by 8% in the bucindolol group (p = .08).

Economic analysis of the smaller U.S. Carvedilol Heart Failure Trials Program was performed using a Markov decision model, clinical data from the trials, and published cost data (144). Trial data were projected out to a lifetime perspective. Projected lifetime costs of conventional CHF care in this model were $28,750. Costs for the carvedilol strategy were $36,420, or $7,600 more than conventional therapy. Carvedilol was projected to extend life expectancy by 0.31 to 0.95 years per patient over the life expectancy without such therapy (6.7 years). This range reflects different assumptions about the persistence of therapeutic benefit. The corresponding cost effectiveness of carvedilol therapy ranged from $30,000 per life-year added to $13,000 per life-year added. Current (2001) discounted retail price for carvedilol is approximately $90 per month, or $1,080 per year.

Other Pharmacologic Agents

The evidence base for the survival benefits of hydralazine and isosorbide in combination is substantially less than for ACE inhibitor therapy (134). Based on the published results of Veterans Administration Heart Failure Trial I, Paul and colleagues (136) estimated an incremental cost-effectiveness ratio for this regimen of $5,600 per added life-year.

Surgical Approaches to Heart Failure

Invasive approaches that have been used to reduce or reverse the heart failure state include CABG (with or without ventricular reconstruction), heart transplantation, and left ventricular assist devices (LVADs).

For patients with ischemic cardiomyopathy, CABG has offered a theoretically attractive but controversial approach. Although registry data suggest a more favorable survival with CABG than with medical therapy, no randomized trial has validated these observations (145). Randomized trial and registry data from the 1970s comparing CABG and medicine demonstrated a magnification in absolute terms of the survival benefits of surgery in patients with impaired left ventricular function (146). Whether these observations extend to patients with advanced heart failure (NYHA class III) and a severely impaired left ventricle (ejection fraction <35%) remains uncertain. In recent years, clinicians at some centers have begun using “viability” radiologic studies such as positron emission tomography or perfusion imaging to identify the subset with substantial ischemic viable myocardium who are presumed most likely to benefit from a high-risk CABG. The Surgical Treatment for Ischemic Heart Failure (STICH) trial will be the first large-scale randomized trial of modern surgical versus optimal modern medical therapy in these difficult patients and will include an economic evaluation as well as substudies to define whether preoperative viability screening is of benefit (145).

Heart transplantation offers a radical but effective therapy for a small subset of patients with advanced heart failure. Although it has been estimated that there are more than 40,000 patients a year with advanced heart failure who could benefit from cardiac replacement therapy, only approximately 2,300 donor hearts are available each year for transplantation. This shortage of available organs relative to organs needed creates some major inefficiencies in the care of patients on the heart transplant list. The availability of a suitable heart for a given patient is, of course, unpredictable, and because available organs are allocated on an illness severity-based priority scale, doctors face an incentive to keep their candidate patients hospitalized in the intensive care unit with intravenous inotropes and a balloon pump to preserve their position at the top of the list. As a consequence, patients may wait for months in the hospital.

No high-quality modern cost data on transplantation have been published, but claims (charge) data are available (147). In 1999, charges per transplant patient averaged $303,000 through the end of the first year (corresponding costs are likely to be approximately half that amount). Hospital charges were $181,000, physician charges $23,000, and organ procurement $24,000. Follow-up care averaged $40,000, and immunosuppressive therapy charges were $11,400. The average medical charges for care after the first year (including angiography, biopsies, and drug therapy) are approximately $24,000. Thus, cumulative 5-year charges for heart transplantation are currently approximately $400,000 (representing probably approximately $200,000 in medical costs). Although no modern cost-effectiveness analysis of heart transplantation has been done, heart transplantation currently has a 1-year survival rate of more than 90% and a posttransplant life expectancy of approximately 9 to 11 years. This represents a huge increment in life-years over medical treatment of advanced heart failure, and the cost per added life-year is therefore likely to fall securely in the economically attractive zone.

Several LVADs have been approved by the U.S. Food and Drug Administration as a bridge to transplant. The acquisition cost of these devices is high, currently $50,000 to $75,000 (not counting costs of implantation or follow-up care). One small observational study suggests that, when used as a bridge to transplant, these devices pay for themselves (148). Of 90 consecutive patients on the heart transplant list who received LVAD, 44 were discharged to home to await their transplant. The cost for pretransplant care at home was $13,200, versus $165,200 for inpatient care. In addition, 30% of the outpatients resumed working, and all were independent in activities of daily living.

The more controversial aspects of LVAD use is as “destination therapy.” As noted earlier, more than 40,000 patients a year could be candidates for this form of therapy if it is approved by the U.S. Food and Drug Administration. The Randomized Evaluation of Mechanical Assistance Therapy for Congestive Heart Failure (REMATCH) trial randomized class IV patients who were ineligible for transplantation to the HeartMate vented electric LVAD or optimal medical therapy (149). If this study shows a survival advantage for the LVAD, a wider indication for these devices could add more than $5 billion to the annual health care budget in the United States. For reference, the total annual cost for heart transplantation in the United States is approximately $700 million, but this figure is constrained by the lack of more donor hearts. An economic analysis of REMATCH is planned.

Disease Management Approaches

Disease management is a composite strategy that seeks to reconfigure the medical care process to provide equal or better outcomes relative to conventional care at a lower net cost. It is based on the use of national peer-reviewed practice guidelines and locally created critical pathways to define standard care goals and the most efficient means of reaching them. Nonphysician medical staff is used to follow patients carefully (in clinic or over the telephone), encourage compliance with prescribed

therapies, and solve problems before they reach a crisis stage. Often, problem solving requires formulating a fresh view of how the medical care system should operate (sometimes referred to as *reengineering*). Outcome measurement and continuous quality improvement are other integral aspects of disease management.

Three randomized trials of disease management strategies involving heart failure patients have been published. Rich and colleagues (132) at Jewish Hospital in St. Louis enrolled 182 hospitalized elderly heart failure patients (mean age, 79 years; mean NYHA class, 2.4) at high risk for readmission into a disease management trial. Enrollment occurred over a 4-year period. The intervention arm consisted of patient and family education by a registered nurse, dietary consultation by a registered dietitian, review and simplification of the medical regimen by a geriatric cardiologist, and intensive follow-up by telephone and home visits. The control arm consisted of standard care. Over the 90-day follow-up period, intervention patients had a 44% reduction in all-cause rehospitalization (p = .035) and a significant improvement in quality of life. Economic assessment showed that the intervention arm was associated with a net $460 cost saving per patient. The cost of the program itself was $216 per patient. More than $1,000 per patient was saved by the reduced need for follow-up hospitalization (132). Compliance with prescribed medical therapy (as assessed by pill counts) was 88% in the intervention arm and 81% in the control arm (p = .003) (150).

A second trial of disease management was conducted among 1,296 veterans who were hospitalized with diabetes, chronic obstructive lung disease, or CHF at nine Veterans Administration Medical Centers (151). CHF was the primary diagnosis in 504 patients. The test strategy in this trial was an intensive primary care intervention delivered by a physician and a nurse that started before discharge and continued for 6 months. Contrary to expectations, patients in the intervention group had significantly higher rates of readmission than did the controls (p = .005). No medical benefits were observed for this intervention, but intervention patients were significantly more satisfied with their care.

The third trial randomized ten community hospitals to a quality improvement intervention versus usual care (152). This intervention had a nonsignificant effect in the beneficial direction on mortality, readmission, and quality of life. The economic effects included a 1.1-day reduction in length of stay (p = .18) and an $817 reduction in hospital charges (p = .31).

These trials point out some of the opportunities and challenges posed by disease management. First, in some situations the opportunities to improve outcomes and reduce costs using disease management strategies appear substantial. Second, opportunities for improvement may well be greater in some segments of the heart failure population than in others. Third, not all disease management interventions will be equally effective. Finally, the effectiveness and favorable economic consequences of any new disease management program need to be proven before general implementation. The Veterans Administration study shows how a seemingly positive intervention can have unintended consequences.

The investigators at Stanford have reported pilot data on their physician-supervised, nurse-mediated, home-based system for heart failure management (MULTIFIT). The key elements of the program were use of the Agency for Health Care Policy and Research Heart Failure Guidelines to direct pharmacotherapy and diet therapy and a nurse manager using frequent telephone contacts to monitor clinical status and enhance patient compliance. Compared with the 6-month period preceding the start of the pilot, patient dietary sodium fell by 38% and mean dose of ACE inhibitor increased significantly. Functional status improved significantly, whereas hospitalization rates declined by 74% and outpatient visits declined by 23% (153).

Prevention of Coronary Heart Disease and Its Complications

Clinically overt CHD has a prevalence of approximately 7 million persons in the United States and is the most common cause of death in this and other industrialized countries (90). It is also a major cause of morbidity and resulting disability. Approximately 2.0 to 2.3 million individuals with CHD in the United States have limitations in their daily activities as a result of the disease. CHD accounts for more than 2.2 million hospital admissions per year and over 10 million outpatient medical visits. The direct medical costs of caring for coronary disease patients in the United States have been estimated at $47.5 billion, and the cost to society of the loss in productivity due to morbidity and premature mortality has been assessed at $43 billion (90). For many years, it has been hypothesized that prevention might be a more cost-effective way of reducing the clinical and economic sequelae of CHD than treatment of symptomatic or decompensated disease. As discussed elsewhere in this text, epidemiologic studies have identified a set of major modifiable risk factors for CHD, and clinical trials have been conducted to define the relationship between modification of these risk factors and subsequent outcome. *Primary prevention* is usually defined as prevention in individuals at risk for the disease but without any clinical evidence that the disease has actually developed. *Secondary prevention* is prevention in patients with clinically manifest disease. In primary prevention, the risk factors that have been most often targeted are hypercholesterolemia, smoking, hypertension, diabetes, and physical inactivity. In secondary prevention programs, in addition to these risk factors, major emphasis is given to the use of aspirin, beta-blockers, and ACE inhibitors in appropriate patients. The medical effectiveness of these interventions is discussed in detail elsewhere. In this section, we review the available work on their economic implications.

In general, effective prevention programs for CHD improve outcomes at a net increased cost (154). Secondary prevention programs usually have more favorable cost-effectiveness ratios than do primary programs. Some clinicians find this counterintuitive because, they argue, prevention programs are usually less expensive on a per-patient basis than is treatment with expensive high-technology therapies. Although this may be true, the total economic picture is very substantially influenced by the number of individuals who must be treated to prevent a single death or major complication. Because risk factors for CHD only define a propensity for future disease, many individuals who are enrolled in primary prevention programs never develop the disease and consequently cannot benefit from the interventions being applied. In contrast, secondary prevention programs target individuals with an established propensity to development of disease-related complications. Consequently, the number needed to treat to prevent one adverse event is small. For example, using data from the West of Scotland trial (largely a primary prevention population), prevention of one additional death by cholesterol reduction with a statin agent would require treating 166 patients for 5 years (155). Using data from the Cholesterol and Recurrent Events (CARE) study of patients with established CHD and modestly elevated cholesterol, prevention of one death would require treating 91 patients for 5 years (156). Using the Scandinavian Simvastatin Survival Study (4S) results in patients with CHD and very elevated cholesterol levels, only 29 patients would have required 5 years of statin therapy to prevent one death (157). Because the direct costs of statin therapy would be similar in the preceding three examples, it is clear that the largest “bang for the buck” (and the most favorable cost-effectiveness ratio) would be obtained in treating the highest-risk patients.

Hypercholesterolemia

Numerous observational studies have established a strong dose-response relationship between total cholesterol levels and CHD risk. The National Cholesterol Education Program has established a target desirable level of less than 220 mg per dL for adults without evidence of clinical CHD. The corresponding low-density lipoprotein (LDL) cholesterol level is less than 130 mg per dL. Earlier primary prevention trials tested diet and pharmacologic regimens that were able to achieve reductions in total cholesterol of approximately 10%. Associated reductions in all-cause mortality were small and largely nonsignificant. Consequently, early cost-effectiveness analysis based on these clinical data generally concluded that cholesterol reduction as a primary prevention strategy was not economically attractive (158).

The West of Scotland Coronary Prevention Study (WOSCOPS) found that primary prevention with pravastatin at 40 mg per day reduced total cholesterol by 20% relative to placebo in 4,159 men older than age 45 years with LDL cholesterol levels of 155 mg per dL or greater. Pravastatin patients experienced a 22% reduction in all-cause mortality (p = .051) (155). Over 4.9 years of follow-up, for every 1,000 patients shifted to the pravastatin arm, there were five fewer deaths, 19 fewer MIs, 14 fewer diagnostic catheterizations, and eight fewer revascularization procedures. An economic analysis using British costs and the WOSCOPS data has been published (159). This analysis estimated that treating 10,000 men such as those in the trial would prevent the development of CHD in approximately 300. The pravastatin therapy cost $3,700 per patient for 5 years and saved approximately $100 per patient as a result of reduced procedures and complications. Life expectancy was increased by pravastatin by 0.10 years, and the cost per year of life added was $32,600.

A cost-effectiveness model of cholesterol-lowering strategies in the United States reported that primary prevention with a statin compared with diet therapy has a cost-effectiveness ratio ranging from $54,000 per QALY to $1.4 million per QALY depending on patient risk level (160). Importantly, the WOSCOPS economic model did not assume a preexisting secondary prevention program (i.e., wait to treat patients once they manifest clinical CAD), which may explain part of the difference with this U.S. model.

The Air Force/Texas Coronary Atherosclerosis Prevention Study randomized 6,605 subjects without clinical CAD and with average cholesterol levels to lovastatin or placebo (161). Over 5 years of therapy, lovastatin reduced acute coronary events by 37% (p <.001). In absolute terms, for every 1,000 patients shifted to lovastatin therapy there were four fewer cardiovascular deaths, 26 fewer MIs, 16 fewer unstable angina admissions, and 31 fewer revascularization procedures. The cumulative 5-year cost of lovastatin therapy was $4,654 per patient, and there was a $524 cost offset due to reduced cardiac events and procedures (net cost of drug therapy $4,130). A cost-effectiveness analysis of this trial has not yet been reported.

The National Cholesterol Education Program has identified an LDL cholesterol of less than 100 mg per dL as optimal in patients with evidence of CHD. Although a number of important secondary prevention trials have been published, two of the most useful for assessing economic impact are the 4S and the CARE trial. The 4S randomized 4,444 patients of both sexes aged 35 to 60 years with a history of angina or prior MI and total cholesterol of 210 to 310 mg per dL to adjusted-dose simvastatin or placebo (157). The majority of patients received 20 mg simvastatin, and 37% required 40 mg per day. Over a median of 5.4 years, simvastatin decreased total cholesterol by 25% and LDL cholesterol by 35% and decreased total mortality by 30% (p = .0003) (157). The study also observed a 37% reduction in the need for revascularization in the simvastatin arm (p <.0001). In a subsequent analysis, the 4S investigators reported that simvastatin therapy reduced hospitalizations for acute cardiovascular disease, including revascularization (81% of which were CABG), by 26% (p <.0001). Over the course of the study, total

hospital days due to cardiovascular disease were reduced by 5,138 days in the simvastatin arm (p <.0001). The beneficial effect of simvastatin on hospitalization first became evident after 10 months of therapy and became statistically significant after 22 months. No effect was seen on the use of antianginal or other cardiovascular drugs.

Using U.S.-derived reimbursement rates as cost weights, the 4S investigators estimated that the observed reduction in hospitalizations would equal a $3,872 reduction in average cost per patient treated with simvastatin (162). With a wholesale price for simvastatin over the trial averaging $4,400 per patient ($4,879 undiscounted), the net cost of simvastatin therapy was estimated to be $528 per patient over the trial or $0.28 per day (an offset of 88% of the drug's cost). The cost of repeat laboratory measurement of lipids and transaminases (three to four in the first year, annually after year 1) added a discounted cost of $250 per patient or an additional $0.13 per day. Thus, the total net cost of the simvastatin strategy was estimated at $778 per patient over a mean of 1,915 days of follow-up (approximately $148 per year). As noted earlier, the benefits of simvastatin on follow-up medical care take 10 months to become clinically detectable and appear to increase progressively as treatment is continued.

Three separate cost-effectiveness analyses have been conducted using the data from the 4S trial. One was done from a Swedish perspective (163); two others were conducted from a U.S. perspective. Schwartz (164) estimated a cost per year of life saved of $18,100 with a cost per QALY saved of $15,100, assuming that costs and benefits only occurred for the duration of the trial. Extrapolating to a lifetime perspective yielded a cost per year of life saved of $5,800, with a cost per QALY saved of $6,100. The most recently published analysis used the empiric data from 4S in a Markov model to evaluate cost effectiveness of therapy for different subgroups (165). In this analysis, costs were derived from four hospitals in Sweden that had patient-based cost-accounting systems. Swedish costs were converted to U.S. dollars. The patient's work status, measured every 6 months, was used to estimate productivity costs saved by simvastatin. This analysis estimated that for 59-year-old men, the cost effectiveness of 5 years of simvastatin therapy was $5,400 per year of life saved; the corresponding figure for 59-year-old women was $10,500. Adding in the productivity costs related to time lost from work saved by simvastatin improved the cost-effectiveness ratios to $1,600 for men and $5,100 for women (165). Extensive sensitivity analyses showed that statin therapy was very economically attractive under a wide range of assumptions.

The CARE study evaluated pravastatin versus placebo in 4,159 patients who were 3 to 20 months post-MI and who had a total cholesterol of less than 240 mg per dL and an LDL cholesterol of 115 to 174 mg per dL (156). Like in other statin trials, pravastatin reduced total cholesterol by 20% and LDL cholesterol by 28%. Death and nonfatal MI were reduced by 24%. The mean cost for 6 years of pravastatin therapy in CARE was $5,500, which was partially offset by a $1,660 savings from reduced cardiac events and procedures (166). A cost-effectiveness model using the CARE data estimated that to add a life-year with pravastatin therapy would cost between $16,000 and $31,000.

Cigarette Smoking

Smoking has repeatedly been identified in observational studies as one of the major reversible risk factors for atherosclerotic disease. No randomized trials have tested continued smoking versus complete cessation, but observational data comparing quitters versus continued smokers have suggested that quitting is associated with reductions in mortality due to cardiovascular disease and lung cancer. Using such data, Tsevat (167) estimated that smoking cessation could add 2 to 5 years to a patient's life expectancy.

Office advice to quit smoking in a primary prevention situation is very modestly effective but also very inexpensive, yielding a cost-effectiveness ratio of $2,000 or less per year of life added (168). Use of nicotine replacement therapies as an adjunct to physician advice has been reported to have cost-effectiveness ratios of less than $10,000 per year of life added (169).

Effectiveness of smoking cessation interventions appears to be somewhat higher in the secondary prevention settings, such as after acute MI or CABG, with cessation rates of approximately 50% to 75% (170,171). One randomized trial of a smoking cessation and relapse program in postoperative CABG patients found that validated continuous nonsmoking status was achieved by 44% of intervention and of control patients at 5.5 years (171). Regression analysis identified two independent predictors of maintained nonsmoking status at 5.5 years, fewer than three previous attempts to quit and definite intention to quit.

In a cohort of 173 smokers with a recent MI, Taylor and colleagues (172) tested a nurse-managed intervention begun in the hospital and continued largely by telephone for 4 months. At 1 year, the intervention group had a smoking cessation rate of 71%, compared with 45% in the usual-care group (p = .003). In logistic regression analysis, two factors predicted 1-year smoking status, smoking status 3 weeks after MI and self-efficacy. The former was strongly related to intention to quit. In this study, the intervention program required 3.5 hours per patient on average.

Krumholz and coworkers (170) created a decision model to estimate the cost effectiveness of the Taylor et al. smoking cessation intervention. The estimated direct costs of the program in this model were $100 (3.5 hours of nurse time at $30 per hour). On the benefit side, the model projected an incremental life expectancy of 1.7 years per quitter. For the base case, the program was assumed to create 26 extra quitters per 100 patients enrolled, yielding a cost-effectiveness ratio of $220 per year of life saved. In sensitivity analysis, even if the program only yielded three extra quitters per 1,000 subjects enrolled, the cost-effectiveness ratio was less than $20,000. Thus, many forms of stop-smoking interventions are very economically attractive.

Hypertension

One in four U.S. adults has hypertension (90). Numerous studies have shown that hypertension is a major risk factor for CHD. Randomized trials have clearly shown that effective treatment of hypertension reduces the risk of stroke and CHF (173). However, the evidence for prevention of CHD has been less persuasive. Metaanalysis of large trials evaluating treatment for mild to moderate hypertension demonstrated a 16% reduction in CHD death and a 21% reduction in all-cause death (174,175). An overview of placebo-controlled trials of ACE inhibitor therapy showed a 30% reduction in stroke and 20% reduction in CHD (176). An overview of calcium antagonists showed a 39% reduction in stroke. Comparisons among agents have not yielded clear evidence of major differences in outcomes. However, another overview of nine trials concluded that calcium antagonists were inferior to other major antihypertensives despite providing a similar level of blood pressure control (177).

Weinstein and Stason's (178) classic analysis from the 1970s found that screening to detect and treat hypertension as a primary prevention had cost-effectiveness ratios of less than $50,000 per QALY saved for a broad range of patient subgroups. Treatment of moderate or worse hypertension was substantially more economically attractive than treatment of mild hypertension (179).

Another important determinant of the cost effectiveness of hypertension treatment as primary prevention is the antihypertensive regimen chosen. In the study of Edelson et al. (180), the cost effectiveness of propranolol for monotherapy of mild to moderate hypertension was $10,900; for hydrochlorothiazide, it was $16,400; and for captopril, it was $72,100 per year of life added. The less favorable cost-effectiveness ratio for captopril in this model was due to the higher cost of this agent and to the pooled literature estimates that suggested a smaller effect on diastolic blood pressure than either propranolol or hydrochlorothiazide. Littenberg (181) also found that cost effectiveness was most favorable when the least expensive antihypertensive regimen was chosen. Results of studies comparing different agents are quite dependent on starting assumptions (182).

The extrapolation of the benefits of blood pressure control from asymptomatic persons with mild to moderate hypertension to hypertensive patients with manifest CHD (i.e., secondary prevention) seems logical and is accepted in medical practice but has not been demonstrated empirically in large-scale clinical trials. Similarly, there have not been any cost-effectiveness models created to evaluate hypertension control in CHD patients.

Physical Inactivity and Cardiac Rehabilitation

A wealth of epidemiologic evidence supports the concept that individuals who exercise regularly have less CHD and longer life expectancies than individuals who do not. It is reasonable to suppose, but less well established, that habitually inactive subjects who begin to exercise regularly will live longer and have less CHD than their persistently inactive counterparts. On the other hand, most exercise programs are quite inexpensive, and exercise does have readily measurable benefits on weight, blood pressure, and serum lipid levels. One study has evaluated the cost effectiveness of exercise to prevent CHD (183). In a cohort of 1,000 hypothetical 35-year-old men, regular exercise in the form of jogging 20 miles per week was assumed to reduce the risk of CHD by 50% (based on published epidemiologic data). The direct costs of the program consisted of exercise equipment ($100 per year) and a portion of an annual physician visit. The productivity costs were estimated as $9 per hour for subjects who disliked exercise, $4.50 per hour for neutral subjects, and $0 for subjects who enjoyed exercise. The resulting cost-effectiveness ratios for regular exercise versus no exercise were $1,359 per QALY added when considering only direct costs and $11,313 per QALY added when productivity costs were also included. This analysis presumes that even subjects who do not like exercise continue in the program. Alternatively, if the program is made voluntary, it saves lives and money, even when productivity costs are included.

Almost all the data about the benefits of regular exercise in patients with CHD come from studies of structured cardiac rehabilitation, primarily involving patients who are recovering from an MI. Exercise training has not been definitively shown to reduce deaths or other cardiac events in patients with established CHD. Most of the studies in this area have been too small or had other methodologic limitations. Two metaanalyses of the available randomized trial data have found a 20% to 25%

reduction in death plus nonfatal MI with exercise (184,185). Dennis and colleagues reported favorable effects of cardiac rehabilitation on earlier return to work after MI, and economic analysis suggests that these programs may reduce morbidity costs and productivity costs (due to lost time from work) (186,187). Oldridge and coworkers (188) have estimated that structured cardiac rehabilitation is cost effective in the post-MI population. The major limitations of structured cardiac rehabilitation are its cost and the fact that only a minority of eligible patients choose to participate.

Multiple Risk Factor Interventions

Although in this section we have so far evaluated risk factor modification as isolated activities, in clinical practice patients often require multiple coordinated interventions. The Stanford Coronary Risk Intervention Program randomized 300 patients with angiographically proven CAD to usual care or multifactor risk reduction (189). The risk reduction intervention consisted of individual programs involving diet, exercise, weight loss, smoking cessation, and cholesterol reduction pharmacotherapy. After 4 years, the intervention patients had a 22% reduction in LDL cholesterol, a 4% decrease in body weight, a 20% increase in exercise capacity, and significant improvement in the Framingham CHD risk score (189). Follow-up angiography showed that this intervention program was associated with a statistically significant attenuation in the progression of coronary atherosclerosis. Clinically, there was a drop in the composite end point of death, hospitalization for nonfatal MI, CABG, or PTCA in the intervention group (p = .05). Furthermore, most of the events that occurred in this group took place in the first year of the study, suggesting that the benefits of these interventions may take up to a year to become clinically evident and may increase progressively over time. Using simple projections based on the published data from the Stanford Coronary Risk Intervention Program, Superko (190) projected that the program would cost approximately $1,500 per patient per year (including medication) but that these costs would be partially offset by reduced hospitalizations for cardiac events. He estimated the net cost of the program as $630 per patient per year.
