DeBusk and colleagues (191) tested a nurse-based case management model of home-based cardiac rehabilitation (MULTIFIT) in 585 post-MI patients at three Kaiser Permanente hospitals. The special intervention group received assessment, education, risk factor counseling, goal setting, and telephone follow-up by a nurse case manager. At the end of 12 months, the intervention group had an 11% greater improvement in functional capacity, a 32% higher smoking cessation rate, and a 19% reduction in LDL cholesterol (all three differences were statistically significant). During 1 year of the MULTIFIT program, each patient received up to four face-to-face visits, 11 telephone contacts, and four mailings. Nurses spent an average of 9 hours per patient over the year. The per-patient charge for nursing salary, office space, and equipment was approximately $550 (192). This model of post-MI cardiac rehabilitation is clearly more economically efficient than traditional hospital-based or community-based cardiac rehabilitation centers, which may charge $1,800 to $3,000 for a 3-month program. Although formal cost-effectiveness analysis of this program has not been conducted, its lower cost along with its competitive effects on cardiac risk factors (summarized previously) should make it more economically attractive than traditional cardiac rehabilitation programs.

Other Pharmacologic Secondary Preventions

Long-term aspirin therapy is the mainstay of secondary prevention efforts in patients with manifest coronary disease (193). The clinical effectiveness is substantial, and the cost is minimal. Therefore, although aspirin use has not been the subject of a formal economic analysis, this therapy clearly belongs in the “best buy” category of medical intervention. Despite these attractive characteristics, much evidence exists that aspirin is underused in patients with coronary disease (194). Long-term use of beta-blockers after MI was modeled by Goldman and colleagues (195). Based on the earlier (prethrombolytic) beta-blocker trials, they estimated cost-effectiveness ratios of less than $15,000 per life-year added, with ratios less than $5,000 for moderate- or high-risk patients. Their model projected a 6-year course of therapy, with 25% mortality reductions by beta-blockers in years 1 to 3, 7% reduction in years 4 to 6, and gradual attenuation of treatment benefit over a subsequent 9-year period. Based on the data from the Survival and Ventricular Enlargement trial, Tsevat and colleagues (196) developed a decision model to assess the cost effectiveness of captopril therapy in 50-to 80-year-old survivors of acute MI with an ejection fraction of 40% or less. Under the assumption that survival benefits of captopril persisted for more than 4 years, these investigators estimated cost-effectiveness ratios of $10,400 per QALY or less (1991 dollars), depending on age. Analysis of the cost effectiveness of early lisinopril use in acute MI based on GISSI-3 data yielded a cost-effectiveness ratio of $2,300 (U.S.) per 6-week death avoided (197). Assuming that the clinical benefits observed in GISSI-3 were sustained over a 10- to 15-year life expectancy, these data suggest that 6 weeks of ACE inhibitor therapy for all post-MI patients may fall into a “best buy” category of economic attractiveness.

CONTROVERSIES AND PERSONAL PERSPECTIVES

As recently as the early 1990s, medical economics was viewed as a scholarly academic discipline that was largely irrelevant to the practice of medicine. Cost is now one of the dominant issues in almost all medical decisions, although it is the controlling issue in only a minority. Demands by payers that medicine demonstrate its value (benefits produced for dollars spent) have thrust economists into the mainstream of the revolution that is currently reshaping medical practice. However, just as clinicians found themselves woefully unprepared to prove the medical benefits of their decisions, economists were unprepared to provide the pragmatic sorts of data that are now required of them. As was discussed earlier, medical economics is principally concerned with matters related to the efficient societal allocation of scarce resources. Economists have paid little attention to measuring the cost of health care, preferring to discuss the abstract notion of “opportunity cost” while leaving the more pragmatic measurement issues to the accountants. Payers and policy makers, however, are not interested in theories or abstract problems of resource allocation. Instead, they wish to understand the costs of care and how they can be reduced or at least controlled. Clinicians are also not interested in theoretical economic exercises. They want to be able to prove that the care they provide their patients is worth the money it costs. Cost-effectiveness ratios are the economists’ measure of value and have some important strengths. However, the need to frame all cost-effectiveness ratios in terms of dollars required to add an extra QALY (9) often stretches the available clinical and cost data beyond credibility.

THE FUTURE

New approaches are needed in this area to meet the demands for information and for relevant measures of medical value. Three major areas need intensive work over the next few years. The first is to improve methods for costing out medical care accurately but efficiently (i.e., with a relatively low cost of data collection). The second is to develop new measures of value that do not require extrapolation out to a lifetime perspective. These measures would not preclude traditional cost-effectiveness analysis but could be used to supplement it. The third area is education of medical practitioners about medical economics. It is only by getting practitioners to use cost data on a daily basis, asking questions about it and challenging it, that we will get better data and ultimately better value-based medical decision making.

In the final analysis, no economic model can dictate how many resources society should expend on health care and what types of health care should be given priority. These are political and ethical questions that transcend medicine. However, the medical profession must constantly strive to achieve better outcomes at an acceptable cost and to continue the dramatic pace of technological advances set over the last century.

OVERVIEW

As medicine enters the era of evidence-based medicine, the need to understand appropriate quantitative methods is becoming more clear. The hierarchy of clinical evidence, ranging from the randomized clinical trial to the individual case report, provides a variety of approaches that can be used to make inferences about diagnostic and therapeutic strategies. Although a comparative experiment was described in the Bible, randomized clinical trials are a product of the twentieth century; the ability to approach complex medical problems quantitatively has only been possible with the advent of the powerful computing capabilities in the last decade.

When reading or planning a clinical study, the concepts of validity and generalizability provide the broad conceptual framework. Clinical research is only meaningful when it is internally valid and when the results can be applied beyond the population from which they were derived. The results of clinical outcome studies should be expressed in terms of relative differences and absolute differences. Practitioners' perceptions of the appropriate clinical strategy vary considerably when results are depicted in relative and absolute terms, because relative differences can be large with only small absolute differences when the events being treated occur infrequently.

Common principles underlying the behavior of clinical therapeutics include the following: Treatment effects are usually modest, qualitative interactions are common, quantitative interactions are uncommon, unintended biologic effects are more common than previously believed, interactions are unpredictable, and long-term effects frequently differ from short-term effects. Given these principles, it is necessary to separate explanatory trials (designed to elucidate biologic principles) from pragmatic trials (designed to determine which therapeutic approaches should be used in practice). Explanatory trials can often use small sample sizes, complex data collection instruments and detailed protocols, whereas the imperative for large sample sizes in pragmatic trials necessitates simple data collection and trial designs with minimal interference with clinical practice. Although type I statistical errors are commonly accounted for in study design, too often multiple comparison problems and type II errors plague the interpretation of clinical research.

Organizing clinical trials with a recognition of the need for checks and balances involving the sponsor, investigators, management of data, and oversight can lead to more successful and meaningful research.

INTRODUCTION

Medical practice has entered an era of "evidence-based medicine," characterized by an increasing societal belief that clinical practice should be based on a combination of scientific information and expert judgment, rather than relying on intuition, memory, or opinion. As our society has exhausted its tolerance for increasing

the proportion of financial resources spent on medical care, the only rational way to allocate resources is to understand whether competing diagnostic and therapeutic approaches provide clinical benefit and, if so, the cost required to achieve that benefit. Simultaneous with the realization that financial support for medical care has limits, the huge investment in biotechnology is beginning to pay off with many new approaches to treating disease. Similarly, genomics, combinatorial chemistry, proteomics (1), and advanced biomedical engineering are leading to a desirable, but challenging, proliferation of diagnostic and therapeutic opportunities. Thus, the need for evidence is increasing faster than resources are being made available to perform the studies that produce the evidence.

This accelerating pace of quantitative research creates a need for practicing physicians to understand the methods of evaluating clinical evidence well beyond the level they learned in most medical schools. The plethora of new studies and the increasing questioning of medical decision making point to the benefits of practitioners better understanding the critical issues in clinical research design. Because of the high visibility and quantitative nature of cardiology, the priority to develop these skills among cardiologists is paramount.

HISTORY

The first chapter of the Book of Daniel in the Bible describes a comparative experiment in which Daniel urged a servant to experiment with refraining from eating the king's food, and indeed, the healthier diet was associated with the finding that "at the end of ten days their countenances appeared fairer and they were fatter in flesh, than all the youths that did eat of the king's food." The modern human clinical trial, however, was not pioneered until 1747, when Lind tried six different treatments for scurvy in 12 sailors (2); despite the small sample size, the virtues of oranges and lemons became evident. Partly because of an inadequate sample size, however, Lind failed to recognize the primary beneficial effect of oranges and lemons, considering "pure dry air" to be the most beneficial intervention.

P. C. A. Louis (3) has been credited with developing the concept of comparative observational studies in the nineteenth century, which he delineated in a treatise entitled "La Méthode Numérique" (4). In casting doubt on the common practice of bloodletting, he clearly identified the concept of confounding and emphasized the need to have comparable groups when making comparisons. In the 1840s, Semmelweis (5) noted that maternal mortality was higher in women giving birth in hospitals in which deliveries were attended by physicians than in hospitals in which deliveries were attended by midwives. He showed that the excess mortality was related to contamination from autopsies, and he succeeded in separating autopsy teaching from attending childbirth by physicians, with a resultant decrease in maternal mortality.

The first randomization was performed by Fisher and Mackensie in 1926 in an agricultural study (6). In developing analysis of variance, they recognized that experimental observations must be independent and not confounded to allow full acceptance of the statistical methodology. They therefore randomized different plots to different approaches to the application of fertilizer. Amberson has been credited with the first randomization of patients, using a coin toss to make treatment assignments in a 1931 trial of tuberculosis therapy in 24 patients (2). The British Medical Research Council trial of streptomycin in the treatment of tuberculosis marked the modern era of clinical trials in 1948 (7). This trial established the principles of randomization for large numbers of patients and set guidelines for administering the experimental therapy and objectively evaluating outcomes.

Modern outcomes research was presaged by important observations from Florence Nightingale, who observed a higher mortality in hospitals than out of hospitals in the treatment of amputation. Her notes provide a detailed accounting of observational study methodology in the adjustment for differences in outcome as a function of baseline characteristics.

In 1914, Codman (8) wrote a treatise about measurement of outcomes that provides a classic discussion of the need for hospitals to evaluate outcomes. He proposed that reimbursement be based on demonstration of results. However, his message was not popular, and his hospital went bankrupt.

In the last decade, computers have enabled rapid accumulation of data in thousands of patients in studies conducted throughout the world. Peto, Yusuf, Sleight, and Collins developed the concept of the large, simple trial in ISIS-1 (9), beginning with the concept that only by randomizing 10,000 patients could the beneficial effects of beta-blockers be understood. The development of client–server architecture provided a mechanism for aggregating large numbers of data and distributing them quickly to multiple users. Finally, advances in the development of the World Wide Web provide an opportunity to share information instantaneously in multiple locations around the world, and the personal digital assistant provides new opportunities for point-of-care data acquisition and retrieval. Innovative approaches to using the Internet are creating communities of practitioners interested in contributing to a body of knowledge about the diagnosis and treatment of patient groups.

PHASES OF EVALUATION OF THERAPIES

Evaluating therapies and interpreting the results as they are presented require an understanding of the goals of the investigation; these goals can be conveniently categorized in a similar manner to the nomenclature used by the U.S. Food and Drug Administration (FDA) (10) to characterize the phase of investigation in clinical trials (*e*Table 43.0.1). Conclusions drawn from a small pilot study of a therapy never before given to humans should be quite different from conclusions drawn from a study measuring clinical outcomes of two therapies used in current practice; thus, regulatory authorities have developed a nomenclature for discussing these phases of investigation.

***e*TABLE 43.0.1** PHASES OF EVALUATION OF NEW THERAPIES

Phase	Features	Purpose
I	First administration of a new therapy to patients	Exploratory clinical research to determine if further investigation is appropriate
II	Early trials of new therapy in patients	To acquire information on dose-response relationship, estimate incidence of adverse reactions, and provide additional insight into pathophysiology of disease and potential impact of new therapy
III	Large-scale comparative trial of new therapy versus standard of practice	Definitive evaluation of new therapy to determine if it should replace current standard of practice; randomized controlled trials required by regulatory agencies for registration of new therapeutic modalities
IV	Monitoring of use of therapy in clinical practice	Postmarketing surveillance to gather additional information on effect of new therapy on treatment of disease, rate of use of new therapy, and more robust estimate of incidence of adverse reactions established from registries

Adapted from Antman EM, Califf RM. Clinical trials and meta-analysis. In: Smith TW, ed. *Cardiovascular therapeutics*. Philadelphia: WB Saunders, 1996:679.

When a new therapy is devised, it must first be studied in normal, healthy volunteers to ensure that no unexpected side effects occur. This type of study is commonly referred to as *phase I*. In some cases, when concern exists that the therapy may be highly toxic, patients in an advanced stage of the disease (with little to lose and much to gain if the treatment was successful) are evaluated instead. Many novel therapies affecting the coagulation system in which the risk of bleeding would not be acceptable for a normal volunteer fall into this category. The most extreme example of this approach was the use of recently deceased subjects (neomorts) in the initial studies of glycoprotein IIb/IIIa inhibitors (11). Although phase I trials may generate substantial enthusiasm, they should not be used to make recommendations for routine clinical practice.

After the new therapy demonstrates some physiologic effect in phase I, it must, in phase II, demonstrate both desired physiologic activity and evidence of clinical benefit in the clinically relevant disease, at least from the perspective of "surrogate" pathophysiologic end points. Because most measures do not reach the established criteria for a surrogate (12), the term *biomarker* is preferred. For example, in a phase II trial, a heart failure therapy would need to demonstrate improvement in cardiac output, left ventricular function, or neurohormonal status. Often investigators are tempted to use these biomarker end points to recommend major changes in practice, but multiple experiences have demonstrated the danger of this approach to recommending changes in clinical practice. Often, even if the biomarkers appear to be improved, large enough trials may show that clinical outcomes are adversely affected. One of the major unresolved conceptual issues in modern cardiovascular research is how to use phase II data to make wise choices about proceeding to the next phase.

The third phase, commonly referred to as the *pivotal phase*, evaluates the therapy in the relevant clinical context, with the goal of determining whether the therapy should be used in clinical practice. For phase III, the relevant end points include measures that can be recognized by patients as important: survival time, major clinical events, quality of life, and cost. A well-designed clinical trial with a positive effect on clinical outcomes justifies serious consideration for a change in clinical practice and certainly provides grounds for regulatory approval for sales and marketing. Although this categorization into phases I, II, and III is convenient in concept, in reality, it may be best to blend the research phases in order to move quickly and efficiently through the development process (13). By law in the United States, regulatory approval is based on evidence that use of the medical product is safe and effective compared with no treatment. Because effective treatments exist for many diseases today, this standard frequently leaves a medical product in an uncertain category relative to other available therapies at the end of phase III. To generate this needed information, directly comparative trials need to be done.

After a therapy is in use and approved by regulatory authorities, phase IV begins. Traditionally, phase IV has had the responsibility of developing more effective protocols for the use of therapies in clinical practice based on inferences gained from monitoring observations and reporting adverse events. The importance of this phase has evolved from recognizing that randomized trials completed by the time of regulatory approval often will not have encountered many circumstances experienced in clinical practice. Examples of phase IV studies include the evaluation of new dosing regimens, as in several ongoing comparisons of low-dose versus

high-dose angiotensin-converting enzyme inhibition in patients with heart failure, and prospective registries of therapeutic usage, such as the National Registry of Myocardial Infarction (14).

With an increasing array of effective therapies, phase IV has been viewed as a time to compare one effective marketed therapy against another. In some cases, this need arises because of changing doses or expanding indications for a therapy, whereas in other cases, the phase III trials did not provide the relevant comparisons for a particular therapeutic choice. Global Utilization of Streptokinase and rt-PA for Occluded Coronary Arteries I (GUSTO-I) was an example of a phase III trial in which a new (accelerated) dosing regimen of alteplase was compared with a standard dose of streptokinase (15). The GUSTO-III trial was an example of a phase IV study initiated because reteplase was approved by regulatory authorities based on a comparison with streptokinase, but it was not compared with accelerated alteplase; thus, GUSTO-III performed that comparison because accelerated alteplase was the reference standard for practice in the United States (16).

A rash of product recalls have focused national attention on phase IV trials. Cisapride was recalled because it caused sudden death due to QT prolongation (17); mibefradil had multiple drug interactions that were known but much more severe than expected (18); and a prosthetic aortic valve was recalled when a comparative trial showed a higher rate of valve leak than expected (19). More direct comparative trials will be done and a more comprehensive system of postmarketing surveillance will be developed to deal with these issues (19,20).

CRITICAL GENERAL CONCEPTS

With rare exceptions, the purpose of a phase III or IV clinical trial or outcome study is to estimate what is likely to happen to the next patient given one treatment or the other. To assess the degree to which the proposed study enhances the ability to understand what will happen to the next patient, the investigator must be aware of an array of methodologic and clinical issues. Although this task requires substantial expertise and experience, the issues can be considered in a broad framework. The broadest but most essential concepts to understanding the relevance of a clinical study to practice are the concepts of validity and generalizability. *e*Table 43.0.2 illustrates an approach to these issues, developed by the McMaster group, to be used when reading the literature (21).

***e*TABLE 43.0.2** QUESTIONS TO ASK WHEN READING AND INTERPRETING THE RESULTS OF A CLINICAL TRIAL
Are the results of the study valid?
Primary guides
Was the assignment of patients to treatment randomized?
Were all patients who entered the study properly accounted for at its conclusion?
Was follow-up complete?
Were patients analyzed in the groups to which they were randomized?
Secondary guides
Were patients, their clinicians, and study personnel blinded to treatment?
Were the groups similar at the start of the trial?
Aside from the experimental intervention, were the groups treated equally?
What were the results?
How large was the treatment effect?
How precise was the treatment effect (confidence intervals)?
Will the results help me in caring for my patients?
Does my patient fulfill the enrollment criteria for the trial? If not, how close is the patient to the enrollment criteria?
Does my patient fit the features of a subgroup in the trial report? If so, are the results of the subgroup analysis in the trial valid?
Were all the clinically important outcomes considered?
Are the likely treatment benefits worth the potential harm and costs?

Validity

The most fundamental question about a clinical trial is whether the result is valid. Are the results of the trial internally consistent? Would the same result be obtained if the trial was repeated? Was the trial design adequate, including blinding, endpoint assessment, and statistical analyses? Of course, the most compelling evidence of validity in science is replication. If the results of a trial or study remain the same when the study is repeated, especially in a different clinical environment by different investigators, the results are likely to be valid.

The Evaluation of Losartan in the Elderly Study and Prospective Randomized Amlodipine Survival Evaluation trials provide excellent examples of the quest for validity. In both cases, an initial trial (22,23) showed a surprising apparent effect of a treatment on mortality; in both cases, follow-up trials—essentially attempting to replicate the surprise finding—showed no such benefit. With similar patient populations and identical drug-dosing regimens used, these findings exemplify the need to have a second trial for cross-validation (24,25).

Generalizability

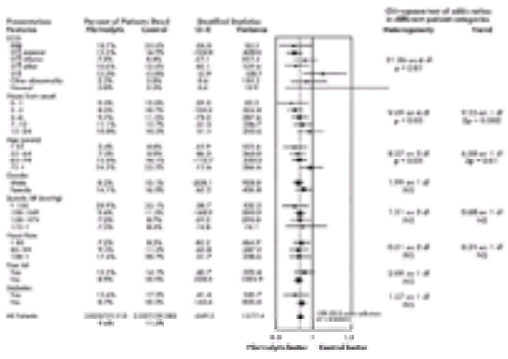
Given a valid clinical trial result, it is equally important to determine whether the findings are generalizable. Unless the findings can be replicated and applied in multiple practice settings, little has been gained by the trial. Because it is impossible to replicate every clinical study in practice, it is especially important to understand the inclusion and exclusion criteria for patients entered into the study and to have an explicit understanding of additional therapies that the patients received. For example, studies done in “ideal” patients without comorbid conditions or young patients without severe illness can be misleading when the results are applied to clinical practice. Failure to perform generalizable trials before marketing approval led to a surprising rate of serious drug interactions with the calcium channel blocker mibefradil (18), leading to its withdrawal from the market.

EXPRESSING CLINICAL TRIAL RESULTS

The manner in which the results of clinical research are reported can profoundly influence the perception of practitioners using the information to decide which therapies to use. A clinical trial produces a different degree of enthusiasm about the tested therapy when the results are presented in the most favorable light, even when the exact results are provided in addition to the risk reduction so that the practitioner can reconstruct the results in different ways (26). Multiple studies (27,28) have demonstrated that physicians are much more likely to recommend a therapy when the results are presented as a relative risk reduction rather than as an absolute difference in outcomes.

An example of a trial that has evoked considerable interest based on a predominant depiction of relative treatment effect is the Scandinavian Simvastatin Survival Study trial comparing simvastatin with placebo in patients with elevated low-density lipoprotein cholesterol and a history of ischemic heart disease (29). The results have usually been depicted as a 30% reduction in overall mortality and a 42% reduction in coronary mortality. Rarely have the results been presented in terms of absolute differences (approximately 0.6% reduction in mortality per year). This difference was highly significant because over 4,000 patients were randomized; the cost-effectiveness data support use of simvastatin in this situation (30). In contrast, the Bypass Angioplasty Revascularization Investigation found almost exactly the same difference between coronary artery bypass grafting and percutaneous revascularization, but with just over 1,800 patients randomized, this difference was not statistically significant, and the conclusion was reached that no major differences in outcome exist between the two technologies in patients with coronary anatomy suitable for either procedure (31). If the same result had been achieved in 4,000 patients, would the same conclusion have been drawn as for simvastatin?

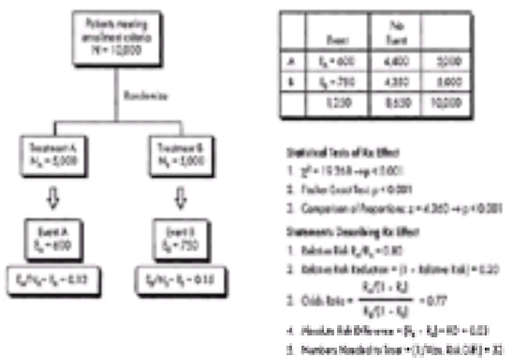
The results of pragmatic clinical trials are most appropriately expressed in terms of the number of poor outcomes prevented by the more effective treatment per 100 or 1,000 patients treated. This measure, representing the absolute benefit of therapy, the number needed to treat, translates the results for specific populations studied into public health terms by quantifying how many patients would need to be treated to create a specific health benefit. The absolute difference can be used to assess quantitative interactions (i.e., significant differences in the number of patients needed to treat to achieve a degree of benefit with a therapy as a function of the type of patient treated). An example is the use of thrombolytic therapy; the Fibrinolytic Therapy Trialists’ collaboration demonstrated that 37 lives per 1,000 patients treated are saved when thrombolytic therapy is used in patients with anterior ST-segment elevation, whereas only 8 lives per 1,000 are saved when patients with inferior ST-segment elevation are treated (*e*Fig. 43.0.1) (32). The direction of the treatment effect is the same, but the magnitude of the effect is different.



***e*FIGURE 43.0.1** Proportional effects of fibrinolytic therapy on mortality. BBB, bundle branch block; BP, blood pressure; df, degrees of freedom; ECG, electrocardiography; MI, myocardial infarction; NS, not significant; O-E, observed – expected; SD, standard deviation.

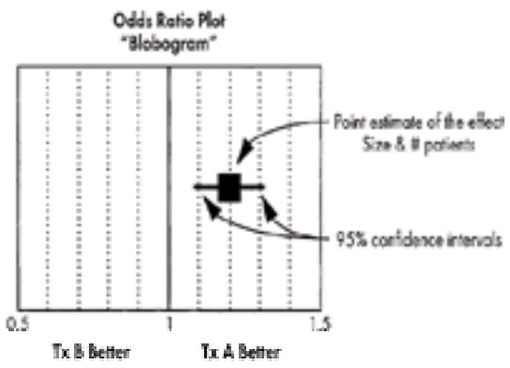
This approach becomes more complex with end points that are not discrete, such as exercise time. One approach to expressing trial results when the end point is a continuous measurement is to define the minimal clinically important difference (the smallest difference that would lead practitioners to change their practices) and to express the results in terms of the number needed to treat to achieve that difference.

The relative benefit of therapy, on the other hand, is the best measure of the treatment effect in biologic terms. This concept is defined as the proportional reduction in risk resulting from the more effective treatment and is generally expressed in terms of an odds ratio or relative risk reduction. The relative treatment effect can be used to assess qualitative interactions, which represent statistically significant differences in the direction of the treatment effect as a function of the type of patient treated. In the Fibrinolytic Therapy Trialists' analysis, the treatment effect in patients without ST-segment elevation is heterogeneous compared with patients with ST-segment elevation (32). *e*Figure 43.0.2 gives the calculations for commonly used measures of treatment effect.



***e*FIGURE 43.0.2** Summary measures of treatment effect. Rx, therapy.

A particularly useful display of data is the odds ratio plot, as shown in *e*Figure 43.0.3. Both absolute and relative differences in outcome should be expressed in terms of point estimates and confidence intervals. This type of display gives the reader a balanced perspective, since both the relative and absolute differences are important, as well as the confidence in the estimate. Without the confidence intervals, the reader has difficulty knowing the precision of the estimate of the treatment effect.



***e*FIGURE 43.0.3** Odds ratio plot. Tx, treatment.

CONCEPTS UNDERLYING TRIAL DESIGN

As experience with multiple clinical trials is accumulating, some general concepts seem worth emphasizing. These generalities do not always pertain, but they serve as useful guides to the design or interpretation of trials.

Treatment Effects Are Modest

The most common mistake in designing clinical trials is overestimation of the expected treatment effect. Most individuals heavily involved in therapeutic development cannot resist the assumption that the pathway being targeted is the most important contributor to patient outcome. Unfortunately, relative reductions in adverse clinical outcomes exceeding 25% are extremely uncommon.

When treatments affecting outcome in acute myocardial infarction (MI) have been assessed, small trials have typically greatly overestimated the effect observed in subsequent larger trials. The reasons for this observation are not entirely clear. One important factor is negative publication bias. Of the many small studies done, the positive ones tend to be published and the negative ones do not (33). A second factor could be analogous to regression to the mean in observational studies: When a variety of small trials are done, only those with a substantial treatment effect are likely to be continued into larger trials. Of course, in most cases, the small trials have so much uncertainty in the estimate of the treatment effect that the true effect of many of the promising therapies is overestimated, whereas the effect of some of the therapies showing little promise based on point estimates from small studies is underestimated. Thus, when larger studies are completed, giving a more reliable estimate of treatment effect, the estimate of benefit tends to regress toward average.

Qualitative Interactions Are Uncommon

A reversal of treatment effect as a function of baseline characteristics is unusual. Many training programs have taught clinicians that many therapies are effective only in select subsets of the population, yet there are few examples demonstrating such a targeted effect. One exception in cardiovascular trials is the probable harm of thrombolytic therapy for patients without ST-segment elevation, although this finding lacks adequate statistical power, and the Late Assessment of Thrombolytic Efficacy trial found thrombolytic therapy to be beneficial in these patients (34). One issue that is underappreciated is the sample size required to prove that such a qualitative interaction actually exists: Given a treatment with an overall 20% reduction in event rates, to detect a subpopulation with a treatment effect of 40% compared with no treatment effect in another subset requires sample sizes more than twice as large as the sample required for the primary comparison.

Quantitative Interactions Are Common

When therapies are beneficial for specific patients with a given diagnosis, they are generally beneficial to most patients with that diagnosis. However, therapies commonly provide a differential absolute benefit as a function of the severity of the patient's illness. Given the same relative treatment effect, the number of lives saved or events prevented will be greater when the therapy is applied to patients with a greater underlying risk. Examples of this concept include the greater benefit of angiotensin-converting enzyme inhibitors in patients with markedly diminished left ventricular function (35), the larger benefit of thrombolytic therapy in patients with anterior infarction, and the greater benefit of bypass surgery in older patients compared with younger patients.

Unintended Targets Are Common

Therapies are appropriately developed by finding a pathophysiologic pathway or target that can be altered and by exploiting that concept using a model that does not involve the intact human. Despite all good intentions, proposed therapies frequently either work via a different mechanism than the one for which the therapy was devised, or they affect an entirely different system. Examples include thrombolytic therapy for MI, which was developed using coronary thrombosis models; unfortunately, this therapy also affects the intracranial vessels. Inotropic therapies for heart failure were developed using measures of cardiac function, but many of these agents, which clearly improve cardiac function acutely, also cause an increase in mortality, perhaps because of a detrimental effect on the neurohormonal system. Most recently, the orally administered glycoprotein IIb/IIIa inhibitors were developed with the concept that blocking platelet aggregation would prevent thrombotic events; surprisingly, excess mortality was observed in a series of trials evaluating this therapy (36). Only after the trials of oral IIb/IIIa inhibitors were completed did new data from cell culture and receptor biology studies demonstrate paradoxical activation of platelets and apoptosis of cardiac myocytes (37,38).

Interactions Are Not Predictable

Clinical trials tend to evaluate only one treatment at a time, yet most cardiovascular diseases are treated with a complex combination of therapies. The typical patient with coronary heart disease or heart failure is now taking more than four different medications at the same time. Unfortunately, predicting whether a combination of therapies would be synergistic, additive, neutral, or negative has proven to be treacherous. In the development of abciximab, the initial trial showed a substantial reduction in ischemic events but an excess of bleeding (39). When the amount of heparin was reduced in subsequent trials, there was concern that the benefit would be lost as the bleeding diminished. The lower doses of heparin indeed produced less bleeding, but surprisingly, the efficacy at preventing ischemic events increased. In retrospect, the added efficacy with less bleeding was a fortuitous and unpredictable finding.

Long-Term Effects Cannot Be Assumed from Short-Term Results

Many cardiovascular therapies produce an early hazard followed by a later benefit. Bypass surgery initially increases the risk of death, and in clinical trials, the survival curves have not crossed for a year. Fibrinolytic therapy produces an excess hazard in the first day. Hormone replacement therapy causes an excess risk of thrombotic events in the first year, and then the curves appear to come together (40). Perhaps no example has generated as much public awareness as the diet combination fenfluramine (fen-phen), which in short-term studies generated weight loss with little apparent toxicity, but in longer-term studies caused both pulmonary hypertension and valvular regurgitation (41,42).

GENERAL DESIGN CONSIDERATIONS

When reading the results of a clinical study or designing a study, the purpose of the investigation is critical to placing the outcome in context. Those who design the investigation have the responsibility of constructing the project and presenting the results in a manner that reflects the intent of the study. In a small phase II study, an improvement in a surrogate pathophysiologic outcome is exciting and could easily lead the investigator to overstate the clinical implications of the finding. Similarly, megatrials with little data collection seldom give useful information about disease mechanisms unless carefully planned substudies are performed. The structural characteristics of trials can be characterized as a function of the following attributes.

Pragmatic versus Explanatory

Most clinical trials are designed to demonstrate a physiologic principle as part of a chain of causality of a particular disease. Such trials, termed *explanatory trials*, need only be large enough to prove or disprove the hypothesis being tested. Major problems have arisen because of the tendency of those doing explanatory trials to generalize the findings into recommendations about clinical therapeutics.

Trials designed to answer questions about which therapies should be used are called *pragmatic trials*. These trials should have clinical outcomes as the primary end point, so that when the trial is complete, the result will inform the practitioner and the public whether using the therapy in the manner tested will result in better clinical outcomes than alternative approaches. These trials generally require much larger sample sizes and a more heterogeneous population.

The decision about whether to perform an explanatory trial or a pragmatic trial has major implications for the design of the study. When the study is published, the reader must also take into account the intent of the investigators, because the implications for practice or knowledge will vary considerably depending on the type of study.

Entry Criteria

In an explanatory trial, the entry criteria should be carefully controlled so that the measurements of interest will not be confounded. For example, a trial designed to determine whether a treatment for heart failure improves cardiac output should study patients who are stable enough for elective hemodynamic monitoring. In contrast, in a pragmatic trial, the general goal is to include patients representative of the population seen in clinical practice, and who the organizers of the study believe can make a plausible case for benefit in outcome. From this perspective, the number of entry and exclusion criteria should be minimized, because the rate of enrollment will be inversely proportional to the number of criteria.

Data Collection Form

The data collection form provides the information on which the results of the trial are built; if an item is not included on the data collection form, it will obviously not be available at the end of the trial. On the other hand, the likelihood of collecting accurate information is inversely proportional to the numbers of data collected. In an explanatory trial, patient enrollment is generally not an issue because small sample sizes are needed. In a pragmatic trial, however, there is almost always an imperative to enroll patients as quickly as possible. Thus, a fundamental concept in pragmatic trials is to keep the data collection form as brief as possible.

The ultimate example of this concept is the ISIS approach of collecting only the front of a single page in a clinical trial (9). This approach has allowed the enrollment of tens of thousands of patients in mortality trials with no reimbursement to the health care providers enrolling patients. Regardless of the ultimate length of the data collection instrument, it is critical to include only information that will be useful in analyzing the trial outcome or understanding why the result occurred.

Ancillary Therapy

Decisions about the use of nonstudy therapies in a clinical trial are critical to its validity and generalizability. Including therapies that will interact in a negative way with the experimental agent could ruin the chance to detect a clinically important treatment advance. Especially in a physiologic experiment, interfering with the primary question by including another therapy would be a serious problem.

Alternatively, in a pragmatic trial, the goal is to evaluate the therapy in the context in which it will be used. Because clinical practice is not managed by a prespecified algorithm, evaluation of the experimental therapy in the context of such an approach is likely to give an unrealistic approximation of the likely effect of the therapy in clinical practice.

Multiple Randomizations

Until relatively recently, enrolling a patient in multiple simultaneous clinical trials was considered to be ethically questionable. The origin of this ethical concern is unclear, but it seems to have arisen from a general impression that clinical research encroaches on clinical practice; thus, more clinical research would be detrimental. More recently, the concept has been proposed that when the best treatment is not known, randomization is desirable (the uncertainty principle). Stimulated by the apparent need to develop multiple therapies simultaneously in the treatment of acquired immunodeficiency syndrome, the concept of multiple randomizations has been

reconsidered.

Factorial trial designs represent a specific approach to multiple randomizations with advantages from the statistical and the clinical perspectives. Because most patients are now treated with multiple therapies, the factorial design represents a clear method to determine whether therapies add to each other, work synergistically, or nullify the effects of one or both therapies being tested. As long as a significant interaction does not exist between the two therapies being tested, both can be tested in a factorial design with a sample size close to the size needed to test one therapy.

LEGAL AND ETHICAL ISSUES

Multiple considerations pertain to the question of whether a clinical trial should be done and how the results of the trial should be disseminated. Perhaps too little thought is given to critical ethical issues before trials are done. Three general principles should be considered when clinical investigation is considered (43). *Respect for persons* embodies the concept that the investigator recognizes that patients are not simply sources of data; they are individuals deserving of the opportunity to provide informed consent, and they should be considered as collaborators in the investigation. *Beneficence* refers to the concept that the research will be done to improve the state of knowledge and that the risks assumed by the subjects in the study are not out of proportion to the potential benefits. This concept has particular relevance to failure to publish negative clinical trials; when a patient has consented to participate in an experiment, failure to use the information gained to advance the state of knowledge raises a concern. *Justice* refers to the concept that the benefits, risks, and inconvenience should be distributed fairly; because volunteering for a study implies a risk is taken to benefit others, efforts must be made to avoid subjecting some groups to risk so as to benefit other groups.

Medical Justification

Each of the proposed treatments in the trial must be within the realm of currently acceptable medical practice for the specific medical condition of the patient. Difficulties with consideration of medical justification typically arise in two areas: Studies are generally initiated because there is a reason to believe that one therapeutic approach is better than another, and many currently accepted therapies have never been subjected to the type of scrutiny being applied to new therapies. These factors create a dilemma for the practitioner, who may be uncomfortable with protocols asking for a change in standard practice. An approach to this dilemma, called the *uncertainty principle*, has been proposed. In this scheme, clinicians should be comfortable offering entry into a study at any time they are substantially uncertain about whether one of the treatments is better than the other. The patient, of course, is given the opportunity to review the situation and make a decision, but for most patients the physician's recommendation will be a critical factor in deciding whether to participate in a study.

An interesting twist on this theme occurs when a treatment has been shown to be effective but is not used as a routine part of practice because of cost. The ESPRIT trial proposed to evaluate a new dosing regimen of eptifibatide compared with placebo in patients undergoing percutaneous coronary intervention (44). Although abciximab had been shown to reduce serious events in this setting, the majority of patients in the United States were not being treated with it because of the cost. The FDA initially rejected the protocol on ethical grounds, but after considerable discussion, a controversial decision was made to proceed in centers not currently using abciximab routinely (45). Clinical equipoise based on assessment of cost effectiveness will increasingly become a critical issue.

Groups of Patients versus Individuals

The ethical balance typically depends on the good of large numbers of patients versus the good of individuals involved in the trial. Examples are accumulating in which a therapy appeared to be better based on preliminary results or small studies, and then was shown to be inferior based on adequately sized studies. These experiences have led some authorities to argue that clinical practice should not change until a highly statistically significant difference in outcome is demonstrated (46). Indeed, the standard for acceptance of a drug for labeling by the cardiorenal group at the FDA is two adequate and well-controlled trials, each independently reaching statistical significance. If the alpha for each trial is 0.05, an alpha value of 0.0025 (0.05×0.05) would be needed for both to be positive. The counterargument is that the physician advising the individual patient should let the patient know which treatment is most likely to lead to the best outcome. In fact, Bayesian calculations could be used to provide running estimates of the likelihood that one treatment is better than the other.

Informed Consent

The U.S. Department of Health and Human Services and the International Guidelines for Biomedical Research Involving Human Subjects provide standards for the process of informed consent. Elements common to informed consent have been defined and should pertain regardless of the exact nature of the investigation. The research project, including the names of the investigators, should be described to the patients. The procedures that will be involved, including follow-up information, should be described in enough detail that patients can envision what participation will entail. The potential risks and benefits of participation should be described, including a description of alternatives to participation in the study. Patients should be reassured that participation in the study is voluntary and that their confidentiality will be protected. Finally, they should be given the chance to ask questions.

An area of increasing confusion is the distinction between clinical investigation and measures undertaken to improve the quality of care as an administrative matter. The argument has been made that the former requires individual patient informed consent, whereas the latter falls under the purview of the process of medical care and does not require individual consent.

Several special situations must be considered in cardiovascular studies. In a cardiac emergency, there is often insufficient time to explain the research project in exact detail and obtain informed consent. When therapies for treatment of acute MI are compared, the time to administration of therapy is a critical determinant of outcome, and time spent considering participation in a protocol could increase the risk of death. Accordingly, an abbreviated consent to participate followed by a more detailed explanation later in the hospitalization has been sanctioned. An even more complex situation occurs in research concerning treatment of cardiac arrest. Clinical investigation in this field almost came to a halt because of the impossibility of obtaining informed consent. After considerable national debate, such research is now being done only after careful consideration by the community of providers and citizens about the potential merits of the proposed research.

Blinding

Blinding is essential in most explanatory trials, because the opportunity for bias is so substantial. In most pragmatic trials, blinding is also greatly preferred to reduce bias in the assessment of outcome. *Single-blinding* refers to blinding of the patient, but not the investigator, to the therapy being given. *Double-blinding* refers to blinding of both the patient and the investigator, whereas *triple-blinding* refers to a double-blinded study in which the committee monitoring the trial is also blinded to which group is receiving which treatment. Despite the rarity of deceit in clinical research, examples of incorrect results caused by bias in trials without blinding (47) and in trials with single-blinding reinforce the value of blinding (48).

When blinding would prevent a true test of a treatment strategy, other methods must be used to ensure objectivity. The clearest example is a trial of surgical versus medical therapy; in this situation, neither the patient nor the primary physician can be blinded. A similar situation exists when one therapy is given in a markedly different manner than another. In some cases a *double-dummy* technique (in which the comparative therapies each have a placebo) can be used, but often this approach leads to too much complexity. An example of the futility of blinding in some cases arose in the GUSTO-III trial, which evaluated emergency administration of thrombolytic therapies (16). The potential advantage of reteplase over alteplase depended on its administration as a bolus with no time delays, and administering a double-dummy therapy rapidly in an emergency situation proved to be an unreasonable expectation.

Given the large number of effective therapies in cardiovascular disease, an increasing problem will be the lack of availability of placebo. It is both complex and expensive to manufacture a placebo that cannot be distinguished from the active therapy and could not affect outcome. Often when a new therapy is compared with an old therapy, or two available therapies are compared, the manufacturer of the established therapy often will not cooperate because it has nothing to gain by participating in a comparative trial with a new therapy. Because a placebo needs to mimic the active therapy enough that the blind cannot be broken, the success of a placebo-controlled trial depends on the cooperation and participation of the manufacturers of both therapies.

Endpoint Adjudication

Most important end points in cardiovascular trials (other than death) require a judgment. When the study is blinded, the decision about whether an end point occurred usually does not require an independent review. However, in trials without treatment blinding, unbiased assessment of end points is essential. This point has been made vividly in trials of cardiovascular devices. In the initial CAVEAT trial comparing directional coronary atherectomy with balloon angioplasty, the majority of MIs during the follow-up period were not noted on the case report form, despite electrocardiographic and enzymatic evidence of these events (49). Even in a blinded trial, the end points of MI, recurrent ischemia, and new or recurrent heart failure are subjectively enough recorded that an independent judgment is thought to be helpful in most cases (50).

INTENSITY OF INTERVENTION

When a therapeutic intervention is tested, one must always consider whether its intensity is appropriate. This issue is quite obvious in the dosing of drugs. In three trials of direct thrombin inhibitors, a twofold error in the dosing of hirudin resulted in a significant increase in the risk of intracranial hemorrhage (51,52 and 53). Perhaps even more important, when the target range for the activated partial thromboplastin time (aPTT) was modestly increased for heparin therapy, the actual observed aPTT increased by only 8 seconds, but the intracranial hemorrhage rate increased to an unacceptable range. Correction of the dosages of hirudin and heparin brought clinical outcomes for both agents within the acceptable range (54,55).

This same issue also exists in behavioral or policy interventions. A trial using prognostic and normative information to assist in end-of-life decision making failed to change behavior, perhaps because the strength of the intervention was not adequate to truly affect the practitioners (56). The major strategic question is how to design appropriate explanatory studies to define the most likely effective strength of the intervention before embarking on a large pragmatic trial.

Surrogate End Points (Biomarkers)

In cardiovascular disease, because of the ready availability of biologic measurements reflecting disease severity or progression, small studies have used pathophysiologic constructs to determine the strength of the intervention for definitive evaluation. Unfortunately, this approach has led to a number of therapeutic misadventures (*e*Table 43.0.3). Antiarrhythmic drugs were developed based on their ability to reduce ventricular arrhythmias recorded on ambulatory monitoring. When the Cardiac Arrhythmia Suppression Trial was terminated prematurely because of a higher mortality with therapies that had been shown to reduce ventricular arrhythmias on monitoring, it became clear that ambulatory monitoring was an inappropriate surrogate marker (57). Similarly, studies developing dosing for therapies for heart failure have used improvement in cardiac output as a surrogate marker. A succession of inotropic (milrinone, ibopamine) and vasodilator (flosequinan, prostacyclin) compounds has been shown to improve hemodynamics in the short term, but the results of chronic therapeutic trials have been disastrous (58). Concern has been raised about blood pressure–lowering drugs; two compounds (diuretics and alpha-adrenergic blockers) that were almost equally effective in lowering the blood pressure had very different effects on mortality and other major clinical outcomes (59).

***e*TABLE 43.0.3** SPECULATION ON REASONS FOR FAILURE OF SURROGATE END POINTS

	End points		**Reason for failure**[a]			
Disease and intervention	**Surrogate**	**Clinical**	**A**	**B**	**C**	**D**
Cardiologic disorder						
Arrhythmia						
Encainide; flecainide	Ventricular arrhythmias	Survival		+		++
Quinidine; lidocaine	Atrial fibrillation	Survival		+		++
Congestive heart failure						
Milrinone; flosequinan	Cardiac output; ejection fraction	Survival		+		++
Elevated lipid levels						
Fibrates; hormones; diet; lovastatin	Cholesterol levels	Survival		+		++
Elevated blood pressure						
Calcium channel blockers	Blood pressure	Myocardial infarction; survival		+		++
Cancer						
Prevention						
Finasteride	Prostate biopsy	Symptoms; survival	++[b]			
Advanced disease						
Fluorouracil plus leucovorin	Tumor shrinkage	Survival		+		++
Other diseases						
HIV infection or AIDS						
Antiretroviral agents	CD4 levels; viral load	AIDS events; survival		+	+	+
Osteoporosis						
Sodium fluoride	Bone mineral density	Bone fractures	+			+
Chronic granulomatous disease						
Interferon-a	Bacterial killing; superoxide production	Serious infection				++

+, likely or plausible; ++, very likely; AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

[a]A, surrogate end point not in causal pathway of the disease process; B, of several causal pathways of the disease, the intervention only affects the pathway mediated through the surrogate; C, the surrogate is not in the pathway of the intervention's effect or is insensitive to its effect; D, the intervention has mechanisms of action that are independent of the disease process.

[b]In settings in which only latent disease is prevented.

Adapted from Fleming TR, DeMets DL. Surrogate endpoints in clinical trials: are we being misled? *Ann Intern Med* 1996;125:607.

Because of these lessons, it is no longer reasonable to accept a proposed surrogate end point unless it has met stringent criteria. For a biologic measure (called a *biomarker*) to truly stand in as a surrogate, it must not only be correlated with the true outcome of interest, but the change in the biomarker measure induced by the treatment must explain a high proportion of the treatment benefit. To be used prospectively, the biomarker must have been validated as a surrogate with more than one treatment.

These lessons about surrogate markers have important implications for clinicians treating cardiac patients. Titrating therapy to a physiologic end point may or may not be the correct approach to improving the outcome of the patient. In the administration of oral beta-blocking agents to patients with heart failure, hemodynamics commonly deteriorate before they improve. Thus, physiologic surrogates as therapeutic targets in individual patients should be validated in populations before they are accepted as standard practice.

CONFLICT OF INTEREST

The concept of an investigator completely free of bias is a theoretical ideal that is not achievable. The degree of bias or conflict of interest can be considered in a graded fashion. Investigators should not have a direct financial interest in an industry sponsor of a clinical trial. Paid consultancies are also considered to be beyond the scope of acceptable relationships with industry. Compensation for work done on a clinical research project should be reasonable for the work performed and should be handled through an explicit contract. Perhaps the most universal and common conflict in clinical investigation is the bias of the investigator because of belief in a particular concept. Blinding greatly reduces this risk, but the vast majority of clinical studies cannot be blinded. Failure to keep an open mind about the basic results of the investigation can cause the researcher to miss critical discoveries.

Several documents have explicitly laid out guidelines for governing conflict of interest (*e*Table 43.0.4). In addition, attention has been focused on the responsibility of those who write editorials to be free of any conflict of interest (60,61). Perhaps most importantly, the inventor/investigator/manufacturer is at special risk of serious conflict. The individual who has invented a new therapeutic approach and proposes to both manufacture the substance or device for early human studies and to conduct those studies must develop a highly proactive approach to safeguarding against conflict. Studies by Lo et al. and McCrary et al. have underscored the need to prohibit any equity holding by investigators involved in the conduct of clinical trials, as well as the fact that simple disclosure of equity interest to an institution is not sufficient protection for individuals engaged in human experiments (62,63).

SPECIAL ISSUES WITH DEVICE TRIALS

Trials of cardiovascular devices raise special issues that deserve careful consideration. In comparisons of devices with other devices or with medical therapy, the orientation of clinicians implanting the devices is often complicated by the fact that their technical skills are an integral component of the success or failure of the therapy. Therefore, failure of therapy can be interpreted as a failure of the physician as well as of the device. Obviously, in most device trials blinding is also impossible. For these reasons, particular focus on methodology is required in the assessment of clinical outcomes in device trials. Ideally, clinical outcomes should be assessed by a blinded review mechanism, and studies should be designed by groups including investigators who do not have a particular interest in the device-related outcomes but who have expertise in the disease-specific outcomes or clinical research methodology.

HYPOTHESIS FORMULATION

Primary Hypothesis

Every clinical study should have a primary hypothesis. The goal of the study design is to develop a hypothesis that allows the most important question from the viewpoint of the investigators to be answered without ambiguity. This issue is obvious in clinical trials, but in observational studies the appropriate approach to the problem is much less clear. Too often, the investigator is tempted to “dredge” the data; no method of tracking multiple analyses exists to develop considerations related to multiple hypothesis testing.

Secondary and Tertiary Hypotheses

The data collection form provides an information infrastructure for organizing questions to be answered by the trial. A number of secondary hypotheses will be of interest to investigators, including analyses of the relationship between patient characteristics and treatment effect.

In addition to answering questions about the therapy being evaluated, the study can address questions concerning other aspects of the diagnosis, treatment, or outcomes of the disease. Constructing pathophysiologic substudies embedded in larger clinical outcome studies has been especially rewarding. The GUSTO-I trial convincingly demonstrated the relationship between coronary perfusion, left ventricular function, and mortality in a systematic substudy (64).

Finally, many interesting issues about medical practice can be addressed through ancillary studies of clinical trials. Comparisons of outcomes in Canada and the United States (65,66) and regional variations in the United States (67) have provided insight into medical practice.

Intention to Treat

One of the most important concepts in the interpretation of clinical trials is that of intention to treat. Exclusion of patients who were randomized into a trial leads to bias that cannot be quantified; therefore, the results of the trial cannot be interpreted with confidence.

The purpose of randomization is to ensure the random distribution of any factors, both known and unknown, that might affect the outcomes of the patients randomly allocated to one treatment or the other. Any postrandomization deletion of patients weakens the assurance that the randomized groups are at equal risk before treatment. Nevertheless, there are several common situations in which it may be reasonable to drop patients from analysis.

In blinded trials, when patients are randomized but do not receive the treatment, it is reasonable to have a study plan that would drop these patients from the primary analysis. The plan can call for substitution of additional patients to fulfill the planned sample size. When this happens, extensive analyses must be done to ensure that there was no bias in determining who was not treated. In unblinded trials, dropping patients who do not receive the treatment is treacherous and should not be allowed. Similarly, withdrawing patients from analysis after treatment has started cannot be permitted in trials designed to determine whether a therapy should be used in practice, because the opportunity to “drop out without being counted” does not exist when a therapy is given in practice.

Publication Bias

Clinical trials with negative findings are much less likely to be published than those with positive results. Approximately 85% of reports in medical journals report positive results (68). In a sobering analysis, Simes found that a review of published literature showed combination chemotherapy for advanced ovarian cancer to be beneficial, whereas a review of published and unpublished trials together showed that the therapy had no significant effect (69). Dickerson and Min found substantial evidence of negative reporting bias in a review of clinical trial protocols submitted to Oxford University and Johns Hopkins University (33). In particular, industry-sponsored research with negative results was unlikely to be published.

Observational studies are probably even more subject to publication bias than randomized trials. Because of the planning and the need for informed consent with randomized trials, the clinical and ethical imperatives to publish the results are substantial. There is no way to estimate the number of observational analyses done. If an interesting result is found, it is likely to be published, whereas mundane results or results counter to the expectation of the investigator are much less likely to be published.

Awareness of this publication bias should lead to several actions by researchers and practitioners. First, researchers must strive to make clinical research results available to the scientific community through publication, regardless of whether those results are consistent with preconceived notions. Second, the reader must be cautious in interpreting studies showing positive results out of the context of independent confirmation; certainty that unpublished negative results from another investigation do not exist cannot be ensured in most cases. Finally, researchers working on systematic overviews are compelled to search through all means for both published and unpublished findings; because positive results are much more likely to be published, combining only published findings can lead to the wrong conclusion.

STATISTICAL CONSIDERATIONS

Type I Error and Multiple Comparisons

The hypothesis testing in a clinical study may be thought of as setting up a “straw man” that the effects of the two treatments being compared are identical. The goal of statistical testing is to determine whether this straw man hypothesis should be accepted or rejected based on probabilities. The type I error (alpha) is the probability of rejecting the null hypothesis when it is correct. Since clinicians have been trained in a simple, dichotomous mode of thinking, as if the *p* value was the only measure of

probability, the type I error is generally designated at an alpha level of .05. However, if the same question is asked repeatedly, or if multiple subgroups within a trial are evaluated, the likelihood of finding a *nominal p* value of less than .05 increases substantially (70). When evaluating the meaning of a *p* value, the clinician should be aware of the number of tests of significance performed and the importance placed on the *p* value by the investigator as a function of multiple comparisons.

Type II Error and Sample Size

The type II error (beta) is the probability of inappropriately accepting the null hypothesis (no difference in treatment effect) when a true difference in outcome exists. The power of a study (1 – beta) is the probability of rejecting the null hypothesis appropriately. This probability is critically dependent on two items: the difference in outcomes observed between the treatments and the number of primary end points. A common error in thinking about statistical power is to assume that the number of patients determines the power; rather, it is the number of end points that determines the power.

The precision with which the primary end point can be measured also affects the power of the study; end points that can be measured precisely require fewer patients. An example of this issue is the use of sestamibi-estimated myocardial infarct size. Measuring the area at risk before reperfusion and then measuring final infarct size can dramatically reduce the variance of the end point measure by providing an estimate of salvage rather than simply infarct size (71). As is often the case, however, the more precise measure is more difficult to obtain, leading to great difficulty with finding sites that can perform the study; in many cases, the time taken to complete the study is as important as the number of patients needed.

For studies using physiologic end points, using the continuous measure generally increases the power to detect a difference. In restenosis trials, the number of patients needed to detect a reduction in diameter stenosis below 50% is greater than the number of patients needed to detect a difference in the mean or median diameter stenosis or minimal luminal diameter.

A review of the *New England Journal of Medicine* in 1978 determined that 67 of 71 studies with negative results had made a significant (more than 10% chance of missing a 25% treatment effect) type II error, and that 50 of the 71 trials had more than a 10% chance of missing a 50% treatment effect (72). The situation has not improved enough since that time. The most common reasons for failing to complete studies with inadequate power include inadequate funding for the project and loss of enthusiasm by the investigators.

It is highly desirable to have a power of at least 80% when conducting a clinical trial; 90% power is preferable. Discarding a good idea or a good therapy because of a study that had little chance of detecting a true difference is obviously an unfortunate circumstance. An inadequately powered study not only has little chance of demonstrating a significant difference in favor of the better treatment, but also because of random variation with small samples, in which the direction of the observed treatment effect is highly unpredictable. There is an overwhelming tendency to assume that if the observed effect is in the wrong direction in a small study, the therapy is not promising, whereas if the observed effect is in the expected direction, but the *p* value is insignificant, the reason for the insignificant *p* value was a sample size that was too small.

Observational comparisons are at least as likely as randomized trials to include too few patients. Yet rarely do observational studies include power calculations. The same type of calculations commonly used in randomized trials can be used to place an observed effect with a *p* value greater than .05 in perspective. By discussing the minimal clinically important difference and providing the reader with an estimate of the probability of finding such a difference if it existed, the author of an observational study can place the study in much sharper perspective.

Equivalence and Noninferiority

The concept of equivalence will become increasingly important in today's cost-conscious environment. When an effective therapy already exists, the substitution of a less expensive (but clinically equivalent) therapy is attractive. By definition, the studies done to establish this ranking of effective therapies must be positive control studies, and substantial effort is required to define equivalence. Sample size estimates require the designation of a difference below which the therapies would be considered equivalent and above which one therapy would be considered superior to the other. Sample sizes are often larger than the requirements to demonstrate if one therapy is clearly superior to the other. Another important element of this issue occurs when a new therapy is thought to be only slightly better than current therapy but may have an advantage in terms of cost, ease of administration, or side effects. In this situation, trials are done to ensure the community that the new therapy is not inferior to the current standard. Sample sizes are lower with such noninferiority testing than either superiority or equivalence testing.

A common example of an issue that will increasingly arise concerns the substitution of a less expensive treatment for MI patients. Given the 10% underlying risk of death at 30 days with contemporary therapies, *e*Table 43.0.5 gives the sample sizes for ensuring that a new treatment does not increase the risk of death by 1%, 2%, or 3%.

***e*TABLE 43.0.5** EQUIVALENCE SAME SIZE ESTIMATES[a]

Old treatment no worse than	Number of patients
1% increase in mortality	32,582
2% increase in mortality	8,575
3% increase in mortality	3,998

[a]Standard treatment mortality estimated at 10%. A new, less expensive therapy is developed: How many patients will it take to prove "equivalence" (alpha = .05; beta = .10)?

Clinicians must beware of studies that are designed with a substantial type II error resulting from an inadequate number of end points and conclusions that the two treatments are equivalent because the *p* value is greater than .05. This approach could lead to a gradual loss of the current level of effectiveness of therapy for cardiovascular conditions. If we were willing to accept that a therapy for acute MI with a 1% higher mortality in an absolute sense was "equivalent," and we examined four new, less expensive therapies that met those criteria, we could cause a significant erosion of the decline that has occurred in acute MI mortality.

Several major cardiovascular trials have been based on the concept of equivalence. The Bypass Angioplasty Revascularization Investigation study was predicated on the hypothesis that percutaneous intervention would not increase the 5-year mortality beyond 2% (31). The International Joint Efficacy Comparison of Thrombolytics study examined the hypothesis that reteplase retained at least one-half the benefit of streptokinase in reducing mortality compared with conservative therapy, and the Assessment of the Safety and Efficacy of a New Thrombolytic 2 trial demonstrated that lanetoplase, given as a bolus, was equivalent to alteplase in terms of both mortality and intracranial hemorrhage (73,74).

Sample Size Calculations

The critical step in a sample size calculation, whether for a trial to determine a difference or to test for equivalence, is the estimate of the minimally important clinical difference. By reviewing the proposed therapy in comparison with currently available therapy, the investigators should endeavor to determine the smallest difference in the primary end point that would change clinical practice. Practical considerations may not allow a sample size large enough to evaluate the minimally important clinical difference, but the number should be known. In some cases, the disease may be too rare to enroll enough patients, whereas in other cases, the treatment may be too expensive or the sponsor may not have enough money. Once the minimally important clinical difference and the financial status of the trial are established, the sample size can be determined easily from a variety of published computer algorithms or tables. We have found it useful to produce plots or tables to enable the investigators to see the effects of small variations in event rates or treatment effects on the needed sample size. In the GUSTO-I trial, the sample size was set after a series of international meetings determined that saving an additional one life per 100 patients treated with a new thrombolytic regimen would be a clinically meaningful advance (15). With this knowledge and a range of possible underlying mortalities in the control group, a table was produced demonstrating that an absolute reduction of 1% (difference of one life per 100 treated) or a relative reduction of 15% could be detected with 90% certainty with inclusion of 10,000 patients per arm.

METAANALYSES AND SYSTEMATIC OVERVIEWS

Regardless of the goal of doing adequately sized clinical trials, clinicians are often faced with therapeutic dilemmas in which there is not enough evidence to be certain of the best treatment. The basic principle of combining medical data from multiple sources seems intuitively appealing, because this approach results in greater statistical power. However, the tradeoff is the assumption that the studies being combined are similar enough that the combined result will be valid. Inevitably, this assumption rests on expert opinion.

*e*Table 43.0.6 provides an approach to reading metaanalyses. The most common problems with metaanalyses are combining studies that have different designs or outcomes and failing to find negative studies that have not been published. There is no question about the critical importance of a full literature search, as well as involving experts in the field of interest to ensure that all relevant information is included. Statistical methods have been developed to help assess systematic publication bias (75). Another complex issue involves determining the quality of individual studies within a systematic overview. Statistical methods have been proposed

for differential weighting as a function of quality (76), but these have not been adopted on a wide scale.

***e*TABLE 43.0.6** HOW TO READ AND INTERPRET A METAANALYSIS
Are the results of the study valid?
Primary guides
Does the overview address a focused clinical question?
Are the criteria used to select articles for inclusion appropriate?
Secondary guides
Is it unlikely that important, relevant studies were missed?
Is the validity of the included studies appraised?
Are the assessments of studies reproducible?
Are the results similar from study to study?
What are the results?
What are the overall results of the review?
How precise are the results?
Will the results help me in caring for my patients?
Can the results be applied to my patient?
Are all clinically important outcomes considered?
Are the benefits worth the risks and costs?

The methodology of the statistical evaluation of pooled information has been a source of tremendous interest. The fixed effects model assumes that the trials being evaluated are homogeneous with regard to estimate of the outcome; given the uncertainties expressed previously, the assumption of homogeneity seems unlikely. Accordingly, a random effects model has been developed that considers not only the variation within trials, but also the random error between trials (77).

An interesting approach to metaanalyses, termed *cumulative metaanalysis*, has been developed. With this approach, as data become available from new trials, they are combined with findings of previous trials with the calculation of a cumulative test of significance. In theory, this approach should allow the medical community to determine the point at which the new therapy should be adopted into practice. Another variation on the theme of metaanalysis is metaregression, a method allowing the evaluation of covariate effects within multiple trials to explain heterogeneity in observed results.

The apparent lack of congruence between the results of metaanalyses of small trials and subsequent results of large trials has been a source of substantial confusion. Metaanalyses of small trials found that both magnesium therapy and nitrates provided a substantial (>25%) reduction in the mortality of patients with MI (78). The large ISIS-4 trial (79) found no significant effect of either treatment on mortality. Although many discussions have been posited for these discrepancies, a definitive explanation does not exist. The major message seems to be that large numbers of patients are needed to be certain of the effect of a therapy in cardiovascular disease. Guidelines for reading metaanalyses are given in eTable 43.0.6.

Systematic overviews followed by direct comparative trials have raised the question of determining when the effect of a treatment can be considered a class effect and when it should be attributed to a specific molecular entity. When a biologic target is identified, multiple ways of altering the biology of that target can be devised; almost certainly, different approaches to altering the target will share some common attributes but will differ with regard to others. Until relatively recently, the tendency has been to assume a class effect until proven otherwise. However, trials have demonstrated differences within the class of platelet inhibitors (80,81), while significant questions have been raised about cholesterol-lowering drugs (82), beta-blockers, low-molecular-weight heparins (83,84), and calcium channel blockers. Thus, lumping all members of a “class” into a systematic overview may ignore important differences within the class, and indirect comparisons of treatment effect within systematic overviews are treacherous.

UNDERSTANDING COVARIATES AND SUBGROUPS

Because of the insatiable curiosity of clinicians and patients about whether different responses to treatment may be seen in different types of patients, an analysis of trial results as a function of baseline characteristics is inevitable. Traditionally, this analysis has been performed using a subgroup analysis, in which the treatment effect is estimated as a function of baseline characteristics taken one at a time (e.g., age, sex, and weight). This approach has been called a *false-positive result machine*, but might just as well be referred to as a *false-negative result machine*. The false-positive results are generated because of the problem of multiple comparisons: By chance alone, a significant difference will be apparent in at least 1 in 20 subgroups, even if there is absolutely no treatment effect (70). In 1980, Lee et al. randomly split a population of 1,073 into two hypothetical treatment groups (the treatments were actually identical) and found a difference in survival in a subgroup of patients, with a p value of <.05.

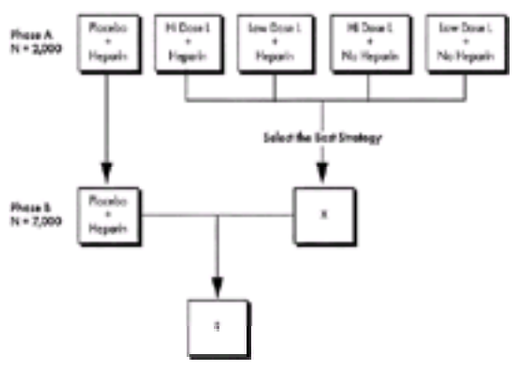
At the same time, given the large number of patients needed to demonstrate an important treatment effect, dividing the population into subgroups markedly reduces the power to detect differences when they are real. Consider a treatment that reduces mortality 15% in a population equally divided between men and women, with a p value for the treatment effect of .03. If the treatment effect is identical for men and women, the approximate p value will be .06 within each subgroup, since each group is half as large. It would obviously be foolish to conclude that the treatment was effective in the overall population, but not in men or women.

A more appropriate and conservative method would be to develop a statistical model predicting outcome with regard to the primary end point for the trial, then evaluate the effect of the treatment as an effect of each covariate after adjusting for the effects of the general prognostic model. This type of analysis, known as a treatment by *covariate interaction analysis*, assumes that the treatment effect is homogeneous in subgroups unless a definitive difference is observed.

An example of this approach occurred in the Prospective Randomized Amlodipine Survival Evaluation trial (23), which observed a reduction in mortality with amlodipine in patients with idiopathic dilated cardiomyopathy, but not in patients with ischemic cardiomyopathy. When an effort was made to validate the finding in the Prospective Randomized Amlodipine Survival Evaluation 2 trial, no mortality benefit was seen in patients with idiopathic dilated cardiomyopathy (25). In the Bypass Angioplasty Revascularization Investigation trial (31), a post hoc analysis showed a significant benefit of bypass surgery in patients with treated diabetes, but not in other patients. The test for interaction has been said to have limited power so that a borderline significant result should attract clinical interest, although there is inadequate experience with this test to be comfortable about interpretation.

PICK THE WINNER

There is no other effective way to develop therapies than measuring intermediate physiologic end points in the early phases of study. Based on favorable physiologic responses, some therapies are brought forward for more extensive studies and others are dropped. However, other approaches to winnowing the possible doses or intensities of therapy must be developed, because these physiologic end points are unreliable. One such approach is termed *pick the winner*. In this design (eFig. 43.0.4), several doses or intensities of the therapy are devised, and at regular intervals during the trial an independent Data and Safety Monitoring Committee evaluates clinical outcomes with the goal of dropping arms of the study according to prespecified criteria.



***e*FIGURE 43.0.4** “Pick the winner” strategy.

THERAPEUTIC TRUISMS

A review of clinical trials points out that many commonly held beliefs about clinical practice need to be challenged. If these assumptions are shown to be less solid than previously believed, a substantial change in the pace of clinical investigation will be needed.

Frequently, medical trainees have been taught that variations in practice patterns are inconsequential. The common observation that different practitioners treat the same problem in different ways has been tolerated because of the general belief that these differences did not matter. Clinical trials have demonstrated, however, that small changes in practice patterns for epidemic diseases can have a sizable impact. An example is the extreme variation in recommendations regarding the preferred aPTT for patients treated with unfractionated heparin. Based on the pathophysiologic surrogate of arterial patency (85,86), the GUSTO investigators adjusted the recommended aPTT upward in the transition from GUSTO-I to GUSTO-IIa. The average 8-second increase in aPTT resulted in a doubling of the rate of intracranial hemorrhage in patients treated with thrombolytic therapy and heparin (51). When the heparin dose was reduced in GUSTO-IIb, the intracranial hemorrhage rate reproduced that observed in GUSTO-I (54).

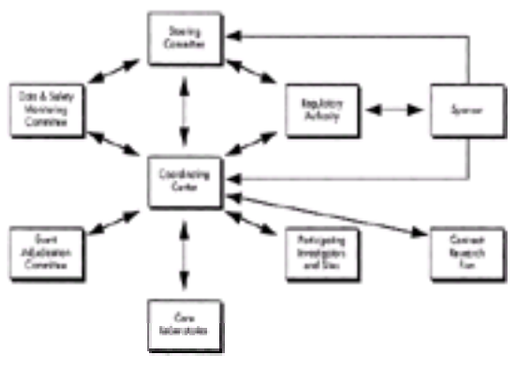
Another ingrained belief of medical training is that observation of the patient provides evidence for changing treatment. Although no one would dispute the importance of following symptoms, many acute therapies have effects that cannot be judged in a short time, and many therapies for chronic illness prevent adverse outcomes in patients with few symptoms. For example, in treating acute congestive heart failure, inotropic agents improve cardiac output early after initiation of therapy but lead to a higher risk of death. Beta-blockers cause symptomatic deterioration acutely but appear to improve long-term outcome.

Similarly, the standard method of determining the dose of a drug has been to measure physiologic end points. In a sense, this technique represents a surrogate end point approach. No field has more impressively demonstrated the futility of this approach than the treatment of heart failure. A variety of vasodilator and inotropic therapies have been shown to improve hemodynamics in the acute phase but subsequently were shown to increase mortality.

Finally, the maxim “do no harm” has been a fundamental tenet of medical practice. However, most biologically potent therapies cause harm in some patients while helping others. The emphasis on the neurologic complications of bypass surgery (87,88) amply demonstrates that a therapy that saves lives can also lead to complications in individuals. Intracranial hemorrhage resulting from thrombolytic therapy exemplifies a therapy that is beneficial for populations but has devastating effects on some individuals. The patients who are harmed can be detected easily, but those whose lives are saved cannot be detected.

STUDY ORGANIZATION

Whether the investigator is contemplating a large or small trial, the general principles of organization of the study should be the same (eFig. 43.0.5). A balance of interest and power must be created to ensure that after the trial is designed, the experiment can be performed without bias and the interpretation will be generalizable.



***e*FIGURE 43.0.5** General principles of study organization.

Steering Committee

In a large trial, the steering committee is a critical component of the study organization. This group designs, executes, and disseminates the study. A diverse steering committee, providing multiple points of view representing biology, biostatistics, and clinical medicine, will more likely organize a trial that will withstand external scrutiny. This same principle holds for small trials; an individual investigator, by organizing a committee of peers, can avoid egocentric thinking about a clinical trial.

Data and Safety Monitoring Committee

The Data and Safety Monitoring Committee (DSMC) is constructed to oversee the safety of the trial from the point of view of the patients being enrolled. The DSMC should include clinical experts, biostatisticians, and sometimes medical ethicists; these individuals should have no financial interest, emotional attachment, or other investment in the therapies being studied. Committee members have access to otherwise confidential data during the course of the trial, allowing decisions to be made in a way that could compromise the objectivity of those conducting the study. Similarly, in a small trial, a smaller group of external reviewers keeping watch over the study can be helpful.

Not only should the DSMC be appointed before the initiation of a clinical trial, but its charter should be agreed on by the sponsor, the steering committee, and the DSMC itself (89,90,91,92,93,94,95 and 96).

Institutional Review Board

The institutional review board (IRB) continues to play a critical role in the conduct of all types of clinical research. Approval by the IRB is generally required for any type of research, even if it is not funded by an external source. The IRB should consist of physicians with expertise in clinical trials, as well as representatives with expertise in medical ethics and representatives of society in the community in which the research is being conducted. Several types of studies are typically exempted from the IRB process, including studies of public behavior, research on educational practices, and studies of existing data in which the research data cannot be linked to individual subjects. Surveys and interviews also may be exempted when the subjects are not identified and the data have a low likelihood of leading to a lawsuit, financial loss, or reduced employability of the subject. Attention has been focused on the need for systematic review of research by IRBs rather than the creation of large amounts of unnecessary paperwork (97).

Major concern has been raised about the level at which IRBs function. A major government report claimed that IRBs do not have the resources or expertise needed to protect human subjects; substantial IRB reform is under way.

Regulatory Authorities

Government regulatory authorities have played a major role in the conduct of clinical research. Requirements by the FDA and other national health authorities define the way industry-sponsored clinical trials are conducted. In general, regulatory requirements include interpretation of fundamental guidelines to ensure adherence to human rights and ethical standards. The FDA and equivalent international authorities are charged with ensuring that drugs and devices that are marketed are safe and effective (a charge with broad leeway for interpretation). Importantly, in the United States, there is no mandate to assess comparative effectiveness or cost effectiveness.

Industry or Government Sponsors

Having provided funding for the study, the sponsor of a clinical trial understandably wishes to be heavily involved in the conduct of the study. Worldwide, the majority of clinical investigation is now done either directly by the pharmaceutical or medical device industry, or indirectly by for-profit clinical research organizations. This approach seems reasonable and desirable for explanatory trials, but pragmatic trials, if not performed by an independent steering committee, run a greater risk of bias, as the sponsor of a study has a large financial stake in the success of the therapy being tested. Even in the case of government sponsorship, trials frequently arise out

of political agendas, with much to be gained or lost for individuals within the scientific community depending on the result.

INTEGRATION INTO CARDIOVASCULAR PRACTICE

Because the goal of clinical investigation is to improve the care of patients, findings of a clinical investigation must be integrated into practice carefully. The old method of each practitioner reading the literature and making individual decisions is inadequate. Recognition of this deficit has led to a variety of efforts to synthesize empirical information into practice guidelines. These guidelines may be considered as different paths to the top of the mountain, with several routes acceptable as long as the difficulty and likelihood of success are known. In addition, large efforts such as the Cochrane Collaboration (98) are attempting to make available systematic overviews of clinical trials in most major therapeutic areas.

A series of reports has demonstrated that adhering to clinical practice guidelines results in better patient outcome (99,100). In the United States, a system has been developed in which professional societies develop the guidelines, and the government provides support for evidence-based practice centers, which provide empirical overviews of the risks and benefits of diagnostic or therapeutic approaches.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Governmental Regulation

Over the past decade, as the U.S. health care system has evolved into a business model, controversy has arisen over the role of government regulation in clinical research. Regulation comes in two forms: regulatory authorities charged with ensuring the safety and efficacy of products sold for medical purposes, and ethical regulation of investigation done for the public good. Although the usual business approach is to assume that the marketplace will sort out beneficial therapies from those that do not work, history belies this belief in terms of medical therapies. Determining medical benefit is complex, and simple observation is inadequate; without requirements for controlled trials, many detrimental therapies in cardiology would likely still be in use. The initial formation of the FDA occurred because of the sale of pharmaceutical products that were lethally contaminated, and every new regulation has resulted from a similar tragedy. The mandate of the FDA extends only to the point of determining that a therapy is safe and effective compared with *no* therapy, however, and does not include the determination of which therapies are more effective when two effective therapies are available. Additionally, the mandate with regard to pharmaceuticals is more stringent with a general requirement for substantial evidence of clinical benefit from randomized, controlled trials, whereas device regulations allow less definitive evidence of clinical benefit. Once a product is on the market, the FDA rigorously controls the advertising and promotion that can be done with that product, but the FDA can deal only with errors of commission rather than errors of omission. Thus, a therapy that lowers blood pressure and has been shown in adequate controlled trials to lower mortality and stroke rates can advertise that benefit. A comparative therapy that lowers blood pressure but never has been shown to reduce mortality and stroke can be advertised as being effective in lowering blood pressure without mentioning the absence of clinical outcome trials.

We believe that the onus is on the medical profession to ensure that adequate clinical trials are done to demonstrate which therapies are most effective. The industry that develops new therapies is obligated only to meet the regulations for being marketed. Managed care organizations are focused on cost rather than outcome; in many cases, incentives exist to impede new therapies from clinical use when they increase expense. Only with the active involvement of health care providers will the needed studies be done to allow the best information to be available to make choices among active therapies.

Composite and Surrogate End Points

The number of important clinical questions far exceeds our ability to address them. For this reason, there is a great temptation to perform clinical trials using composite and surrogate end points. Composite end points have the advantage of creating an outcome scale that allows for categorical or continuous measures that add power to the study. However, the problem arises that less important end points can drive the difference, when small differences in a more important end point (such as mortality) could not possibly be detected. Similarly, surrogate end points are hampered by constant uncertainty about whether the surrogate will work, particularly because the difference between therapies might relate to an outcome dictated by an unexpected effect of the therapy. For these reasons, surrogates and composites should be regarded as intermediate approaches to determining which therapies need to be tested definitively. One exception is when a minor modification is made to a drug or device, and a consensus exists that the modification will not fundamentally alter the effect of the treatment. Practitioners and investigators need to eschew the temptation to substitute surrogates for adequate measures of health outcomes in large enough populations. Instead, the clinical community should focus on more efficient methods of aggregating large amounts of information at a lower cost.

Randomized Trials versus Observational Studies

Randomized trials and observational studies represent different approaches to answering questions. Traditionally, the randomized trial has been hampered by two factors: enrollment of selected patients perhaps not representing clinical practice and concern about human experimentation. It is simply a fact that given the current organization of medicine, the number of therapeutic questions will far exceed the number of randomized trials that can be performed. Having been involved in numerous randomized trials and observational treatment comparisons, it is our belief that much more effort is needed to expand the ability to perform randomized trials. Until the technology revolution allowing the rapid accumulation of information from multiple sites and the introduction of the large, simple trial methodology, it seemed that observational studies were needed to fill in the huge gaps in clinical therapeutics (101). With current capabilities, the major role of observational studies should be to generate hypotheses, fill in information about small variations in practice, and deal with the extrapolations necessary to inform decisions about chronic disease management. Another important use of observational databases is to provide audit and feedback to practitioners about whether they are adhering to guidelines for practice. Given the fact that most patients live for years with cardiovascular disease, the long-term implications of therapies such as choice of prosthetic valve, choice of revascularization method in stable angina, and risk factor modification require extrapolations beyond the time frame that can reasonably be measured. The technology half-life is now so short that long-term randomized trials have the risk of being historical artifacts.

Sharing of Information

Given the for-profit nature of the medical products and pharmaceutical industry and the increasingly financial orientation of the health care delivery system, a risk exists that important medical information will not be available. The financial incentive in the medical products industry has stimulated tremendous creativity and should be preserved. A potential conflict exists, however, between the professional ethic of the health care provider to share information to improve the delivery of health care in broader terms, and the need of financially driven delivery systems to maintain a competitive edge. This potential conflict ironically arises at a time when the ability to rapidly share data and their interpretation has improved in an exponential fashion. Patients expect that when medical research is done, the information will be shared; one could argue that information sharing to advance health in general is a critical part of the ethical contract between provider and patient when informed consent is obtained.

THE FUTURE

Because of the continuing explosion of knowledge about the biology of heart disease and society's inability to increase the financial outlay for the unfettered use of biology and technology, the future of clinical investigation is bright. Without quantitative information, there is no rational method to make decisions about what will be supported in medical practice and what will be discarded.

Over the next several years, cardiovascular practitioners will be increasingly using computerized databases to capture information at the point of care. Early efforts in this area, focusing on procedure reports to meet mandates from payers and quality reviewers, will be replaced by systems aimed at capturing information about the entire course of the patient's encounter with heart disease. Although the impetus for this approach will come from those who pay for health care, practitioners will find the information to be useful for justifying rational medical care and improving the overall efficiency with which it is delivered. Multimedia presentations will allow the clinician to view medical records and imaging studies simultaneously in the clinic or in the hospital. To efficiently exchange information, the nomenclature of cardiovascular diagnosis, treatments, and outcomes will progressively become standardized.

The computerized management of information will be part of an inevitable coalescence of practitioners into integrated health systems. To efficiently care for populations of patients at a reasonable cost, practitioners will work in large, geographically linked, and economically interdependent groups. This integration of health systems will propel outcomes research into a new era in which strategies of care can be tested over time and refined in continuous learning processes for health care providers.

Although integrated health care systems will provide the structure for medical practice, global communications will provide mechanisms to quickly answer questions about the diagnosis, treatment, and prognosis of heart disease. The ability to aggregate information about thousands of patients in multiple health systems will change the critical issues facing clinical researchers. Increasingly, attention will be diverted from efforts to obtain data, and much effort will be required to develop efficient means of analyzing and interpreting the types of information that will be available.

Ultimately, leading practitioners will band together in global networks oriented toward treating illnesses of common interest. When a specific question is identified requiring randomization, the studies will be much simpler because the randomization can simply be added to the computerized database, and information that currently requires construction of a clinical trials database will be immediately accessible without additional work. Information systems will be designed to provide continuous feedback of information to clinicians, supporting rational decisions about therapy. In essence, a continuous series of observational studies will be in progress, managed by a community of practitioners linked via the Internet, assessing outcomes as a function of diagnostic processes and therapeutic strategies.

OVERVIEW

A clinical database is a systematic collection of observations related to patients and/or clinical processes. With the advent of relatively inexpensive and sophisticated computer technology, databases can be used for information retrieval, case finding, description of cohorts, and predictive modeling of outcomes and risks. Databases are increasingly being used for a process known as *outcomes management*, or technology of experience. According to outcomes management, predefined standards and coding systems are used to describe systematically all patients and outcomes encountered. Large databases are then used to identify variances in outcome that may be related to processes in patient care. Although this process is potentially very powerful for identifying and improving deficiencies in patient care, it suffers from a number of inherent methodologic difficulties.

Databases in cardiology have been developed and described in five major settings: (a) population-based studies, such as the Framingham Heart Study, which are used to describe risk factors for and the natural history of cardiovascular disease in the community; (b) disease-oriented registries, which describe care processes for and outcomes of patients with specific problems, such as acute myocardial infarction; (c) procedure- or technology-oriented registries; (d) government-mandated and administrational databases; and (e) registries derived from randomized clinical trials. Newer database technologies, including the development of object-oriented databases, along with the computerized medical record, represent means by which clinical database methods can be incorporated into routine clinical care.

GLOSSARY

American Standard Code for Information Interchange (ASCII): A code representing English characters and numbers with each letter assigned a number from 0 to 127 (7-bit ASCII) or 0 to 255 (8-bit ASCII) that is independent of machine (computer) and operating systems. A more universal standard is ISO Latin-1, used on the World Wide Web.

Attributional validity: Whether an apparent association between a variable and an outcome reflects reality as opposed to confounding by an unknown or unconsidered covariate.

Case-control study: A study design in which patients with and without a certain outcome are identified and then compared with respect to an exposure variable of interest.

Case-mix adjustment: Identifying and controlling for patient-specific factors over which physicians and health care institutions have no control and that may explain variances in outcome.

Categorical variable: A variable that can have only a finite set of values.

Clinical model concept: A model whereby outcomes are related to patients factors, physician plan factors, and hospital execution factors.

Coding system: A system for describing outcomes, clinical findings, and therapies according to a standardized format (e.g., Current Procedural Terminology; International Classification of Diseases, Ninth Revision, Clinical Modification; Systemized Nomenclature of Medicine).

Cohort study: A study design in which a population cohort is prospectively defined and divided according to the presence or absence of an exposure variable of interest and then followed over time for the occurrence of prespecified outcomes.

Colinearity: Spurious associations or lack of associations in a multivariable model due to excessive correlation of covariates with one another.

Computerized patient record: A type of clinical database in which an electronic medium is used to capture, process, analyze, and retrieve values for variables representing the entire clinical process.

Content validity: Appropriate and complete selection of covariates in a predictive model.

Continuous variable: A variable that can have an infinite set of values.

Cox proportional hazards model: A multivariable model that relates the log of the unspecified hazard function ratio between groups of patients to a linear equation.

Data dictionary: A set of uniform definitions for data elements.

Data element: A specific piece of organized information about a person or event.

Database design: A model according to which data elements are linked logically to one another.

Database management system: A set of computer programs that manage access to, modification of, and analyses of a database.

Database standards: Agreed-on methods for defining terms and interfaces, thus allowing cross-communication between databases.

Extensible Markup Language (XML): A formal, concise, human-legible machine (computer)- and operating system–independent language that describes both data entities (objects) and the behavior of computer programs (XML Processor) to understand and present them. This is achieved through markup, which encodes (tags) a description of the entity's storage layout and logical structure.

External Data Representation (XDR): A standard for describing and encoding data in a fashion that is machine (computer)- and operating system–independent. It uses a language to describe data formats (structure) and has been particularly useful in exchange of so-called binary data (data, such as real numbers, that are not human-readable).

Face validity: The clinical sense of a prediction model—that is, the model makes sense given current understanding.

Field: A placeholder for a specific value regarding a person or event; synonymous with *variable*.

Flatfile: A single data table that contains columns representing variables and rows representing bases of observations, for example, individuals. The table has no structural information about the data values themselves.

Hazard function: The instantaneous risk of a time-related event.

Hierarchical database: A database model based on a nested root-subordinate segment structure.

Interaction: Also known as *effect modification* or *modulation*; a situation in which the strength of association between one variable and an outcome is affected by another variable; to be distinguished from confounding, in which an association between a variable and an outcome is only a reflection of the association between another variable with the index variable and with outcome.

Internet: A complex system of worldwide interacting computer networks.

Logistic regression model: A multivariable prediction model in which the log of the odds of a time-fixed outcome event is related to a linear equation.

Metadata: Data about data—that is, information describing other data. Metadata in one context may be data in another, in effect metadata describing metadata. In a database context, metadata is usually considered the structural information associated with both data and the database organization.

Object-oriented database: A database model in which complex data structures (objects) are used that consist of both values for variables and instructions for operations to be performed on the data.

Outcomes management: A process by which clinical processes and outcomes are recorded systematically in large databases and then analyzed to detect variances in outcome that can be improved by altering those processes.

Overfitting: Using too many covariates for the number of outcome events in a multivariable predictive model; can lead to spurious or incorrect associations.

Predictive modeling: A process by which a clinical database is used to describe mathematically the likelihood of outcome events, given a set of values for variables of a new patient.

Predictive validity: How well a multivariable predictive model predicts outcome in a database separate from the one from which the model was derived.

Relational database: A database model that consists of multiple cross-referenced tables that can be linked together by set(s) of user-defined "linking variables" and queried using Structured Query Language.

Reliability: Reproducibility or stability of data measures.

Semistructured data: Complex data elements whose contextual structures are embedded along with the values for variables, rather than being dependent on an external data structure. As such, the data elements are simultaneously independent self-defining entities and self-organizing given a specific query.

Spreadsheet: A table of values arranged in rows and columns in which values at row-column intersections (called *cells*) can have predefined relationships with other cells. Data structure accompanies the spreadsheet.

Time-oriented database: A database model in which time is the organizing theme to facilitate temporal reasoning based on temporal attributes (duration) and temporal relations to other data (temporal order).

Validity: How well a data element or predictive model reflects what is really supposed to be measured or predicted.

World Wide Web: A technology by which access to the Internet is made easy by use of graphical hypertext-linked interfaces.

INTRODUCTION

In the late 1940s and early 1950s, epidemiologists from the U.S. Public Health Service and academic cardiologists and internists in the Boston area collaborated to develop a population-based database of cardiovascular disease in Framingham, Mass. (1,2). The early development of the Framingham Heart Study database was fraught with difficulties (3): Methods of population sampling were not well developed, the natural history of coronary artery disease (CAD) was poorly understood, the clinical manifestations of CAD were known to only partially reflect pathologic events, the modern "computer era" had not yet begun, and modern biostatistical science was in its infancy. Nonetheless, the investigators successfully assembled a cohort of more than 5,000 adults who have now been systematically followed for nearly 50 years (1); later in the 1970s, a new cohort based on the offspring and spouses of offspring of the original cohort was assembled and continues to be followed (4). Numerous analyses of the characteristics and outcomes of the participants in the Framingham Heart and Offspring studies have yielded invaluable insights into the risk factors, pathogenesis, and natural history of cardiovascular disease (5); the Framingham and other population-based databases continue to be fruitful sources for cardiovascular investigators today (6,7,8,9,10,11,12,13 and 14).

The Framingham Heart Study is illustrative of many of the attributes of a successful database (15). The database was assembled and continues to be maintained by a large, multidisciplinary team with involvement of clinicians, classic epidemiologists, computer engineers, and biostatisticians; they have been able to depend on adequate and stable funding. The goals of the database were well-defined, leading to high-quality, focused data collection. Efforts have been consistently made to keep

the database relevant, with appropriate addition, alteration, and deletion of data fields as new technologies and understanding of disease processes change the questions that investigators wish to answer. Finally, and perhaps most important, dynamic and strong leaders have championed the development, implementation, use, and analyses of the database as well as publicly advocated its benefits.

With the advent of the computer, large databases became possible in clinical environments as well. Early examples of clinical databases included the Duke Databank for Cardiovascular Disease (16), which was established in 1969, and the Coronary Artery Surgery Study database (17). Today, clinical databases have expanded into multiple areas of practice and investigation, presenting tremendous opportunities for improving knowledge about and care of patients with cardiovascular disease but also frustrating developers and users with numerous technical and inherent design problems.

This chapter reviews population-based and clinical databases, with particular attention to their applications in cardiology. The use of these databases for clinical investigation, quality assessment, and outcomes analyses are explored.

WHAT IS A DATABASE? DATABASE TECHNOLOGY, TERMS, AND DEFINITIONS

A clinical database is a systematic collection of facts about individual patients or clinical events (Table 44.1). Facts about a person or event might include, for example, last name, patient identifier, birth date, heart rate at the time of admission, or medications used.

Concept	Description	Types
Fields (variables)	Factor information about a particular subject or patient; resumes data definitions (metadata)	Discrete (categorical) Dichotomous (yes/no) Ordinal (e.g., New York Heart Association functional class) Polytomous (lists) Continuous
Management system	Computer programs that manage access to and use of databases	Multiple services required: Data sharing Consistency, error checks Security Protection and backup Timeliness Standards for entry Query engine Temporal attributes Extensibility
Design	Model by which variables are logically linked to one another	Flatfile Spreadsheet Relational Object-oriented Time-oriented Semistructured
Focus	Orientation of developers and questions of interest	Disease Population Procedure/therapy/device Computerized patient record Values for variables of all health care-related data

TABLE 44.1 BASIC CONCEPTS OF DATABASE CONSTRUCTION

Computer-based databases divide these facts into (a) what the fact is, which can be termed a *variable* or in specific contexts a *field* or *column name*; (b) the specific *value* for the variable for an individual patient; and (c) *structural* information, including the name of the data element, unique identifier for the data element, version, authorization information, language, definition, obligation (whether the data element is required or not), data type (e.g., numerical or character), limits (e.g., age cannot be less than 0 or more than 120), author (who or what obtained and recorded the information), time stamp, temporal attributes, and many other attributes of the variable and value. All these properties of a clinical fact constitute a data element either implicitly in most traditional databases or explicitly in semistructured data.

A collection of data elements that relate to one specific person or clinical event constitutes a *patient record*. Thus, a clinical database can be thought of as a potentially limitless collection of patient records consisting of data elements. In the simplest database designs, the patient record may constitute a single row in a table, with one or more columns of variables containing data for that patient.

Focuses of Clinical Databases

Clinical databases can have one of two primary focus types: (a) disease- or population-oriented or (b) procedure-, therapy-, or device-specific (15). Both of these types of databases are used in cardiology. The Framingham Heart Study, the Nurses' Health Study (18), the Cardiovascular Health Study (19), and a hospital-based computerized patient record are examples of population-oriented databases. The Duke Databank for Cardiovascular Disease (16) is a disease-oriented database that is focused primarily on CAD. The National Heart, Lung, and Blood Institute angioplasty registry (20) and the Cardiac Transplant Research Database (21) are examples of procedure-oriented databases.

Types of Database Elements

Possible values for clinical database variables can be either *categorical* or *continuous*. Categorical variables may be limited to only two possible values and thus be *dichotomous*; examples include yes or no, 0 or 1, male or female, and presence or absence of chronic heart failure. Alternatively, categorical variables may be *ordinal*—that is, have a limited list of possible values that bear an ordered relation to one another; examples include the Canadian angina class, the New York Heart Association functional class, severity of mitral valve regurgitation, and pain scales. These types of measures have been termed by Feinstein as *clinimetrics* (22). Finally, categorical variables may be *polytomous*—that is, have an unordered but finite list of possible values, such as etiology of subacute bacterial endocarditis or names of bones in the body.

Continuous variables have a theoretically infinite number of possible values. Examples of continuous elements are age, blood pressure at admission, peak creatine kinase level after an index myocardial infarction, or number of hours between symptom onset and performance of emergent primary percutaneous coronary intervention.

Data Dictionaries and Metadata

If data are to be understood, valid, and reliable, it is essential that all data elements be defined precisely. A common means of handling this is to create a separate computer file that contains the list of all files in the database, a list of all variables, definitions and data type of each variable, and lists along with definitions of all possible values with each variable. Such a file is known as a *data dictionary* (23). Certainly, simple-to-follow yet precise definitions allow for high-quality entry of data by multiple personnel and guard against unneeded redundancies (24).

With the advent of worldwide exchange of information, attention has focused on data definition and formatting *that are independent of specific machine types and operating systems* and using internationally agreed-on standards. Data definitions are now more fully expressed in terms of *metadata*. Metadata are data about data that contain all structural attributes of the data and database. Until recently, metadata have been exploited mainly in presenting a single user image of multiple, disparate databases, possibly in multiple locations, as if they were one. More recently, it has been suggested that all input and output of data could, in theory, be managed through a metadata "layer." The metadata may be separated from the data to form part of the structure of the database, in which case, data elements are simple, consisting of just the value, or they may be directly associated with each data element, in which case data elements may be complex.

Structure and Content of Clinical Databases

Determination of the size, structure, and content of clinical databases has been a major source of frustration, in part because no standards for these existed before the modern computer age. Dolin points out that any database that is to be used for assessment of outcomes must contain information in three key areas: input, intervention, and outcome (25). Input data include demographics, family history, reproductive history, social history, types of episodes and encounters (e.g., ambulatory, emergency, critical care), signs and symptoms, diagnoses, and test results. Intervention data include information on medications, immunizations, operations, procedures, functional assessment, and socioeconomic assessment. Outcomes data include death, disability, discomfort, drug toxicity, and dollar costs; the last includes service costs, hospital days, and days of missed work. Some validated data already exist for assessing outcomes in specific situations; an example would be the Acute Physiology, Age, Chronic Health Evaluation III for analyses of outcomes in noncoronary critical care units (26).

Ellwood describes certain rules that should be followed if a large clinical database is to remain robust over time (27). The goals of assembling the database have to be prospectively determined to define appropriate data elements. The size of the database must be carefully considered; large databases contain more information, but excessively large numbers of data elements can lead to significant deterioration of data quality. Although data may be collected in many geographic locales, a

mechanism for centralizing data is essential. Finally, the ideal clinical database is not confined to hospital events.

Database Standards

For clinical data obtained outside the confines of a clinical trial or registry to be considered reliable for analyses, it is absolutely essential for standards to be developed to allow for data fields to be validly compared between different databases and to allow data to be transferred between systems. As stated by McDonald and Hammond (28), “standards let us mix and match components, create large assemblies from many parts, and communicate efficiently.”

Coding Systems

Coding systems for clinical databases can be divided into clinical classifications and nomenclatures (29,30). A clinical classification system is designed to group patients for specific reasons, such as analyzing clinical or financial outcomes, whereas a nomenclature system seeks to specifically represent clinical findings, therapies, and outcomes in an accepted, standardized format. In reality, there is considerable overlap between classification and nomenclature coding systems. Examples of currently popular coding systems include the *International Classification of Diseases, Ninth Revision, Clinical Modification* of the U.S. Government Printing Office (31), *International Classification of Diseases, Tenth Revision* of the World Health Organization (32), Systemized Nomenclature of Medicine of the College of American Pathologists (33), Unified Medical Language System of the National Library of Medicine (34), Current Procedural Terminology of the American Medical Association (35), and the North American Nursing Diagnosis Association (36).

Data Exchange

Exchange of data in a universal format according to internationally agreed upon standards is much more important now than in the past. Older standards included the ASCII English character set. This has been replaced for the World Wide Web by a more universal standard (ISO-8859-1 Latin-1) that represents non-English characters. For exchange of data that cannot be represented by characters or real numbers, an external data representation standard (XDR) has been introduced. XDR is a language that describes both data structure (metadata) and the data themselves. In the domain of clinical medicine, universal standards have been developed such as Health Level 7 (HL7) that define complex data elements, including not only values for laboratory tests, but also extensive process information. As of this writing, however, the standard that is ermeating the world most rapidly, because of its tie to the World Wide Web, is XML, which was initially envisioned as a universal language for documents but later became recognized as a medium of data exchange. Thus, the new HL7 (version 3.0) will be cast into an XML format. As a result of the U.S. Food and Drug Administration Modernization Act of November 1997, more than 5,000 clinical research trials have been represented in a publicly accessible system (see http://www.clinicaltrials.gov/), with data being provided primarily by National Institutes of Health in XML format.

Database Management Systems

For databases to be useful, they have to be accompanied by a database management system (37), which is a set of computerized programs or algorithms that manage access to the database (38); a user interface by which data entry and retrieval efforts occur; an “analysis module” by which specific patterns for data fields are sought or rejected; and a query engine such as Structured Query Language, which enables users to retrieve, modify, and analyze subsets of data with the aid of standard statistical programs. The ways in which these elements of databases are organized characterize their technical and data architecture.

Kahn (24) outlined seven essential services provided by database management and related systems: (a) data sharing, by which multiple users can have simultaneous access to data over a computer network; (b) data consistency, ensured by error checking and calculated constraints (e.g., no person can have an age of more than 100 or 120 without verification from the user); (c) data security with authorization controls; (d) data protection with backup and retrieval functions in case of software or hardware catastrophes; (e) data timeliness, by which data become immediately available to all those who have access privileges; (f) data standards with data definitions for database entry; and (g) as mentioned above, data use with programs for producing queries, retrievals, and reports.

For clinical data, several additional specialized services are important. Because clinical data and events are nearly universally time-related, use of a query language that recognizes temporal attributes is critical (39). Examples include queries as to how many myocardial infarctions a patient may have had, when the first or last one occurred, and the duration of hospitalization for each; temporal changes in blood pressure; or the severity of the most recent episode of rejection in a heart transplant patient.

Another service of growing importance is database extensibility. Adding new facts—variables—to most existing databases requires change in the structure of the database itself. This imposes at times monumental database maintenance problems, as advances in medical knowledge increase and as the need for cross-disciplinary databases is demanded. A response to this has been academic work in the area of extensible object models and semistructured data (40). These approaches envision “packaging” metadata (structural information about the new data) directly with the values for variables and are described in more detail below.

Database Designs

A *database design* refers to the model that describes which data fields are logically linked to one another (41); the most commonly cited database designs are flatfile, spreadsheet, hierarchical, relational, and object-oriented. The simplest design is a single table of values called a *flatfile*. A flatfile is non–self-documenting, requiring a separate data dictionary to accompany the data file. The next simplest design is the spreadsheet. It is superior to the flatfile in containing not only self-documentation, such as column headings, but also in allowing in-place associations to be established among the data cells themselves. A major limitation of flatfiles and spreadsheets is that they have primarily been proprietary products requiring either export in a more universal form or the definition of a software driver that permits direct communication.

One of the earliest database designs was the *hierarchical* model. This consisted of linkage of multiple collections of similar information into a tree structure, with a root and child nodes like branches and ending with leaf nodes. In effect this model acts as a collection of index cards in which each card has a small number of variables (e.g., demographics) about one patient. A major disadvantage of this database design is that hierarchies are rather arbitrary. For example, one might think of the heart as the root of a hierarchy of the cardiovascular system. However, one could imagine it also in the domains of infectious disease (bacterial endocarditis), developmental disorders, neuroendocrine function, a hierarchy of surgical procedures, and many others. Thus, use of a single hierarchy rapidly becomes limiting. Today, hierarchical database models have been extended to polyhierarchical models, which are of interest in medical nomenclature.

A database model that ties together multiple tables of information provides more flexibility and is called a *relational model*. Relational databases allow for very efficient and powerful storage of large quantities of information (38,42). The multiple tables in a relational database are linked together by user-defined cross-references, or “linking variables” (Fig. 44.1). As an example, a database might be designed to contain a patient’s name and the name of the primary physician. In a hierarchical or flatfile design, the name of the primary physician would have to be individually entered for each patient; thus, the names of physicians who care for more than one patient might have to be entered multiple times. A relational database would have a separate table with the names and characteristics of all primary physicians; thus, when it comes time for the user to enter the name of the primary physician, he or she can simply refer to the primary physician table and, using a “pick list,” click the appropriate name. Data entry is therefore easier and of better quality. The relational database also allows one to modify a data element in one table with assurance that the same data element in other tables will be automatically updated without a need to alter programs that use the data.

ID#	Lastname	Age	Gender	Physician
22005	Jones	45	M	Lauer
22006	Smith	52	F	Fortin

ID#	PCW	PAS	PAD
22005	23	62	27
22006	12	25	13

Physician	Gender	Institution
Lauer	M	Cleveland Clinic
Fortin	M	Duke University

FIGURE 44.1 Schematic of a relational database. Tables are linked to one another by linking variables (in this case, ID# and Physician). Data entry of “Physician” into the first table is made easy by linking to data available in the third table.

Relational databases are, however, static repositories of data. Imagine a database that could note that an entered value for a glucose tolerance test was well above the normal range and therefore set into motion a predetermined sequence of activities, such as paging the physician, printing a diabetic diet based on patient characteristics, discovering a clinical trial of pancreatic islet transplantation, or a host of other functions. This is possible in *object-oriented* databases. Objects contain not only data, but also *instructions* as to what might be done with them given that certain data values are present. A major modern challenge in clinical database technology has been to define an object model of medicine and all its accompanying behaviors.

Although the relational model is the most pervasive in clinical databases today, two other challengers deserve mention: an old technology, *time-oriented* databases, and a new technology, *semistructured* databases. Time-oriented database models have been of interest since at least the early 1980s, particularly in cardiology (43,44). Over the last 10 years, new query tools have been developed, particularly at Stanford University, for exploiting the power of such databases (45).

The other model represents a complete departure from traditional database design: semistructured databases. Semistructured databases permit the self-assembly of an *ad hoc* structured database at the time of an analysis using information embedded in the data elements themselves. This is the exact opposite of the traditional approach to structured databases, in which the database is first assembled and only then is an analysis performed. The semistructured database model provides the most flexibility available today in database design because hierarchical, relational, object-oriented, or time-oriented structured databases can be assembled at the time of selection of variables for analysis or query, depending on the specific needs of that time. Ideas about semistructured databases sprung up simultaneously in several disciplines in the early 1990s, such as that in medicine by Dr. John Kirklin and his colleagues at the University of Alabama at Birmingham and the computer science department of Stanford University (40,46). A query language known as *Lore* for a semistructured database has been developed at which time it was recognized that much of the information on the World Wide Web could be considered semistructured data. In particular, the special extensible object language developed for storing and retrieving semistructured data was discovered to have extensive homology to XML (47).

Data Quality

Missing Data

Rigorously run prospective randomized clinical trials and some multicenter registries have specific mechanisms in place to ensure comprehensive data collection. In most cases, specific people are assigned to collect and document data and others to enter them into the computer, with both of these processes occurring independently of routine clinical care. Observational clinical databases in which data are obtained as part of clinical care are often plagued, however, by missing data, which can seriously affect accurate analyses and development of prediction models (eTable 44.1.1) (27,48).

***e*TABLE 44.1.1** LIMITATIONS OF OBSERVATIONAL DATA

Type of limitation	Description and causes
Missing data	Clerical errors
	Busy practitioners enter data hurriedly
	Patients seek care from outside providers
	Tests and procedures not ordered
	Coding restrictions
	Concept recorded in different field
Inaccurate data	Reliability: inter- and intraobserver consistency
	Validity: data truly represent what they are supposed to measure
Bias	Systemic causes of missing data
	Appropriate covariates not captured
	Definitions of, and therapies for, disease change over time
	Different measurement methods
	Gaming: coding to maximize reimbursement or optimize risk-adjusted outcomes rather than to best reflect clinical reality

Data may be missing for a number of reasons. Subjective data, such as diagnoses, that need to be recorded by a clinician may be missed because of inadequate documentation by busy practitioners (27). Some data may be missed because patients often seek care from multiple providers, who do not enter all data into the same database. One area where this can lead to serious inaccuracies is in the documentation of medications (49). Data that are recorded initially on paper and then entered into the computer as a separate act may be lost for clerical reasons. If a patient's condition does not lead to the collection of certain data, this can lead to missing fields; a common example of this might be coronary anatomy data in patients with chest pain and normal stress tests. In real clinical practice, most of these patients are not referred for coronary angiography. Thus, attempts to analyze the clinical effectiveness of stress testing are inherently limited by a bias related to systematically missing data (50).

Missing data elements can lead to very serious misinterpretations. For example, Iezzoni et al. analyzed an administrative database and found that among patients hospitalized with stroke, myocardial infarction, pneumonia, or congestive heart failure, the presence of comorbidities such as hypertension, angina, diabetes, or valvular disease was associated with a paradoxically lower mortality rate (51). The reason for this finding is that only five diagnoses were permitted on the discharge abstract, and thus the patients with many principal diagnoses were more likely to have less serious comorbid conditions recorded. Others have confirmed this type of problem as well (52).

Data may appear to be missing when in fact a certain concept may be recorded in more than one field. For example, Iezzoni found that the concept of "chest pain" could be found under one of three Medicare Diagnosis Related Groups in an administrative database: chest pain, angina, or atherosclerosis (53).

Methods of Dealing with Missing Data

In any large database, missing data are almost always a problem. Variables with a large amount of missing data may be considered poor-quality variables and should be eliminated from consideration in analyses. For example, some cardiologists may doubt the value of the ejection fraction, preferring an integrative, qualitative assessment of systolic ventricular function. In such an institution, measurements of ejection fraction may be unavailable for a large number of patients. Despite its consistent association with survival, the ejection fraction in these institutions should simply not be considered a variable that can be used with any degree of credibility.

As described by Little and Rubin (54) missing data can be classified into three specific types: (a) *missing completely at random*, in which patients with missing data cannot be in any way distinguished from those without missing data; (b) *missing at random*, in which the pattern of missing data is due to some external cause unrelated to the variable with missing data; or (c) *not missing at random*, in which the mechanism by which data are missing is directly linked to the variable itself. An example of the last case is lack of stress testing data in a patient with cardiogenic shock.

A number of methodologies have been developed for the management of missing data. However, developments in this field have largely involved survey data, where large amounts of missing data are the norm. This is a quite different situation from that pertaining to high-quality cardiologic databases, where investigators are typically faced with a large number of scattered individual holes in the data. Any given variable may have a rather small amount of data missing. However, a large percentage of the patients, sometimes all, may have at least one piece of information missing. It has been argued by some that missing-data strategies must be entirely different in this situation than in the situation in which large volumes of data are missing (55).

As a general rule, entire records of patients or subjects with any missing data should not be automatically deleted. The deletion strategy may be reasonable with survey data but is not reasonable with sporadic scattered missing data, such as occurs in cardiologic databases. The exception to this rule may be missingness of the specific outcome variable of interest—that is, *incomplete follow-up*. Incomplete follow-up, particularly less than 80%, presents serious bias problems, as patients who are lost to follow-up tend to be very different from those who are easily followed—for example, they often turn out to be dead!

Several strategies for dealing with missing data are commonly used. The simplest is mean value imputation, in which the mean value of a particular variable for the entire nonmissing population is substituted for the missing value. Although statisticians often decry this approach, it may well be reasonable when less than 5% of the values for any given variable is missing. A more sophisticated approach is informed mean value imputation. For example, if it is known that a patient with a missing blood glucose value is diabetic, that missing value could be imputed by using the mean blood glucose value of diabetic patients who do not have missing data.

Other more complex imputation schemes include nearest-neighbor matching, imputation from regression equations, and propensity analysis. In nearest-neighbor matching, a missing value is imputed by taking the same nonmissing value from another patient who is otherwise very similar. In propensity analysis a logistic regression model is created that defines the probability that a particular dichotomous variable has a value of yes (or 1) compared with no (or 0); for patients with

missing data, a value of 1 may be imputed if the propensity model finds that the probability that that patient would have had a value of 1 is more than 50%.

Finally, a number of very complex, computer-intensive methods have been developed to account for missing data, either with or without explicit data imputation; these methods may or may not be clearly applicable to the cardiologic database setting. These include Rubin's multiple imputation methodology, which was developed specifically for surveys (56,57) and a companion technique that uses the bootstrap (58). These methods address an important issue in missing-value imputation and management, namely, the preservation of the distributional structure of variables that is disturbed when a large amount of imputation is made using a single value.

Most of these imputation methods implicitly assume the data are missing at random. It may well be true that, instead, there is a systematic pattern in the randomness that may be present. One technique that may be used to determine this is to generate a missing-value indicator that identifies patients or subjects for which data have been imputed for a specific variable. This indicator can be incorporated into multivariable models, both to test the association of missingness with outcome, such as when certain tests cannot be performed because of the dire condition of the patient, and in some sense, to adjust for that systematic missingness. Use of this strategy requires that missingness is associated with at least a few events of interest (five to ten); otherwise no estimate can be made.

Data Credibility

When considering the accuracy of data, one must assess both reliability and validity. *Reliability* refers to how stable or reproducible measurements are. If several independent reviewers code a certain set of measurements or abstract information from a chart in very similar ways, the data can be considered to be reliable. *Validity*, on the other hand, refers to the issue of whether the data represent what they are really supposed to measure. For example, in one database the diagnosis of "myocardial infarction" turned out to be incorrect in 57% of recorded cases (59).

The relative accuracy, in terms of both reliability and validity, of data depends on a number of factors (60). One must consider how and by whom the data are actually collected, codified, and recorded. An ideal situation would be on-line recording of information by clinical providers, but this is often not practical. If data are collected or entered by people unfamiliar with clinical issues, the likelihood of error is increased. The location where measurements are made is important—for example, blood pressure readings would be expected to be more accurate if obtained from a hypertension clinic rather than an orthopedics ward (27). If data are collected from discharge abstract information, validity may be compromised because the severity of diagnoses or conditions is often not coded, coding of clinical events may be clouded by physicians' concerns regarding the recording of complications that may later be held against them in court or by peer review organizations, and data are often based on attestation sheets that are compiled by clerks who do not have physicians' knowledge or have access to a dictated narrative summary of a hospitalization (61).

Good-quality databases require frequent and systematic checks of reliability. Investigators often measure intrarater, and, more important, interrater, reproducibility. A random set of records might be chosen for independent review by two different data collectors/abstractors who are blinded to each other's views and identities. Data are more likely to be reliable when they are collected prospectively by well-trained abstractors who are using standardized definitions and who routinely undergo interrater quality checks (60). Furthermore, computer programs can be written to minimize errors by identifying inconsistencies—for example, a person cannot have a test performed on a date that occurs before his or her birth date. Thus, should a date be entered in error, the database management system can alert the user of a likely data quality problem.

In the construction of databases that assist in obtaining high-quality information, three common mistakes and their remedies should be mentioned. First, to the uninitiated, it is not uncommon for a data field to be populated by more than one atomic value. The remedy is to ensure that every data element consists of only one variable-value pair. Typical examples are spreadsheets in which the investigator has recorded the date of birth and age in the same field, multiple attributes of a mitral valve repair in a single field, or catheter type and size in the same field. Second, investigators may code a variable inconsistently, such as with uppercase versus lowercase letters, abbreviations, misspellings, and the like. To ensure consistency, insofar as possible, pick lists of mutually exclusive and exhaustive values for variables should be constructed from which the investigator chooses the appropriate answer. Among those appropriate answers should be one or more indicators for missing values: The answer may be truly unknown, the information to determine the answer may be unavailable, or information may be insufficient to answer the question with credibility. The third common problem is the practice of physicians to code by exception. This leads to a database design of lists of responses that are not mutually exclusive. Typical examples are so-called multiple pick lists, in which one to several of the responses may be chosen. This practice leads to systematic errors, particularly errors of omission (62). The solution to this problem rests with database design, in which all responses for all variables are mutually exclusive.

WHAT ARE THE USES OF CLINICAL DATABASES?

Fundamental Uses of Clinical Databases

As described by Safran (63), there are four fundamental uses of clinical databases: (a) results reporting, (b) case finding, (c) cohort description, and (d) predictive modeling. *Results reporting* refers to the ability to retrieve information about a specific patient or procedure; this is the type of activity by which practicing clinicians would most often interact with, or at least "seek rewards" from, a clinical data repository. Case finding involves looking for patients with similar problems or outcomes as a patient of interest, often to direct management based on prior individual experiences. Cohort description seeks to simply describe a group of patients or procedures based on a common set of attributes. Finally, prediction modeling involves applying sophisticated analytical methods to describe changes or associations that can lend insight into the natural history of disease processes, the effects of different clinical interventions, and/or quality of care within given institutions or by specific providers. It is this use of databases that presents the most powerful, and perhaps also the most controversial, benefit of computerized clinical information technology.

Case for Outcomes Management

In the 1988 Shattuck Lecture to the Annual Meeting of the Massachusetts Medical Society, Paul Ellwood advocated the nationwide adoption of outcomes management, which he described as a new "technology of patient experience" (27). Work by Wennberg and others (64,65 and 66), which showed tremendous variation of practice patterns without clear differences in patient outcome, has caused the public and third-party payers to demand better-quality information by which the clinical effectiveness of various interventions and providers can be systematically studied. Practice variation is a ubiquitous problem in medicine; within cardiology, recent evaluations of the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries database, for example, have revealed marked geographic variation of management of postinfarct patients within the United States and among countries (67,68 and 69), with varying differences in clinical outcomes. In addition to patients and payers, physicians too are frustrated by their inability to accurately and quantitatively predict the impact of their care on patient outcomes, as good-quality data from randomized controlled trials simply do not exist for many common clinical scenarios (70). To help solve these problems, the process of outcomes management would seek to use high-quality data based on real patient experiences to help physicians, payers, and patients make the most rational choices.

Ellwood described four processes by which outcomes management occurs (*e*Table 44.1.2): (a) adoption of database standards and clinical guidelines; (b) routine systematic measurements of patient outcomes at appropriate times (or follow-up); (c) pooling of clinical, outcome, and financial data into enormous databases; and (d) careful analyses and dissemination of results of these analyses to appropriate parties.

***e*TABLE 44.1.2** THE PROCESS OF OUTCOMES MANAGEMENT

Process	Description	Examples
Adoption of standards and guidelines	Standards: allow for comparisons between databases	Standards: *International Classification of Diseases, Ninth Revision, Clinical Modification*; Health Level 7; Systemized Nomenclature of Medicine
	Guidelines: allow for meaningful measurements of impacts of interventions	Guidelines: American College of Cardiology/American Heart Association guidelines on management of acute myocardial infarction
Measurement of outcomes	Uniform follow-up for clinically relevant, objective, unbiased, predefined end points	All-cause mortality
		Quality of life
		Costs of care
Pooling into databases	Data fields determined and defined based on standards, guidelines, likely risk-determining characteristics, and outcomes	See Table 44.3
Analyses and dissemination	Provide for publication and/or appropriate parties along with feedback	Risk-associated mortality
		Assessment of patient risk prior to procedures
		Postmarketing drug surveillance
		Assessment of practice variation in process and outcomes

Type of database	Examples
Population-based studies	Framingham Heart Study Physicians' Health Study Nurses' Health Study Cardiovascular Health Study
Disease-oriented registries	National Registries of Myocardial Infarction Minnesota Heart Survey Duke Databank for Cardiovascular Disease
Technology- and procedure-oriented registries	Cardiac Transplant Research Database United Network for Organ Sharing database National Heart, Lung, and Blood Institute registries on percutaneous transluminal angioplasty and new technologies Northern New England Cardiovascular Disease Study Group Surgeons' National Database Veterans' Affairs Cardiac Surgery Database The Cleveland Clinic Foundation Exercise Stress Laboratory Database
Administrative and abstracted based on administrative databases	New York State Cardiac Surgery database Health Care Financing Administration Cardiovascular Care Project American College of Cardiology
Randomized clinical trial registries	Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries trials Thrombolysis in Myocardial Infarction trials Coronary Artery Surgery Study Beta-Blocker Immediate Survival Study

TABLE 44.3 EXAMPLES OF DATABASES IN CARDIOLOGY

The enormous databases to be used in the outcomes management process may be organized according to the *clinical model concept* (Fig. 44.2), as described by Steen (71). This model divides clinical encounters into four sets of data elements: (a) patient factors, (b) physician plan, (c) hospital execution, and (d) outcome measures. Patient factors are extremely important to recognize and codify properly, as they represent variables that are related to outcome but over which providers have little or no control. These include specific disease entities, comorbidities, socioeconomic background, compliance, and satisfaction. The physician plan has two major components, namely, an assessment of diagnostic probabilities and an assessment of the urgency of action needed to address them. Between the physician plan and outcomes are hospital execution factors; no matter how excellent a physician's assessment and plan are, if hospital systems fail to respond to them in an efficient and timely way, adverse outcomes may result. For example, an emergency room physician may quickly and accurately diagnose acute myocardial infarction and appropriately prescribe thrombolysis, but if pharmacy, transport, and clerical staff are not properly organized, there may still be significant delays in implementing therapy. Outcome measures include not only standard mortality and morbidity measures, but also "softer" end points such as quality of life and costs of care.

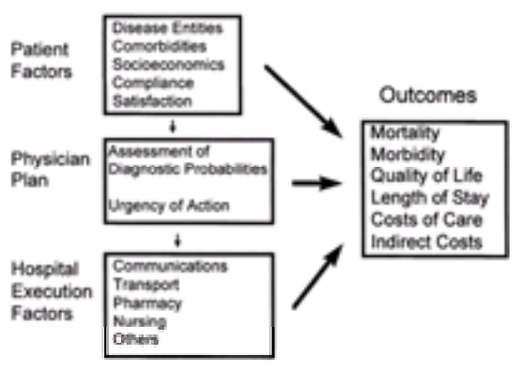

FIGURE 44.2 The clinical concept model. Patient factors, physician plan, and hospital execution factors all play a role in determining patient outcomes.

Analyses of enormous databases can be used to achieve a number of objectives (72). These include assessment of patient risk based on clinical characteristics and medical test results, risk-adjustment assessment of quality of care, postmarketing drug surveillance, assessment of resource consumption, analyzing and improving clinical decision making, identifying and correcting variations in physician practice, and aiding in collaborative clinical research projects.

Why Not Just Use Randomized Controlled Trials to Determine Clinical Effectiveness? Bias and Unexplained Confounders

A major component of outcomes management is determination, based on analyses of large observational clinical databases, of how outcomes are associated with physician plan and hospital execution factors after "adjusting for" patient factors. Some have argued, though, that using observational databases to assess the impacts of therapies or behaviors under physician or patient control is inherently flawed and that randomized trials can appropriately answer these questions (73). This belief is held so strongly that one major textbook on clinical epidemiology (74) recently stated, "If you find that a study was not randomized, we'd suggest that you stop reading it and go on to the next article." Indeed, today the randomized controlled trial is considered by many to be the gold standard method of assessing the relative impact of different therapies.

The main strengths of randomized controlled trials are reviewed by Moses (75): (a) assembly of a single, well-defined inception cohort; (b) elimination of potential biases and confounding, particularly those caused by unknown or unmeasurable factors; and (c) adherence to well-defined clinical care and data collection protocols with vigorous quality assurance and safety mechanisms in place. However, as reviewed by Califf (76), clinical trials suffer from several inherent limitations: (a) they are expensive and sometimes very time-consuming; (b) therapies change such that by the time trial results are reported, new technologies become available that may replace the methods used; (c) many patients, particularly those with comorbidities or the elderly, are excluded; (d) trials are performed more often in patients at tertiary referral centers, raising generalizability questions; and (e) the benefits of a therapy as noted in the ideal conditions of a clinical trial may not necessarily apply to the "real world" of clinical care. Furthermore, some clinical treatment questions simply cannot be answered with randomized trials. For example, a study found that a prolonged door-to-balloon time was associated with a higher mortality among patients undergoing primary angioplasty for acute myocardial infarction (77). It is difficult to imagine that the validity of this finding could be tested by a controlled trial in which patients would be randomized to an immediate versus a delayed angioplasty (70).

Causes of Bias

Although some have found that analyses of clinical databases can lead to conclusions that are consistent with those from presumably unbiased randomized clinical trials (78,79 and 80), the presence of bias remains a major impediment to the widespread acceptance of clinical databases as a valid source of insights on clinical effectiveness (73,75,81). There are many potential reasons for bias. Data that are systematically missing because of patient or condition-specific reasons can lead to serious misinterpretations, as described above. Patients who visit a given health facility less frequently because they are less ill or because they "shop around" for care may have fewer data available (27). Patients may be selected for treatment or interventions for reasons that, no matter how ostensibly comprehensive a database is, are simply not adequately captured. For example, some patients may not receive therapies because they are "too sick," making it appear that healthier patients do worse than they really do after undergoing those therapies. Definitions of disease and the nature of therapies are often unstable over time, making comparisons between time eras difficult (82). For example, both medical and surgical therapies for CAD have changed dramatically over the past 15 to 20 years, making comparisons between them problematic if assessed over long periods. Because of more intensive screening and treatment of coronary risk factors, some patients with milder forms of disease may be identified now, whereas they may have been missed in years past. Measurement bias may occur because patients in different groups have certain variables measured in different ways (83).

Other types of bias are more germane to administrative databases such as Medicare. The federal government asks hospitals to record additional diagnoses that "affect patient care in terms of requiring clinical evaluation, therapeutic treatment, diagnostic procedures, extended length of hospital stay, or increased nursing care and/or monitoring"(84). Such a statement is subject to broad interpretation, especially when considering that hospitals have an incentive to record diagnoses in such a way as to maximize reimbursement. Other administrative or government databases that are used to assess quality of care may suffer from a form of bias known as "gaming," in which the severity and presence of comorbidities that may have an adverse impact on outcome are exaggerated, leading to a form of "clinical inflation" (85). Individual providers would have an incentive to do this to improve their "risk-adjusted" outcomes, but in the aggregate, this practice leads to decreased power of the database.

Risk Adjustment and Measurement of Case Mix

One important method of overcoming bias in observational databases involves developing and applying prognostic risk models to control for severity of illness. Examples of such risk prediction models include the Acute Physiology, Age, Chronic Health Evaluation score (86), the Severity of Illness Index (87), the Charlson comorbidity score (88), the risk prediction model derived from the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries study (89), and a measure of prognosis among patients with CAD derived from the Duke Databank for Cardiovascular Disease (90). Using this approach, Duke

investigators have found that conclusions drawn from an observational database compare well with those obtained from randomized controlled clinical trials (91).

Case-mix adjustment (92) specifically refers to identifying patient-specific factors that may explain differences in outcomes among patients cared for by different providers or institutions. The validity of case-mix adjustment has been questioned because of a number of unresolved methodologic issues. The use of diagnoses to describe patient illness may fail to adequately describe risk (93). There is considerable controversy over whether data obtained or measured after a clinical intervention should be included as part of risk adjustment. Some patients are evaluated with more sophisticated technology, which could bias comparisons in that those patients not selected for certain imaging techniques may have major comorbidities missed. The source of data abstraction is also key: Administrative or financial databases, although readily available and large, often do not have the richness of clinical detail needed to make a valid assessment of illness severity or comorbidities (72,93,94). Small numbers of patients with specific diagnoses in individual hospitals may also cloud case-mix adjustments (95).

Overcoming Bias

To correct for systematic (biased) differences between groups, Moses argues that three objectives must be met (75): (a) the sources of bias—that is, the relevant covariates—must be known; (b) those variables must be systematically and uniformly measured; and (c) appropriate statistical techniques must be used to overcome misleading conclusions. A statistical method known as *propensity analysis* (see Modern Multivariable Techniques) has been proposed as a method of assessing unbiased treatment effects in observational studies (96,97 and 98). Nonetheless, the inability to fully identify and describe unknown, unmeasured covariates that may play a major role in why patients or their physicians behave in certain ways is considered by some to doom even the most sophisticated statistical analyses (73). This argument has been used to criticize observational studies with troubling conclusions, as in, for example, reported higher myocardial infarction rates among hypertensive patients taking calcium channel blockers (99), worse outcomes in critically ill patients monitored with pulmonary artery catheters (100), and possibly adverse interactions between aspirin and angiotensin-converting enzyme (ACE) inhibitors in patients with and without heart failure (101). Other reports have suggested that standard adjustment techniques may lead to misleading conclusions about, for example, the quality of care of patients being treated for heart failure (102) or identification of outlier surgeons performing coronary bypass surgery (103).

Randomized Trials and Observational Studies: Empirical Evidence

Even setting aside all the arguments that biases and confounding can be overcome, critics of treatment assessments based on observational analyses point to studies in which observational data inflated positive treatment effects when compared with randomized trials (79,104,105,106,107 and 108). These comparisons were based on studies done in the 1970s and 1980s, when database technology and analytical methods were less developed than they are today. Benson and Hartz performed a systematic comparison of results of randomized trials and observational studies that were published between 1985 and 1998 (79). Figure 44.3 shows their analyses of cardiac treatments based on eight articles; in nearly all cases, randomized trials and observational studies yielded remarkably similar results. The one discrepant comparison involved low-risk patients undergoing bypass surgery or angioplasty; the authors suggested that the unusually low bypass surgery mortality rate in the randomized trial might have explained the difference.

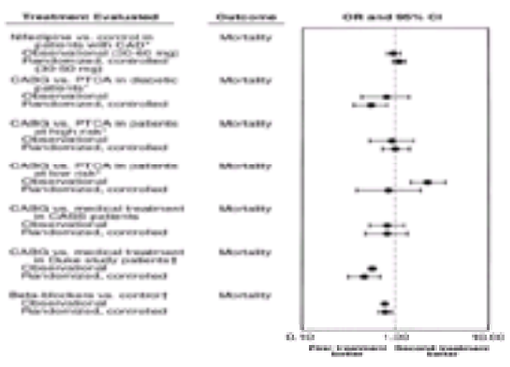

FIGURE 44.3 Results of observational studies and randomized, controlled trials of cardiologic treatments. The figure is based on data from eight articles. *, studies that reported relative risks rather than odds ratios; †, studies that reported neither a confidence interval nor a *p* value for the odds ratio; CABG, coronary artery bypass graft surgery; CAD, coronary artery disease; CASS, Coronary Artery Surgery Study; CI, confidence interval; Duke, Duke Databank for Cardiovascular Disease; OR, odds ratio; PTCA, percutaneous transluminal coronary angioplasty. (From Benson K, Hartz AJ. A comparison of observational studies and randomized, controlled trials [see comments]. *N Engl J Med* 2000;342:1878–1886, with permission.)

A similar comparison of randomized trials and observational studies was also reported by Concato and colleagues (80). Based on published metaanalyses, they compared the results of 14 randomized trials and nine cohort observational studies that assessed the impact of treatment of hypertension on occurrence of coronary heart disease events. The randomized trials, which enrolled a total of 36,894 patients, found a positive treatment effect (risk ratio, 0.86; 95% confidence interval, 0.78 to 0.96). The cohort studies, which described a much larger patient sample of 418,343 patients, found a remarkably similar positive treatment effect (risk ratio, 0.77; 95% confidence interval, 0.75 to 0.80). Another comparison of 14 randomized trials and seven cohort studies that evaluated the impact of antihypertensives treatment on stroke again found remarkably similar positive treatment effects; for the randomized trials the risk ratio was 0.58 (95% confidence interval, 0.50 to 0.67), whereas for the cohort studies the risk ratio was 0.62 (95% confidence interval, 0.60 to 0.65).

Incorporating Guidelines into Clinical Databases

Object-oriented database technology presents a whole new potential function for clinical databases, namely, computer-assisted interventions. As previously mentioned, object-oriented databases not only contain data but also instructions of how certain types of data combinations are to be handled; these instructions could well be clinical guidelines, such as those published by the American College of Cardiology and the American Heart Association, on a variety of topics (109,110,111,112,113 and 114). Recent reports on the frequency and dangers of medical errors (115,116,117,118,119 and 120), most of which are primarily due to systems errors rather than individual human failings or negligence, highlight the potential value of using object-oriented databases for providing clinicians with point-of-care information and practical advice. A number of reports have already demonstrated the clinical benefits of incorporating clinical guidelines into computerized clinical databases to generate physician reminders (121,122,123,124,125,126,127 and 128); nonetheless, this process is uncommonly practiced in most institutions.

ANALYTICAL METHODS

Univariable Methods

The fundamental goal of any data analysis is to describe an association between an exposure and an outcome. An exposure could be a treatment or a characteristic, such as cholesterol level, whereas an outcome could be mortality or morbidity or the result of a blood test.

Three analytical approaches are commonly used to establish associations between exposures and outcomes. In a *cohort study,* a group of patients is prospectively assembled and then classified according to the presence or absence of an exposure variable of interest, after which time the patients are followed for the occurrence of an outcome event. In a *case-control* study, patients are selected according to whether or not the outcome occurred and are then compared for the presence or absence of an exposure variable. In a *clinical trial*, a group of patients is assembled and then treatments assigned, typically by random allocation, after which patients are followed for the occurrence of outcome events. In reality, a clinical trial is a kind of cohort study.

When comparing continuous variables between two groups (e.g., blood pressure with and without treatment), commonly used statistical tests include the Student's *t* test when the variables are normally distributed (i.e., follow a gaussian bell-shape curve) and the Wilcoxon rank sum test when an assumption of normal distribution cannot be made. When three or more groups are being compared, the analogous tests are analysis of variance and the Kruskal-Wallis test. The purpose of these statistical tests is to determine whether any apparent association between the exposure and outcome are merely due to chance; the probability that the association is merely due to chance is expressed as the *p* value.

When comparing categoric variables, the commonly used statistical test is the chi-square test, which again determines whether an apparent association between an exposure and an outcome are due to chance. Often it is more helpful to describe the magnitude of difference between groups. This is done by calculating relative risk

differences, absolute risk differences, number needed to treat to prevent one outcome event, and their confidence intervals (see Chapter 43).

Survival Analyses

In survival analyses, the outcome of interest is not only whether a particular patient died or suffered from an adverse event but also the *length of time* until that event did or did not occur. Three mathematical descriptions are often given regarding survival, namely the *survival function*, the *probability density function*, and the *hazard function*. The survival function S(t) is the probability that a person has lived longer than any given time T. The probability density function f(t) is the negative derivative of the survival function. The hazard function is the ratio of f(t) to S(t) [i.e., f(t)/S(t)] and can be thought of as the instantaneous risk of an event, such as death, given that a person is still alive and free of the event at time T.

An important concept regarding survival analyses is that of *censoring*. In a chronic care study, patients are enrolled over a long period, while follow-up must by necessity end on a certain day. Thus, even among patients who survive, the length of follow-up will be variable: Those patients who were enrolled early in the study will have had a long period of follow-up, whereas those enrolled later will only have been followed for a short period. Patients who do not experience an outcome event before the end of follow-up are considered to be censored. Robust survival methods take censoring into account when attempting to link certain exposures to length of time free of an outcome event. Readers who are interested in learning more about censoring and survival analysis methods are encouraged to read elsewhere (129,130 and 131).

Multivariable Methods

Analyses of large clinical databases usually involve multivariable regression techniques. Multivariable regressions are used to develop models by which outcomes can be predicted or to evaluate the impact of particular variables of interest on outcome after considering potential confounding or interaction from other variables. The development of regression models includes four key steps (71): (a) population selection, (b) outcome selection, (c) type of regression, and (d) variable selection. Other critical aspects of model development include formal testing for goodness of fit and validity as well as assessment for possible interactions (132).

The type of regression model chosen depends in large part on the outcome variable of interest. Many analyses are interested in binary outcomes such as death, occurrence of a major nonfatal cardiac event, or readmission to the hospital within a given time. If the outcome is time-independent (e.g., in-hospital mortality, readmission any time within 30 days), then logistic regression is the most common type of model chosen (133). The logistic model seeks to predict outcomes according to a linear equation:

$$\log \text{Odds}_{event} = a + b_1x_1 + b_2x_2 + b_3x_3 + \ldots + b_ix_i$$

where

- Odds = $(\text{probability}_{event})/(1 - \text{probability}_{event})$,
- a = y-intercept,
- $x_1, x_2, x_3, \ldots, x_i$ are variables chosen for the model (e.g., age, gender, number of diseased coronary arteries), and
- $b_1, b_2, b_3, \ldots, b_i$ are "parameter coefficients," which are estimates based on examination of the data relating each variable to the log Odds_{event} after adjusting for all other covariates.

Logistic regression modeling consists of estimating values and standard errors of parameter coefficients based on observed outcomes in a selected data set. Although much of the work of modeling is performed by computers using powerful statistics packages (e.g., PROC LOGISTIC of the SAS System, Cary, NC), the validity of the models developed depend largely on appropriate model specification and variable selection by the investigators. Models can be built in a number of ways, including simple inclusion of all variables, forward or backward selection, and cluster analyses; the method of model building used can have a significant impact on results (134).

When the outcome is time-dependent, such as time free of death or major nonfatal cardiac events, survival analyses are used. The most popularly used multivariable model for survival outcomes is the Cox proportional hazards regression (135). The hazard function of an event describes the instantaneous risk of its occurrence. Cox proposed that if the ratio of the hazard functions between different groups (known as the *hazard ratio* or *relative risk*) can be assumed to remain constant over time, then the hazard ratio can be modeled:

$$\log [\text{Hazard}_{event}(x,t)/\text{Hazard}_{event}(0)] = a + b_1x_1 + b_ix_i + b_3x_3 + \ldots + b_ix_i$$

where $\text{Hazard}_{event}(x,t)$ refers to the hazard function at time t given circumstances $(x_1, x_2, x_3, \ldots, x_i)$ and $\text{Hazard}_{event}(0)$ is the hazard function for a hypothetical patient where all $x_1, x_2, x_3, \ldots, x_i$ are equal to 0. Analogous to the logistic regression model, each parameter coefficient estimates the association between its associated variable and the log of the hazard ratio after adjusting for all other covariates considered. Also, models can be built according to forward and backward selection techniques.

Many situations in clinical cardiology are characterized by rapidly changing hazard functions over time. For example, after myocardial infarction the hazard of death is exceedingly high during the first few days and then rapidly falls (136). Risk factors for death may be also be time-dependent—that is, those characteristics that predict death during the first 30 days after acute myocardial infarction may be quite different than those that predict death from months 2 through 12. One way of dealing with this is to use logistic regression techniques to analyze risk during the early period and Cox regression techniques for late events. However, this approach suffers from establishing an arbitrary cutoff time. Blackstone and colleagues have described a parametric modeling system for describing time-varying hazard functions by decomposing patterns of risk into phases and then systematically assessing risk factors that apply to each of these phases (137). Thus, after myocardial infarction, the first phase would be one of an initially very high hazard with a rapid decline, followed by a prolonged phase of relatively constant hazard. The use of this type of multivariable analysis in the hazard function domain has been used extensively, for example, to describe risk of death (21) and rejection after cardiac transplantation (138).

When the outcome of interest is a continuous variable, such as length of stay or cost of care, linear regression techniques are often used for predictive modeling:

$$\text{Outcome} = a + b_1x_1 + b_2x_2 + b_3x_3 + \ldots + b_ix_i$$

Linear regression models are derived using the "least squares technique," by which parameter estimates are derived that minimize the squares of the differences between actual and predicted outcome values.

Problems with Multivariable Models

Multivariable regression, when properly performed, allows for powerful analyses of large datasets. However, failure to consider inherent limitations and assumptions on which the models are built can lead to serious misinterpretation or invalid results (Table 44.2). Serious error can result from a number of problems: (a) model overfitting, (b) inappropriate use of a linear model, (c) violation of proportional hazards, (d) failure to test for interaction, (e) inappropriate variable selection techniques, (f) colinearity of variables, and (g) excessively influential observations (139).

Type of limitation	Description and possible solutions
Model overfitting	Too few outcome events for number of covariates Use no more than one covariate per ten events
Inappropriate linear assumption	Linear model incorrect Test with goodness-of-fit or examination of residuals Use nonlinear techniques or transformations
Violation of proportional hazards assumption	Ratio of hazard function between groups fails to remain constant over time Use hazards analyses Time interaction terms Divide into arbitrary time periods
Failure to account for interaction	One or more variables may modify the strength of association between outcome and another variable Incorporate interaction terms in analyses
Inappropriate variable selection	Forward and backward analyses may not reflect clinical reality Important covariates missing Consider sequential models, principal components/cluster analyses
Colinearity	Covariates closely associated with one another Test with variance inflation factors or cross correlation matrices
Excessively influential observations	Formally test

TABLE 44.2 LIMITATIONS OF MULTIVARIABLE ANALYSES

Model overfitting is a common error in which the number of outcome events is too few for the number of covariates considered (132). If there are very few events, the parameter coefficients derived from a regression model are inherently untrustworthy, with the risk for poor precision of estimation or, worse, detection of outright spurious associations. It has been proposed that there must be at least 10 outcome events for each covariate considered for a model to be considered valid (132,140).

Most multivariate regressions use linear models to estimate outcome, but often the risk of events does not follow a linear gradient. For example, a change in ejection fraction from 60% to 50% does not have the same prognostic significance as a change from 40% to 30%. Formal methods exist for confirming the appropriateness of linear models (133); nonlinearity can be examined by performing logarithmic transformations on independent and/or dependent variables or by incorporating quadratic or other exponential terms in the model.

The proportional hazards model of Cox is dependent on the assumption that the hazard ratio remains constant over time. This assumption is sometimes not valid. For example, a comparison of medical and surgical therapies for coronary disease might find that during the first month of follow-up, surgical therapy carries a worse survival because of perioperative complications. However, after the end of the first month, surgical therapy might be associated with a better survival. A Cox model that includes both periods of time would be invalid because the hazard ratio relating surgical to medical therapies changes markedly during the first few months of follow-up. Formal methods have been derived to test the proportional hazards assumption (129,130 and 131,141,142).

Interaction is an exceedingly important phenomenon that is often ignored. When the strength of association between an outcome and one particular variable is affected, the level of another variable, “effect modification,” or interaction is present. For example, heparin dose is associated with risk of bleeding in most patients, but this association is much stronger in lower-weight patients than in obese patients. In this case, there is an interaction of body weight with heparin dose regarding the outcome of bleeding risk. Unlike confounding or bias, which potentially can invalidate an apparent association, interaction is of great clinical interest and should be actively sought by investigators when developing multivariate models.

Statistical software packages offer investigators forward or backward variable selection techniques by which the computer inserts or deletes variables from models based on the relative strengths of association between them and the outcome. Although attractive on the surface, forward and backward selection often do not take into account biologic sensibility in constructing models and thus may lead to misleading results. “Principal components” and cluster analyses are approaches by which stepwise approaches can be made to better approximate biologic reality (143).

Regression models are all based on the assumption that all covariates exist independently of one another; in real life, this is almost never the case. Models can yield highly imprecise or even nonsensical parameter estimates when high degrees of correlation, or “multicolinearity,” exist between covariates. For example, measures of ejection fraction and cardiac output may be highly correlated.

Regression models are sometimes heavily influenced by a small number of observations that have extreme values for certain variables. Subjects with extreme values, such as exceedingly long lengths of stay after surgery, are known as *outliers*. It is often not clear how best to handle outliers, as sometimes they are reflective of clinically important events. Outliers may be excluded from analyses, but it is not enough to just use statistical techniques to show that a particular observation is an outlier; appropriate biologic justification is essential. For example, an analysis of blood pressure and left ventricular mass may be excessively influenced by one patient with hypertrophic obstructive cardiomyopathy. Because we understand this disorder to be biologically distinct from hypertensive heart disease, it may well be appropriate to exclude such an outlier. Another related problem, important to analyses of quality of care, is that multivariable models tend to overestimate risk among low-risk patients and underestimate risk among high-risk ones (144).

Model Validation Techniques

Even when the above problems are appropriately avoided or dealt with, multivariable models may still not be valid predictors of outcome. Several different types of validity need to be considered (60). *Face validity* refers to the clinical sense that a model has. For example, many models of risk of valve surgery do not include endocarditis as a covariate because in many series this is a relatively uncommon occurrence. Nonetheless, most surgeons would argue that endocarditis is an important predictor of outcome. *Content validity* depends on the appropriate and complete selection of covariates that are related to outcome. Closely related to this is *attributional validity*, which relates to whether an apparent independent association between a variable and an outcome is really true or whether it is confounded by a covariate that was not considered in the model. Thus, different “risk-adjusted” outcomes among different operators may be real or may exist because not enough variables were considered for adequate risk adjustment.

Predictive validity refers to how well a model actually predicts outcome. Within the database studied, there are formal methods for testing the ability of a multivariate model to accurately discriminate high-risk subjects from low-risk subjects. For example, for a binary, time-independent outcome in a logistic regression model, the c-index, or area under the receiver operating characteristic curve, is often reported: A value of 1.0 implies perfect discrimination, whereas one of 0.5 is consistent with nothing better than random chance. Hosmer and Lemeshow (133) have derived a “goodness-of-fit” statistic that tests the validity of logistic models. The predictive validity of linear regression models can be measured using the model R^2 statistic: This reflects what proportion of the variance of the outcome variable can be explained by the variables included in the model. For example, many models of left ventricular mass in populations report R^2 values of well under 0.5, suggesting that many of the important determinants of this variable are either not known or not yet accurately measured.

Another dimension of predictive validity is how well a regression model predicts outcomes in datasets different from that upon which it was derived. For example, one can study a series of coronary interventions and come up with a prediction model of adverse events. To test the validity of the model, it can be used to predict the likelihood of events in a different set of patients. Some investigators will formally report results from “test sets” and “validation sets,” which are two entirely different groups of patients from which multivariate predictive models are derived and then tested. There are also methods, such as the “jackknife” and “bootstrap,” by which model derivation and validation can be performed on the same dataset (145).

Modern Multivariable Techniques

Because of the recognized limitations of standard multivariable techniques, several newer methods have gained popularity among clinical investigators and biostatisticians. *Propensity analysis* is a technique by which a new variable, called the *propensity score*, is derived from a logistic regression model where the exposure variable becomes the dependent variable (96,97 and 98). As an example, in a study relating delayed door-to-balloon time to increased mortality among patients undergoing primary angioplasty for acute myocardial infarction, the investigators modeled the likelihood of having longer than a 2-hour delay (77). The result of this modeling is that for each patient a probability of having a delayed door-to-balloon time could be calculated and incorporated into multivariable models. Propensity analysis has been shown to analyze and adjust for baseline differences much more effectively than standard multivariable methods (98).

Information theory attempts to identify optimal models by considering both the number of variables considered in a model and the model’s goodness of fit to a particular data set (146). For any given data set, the more variables a model has, the closer the model will fit the data, but this comes at the expense of modeling peculiarities of the specific data set that are unlikely to be true of data sets elsewhere. When information theory is used, multiple candidate models are considered based on prespecified biologic knowledge and then a calculated value, such as the Akaike Information Criterion (147), is used to identify the best model (146).

In a number of settings, the search for insight into mechanisms and outcomes of disease by explicit biomathematical or biostatistical modeling may be subservient to the need to classify. Should the patient be catheterized, be operated on, be withdrawn from therapy, be expected to have a prolonged stay, or be managed as if convalescence were proceeding normally after operation? Classification problems such as these have been approached by biostatistical methods, such as optimal classification tree methods (148,149,150 and 151). However, alternative analytical methods have been developed in the disciplines of computer science and applied mathematics that may perform better or at least equivalently. One such method is *artificial neural networks*.

An artificial neural network can be thought of as a potentially time-varying, adaptive, complex, nonlinear mapping from the input variable space (patient characteristics, measurements, attributes) to the output class space. The mapping is often termed the *transfer function*. This transfer function is generally, although not necessarily, a “black box” consisting of hidden layers of weighted combinations of variables (152). In direct comparisons of traditional statistical modeling versus artificial neural networks, classification results have tended to be similar (153,154 and 155).

DATABASES IN CARDIOLOGY

Many cardiology-oriented clinical databases have been developed and are actively used today. This section is not meant to be exhaustive; it provides a brief summary of how some of these databases have been developed and are being applied. Cardiology databases can be roughly divided into five major types: (a) population-based epidemiologic studies; (b) disease-oriented registries; (c) technology- and procedure-focused registries; (d) administrative, financial, and government-sanctioned databases that relate to cardiac issues; and (e) databases derived from randomized clinical trials (Table 44.3).

Population-Based Studies

Framingham Heart Study

The Framingham Heart and Offspring studies are prototypic population-based cardiovascular epidemiologic databases (1,2,3,4 and 5,156). The original cohort consisted of 5,209 adults between ages 18 and 62 years. Since the late 1940s this group has been invited back every 2 years for serial examinations that have consisted of a detailed medical history, physical examination, electrocardiogram, laboratory studies, and imaging studies. In the 1970s, offspring and spouses of the offspring of the original cohort formed a second group of approximately 7,000 adults for the Framingham Offspring Study. This group has been invited for follow-up examinations every 4 years. One of the major strengths of the study has been the nearly complete follow-up with high-quality descriptions of outcome events. Over the past few decades new technologies have been incorporated into the study, including echocardiography, exercise testing, Holter monitoring, heart rate variability analyses, carotid Doppler studies, and sophisticated genetic tests.

The concepts of risk factors, or characteristics that define high-risk subsets of populations initially free of disease, and multivariate risk formulation, according to which risk could be attributed to multiple risk factors, were first coined by Dawber and Kannel (156) and have been extensively developed over several decades. Despite criticism of the epidemiologic method (157,158), work derived from the Framingham Heart Study database has formed the foundation for much of our understanding of the nature of atherosclerotic cardiovascular disease. The epidemiologic method continues to be a valid source of valuable insights in the 1990s, as evidenced, for example, by recent Framingham Heart Study work in the areas of lipid abnormalities (159), homocysteine metabolism (160), risk factor clustering (161), echocardiographic left ventricular mass (162), coronary heart disease risk prediction instruments (163), and mortality risks associated with atrial fibrillation (9,164). As an example of the ongoing power and relevance of the Framingham Heart Study, independent investigators recently found that the Framingham risk prediction instrument accurately identified absolute coronary heart disease risk in a cohort of British hypertensive men (165).

Physicians' and Nurses' Health Studies

The Physicians' Health Study was originally conceived as a randomized trial of aspirin and b-carotene for prevention of coronary heart disease events and cancer among 22,071 male physicians aged 40 to 84 years (164). The aspirin part of the trial was stopped prematurely due to a marked reduction in coronary events among those participants randomized to aspirin (166). However, the database derived from the Physicians' Health Study has been quite comprehensive and has been used to examine a number of issues, including the prognostic importance of endogenous tissue-type plasminogen activator (167), homocysteine (167), C-reactive protein (168), fibrinogen (169), ACE gene polymorphisms (170), adhesion molecules (171,172), and lipoprotein(a) (173).

The Nurses' Health Study was started in 1976 as a prospective study of 121,700 female registered nurses aged 30 to 55 years (174). A questionnaire was sent to the nurses covering information about age, weight, height, smoking, cardiac history, reproductive history, drug use, dietary and other lifestyle habits, and other factors. Every 2 years, subjects were sent a repeat questionnaire to update their data. The Nurses' Health Study database represents a very large population sample of women; very good quality follow-up, careful verification of outcome events, and large numbers of outcome events have allowed for a number of powerful analyses. The database has been used to examine the importance of obesity (175), smoking (176), and lack of postmenopausal hormone replacement (18) as cardiovascular risk factors in women (19,177). Recent work from the Nurses' Health Study has included reports on the prognostic significance of whole grain, saturated fat, nut, dietary fiber, and egg consumption (178,179,180,181,182 and 183); weight cycling (184); abdominal adiposity (185); use of calcium channel blockers for hypertension (186); intake of folate and vitamin B_6 from dietary sources and supplements (187); and physical activity (188,189).

Cardiovascular Health Study

The Cardiovascular Health Study is a population-based study of coronary heart disease and stroke among adults aged 65 years or older. This database has been developed because of the well-documented aging of the U.S. population and the fact that much of the morbidity and mortality associated with cardiovascular disease occur among older adults. By routinely performing diagnostic studies among asymptomatic elder adults, the database is designed to learn more about "subclinical" cardiovascular disease and its association with overt clinical events, as well as to learn more about conventional and hypothesized risk factors for cardiovascular disease. The cohort includes 5,201 ambulatory subjects who were recruited in 1989 and 1990 from four field centers: Forsyth County, North Carolina; Sacramento County, California; Allegheny County, Pennsylvania; and Washington County, Maryland, with the coordinating center located at the University of Washington, Seattle. Cohorts were assembled by random sampling from Medicare eligibility lists. Examinations included detailed home health, dietary, and psychosocial interviews as well as measurement of blood pressure, height, weight, physical activity, functional status, and neurologic function; spirometry; electrocardiography; echocardiography (190); carotid ultrasonography; and blood laboratory studies. Early reports from this study yielded valuable insights on cardiovascular in the elderly, with, for example, reports on the population prevalence of atrial fibrillation (191) and on determinants of left ventricular mass (192). Recent reports have addressed the prognostic importance of aspirin use (193), silent myocardial infarction (194), ankle-arm index (195), daytime sleepiness (196), and carotid artery intima and media thickening as detected by ultrasound (197).

Disease-Oriented Registries

Myocardial Infarction Registries

The National Registry of Myocardial Infarction was organized in 1990 as a postmarketing survey of the treatment of myocardial infarction in 1,073 U.S. hospitals (198). Participation in the study is voluntary, although hospitals are encouraged to enter data on consecutive patients irrespective of presentation or treatment. For each patient, a simple one-page form is filled out and sent to a central data coordinating center; the form covers demographics, presentation of illness, electrocardiographic findings, treatment, clinical course, including complications, and status at time of hospital discharge. To ensure data quality, all data abstractors undergo training, and internal computer audits are present to check for inconsistencies, missing data, and out-of-range values. In the first 3 years of activity, the registry recorded data on 240,989 patients with acute myocardial infarction. The database was first used to examine treatment patterns in clinical practice outside the settings of clinical trials (175), use of thrombolytic drugs in elderly patients (199), and the association between thrombolytic therapy and myocardial rupture (200). Recent work from this registry and from its successor, National Registry of Myocardial Infarction 2, which now includes close to 1 million patients, has included reports on prevalence of primary angioplasty (201,202), door-to-needle time (203,204), door-to-balloon time (77), bundle branch block (205,206), myocardial infarction without chest pain (207), procedural volume and outcome (208), economics of myocardial care (209,210), risks for intracranial hemorrhage (211), early use of ACE inhibitors (212), seasonal distribution of myocardial infarction (213), and outcomes in blacks (214) and women (215).

Duke Databank for Cardiovascular Disease

A prospective database on patients referred for diagnostic and therapeutic cardiovascular procedures has been in place at Duke University since the early 1970s (16,126). One of the original goals of the database was to help physicians better care for patients by examining prior experience in a systematic manner. The database eventually broadened to include information on patients with suspected coronary disease as well as to incorporate a medical record system used for routine clinical care (16). Currently, the database functions in administrative, research, and clinical care arenas. Reports from the Duke Databank for Cardiovascular Disease cover a vast array of topics, including exercise treadmill testing (216) and prognosis of CAD patients treated with different modalities (217,218 and 219). One important study compared survival rates with medical therapy, coronary angioplasty, and coronary artery bypass grafting in 9,263 patients who were followed for a mean of 5.3 years, during which there were 1,665 deaths (220). The large number of outcome events allowed for detailed Cox proportional hazards analyses, which identified that only nine baseline characteristics were predictive of death. Ejection fraction, age, and coronary anatomy were the three most predictive factors. After considering these characteristics, the authors then identified patient subsets that had better outcomes with angioplasty and other subsets with better outcomes with coronary artery bypass grafting.

Technology- and Procedure-Oriented Registries

Cardiac Transplantation Databases

The Cardiac Transplant Research Database was initiated in 1990 when 25 major cardiac transplant centers agreed to share data on the clinical characteristics and

outcomes of patients undergoing cardiac transplantation. Each center was responsible for completing coded forms and sending them to a central data processing center at the University of Alabama at Birmingham. During computer entry, all data were checked for validity with range and inconsistency checks, and all missing or "suspicious" data elements were forwarded back to the original centers for correction and completion. During the first 18 months of operation, data on 911 patients were collected and used to identify risk factors for death after heart transplantation (21). This database has subsequently been used to rigorously study a number of issues related to outcome after heart transplantation, including donor-specific characteristics associated with outcome (221), pretransplantation risk factors (138), influence of human leukocyte antigen mismatching (222), risks for late recurrent rejection (223), and impact of trends in practice on outcome after transplantation (224). The Cardiac Transplant Research Database has been used to develop predictive software by which clinicians can very quickly compare potential transplant recipients to previous recipients to predict long-term outcome and thereby use the database to make more efficacious point-of-care decisions (225). Recent reports have addressed cardiac allograft vasculopathy (226) and the prognostic importance of pretransplantation body mass (227).

Angioplasty and Percutaneous Revascularization Registries

The first percutaneous transluminal coronary angioplasty was performed by Gruntzig et al. (228) in Zurich, Switzerland, September 16, 1977, with data on four patients presented at the American Heart Association meeting in November of that year. Less than 2 years later, in March 1979, the National Heart, Lung, and Blood Institute established a percutaneous transluminal coronary angioplasty registry through which a centralized accumulation of data obtained from multiple centers would allow for a rapid and systematic assessment of procedure-related outcomes (20). The registry collected data on 3,248 patients who underwent angioplasty at 105 different centers between 1977 and 1981; after September 1981, consecutive cases were no longer recorded. In 1985, 15 centers that contributed to the original registry cooperated to form a second registry that recorded data on all patients undergoing angioplasty between August 1985 and May 1986.

The structure of the original registry has been described by Mullin et al. (20) and is illustrative of the multidisciplinary team approach required for a database to be successful. The overall administration and policy making for the registry came from the Cardiac Diseases Branch of the National Heart, Lung, and Blood Institute Program Office. A steering committee, made up of both elected and appointed investigators, met several times a year to review policy and scientific direction. Collection, verification, storage, and analysis of all data were performed at a central data-coordinating center at the University of Pittsburgh.

Because of the increasing use of new devices, particularly coronary stents, a new registry known as *New Approaches to Coronary Intervention* was established with the aid of the National Heart, Lung, and Blood Institute in the early 1990s (229,230). This database has been used to study a number of important issues, including the association of use of new technologies with outcome (229), coronary artery size (231), and the impact of race (232).

Cardiac Surgery Databases

In 1986, the Health Care Financing Administration encouraged public release of crude mortality statistics for coronary bypass grafting (233). Because of concern that administrative and financial databases that were being used to assess mortality after coronary artery bypass grafting did not have the richness of clinical detail to provide fair, risk-adjusted measures of outcome, a number of groups assembled clinically oriented databases. The Northern New England Cardiovascular Disease Study Group collected data since 1987 on more than 60,000 patients undergoing coronary bypass surgery in the five northern New England hospitals performing the procedure (234,235 and 236). Data were collected on demographic data, cardiac and angiographic variables, priority of surgery, and comorbidities using the Charlson comorbidity index (88). Results of interim data reports are given to participating centers and surgeons in the hope that feedback will result in changes of processes that can lead to better outcome. The study group has noted improvements in risk-adjusted mortality and in reducing costs, improving patient satisfaction, and matching patient expectations with outcomes (237,238 and 239). Recent publications from this database have included reports on operator volumes and outcomes (240), obesity (241), preoperative aspirin use (242), and mediastinitis (243).

In 1989, the Society of Thoracic Surgeons established a national database for cardiac surgery (244). It may well be the largest cooperative database of its kind in medicine, with more than 500 participating sites and more than 1.5 million patients. The national data warehouse and analysis center are located in the Duke Clinical Research Institute. The database is voluntary, and in the first 10 years of its existence, data have largely been acquired from community-based cardiac surgery practices and only a few university-based academic practices. Because of its political clout and the adoption of its data elements for statewide and payor quality initiatives, its generalizability has become greater as academic institutions have joined its ranks.

The major strength of the Society of Thoracic Surgery database is in very high numbers. However, to attract continuing participation, the number of data elements collected from participants has been reduced to a core number that appear to influence outcome, and for the most common operations. Recent major publications have focused on risk adjustment, logistic regression models of early risk after coronary artery bypass grafting (245), and cardiac valve replacement (246).

The Cleveland Clinic Foundation Stress Laboratory Database

Beginning in September 1990, all patients undergoing stress testing at The Cleveland Clinic Foundation had their medical histories, medication lists, and exercise test results entered prospectively and immediately on-line into a computerized database (247,248). An early application of the database was to assess whether an association exists between exercise hypertension and angiographic severity of coronary disease (249). By linking stress test results with the Social Security Death Index (250,251), the database has been used to describe the prognostic importance of a number of exercise test findings, including exercise capacity (248), chronotropic incompetence (252), and an attenuated heart rate recovery (253,254).

Administrative, Financial, and Government Databases

New York State Cardiac Surgery Database

Beginning in 1989, all centers performing coronary artery bypass grafting in the state of New York were required by the New York State Department of Health to provide data on a quarterly basis on all patients undergoing the procedure; with these data, risk factors for death and the calculation of hospital-based adjusted mortality rates were reported (255). Each hospital was provided feedback regarding its own actual and expected mortality rates. After 4 years, a significant reduction in risk-adjusted mortality was noted (256), with subset analyses suggesting that the improvement in outcome may have been related to centers responding to data reports by making positive changes in personnel and processes (257). At one cardiac surgery program with a very high reported risk-adjusted mortality, initial frustration with the database gave way to a careful, systematic evaluation of outcome at that center (258). The program directors were able to identify the primary source of their high mortality rates, namely, emergency cases, especially those with recent acute myocardial infarction. They deliberately worked to change the processes by which these patients were managed, with many more patients receiving intraaortic balloon pumps before going to the operating room. Since making these changes, this program has noted a marked decline in its risk-adjusted mortality. Other investigators have suggested, however, that the apparent improvements in outcome since the establishment of the database reporting system may be more due to rejection of high-risk patients, with some of them being referred out-of-state to other centers (257,259).

The story of the New York State Cardiac Surgery Database took an interesting twist in 1991, when *Newsday*, invoking the Freedom of Information Act, successfully sued the New York State Department of Health for surgeon-specific mortality data (260). Since then, operator-specific mortality data have been publicly released yearly, with each surgeon assigned a risk-adjusted mortality rate and a notation as to whether that mortality rate is statistically better, the same, or worse than average. Interestingly, the public release of surgeon-specific mortality data has had little impact on cardiologists' referral patterns (261). Topol and Califf (262) point out that the extension of traditional risk-adjustment data modeling methods to individual operators, or "scorecard medicine," raises a number of concerns, including (a) failure to account for outcomes other than mortality; (b) difficulty establishing an appropriate reference group; (c) limited sample sizes with small numbers of outcome events for each surgeon; (d) difficulty with risk adjustment and appropriate weighting of variables, as well as "rewarding" operators for taking on very high-risk patients; and (e) logistical problems with proper collection and maintenance of costly data. The American College of Cardiology has already taken steps to address these problems not only through the publication of guidelines but also through the establishment and maintenance of a national database of cardiac procedures (263).

Medicare, the Health Care Financing Administration, and the Cardiovascular Care Project

The process by which Medicare monitors and attempts to improve quality of care among its beneficiaries has undergone a marked change during the past 5 to 15 years, with less emphasis on identifying and removing "bad apples" and more on affecting mainstream care processes (61,264). The Cardiovascular Care Project represents an effort by many different physicians, health service researchers, and professional societies to identify and measure a variety of "quality of care indicators" for patients presenting with acute myocardial infarction and for those undergoing myocardial revascularization. Examples of quality indicators for acute myocardial infarction include percentage of eligible patients receiving therapies such as aspirin, thrombolysis, ACE inhibitors, and beta-blockers; percentage of smoking patients who receive smoking cessation counseling; and percentage of patients who undergo or are scheduled to undergo some form of stress testing or cardiovascular imaging at the time of discharge. A four-state pilot study from this project reported multiple opportunities for improvement among Medicare myocardial infarction patients (265). A number of important reports about quality of myocardial infarction care (266,267) have more recently appeared based on this database, including publications about why "America's best hospitals" have lower myocardial infarction mortality rates (268), the importance of physician specialty (269), the use of

beta-blockers (270,271), and the impact of mental illness on the use of cardiovascular procedures (272).

Databases Derived from Randomized Clinical Trials

Although randomized clinical trials are designed to answer specific therapeutic questions, investigators often use them to assemble large observational databases that can be used to study natural history, prognosis, diagnostic questions, and outcomes related to interventions other than those tested. A prototypical example of this is the Coronary Artery Surgery Study, from which a large database was created of 24,959 patients with suspected or known coronary disease who were admitted to one of 15 clinical centers between 1974 and 1979 (273). Although the study results regarding the impact of coronary bypass surgery were published nearly 15 years ago (274), the database emanating from that study continues to provide insight regarding the prognosis of patients with coronary heart disease (275). Some clinical trial registries, such as that of the Studies of Left Ventricular Dysfunction, include patients who were not included in the trial itself (276). Other examples of clinical trial registries being used as observational databases for answering questions unrelated to the trial itself include an analysis of gender and management of acute myocardial infarction from the Myocardial Infarction Triage and Intervention Registry (277); an analysis of the impact of race, age, and sex on management of unstable angina from the Thrombolysis in Myocardial Ischemia III Registry (278); and an analysis on the impact of elevated blood pressure on presentation mortality and stroke outcomes after acute myocardial infarction from the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries Registry (279). More recent observational studies based on clinical trial databases include reports on the combination of aspirin and ACE inhibitors in patients with coronary disease (101) and on the impact of diabetes and lesion characteristics among patients undergoing myocardial revascularization (280).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Formally organized databases have existed in cardiology for more than 50 years, even predating the modern computer age. The last 5 to 10 years have witnessed an explosion in database numbers and sizes, such that very large databases now exist in virtually all areas of clinical cardiology. The use of these databases to analyze the importance of patient characteristics and clinical test results for predicting long- and short-term risks is well-established. In the realm of therapeutics, however, there remains considerable controversy, with some strongly believing that the real-world effects of drugs and procedures can be validly assessed by careful analyses of observational databases, whereas others argue that therapeutic effectiveness and safety can only be measured with randomized, controlled trials. There will always be skepticism of database models that describe risk-adjusted outcome, especially for those individuals and institutions where the outcomes appear to be poor. Clinical science is very complex, and clinical knowledge continues to explode; thus, one can always argue that case mix can never be wholly adequately adjusted for. Improvement of analytical methods and ways to identify and adjust for bias and confounding must remain a high priority within the clinical database and research communities.

Once it is widely accepted that, when properly analyzed, observational databases can be used to assess the impacts of treatments on outcomes, it will then become, we believe, incumbent on the cardiology community to implement Ellwood's technology of experience into routine clinical care. This means careful design and universal use of computerized patient records as well as computerized recording of the nature and outcomes of all cardiac procedures. Considerable investment will be required to purchase hardware and software; employ support personnel; and train and support clinical researchers who will have the skills, enthusiasm, time, and resources needed to appropriately analyze observational databases and disseminate their results. The existence of large databases, along with the rapidly improving technologies to develop, store, manipulate, and analyze them, means that we owe our future patients nothing less.

THE FUTURE

The future of clinical databases in clinical cardiology is uncertain. Academic cardiologists will likely continue to nurture and develop population-based, disease-oriented, and procedure-oriented registries, and these will continue to provide new and valuable insights into the nature and optimal management of cardiovascular disease. Some of these databases are growing to truly humongous sizes, allowing for previously unimagined statistical power. Professional societies, such as the American College of Cardiology, are also actively developing databases for outcomes assessment. However, it is very unclear how computerized databases will be used at the level of routine clinical care. It is hoped that academic and clinical leaders will successfully champion the enormous benefits of the "power of information." One cardiac surgeon who has successfully used a clinical database to improve his outcomes may have seen the future: "'Playing by the numbers' has radically changed the way people involved think about their jobs. We have moved from feeling out of control to feeling in control, from being reactive to being proactive, and from not knowing to beginning to know" (237).

OVERVIEW

Quality of care is linked with achieving the best outcomes for patients, but the term is a complex one that can mean access to care, the appropriateness of procedures or tests, absence of errors, or patient satisfaction level. It is difficult to measure, particularly when one deviates from using mortality as the principal outcome, because of the intrinsic difficulties of risk-adjustment modeling. Despite some of these limitations, the use of “report cards” or “scorecards” is more commonplace than ever for evaluating managed care organizations, individual hospitals, and, in some cases, even the physicians themselves.

Much is being done to improve the methodology of assessing quality, and this will help make the process more acceptable and meaningful. One of the major issues that has emerged is the remarkable expense required to collect data at community and academic centers for such analytical work to be performed. For several cardiovascular procedures and diagnoses—including coronary artery bypass grafting (CABG), percutaneous transluminal coronary intervention (PCI), and acute myocardial infarction (MI)—the relationship of volume to operator or hospital has turned out to be a pivotal index for outcomes. Consistently, across the procedures and diagnoses, low volume reflects suboptimal quality. Although one solution is to regionalize centers (“centers of excellence”), an alternative is to have risk-adjusted modeling data available to secure the level of care provided by low-volume operators. Mortality is only one outcome that needs to be considered and, although easier to measure, should not override key morbidity outcomes such as stroke, MI, or functional status. On the other hand, the best measurement of overall quality related to outcomes may be considered the total mortality of the population seen in a health system rather than the mortality for a particular segment such as bypass surgery or acute MI. The focus on medical errors by the Institute of Medicine (IOM) report in 1999 brought these issues to the forefront (1,2,3,4 and 5). For the field to further evolve, report cards of the report cards will need to be assessed on a frequent basis. A major objective in the field is to drive quality to an unprecedented high level.

HISTORICAL PERSPECTIVE

Although the quality of medical care has been considered since the beginning of the medical profession, Florence Nightingale is generally credited with the fundamental insights in her book *Notes on Hospitals*, published in 1863 (6). In this review of hospitals in London and the United Kingdom, she noted a 91% death rate in the 24 hospitals in London as compared with 40% in 55 county and regional facilities. She recommended sweeping changes in operation and location of the London hospitals and was a veritable pioneer to advance the quality of medical care (6,7). Her vision of the field is well exemplified by her writing:

> Accurate hospital statistics are much more rare than is generally imagined, and at best they only give the mortality which has taken place in the hospitals, and take no cognizance of those cases which are discharged in a hopeless condition, to die immediately afterwards, a practice which is followed to a much greater extent by some hospitals than others.
> We have known incurable cases discharged from one hospital, to which the deaths ought to have been accounted and received into another hospital, to die there in a day or two after admission, thereby lowering the mortality rate of the first at the expense of the second” (6).

Ironically, nearly 135 years later, we are still coping with many of the same issues—suboptimal data collection, lack of adequate follow-up, interhospital transfer of high-risk patients who do not “show” on report card instruments, and less-than-expected accountability.

In 1914, Ernest Amory Codman, a surgeon in Boston, formed his own hospital known as End-Result Hospital, based on the philosophy that hospitals should study their mortality rates and that hospitals with the lowest adjusted mortality should be able to charge the highest rates (8,9). He told the Philadelphia Medical Society the following:

> We must formulate some method of hospital report showing as nearly as possible what are the results of the treatment obtained at different institutions. This report must be made out and published by each hospital in a uniform manner, so that comparison will be possible. With such a report as a starting point, those interested can begin to ask questions as to the management and efficiency” (8).

Despite these pioneering concepts, Codman’s hospital went bankrupt, and the idea was not adopted. This may be telling, as the cost of collecting data for report cards is a significant burden.

Intuitively, the need for risk adjustment of relevant patient demographic features is essential for comparison of outcomes. However, it was Roemer and colleagues (10) in 1968, and later Iezzoni and others (9,11), who demonstrated the critical need of adjustment for severity of illness.

Substantial national attention was drawn to quality assessment when the U.S. Health Care Financing Administration (HCFA) began publishing hospital mortality rates in 1986 (12,13). There was substantial concern over the risk adjustment used in this project, given the limited data in the Medicare administrative billing database (9,14); ultimately, HCFA stopped the release of hospital mortality reports (12). This, too, is a telling historical anecdote. The difficulties in risk adjustment are significant, and this indeed represents a formidable challenge for the future of quality assessment. In the early 1990s, Chelimsky (15) noted that there was much more interest in the cost of health care than in quality. Clearly, the lay press, as represented by *The New York Times*, focused on cost and access rather than quality indicators. But in recent years, although cost continues to be a central factor, there has been considerable research dedicated to the quality of medical care (16,17,18,19 and 20). In some instances, there has been application of relatively crude assessment tools in clinical practice; as a result, the field has been quite controversial. Some cardiologists and internists have the sense that quality assessment is simply a means of camouflage to reduce costs; others feel they are being harassed by such efforts. Nevertheless, if quality assessment is properly done in cardiovascular medicine, there is significant potential improvement in patient care (21).

DEFINITION OF QUALITY OF CARE

General

Despite the fact that quality of care became a standard phrase in the late 1990s, the operational definition of *quality* has been a source of confusion and difference of opinion. The IOM (22,23,24 and 25) defined *quality* as the "degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." The technical excellence of the care that is provided, with special emphasis on the physician-patient relationship, is a common theme for most definitions of *quality of care*. Two factors drive the technical quality—the appropriateness of the services provided and the skill with which the appropriate care is performed.

One reason why cardiovascular medicine has been a major focus of quality efforts is that the most obvious health outcome—death—is common in patients with identified cardiac disease. This ease of measurement coupled with the high cost of cardiovascular care has made cardiology a focal point for quality measurement activities.

The determination of quality depends to some extent on the perspective of the person for whom the assessment is done. Patients, health care providers, and policy makers tend to have somewhat different, though considerably overlapping, concepts regarding quality. Patients tend to focus on the nature of the interactions with providers, including personal attention, courteous behavior, and prompt service, elements of what has been termed *patient satisfaction*. A major issue is the view that patients, as consumers, should have all of the information necessary to make judgments about the value of medical services, the concept of "patient-centered care" (22).

In contrast, providers tend to emphasize the technical aspects of quality, including whether correct decisions regarding diagnostic or therapeutic strategies have been made and whether those strategies have been executed with proper skill and knowledge. Policy makers and managers of health plans or health benefits organizations are most interested in measures of health and satisfaction of the overall population rather than a single measure of health. Integrating these different perspectives can be a daunting task, and most quality assessments tend to emphasize one of the three perspectives. Ultimately, quality of care is evaluated at three different levels—structure, process, and outcome (26).

Clinical practice guidelines are a pivotal part of defining quality on an evidence basis, with a list of class IA, IB, II, and III recommendations. By simply counting the number of times such recommendations are followed as a proportion of the number of opportunities, one can derive a quality measure which should relate quite nicely to outcomes.

Structure

The *structure* of a health care system refers to the characteristics of physicians, other health care providers, and the facilities in which they deliver health care. For cardiology practice, the critical structural characteristics comprise the specialty status, practice organization, availability of facilities for noninvasive and invasive testing and therapeutic intervention, and the types of disease management programs. Recent information has demonstrated that both specialty status (27) and environment, such as teaching or financial status of hospitals (28,29), have an influence on mortality. These studies reinforce the component of structure for determining quality of care.

Process

The "time-honored" method of peer review has been the morbidity and mortality conference. In this approach, when a poor outcome occurred, the patient's care was reviewed in front of a peer group. This approach suffered from lack of consistency and frequently did not provide the type of information that could lead to systematic improvement in the delivery of care. In a sense, quality assessment has followed the same course as clinical investigation: from anecdote to systematic quantitative assessment.

An appealing approach to measurement of quality is to determine when it is known that one diagnostic or therapeutic strategy is superior to an alternative and to measure how often the preferred strategy is used rather than the inferior strategy (26). "Doing the right thing at the right time" in concept can be measured relatively easily, and because multiple patient encounters occur, this sort of process measurement has a frequency of events high enough to allow for meaningful quantitative measures. Thus, measurement of the proportion of post-MI patients treated with aspirin and beta-blocker drugs has become a standard method of assessing quality.

The use of statins in patients with atherosclerosis and low-density lipoprotein of more than 100 mg per dL is a useful index. A recent report by Bradley and colleagues (30) on beta-blockers after acute MI highlights the process issues. Eight representative hospitals across the United States were selected to prospectively study the use of beta-blockers (Table 45.1). The range of improvement varied between 30% and –21%. The key factors characterizing improvement were administrative support, support and leadership among clinicians, use of data, explicit goals, and the proper design and execution of initiatives to affect change (30).

State	Staffed beds	Beta-blocker use rate, patients, %		Absolute change in beta-blocker use (% points)	Beta-blocker use rating	
		Baseline	Follow-up		Improvement	Follow-up
California	277	43	70	+30	High	High
Ohio	438	47	69	+22	High	High
Florida	628	56	68	+12	High	High
California	353	39	46	+7	Average	Medium
New York	237	61	67	+6	Average	High
Arkansas	275	29	35	+6	Average	Low
Missouri	708	63	47	-16	Low	Medium
Minnesota	110	66	45	-21	Low	Medium

*Beta-blocker use rates were calculated as the number of patients who received beta-blockers at discharge divided by the total number of patients discharged from each hospital during the relevant (baseline or follow-up) period.

TABLE 45.1 LISTING OF STUDY HOSPITALS

Another increasingly used measure is the time from admission to the emergency department to the administration of thrombolytic therapy. In patients with congestive heart failure, the proportion of patients with left ventricular function measurements and the proportion of patients receiving angiotensin-converting enzyme inhibitors among those with reduced systolic function comprise data-derived explicit process measures.

This approach of using explicit process-based criteria derived from results of randomized trials has increasingly supplanted traditional peer review, which consisted of a review of the chart by an independent expert to assess the degree to which care of the patient seemed to reflect community standards with nonquantitative feedback to individual practitioners. The weaknesses of this nonquantitative, implicit assessment are obvious. The lack of consistency increases the chance of arbitrary use of the

information for negative feedback rather than providing standards by which self-improvement can be made.

Brook and colleagues (26) described the rationale for the subjective approach. An expert or a “peer” reviews the documentation in the medical record. The first question asked in the examination is whether the basic approach to patient care was adequate by community standards. The second question is whether a different approach to care would have improved the outcome. Finally, these two elements are put together to determine whether the overall quality of care was “acceptable.” Multiple problems have been encountered with this approach, including difficulty identifying peers or experts to perform the review (excellent practitioners spend their time caring for patients and not reviewing others’ charts) and inadequacies in the typical medical record in terms of providing the best information for quality assessment.

An appealing method that combines process and intermediate measures of outcomes is to identify a physiologic outcome that would fall within an excellent, acceptable, or unacceptable range based on what is known about the disease pathophysiology and its management (26). An example of this type of measure is the assessment of hemoglobin A_{1C} in patients with diabetes. It is assumed that excellent care for diabetes will result in low hemoglobin A_{1C} levels, although multiple methods of achieving these levels might be acceptable practice (diet, exercise, insulin, oral hypoglycemic agents). Therefore, a quality assessment might simply consist of measuring the proportion of patients seen by a practitioner for longitudinal care with acceptable hemoglobin A_{1C} measures.

This approach can be extrapolated to populations of patients by evaluating the proportion of patients meeting the physiologic target. Variation in compliance would be expected in a population, and therefore an acceptable range of uncontrolled diabetic patients could be defined based on community data. The proportion of patients with adequately controlled blood pressure or stable weight could also be quantified and compared using benchmarking methods. Of course, these measures are subject to gaming in the same way as complex outcome measures, by steering high-risk patients for poor outcomes or poor compliance away from the practice (21).

Appropriateness

A more formal means of assessing whether the “right thing was done at the right time” is to evaluate its appropriateness. Whether a diagnostic or interventional procedure was properly indicated and needed is an alternative assessment of process. To determine the “appropriateness” of a medical procedure, it is necessary to have the circumstances judged by an independent group of health care professionals, with access to the medical records and relevant laboratory information. Ratings of appropriateness have been used for CABG, PCI, coronary angiography, and other cardiovascular procedures (31,32,33 and 34). However, it is cumbersome to review the patients on a case-by-case basis. The qualitative and subjective aspects, in trying to assess whether the accepted criteria or indications have been met, can be difficult to resolve. Accordingly, a considerable proportion of the procedures performed for patients wind up being scored as “uncertain.” Still, the level of appropriateness of a given procedure may be used as an index of quality of a given hospital, health care system, or even operator.

Medical Errors

One of the most controversial areas to have been highlighted in recent years is that of medical errors. The IOM report issued in 2000 (initially issued in 1999) (1) set off considerable debate in the medical community and peer-reviewed medical literature (2,3,4 and 5). The report claims that at least 44,000 to 98,000 deaths occur in American hospitals each year that are attributable to medical errors. The IOM notes a “cycle of inaction” and calls for prevention of errors and resultant injuries, along with better accountability and dedicated research. In review of the literature surrounding the report, it is clear that medical errors constitute a problem. But what remains unclear is whether the magnitude of the problem has been exaggerated. On one hand, noted authorities such as Brennan (2) and McDonald et al. (3) have questioned the report’s accuracy and potential for harm itself. Others such as Leape (4) and Meyer et al. (5) stand firm behind the report. Of note, Meyer et al. represent the Agency for Healthcare Research and Quality, which stands to gain considerable federal funding for research in this area. Much of the debate is related to the data from which the potential error death toll is extrapolated, such as a 1984 study of New York hospitals, and a 1991 to 1992 study in Colorado and Utah hospitals (2). For example, postoperative hemorrhages are classified as “errors” when most physicians would not consider this as an appropriate categorization. Another example of potential miscalculation was that of medication errors that were attributable to drug abuse rather than an iatrogenic cause (3). The IOM report calls for a future 50% reduction in the incidence of errors, but there is no accurate incidence available in a general medical population. Some data suggest that safety has already improved from the 4% to 5% rate of injury reported in California in 1976 to the 2.9% in Colorado and Utah in 1992 (2).

Recently, Hayward and Hofer (34a) estimated the number of deaths from medical errors in the United States to be 5,000 to 15,000 per year. The gross discrepancy (one-tenth of the IOM estimate) was attributed to inaccurate definitions of what constitutes a medical error. Hayward and Hofer looked at 111 in-hospital deaths at seven Veterans Administration hospitals between 1995 and 1996 and concluded that a very small proportion (0.5%) of patients would have lived at least 3 months in good health if optimal care was delivered.

Despite the media attention and headline-grabbing nature of the IOM report and the flurry of additional editorials, the positive side is more focus and attention to the issue of quality of care. Many examples have been developed in cardiovascular medicine. MI, which has the greatest profile of conditions in the field, has been the subject of several recent papers on errors in medication (35,36,37,38,39,40,41 and 41a) and of media coverage. The alarming newspaper coverage of one of the first reports of errors in fibrinolytic dosing in acute MI read “up to 25% of heart attack patients who are given the two most widely used clot-busting drugs during heart attacks get the wrong doses, doubling their death rates.”

It is particularly confounding to analyze medication errors in the treatment of acute MI, because patients die before they can receive the complete dose, and this could be wrongly classified as an “error.” In Figure 45.1, a report from the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) III trial by Goodman et al. highlights the association between deviation in planned dosing and mortality, both for alteplase and reteplase (35). The difficult issue, however, is to establish cause and effect, and none of the studies to date was prospectively defined to address this pivotal question. It seems logical that bolus fibrinolytic agents such as reteplase or tenecteplase may reduce errors in dosing, as compared with the complex regimen of accelerated alteplase, which required a 90-minute infusion and different doses of the drug in three discrete phases (bolus, initial 30 minutes, next 60 minutes). Similarly, excessive dosing could result in intracranial hemorrhage or other life-threatening bleeding complications. As with the overall problem of medical errors, we can be assured that there is indeed a problem, but the precise quantification is quite difficult with fibrinolytics in acute MI.

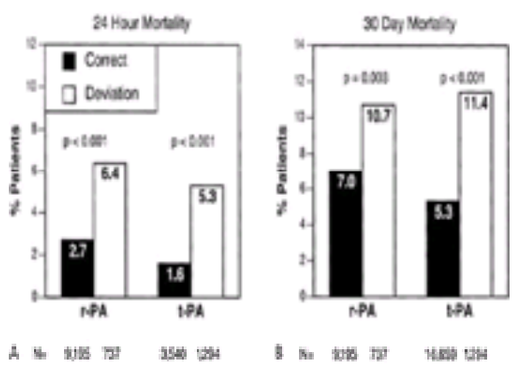

FIGURE 45.1 Mortality at 24 hours **(A)** and 30 days **(B)** in the GUSTO III trial by correct or incorrect fibrinolytic dosing. r-PA, reteplase; t-PA, alteplase. (From Goodman S, et al. Presented at the American College of Cardiology, March 2001, with permission.)

It should be noted that the IOM report and related studies have focused only on in-patient medical errors. Although these are relatively easier to measure (despite controversy over definitions), important errors also occur in the outpatient arena, and those represent a major challenge for our health care system.

Outcomes

The concept that medical outcomes should be the gold standard of quality assessment is not difficult. However, a number of problems with collection and assessment of the relevant data severely limit the degree to which outcomes can be used in the current environment. Several studies found that when both process and outcomes are measured with adequate power, the two indicators point in the same direction (26). The list of potential key outcomes include mortality, morbidity, cost, and patient satisfaction.

Mortality

Mortality is the most appealing outcome to use in the assessment of quality in cardiovascular disease. It is easy to measure and difficult to manipulate. Additionally, as compared with many other medical problems, mortality is the critical outcome in the treatment of most cardiovascular problems.

Only certain cardiovascular diagnoses or procedures have an appreciable risk of mortality to make them suitable for a parameter of quality assessment. In patients who present with either acute MI or congestive heart failure or who undergo cardiac transplantation or coronary artery bypass surgery, the proportion of expected deaths may be adequate to use this as a benchmark of the quality of care. But for the common diagnoses such as unstable angina, evaluation of chest discomfort, or procedures such as percutaneous coronary revascularization, the fatality rates are too low for meaningful assessment. Thus, despite its importance, death is rare enough that in most circumstances adequate numbers of deaths cannot be accumulated to develop statistically robust estimates.

Furthermore, although statistical models to predict mortality have been developed more extensively for cardiovascular procedures and problems than for other medical conditions, the majority of the variance in mortality cannot be explained by known factors. Accordingly, considerable debate remains about whether differences observed in mortality outcomes between systems, practices, or practitioners represent differences in quality, differences in risk status of the population before treatment, or random variation.

Beyond the problem of low incidence and potential of random variance, mortality may not be the most important outcome to assess for a given diagnosis or procedure. For example, with percutaneous revascularization, the occurrence of periprocedural MI and the need for emergency bypass surgery or repeat PCI are much more common adverse outcomes than mortality. Furthermore, the durability of the procedure is reflected by the avoidance of the need for repeat procedures during extended follow-up, along with the patient being symptom-free. In such patients, an assessment of mortality does not indicate the important outcomes that one needs to know to adjudicate the quality of a particular center or even operator.

There are certain instances in which mortality and morbidity may not track. For example, in a center where patients undergo CABG with a low mortality but with a heightened risk of perioperative stroke or mediastinitis, one could be misled by the low occurrence of fatal outcomes. Indeed, Silber and colleagues (42) identified a poor correlation between nonfatal and fatal complications of CABG in 57 hospitals and nearly 17,000 patients. Of note, this study also suggested that sites that record details of medical care may be the ones with the lowest operative mortality.

Major Morbidity

Major morbidity has advantages as a measure of quality in that it is more common and it is usually detectable in the medical record. However, the imperfections of major morbidity result from variability in definition, degree of documentation, and adjustment models. Although the general concept of MI or stroke is intuitively obvious, the actual classification of individual cases is highly variable. The diagnosis of MI is dependent on timely measurement of enzymes and electrocardiograms, the type of enzyme assay used (creatinine kinase-MB, troponin), and appropriate interpretation of the data with recording in the medical record. Particularly with cardiovascular procedures, there is a well-described bias of the person performing the procedure to minimize procedure-related difficulties; in clinical trials of percutaneous interventional procedures, detection of nonfatal MI by the practitioner occurs at much lower rates than does detection by a clinical events committee (43). Additionally, uncertainty concerning the accuracy of statistical models to adjust for differences in baseline risk for death is multiply compounded in the prediction of nonfatal events.

Cost

The use of cost as a measure of quality is controversial. In the in-patient setting, costs are increasingly measured for administrative reasons to ensure the financial viability of hospitals. Because patients are also concerned about cost, it is reasonable to consider that high-quality physicians or practices might be defined as providing excellent outcomes or evidence of excellent process at a reasonable cost. Outpatient costs are more difficult to obtain and have not become a commonly used measure for comparative data.

With the availability of extensive financial data in some centers, it is often easier to measure hospital and professional costs rather than clinical outcomes. Such indices as length of stay or cost per case have been increasingly used in recent years but may not accurately reflect quality of care. Ideally, the best outcomes can be achieved at the lowest cumulative cost. Interestingly, the state of Pennsylvania technology assessment program showed an inverse correlation between hospital costs and outcomes for coronary artery bypass surgery (44) that was not expected. The centers with the lowest cost tended to also achieve the best outcomes. Whether this will occur with other diagnoses, procedures, and even for this particular operation in other health care systems remains to be seen. The economy of scale with high volume may be a principal driving factor when there is a direct relationship between quality and cost. At times, use of “big ticket” items such as stents or abciximab may be linked to much higher costs but would be expected to provide reduced risk of ischemic complications.

Patient Satisfaction

Patient satisfaction, like cost, has become a standard administrative measure to ensure that practices remain economically viable. It can be measured quickly and efficiently, just as satisfaction with other services can be measured in our society. Large numbers can be aggregated to allow accurate statistical comparisons to be made.

However, little relationship exists between the satisfaction of the patient with the encounter and the technical quality of care delivered. A patient undergoing an uncomplicated percutaneous intervention that was not indicated in the first place may have felt that the care was excellent, but the judgment about whether the procedure was indicated requires substantial medical knowledge. Patient satisfaction is typically rated via questionnaires and may be difficult to interpret. The parameter that seems to drive this in a favorable direction is time with the physician and the sense that the physician is giving the patient undivided attention and utmost priority. However, factors such as parking at the hospital, the cafeteria, accommodations, reading materials in the waiting room, the service orientation of ancillary personnel, and many others play a role in the composite experience. Therefore, patient satisfaction is an important parameter to survey, but its relationship with clinical outcomes is not established. It is possible that the three different indices of clinical outcomes, cost, and patient satisfaction may go in different directions. For the low-volume center that is characterized by exquisite customer service and long physician and physician extender visits, for example, there may be excellent patient satisfaction but excessive costs and suboptimal outcomes. Nevertheless, with health care plans that rely on patient subscription, this may be one of the most important indices to evaluate a program’s success.

METHODS OF MEASUREMENT

The validity of proposed measures of quality cannot be understood without a thorough knowledge of the source of data. A major problem with interpretation of much of the data made available to the public has been the reliance on inaccurate sources of data and extrapolation beyond the limits of the data. Because most of the medical record consists of handwritten notes, there is no available method of aggregating information that captures the interaction between the health care provider and the patient in most systems. Consequently, administrative databases or medical record reviews have formed the basis for most quality assessments.

Administrative Databases

Administrative databases designed to allow patient billing and tracking for financial reasons provide excellent information concerning demographics, procedures, and survival. However, this information does not reflect the modifying medical information concerning severity of illness, complications, or medical outcomes other than death. Multiple studies have demonstrated that the clinical information contained in administrative databases is incomplete and often erroneous and misleading. Comparisons of insurance claims information with clinical databases have demonstrated poor concordance rates in classifying patient diagnosis, ranging from 0.09 for unstable angina to 0.83 for diabetes (45).

Administrative databases such as Medicare or those at state departments of health are especially attractive to use because they contain large data sets with the sufficient outcomes needed to analyze the relationship of a hospital or clinician to outcomes. However, these databases were frequently not designed to perform such an analysis and may be quite insufficient with respect to missing data. Often, only mortality data are available with limited demographic information. These typically represent retrospective ad hoc assessments. Many of the data, if not all that have been entered, have not, ironically, been quality-assured except for the financial component. More recently, using an administrative database to prospectively capture relevant data, such as is ongoing in New York for PCI procedures, is a powerful means of combining large numbers of patients, outcomes, and establishing the relationship.

Medical Record Review

Although administrative or claims databases certainly have problems, the medical record itself has many deficiencies that make chart audit a suboptimal exercise. The nomenclature used to describe similar phenomena varies from practitioner to practitioner. Pertinent negatives are frequently not mentioned so that the reviewer must assume that if a finding or procedure is not mentioned in the medical record, it was not evaluated or done. In an adverse event reporting study, a chart audit missed

more than half of adverse events related to medications (46). On the other hand, physician reporting of adverse events in the same study was equally remiss for identifying the outcomes but twice as likely to detect the important, preventable events. The physician-reporting mechanism was considered less costly: $15,000 compared with $54,000 (46). This study emphasizes some of the pivotal shortcomings of chart review—its lack of accuracy and high cost.

Clinical Databases

Very few clinical databases are used in concurrent patient care. Such databases tend to have considerably more information that is relevant, with data having more likely been verified by source medical record or other documentation, and are easier to work with. A clinical database can take the form of a single center's results, a clinical trial, or a consortium of sites. Prospective randomized clinical trials are emerging as a powerful tool to provide information on outcomes between different health care systems or regions (47,48).

Risk Adjustment

Although it seems that determining the severity of illness for patient groups and performing risk adjustment might be straightforward, this has not proved to be the case (49,50 and 51). There is considerable debate about what constitutes the clinical vital facts; whether to use administrative data alone or incorporate relevant laboratory data; and the value of further clinical data that can be obtained only via the time-consuming, labor-intensive, and expensive abstraction of medical records. Several proprietary commercial severity measures have been used (*e*Table 45.1.1). Of these, the MedisGroups has been adopted by Pennsylvania for the "consumer guide" for CABG; the Acute Physiology and Chronic Health Evaluation III "physiology score" has been widely used to assess quality of care for intensive care units. Of note, direct comparisons of these four severity measures showed considerable variance, with only about 80% of patients receiving similar rankings between severity tools (49).

***e*TABLE 45.1.1** FOUR SEVERITY MEASURES

Severity measure	Source	Data used and definition of severity[a]	Classification approach	Derivation[b]
MedisGroups (Westborough, MA)	MediQual Systems, Inc. death; score calculated within 64 disease groups	Clinical data; in-hospital	Probability ranging from 0 to 1 modeling	Empirical
Physiology score	Patterned after acute physiology score of APACHE III	Clinical data; in-hospital death for patients in intensive care unit	Integer score starting with 0; APACHE III's Acute Physiology Score ranges from 0 to 252	Empirical modeling with clinical guidance
Disease staging	SysteMetrics/MEDSTAT Group (Santa Barbara, CA)	Discharge abstract; probability of in-hospital death	Probability ranging from 0 to 1	Empirical modeling
All patient refined diagnosis-related groups	3M Health Information Systems (Wallingford, CT)	Discharge abstract; total hospital charges	Four severity classes (A, B, C, and D) within adjacent diagnosis-related groups[c]	Empirical modeling with clinical guidance

APACHE III, Acute Physiology and Chronic Health Evaluation III.

[a] Discharge abstract: standard hospital-discharge data elements, such as basic demographics and diagnosis and procedure codes. Clinical data: clinical information, such as vital signs and test results, abstracted from the medical record.

[b] *Derivation* indicates the principal method used to create the severity scoring method. *Clinical guidance* reflects primarily the use of expert physician guidance; *empirical modeling* indicates primarily the use of statistical techniques.

[c] Adjacent diagnosis-related groups were formed by grouping individual diagnosis-related groups previously split by complications and comorbidities.

From Iezzoni LI, Ash AS, Shwartz M, et al. Predicting who dies depends on how severity is measured: implications for evaluating patient outcomes. *Ann Intern Med* 1995;123:763–770, with permission.

The discriminatory power of a particular model for risk adjustment can be assessed by comparing c-statistics, which are equivalent to area under receiver-operating characteristic curves (50). Pine and colleagues (51) showed that a model that relies solely on administrative data compares favorably (good concordance) to one that incorporates administrative, laboratory, and clinically extracted data, with an area under receiver-operating characteristic curves of approximately 0.85. This remains controversial, as many studies have demonstrated the added value of the laboratory and additional clinical data. Nevertheless, review of these data is instructive to highlight some of the difficulties encountered in performing risk adjustment of patients, even for mortality outcomes.

WHO IS MEASURING QUALITY?

Because participants in health care ranging from the patient to the practitioner to the health care administrator are interested in quality, considerable overlap exists in the assignment of responsibility of its assessment. An understanding of the roles currently assumed by various organizations could allow the practitioner to develop an approach to responding to the demands and needs of the various constituents.

H4>Centers for Medicare and Medicaid Services

As the largest single payer for health care delivery in the United States, the government has been concerned with the quality of medical care since its beginning. The evolution of thinking about how to assess quality has been propelled by the initiative that the Centers for Medicare and Medicaid Services (formerly HCFA) has taken in making risk-adjusted data for such procedures as CABG or cardiac transplantation available to the public. The public availability of this information has also allowed for ascertainment of outcome data for various constituents to use for benchmarking and advertising. Given that the clinical information contained in the Centers for Medicare and Medicaid Services database reflects diagnoses recorded for billing purposes, this approach has been highly controversial (14,52) and, ultimately, for in-hospital mortality data the practice was abandoned in 1993.

National Committee on Quality Assurance

The National Committee on Quality Assurance (NCQA) was founded in 1979 as an effort to establish a system of quality assessment by national managed care organizations (35). In addition to a primary interest in the importance of quality assessment, this organization was provided as an alternative to government intervention. With grant funding, the NCQA became independent of the national managed care organizations and its board was altered to provide a societal perspective on quality. One perspective on the NCQA is that it represents the most powerful single organization through which employers can participate in the assessment and the improvement of large health plans.

The method by which the NCQA accredits health plans includes a review of operations and an assessment using the Health Plan Employer Data and Information Set (HEDIS). HEDIS is a continually evolving set of measures designed to assess quality, access, and satisfaction in addition to critical issues in finances and administration. The measures are simple, and the HEDIS measures in use in 1996 included only whether cholesterol screening was used as a cardiovascular outcome measure. In *e*Table 45.1.2, a version of HEDIS is provided. More disease-specific measures are currently being added to the system. In a review of the NCQA, Iglehart (53) reported that the organization is growing and making a difference despite the rudimentary nature of the instruments being used and concern about the cost by managed care organization administrators.

***e*TABLE 45.1.2** COMPONENTS OF HEALTH PLAN EMPLOYER DATA AND INFORMATION SET 2.5

Quality (9 measures)

Preventive medicine
- Childhood immunization
- Cholesterol screening
- Mammographic screening
- Pap smears for cervical cancer

Prenatal care
- Low birth weight
- Prenatal care in first trimester

Acute and chronic disease
- Hospital admissions for asthma
- Retinal examination for diabetes

Mental health and substance abuse
- Ambulatory follow-up after hospital treatment of major affective disorders

Access and patient satisfaction (5 measures)

Access
- Percentage of members 42 to 64 yr old with visit to the plan in previous 2 yr

Number and percentage of primary care physicians accepting new patients
Existence of access standards for various types of visits and telephone responses
Satisfaction
Percentage of members who are “very satisfied” with the plan
Provision of plan satisfaction surveys
Membership and use (approximately 20 measures)
Indicators providing data on membership and the use of services in various categories, including frequency of selected surgical procedures, rates of hospitalization, nonacute in-patient care and ambulatory care, maternity and obstetrical care, drug utilization, and care for mental health and chemical dependency
Finance (approximately 15 measures)
Indicators of performance (income and loss rates), liquidity (cash on hand), efficiency (measures of uncollected funds due), and compliance with statutory requirements (e.g., financial reserves)
Plan management (approximately 15 measures)
Indicators providing descriptive information on the network of providers (board certification of physicians, turnover, and compensation) and on clinical management, including management of quality, preventive care, case management, utilization review, and risk management

From Epstein A. Performance reports on quality—prototypes, problems, and prospects. *N Engl J Med* 1995;333:57–61, with permission.

State agencies (peer review organizations) have focused on quality assurance in the practice of medicine but have generally not collected large data sets on particular diagnoses or procedures. Some exceptions are highlighted in the subsequent section on outcome assessment by procedure.

Agency for Healthcare Research and Quality

In the United States, the new federal agency responsible for quality health care is the Agency for Healthcare Research and Quality, formerly the Agency for Health Care Policy and Research. The agency has solid government funding and an ambitious agenda to improve the country’s health care delivery.

State Agencies

In the late 1980s, New York State instituted mandatory reporting of baseline characteristics and outcomes in patients undergoing CABG. Since then, percutaneous interventional procedures have been added to the mandatory reporting scheme. This approach has caused substantial controversy both because of the public disclosure of this information and because of uncertainty about whether this system has actually improved care. Pennsylvania and California have instituted similar programs for producing outcome report cards for acute myocardial infarction and revascularization procedures.

Regional Efforts

The Northern New England Group has organized major hospitals performing coronary revascularization in the New England region, with a goal of improving quality through the collection and dissemination of process and outcome data. A common database has been developed and used to provide scorecards for outcomes, and serial measures of process have been used to document improvement in the quality of care.

Cities

A number of metropolitan areas have now developed business coalitions interested in assessing the quality of medical care. This approach was quite visible in Cleveland with the organization known as the Cleveland Health Quality Choice. Formed in the early 1990s by the Cleveland Metropolitan Business Coalition to facilitate selection of hospitals, the 30 centers were ranked on a quarterly basis for risk-adjusted mortality for five different diagnoses (50), including acute MI and congestive heart failure. The data were published in the newspaper along with other indices such as patient satisfaction and length of stay. Ultimately, the rating system was terminated when the costs of accruing the data specific to the project became unacceptable to some of the large hospital providers.

Managed Care Organizations

Individual managed care organizations typically provide individual assessments of quality and satisfaction, but the major method of ensuring accountability is external accreditation. The HEDIS measures (eTable 45.1.2) administered by the NCQA have become the standard, although these measures have almost no relevance to the care of patients with cardiovascular disease.

Professional Societies

Although professional societies can provide standards for quality assessment, the responsibility of professional societies to guard the welfare of their members makes actual assessment of the quality of individual practitioners difficult. An approach adopted by the American College of Cardiology focuses on the development of standards for data collection that will allow the assessment of structure, process, and outcome measures (54). The Society of Thoracic and Cardiovascular Surgeons is far ahead of the American College of Cardiology, and output from their database has been linked to driving better quality at institutions throughout the United States.

Individual Hospitals

The interest of individual hospitals in quality measures has been primarily to promote excellence in the quest for managed care contracts or public attention. However, in this process substantial progress has been made at the local level in the ascertainment and aggregation of major procedural outcomes. The major mechanism of quality assessment in this manner has been the use of clinical databases. The American College of Cardiology is playing a major role in focusing commercial database sponsors on common nomenclature and collection of baseline clinical data that will allow for adjustment according to baseline risk.

The National Hospital Network provides one example of a large group of hospitals that have organized for contracting purposes and to that end have developed common standards for data capture. This database provides reports to individual institutions, benchmarking them against other institutions in the network with regard to patient characteristics, choices of procedures, and outcomes. The database has provided substantial documentation of a wide variation in practice patterns related to choice of devices, even in high-volume institutions.

QUALITY OUTCOMES FOR PARTICULAR CARDIOVASCULAR PROCEDURES AND DIAGNOSES

Coronary Artery Bypass Surgery

The most extensively studied medical procedure for relationship of volume to outcome is bypass surgery. The procedure is ideal for scorecard analysis because it is frequently performed, it carries an appreciable risk of mortality, and there has been extensive refinement of the features that are important for risk adjustment. Luft and coworkers (55,56 and 57) pioneered much of this effort and were among the first to document the inverse relationship between hospitals with low volume and high mortality in the late 1970s. In the mid-1980s, the HCFA and Veterans Affairs hospitals began reporting hospital CABG activity and risk-adjusted mortality on an annual basis to the public (9,12,13,21,58). As early as 1989, Hannan and colleagues (59) from New York State noted that the surgeon’s annual volume was even more critical a determinant than the hospital volume of CABG for risk-adjusted mortality. In 1991, two influential studies from the Northeast demonstrated the extensive interhospital, interoperator, and geographic variability for CABG risk-adjusted mortality outcomes (60,61). There has been considerable effort and clinical investigation in the Northeast on this topic, especially in New York, Pennsylvania, and northern New England (59,60 and 61).

In New York, a pivotal study in 1990 described the statewide Cardiac Surgery Reporting System and tracking of the 28 hospitals performing CABG, with four hospitals demonstrating mortality rates that were significantly higher than expected—one with a death rate of 14.3% and only 63 cases during a 6-month period in 1989 (62). These data attracted considerable attention in December 1991, when a newspaper sued the State Department of Public Health for access to the operator- and hospital-specific data. A supreme court in New York ruled that the citizens of the state have a right to know these data and granted the newspaper access, setting a national precedent for public disclosure of not only hospital-specific but also physician-specific crude and risk-adjusted mortality data (21,63).

The findings in New York of certain hospital outliers were replicated in other parts of the country (62,64). Pooling seven studies that examined the relationship between hospital volume and mortality outcome for CABG, Sowden and coworkers (65) showed that the adjusted relative risk of dying was between 0.44 and 0.83 for surgery in a high-volume hospital (cutoff of high volume ranging from 150 to 223 cases per year). Of interest, in Ontario, Canada, where there are no low-volume hospitals (all performed more than 300 cases per year in 1992 and 1993), there were no outliers and the in-hospital mortality was consistently low in all nine hospitals (66). These findings certainly provide a foundation for the call for “regionalization” that many of the studies have beckoned (57,64,66,67). Of note, in contrast to California there is

considerable lack of a regionalized approach. In California, 91% of patients are within 25 miles of a center that offers bypass surgery, as compared with 82% in New York and 60% in Canada (67). Along with this, in 1987 to 1989, 31% of California hospitals performed fewer than 100 CABGs per year, as compared with 10% in New York and 0% in Canada (67).

The tracking of hospital- and operator-specific risk-adjusted mortality has been associated with a reduction in mortality not only in New York and northern New England but also in Massachusetts, where there is no centralized tracking (68,69,70 and 71). Hannan and colleagues (68) reported a New York statewide 41% decrease in risk-adjusted CABG mortality (from 4.2% to 2.5%) from 1989 to 1992. This mortality decline could not be explained by shifts of patients from low-volume to high-volume surgeons, changes in patient mix, or improvement of performance of surgeons with low volumes (69). Rather, it was suggested the improvement was related to the influx of new cardiac surgeons with better results and the exodus of some low-volume surgeons with high risk-adjusted mortality (69). As with New York, O'Connor and colleagues (70) reported a 24% reduction in mortality from 1987 to 1993 for patients undergoing surgery in Maine, New Hampshire, and Vermont. Quite comparable to the improved cardiac mortality observed in New York, in Massachusetts the observed mortality rates decreased from 4.7% to 3.3% from 1990 to 1994 (71), despite the absence of statewide reporting of outcomes.

The relationship of surveillance reporting systems and improvement of outcomes has fueled considerable controversy and has important implications on regional and national health care policy (72,73 and 74). It remains unclear that a statewide report card directly influences outcomes because the CABG mortality rate has decreased on a national level (72). Green and Wintfeld (74) harshly criticized the claims of the New York State Department of Health's first physician-specific mortality report by objecting to the validity of the risk-adjusted mortality model, changing of definitions from any in-hospital death to in-hospital death within 30 days, and changing in coding of key risk factors (renal failure, congestive heart failure, chronic obstructive pulmonary disease, and low ejection fraction). Examples that they cited were a 350% to 600% increase in coding of renal failure (with a change in definition to creatinine of more than 2.5 mg per dL instead of dialysis) and increase in coding of chronic lung disease from 2% to 53% (74).

Chassin and members of the New York State Department of Health (75,76) strongly objected to these critique points and quantitatively assert that the reduction of CABG is real and attributable to the reporting system. Omoigui and coworkers (77) from The Cleveland Clinic Foundation showed that patients from New York State outmigrated to The Cleveland Clinic with increased frequency during the period of the statewide reporting system, and these patients were distinctly higher risk. However, the number of patients who were shown to outmigrate from New York could not have accounted for the marked reduction in CABG-related mortality during the period under study (75,76 and 77); perhaps it accounted for a small contribution (75,76,77 and 78).

The statewide reporting mechanism of CABG results has also been available in Pennsylvania since 1990 with hospital and professional charge data, in addition to hospital- and physician-specific outcome data (Fig. 45.2) (44). Recently, Schneider and Epstein (79) surveyed Pennsylvanian cardiologists and cardiac surgeons and claimed that the state's *Consumer Guide to Coronary Artery Bypass Surgery* has limited credibility and raised concern that such a guide could have an unfavorable effect on access to CABG for the most severely ill patients who need surgery the most.

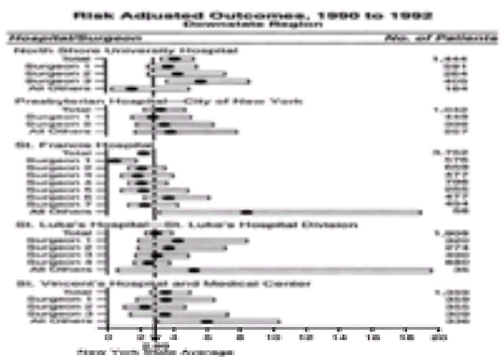

FIGURE 45.2 Risk-adjusted coronary artery bypass surgery mortality data (black dots are point estimates) with 95% confidence intervals (*horizontal bars*) for representative hospitals in Downstate New York. (From Topol EJ, Block PC, Holmes DR, et al. Readiness for the scorecard era in cardiovascular medicine. *Am J Cardiol* 1995;75:1170–1173, with permission.)

The New York CABG database has offered a window to the effect of managed care insurance (80). Recently, Peterson et al. used the New York CABG database to analyze access to care and elderly patient outcome (81). This group of investigators also examined the difficulties of risk adjustment for comparing CABG mortality results (82). The refinement of risk-adjusted indices for CABG has continued with work by Ivanov et al. (83).

In summary, report cards on CABG have been extensively used in many parts of the country, but their true effects on favorably modulating mortality are not completely accepted. This particular operation has been the "front-runner" in the field for hospital- and physician-specific outcomes and the testing grounds for public disclosure. Surely the lessons learned from the experience and controversies will be instructive in other procedures and diagnoses in cardiovascular medicine.

Percutaneous Coronary Intervention

PCI has been more difficult to study and produce scorecards for because, although the procedure is very frequently performed, the mortality is quite low (approximately 1% or less) and the morbidities of emergency bypass surgery or MI are difficult to define, especially in a post hoc analysis of a large administrative database (84). Nevertheless, the studies that have been reported parallel the findings of CABG, with a clear-cut inverse relationship of hospital and operator volume and adverse outcomes. Hannan and associates (85) studied more than 5,800 patients in New York State to delineate a multivariate risk-adjusted model. One of the first activity-to-volume relationship studies was performed by Ritchie and colleagues (86), who showed, using nearly 25,000 procedures in the state of California during 1989, that urgent CABG was progressively more likely as hospital percutaneous transluminal coronary angioplasty (PTCA) volumes fell below 200 per year. Further, in patients having PTCA related to a principal diagnosis of acute MI, the relationship of hospital volume to adverse outcomes was exaggerated in hospitals with an annual volume of fewer than 200; the death or urgent CABG rate was 12.4%.

The Society for Cardiac Angiography and Interventions reported on more than 19,500 consecutive patients in 48 hospitals in North America. Most of the hospitals performed more than 200 PTCAs per year, and the major finding was fewer major complications in centers performing more than 400 procedures per year (a 44% risk reduction, risk-adjusted) (87). Of note, if the threshold of 400 cases is used, these data suggest a 2-fold reduction in mortality, a 10-fold reduction in emergency CABG, and an 18-fold reduction in periprocedural MI (87).

The relationship of hospital volume to major complications was studied by Jollis and colleagues (88) using the Medicare database of more than 217,000 patients. As shown in Figure 45.3, there was a definite relationship of hospital volume and mortality as well as the rate of CABG during the index hospitalization. Of note, the patients undergoing PTCA in hospitals without surgical backup had the highest mortality (9.9%), which may be attributed in part to a higher proportion of primary PTCA for acute MI.

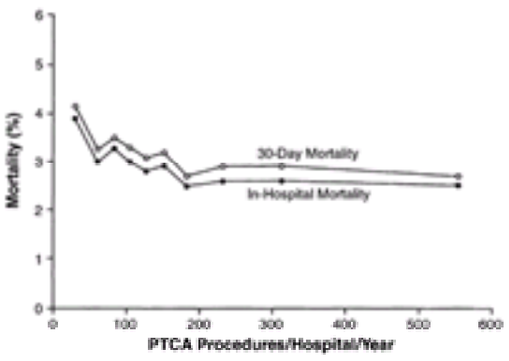

FIGURE 45.3 Mortality among Medicare beneficiaries who underwent percutaneous transluminal coronary angioplasty (PTCA) from 1987 through 1990, according to the volume of PTCA procedures at the hospitals where they were treated. The points on the curves correspond to the mortality rates among patients treated at hospitals with volumes of 1 to 46, 47 to 70, 71 to 93, 94 to 114, 115 to 137, 138 to 166, 167 to 206, 207 to 261, 262 to 371, and 372 to 987 procedures per year. (From

Jollis JG, Peterson ED, DeLong ER, et al. The relation between the volume of coronary angioplasty procedures at hospitals treating Medicare beneficiaries and short-term mortality. *N Engl J Med* 1994;331:1625–1629, with permission.)

Operator-specific results in PCI have been studied by many groups, and parallel trends of a volume to outcome relationship have been shown (87,88,89,90,91,92 and 93). Ellis and associates (90) pointed out some of the difficulties in categorizing a “poor” operator or outliers with a database of nearly 5,000 procedures. By using a 50 cases per year dichotomization for low- and high-volume operators, Shook and colleagues (92) demonstrated a near doubling of emergency bypass surgery (2.1% vs. 3.9% for low-volume operators) and significant differences in length of stay as well as hospital costs. The 2001 guidelines for the American College of Cardiology/American Heart Association call for a minimum of 75 cases per year (94). Still, it is estimated that in the United States, 55% of physicians perform fewer than 75 procedures per year and 46% of hospitals perform fewer than the recommended 400 per year (95).

The data set from New York State for all 62,670 patients undergoing PCI between 1991 and 1994 is illuminating and further corroborates the volume relationship (96). As shown in Figure 45.4, patients undergoing PCI by cardiologists with annual volumes of fewer than 75 cases had a substantial rise in same-day bypass surgery need. Risk-adjusted mortality was unfavorably affected in hospitals with annual PTCA volumes of fewer than 600. Although not as striking, the relationship of activity and mortality outcomes by hospital and operator was similar. The New York State data have been made available to the public (97). These data provide independent verification of the critical relationship of major complications and PTCA hospital and physician volume.

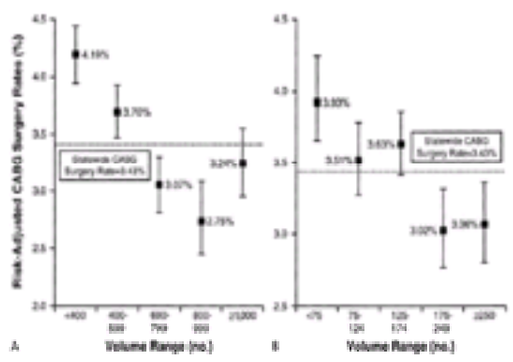

FIGURE 45.4 A: Risk-adjusted coronary artery bypass grafting (CABG) surgery rates for different hospital percutaneous transluminal coronary angioplasty volume ranges. Data presented as mean, with 95% confidence intervals indicated by the vertical bars. **B:** Risk-adjusted CABG surgery rates for different cardiologists’ percutaneous transluminal coronary angioplasty volume ranges. Data presented as mean, with 95% confidence intervals indicated by the vertical bars. (From Hannan EL, Racz M, Ryan TJ, et al. Coronary angioplasty volume-outcome relationships for hospitals and cardiologists. *JAMA* 1997;277:892–898, with permission.)

Much recent work has reinforced the operator-volume and outcome correlation in PCI (98,99,100,101,102,103,104,105,106,107,108,109,110,111,112,113,114,115,116,117,118 and 119). A prototypic example of the relationship was reported by McGrath et al. (119) involving 167,208 Medicare patients in 1,003 hospitals and 6,534 operator-physicians. The need for CABG by operator volume and the hospital volume–mortality relationships are presented in Figure 45.5. Although the operator volume did not affect mortality and the hospital volume was not associated with urgent CABG use, the relationships that were found appear to be quite convincing and reinforced by the bulk of the other parallel studies.

Relation between operator and hospital volume and outcomes following percutaneous coronary interventions in the era of the coronary stent. *JAMA* 2000;284:3139–3144.)

Acute Myocardial Infarction

The risk-adjusted modeling for acute MI in the reperfusion era was addressed by Lee and colleagues (120) and in a large Medicare cohort by Normand and associates (121). Many states and regions have begun to analyze outcomes for acute MI by hospital. In December 1993, the state of California published the California Hospital Outcome Project, which provided extensive data for the diagnosis and outcome for patients presenting with acute MI for every hospital in the state. Representative data are summarized in eTable 45.1.3 (122,123). Beyond the outcome of mortality, important parameters such as the time to treatment, the use of thrombolytic therapy or catheter-based reperfusion, and the use of aspirin and other adjunctive medications are reflective of the quality of care for MI patients (121). Significant regional and global variability exists in the use of angiography, PTCA, adjunct medications, and outcomes (46,47). Interestingly, the availability or age of the patient appears to be driving most of the coronary angiography performed after MI in the United States, rather than the expected medical indication of recurrent ischemia (124). The care pattern is affected by not only whether a primary care physician is involved but also improved when a noninvasive or invasive cardiologist is involved (27,125,126 and 127) and is affected by the type of hospital (128,129). The tremendous variability in practice patterns, even in the United States, with limited long-term data for large populations, underscores the uncertainty as to the appropriate level of aggressiveness.

From Topol EJ, Block PC, Holmes DR, et al. Readiness for the scorecard era in cardiovascular medicine. *Am J Cardiol* 1995;75:1170–1173, with permission.

Two studies suggested that involvement of a cardiologist in the care of a patient with acute MI may have a particularly beneficial impact on survival (27,130,131,132,133 and 134). In the Medicare study performed by Jollis and coworkers, involving 8,241 patients in four states in 1992, a significant relationship of risk-adjusted mortality reduction was demonstrated according to the specialty of the admitting physician. The odds reduction of mortality of approximately 12% to 15% for a cardiologist versus a primary care physician (Fig. 45.6) is noteworthy, as this represents at least as much of a benefit that has been targeted in several large-scale

MI intervention trials (135,136,137 and 138). Willison et al. and others provide data and insight to reinforce Jollis' report (139,140 and 141). Consistent with the mortality effects was the use of evidence-based medications such as beta-blockade, aspirin, and angiotensin-converting enzyme inhibitors. A similar pattern of physician specialty and outcome was found for patients with unstable angina (142). An analysis of superior outcomes for MI in the 40 "top" heart hospitals reinforced the use of evidence-based treatment (lytics, aspirin, beta-blockade) as a marker for improved quality of care (143). Like the critique of scorecards, a point of vulnerability is the validity of the risk-adjusted modeling for making key comparisons in these large administrative data sets. Of interest, if the gradient of mortality reduction of 10% to 15% (or more) can be achieved through improvement of process, such as the reduction of time to thrombolytic treatment by 1 hour on average associated with a 15% reduction of 30-day mortality, then meaningful improvement in outcomes can be derived and anticipated in the most common killer of patients in Western society today.

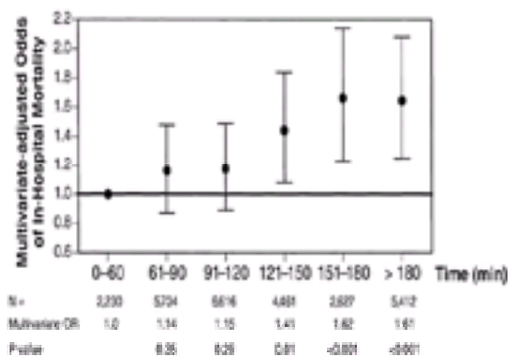

FIGURE 45.6 Multivariate-adjusted relationship between door-to-balloon time and mortality (c^2 trend = 99.5; p <.01). Error bars indicate 95% confidence intervals. *Door time* refers to arrival at the hospital; *balloon time* refers to the time of first balloon inflation of the primary angioplasty procedure. OR, odds ratio. (From Cannon CP, Gibson CM, Lambrew CT, et al. Relationship of symptom-onset-to-balloon time and door-to-balloon time with mortality in patients undergoing angioplasty for acute myocardial infarction. *JAMA* 2000;283:2941–2947, with permission.)

Outcomes research in acute MI reperfusion has been very helpful in demonstrating the importance of door-to-balloon time, hospital volume, and mortality. Using the National Registry of Myocardial Infarction data in 27,080 patients and multivariate adjustment, Cannon et al. showed the striking direct relationship of door-to-balloon and the odds ratio of mortality (Fig. 45.6) (144). Furthermore, these investigators went on to show the hospital volume–mortality relationship with primary angioplasty (Fig. 45.7) (144). Using the National Registry database from 1994 to 1999 in 62,299 patients, Magid et al. provided a comprehensive analysis of both thrombolytic therapy and primary angioplasty (145). As summarized in Figure 45.8, low-volume hospitals (fewer than 16 patients per year) had the longest door-to-balloon time and achieved similar in-hospital mortality for lytics or catheter-based reperfusion. On the other hand, the high-volume MI centers had better door-to-balloon times and better results for PCI compared with lytics (p <.001 for a strategy-hospital volume interaction) (145). Tu and colleagues have taken the field a step further by analyzing MI outcomes in 98,194 patients treated by 5,374 physicians in Canada (146). A strong inverse relationship between average annual volume of MI cases treated by the admitting physician and mortality rate was demonstrated (Fig. 45.9) (146).

Relationship between annual volume of patients treated by admitting physician and mortality after acute myocardial infarction. *JAMA* 2001;285:3116–3122, with permission.)

The health care system and type of hospital have also been the subject of study for MI outcome research. The advantages of teaching and academic centers

(147,148), those that have on-site revascularization (149) and Medicare compared with the Veterans Health Administration (150,151), have all been explored.

COMMON THEMES AND PROBLEMS

Process versus Outcome

The debate about whether quality of care measurements should focus on the process of care or outcomes remains highly controversial. Advocates of measuring process point to the near impossibility of being certain that outcomes can be risk-adjusted and to the huge costs of measuring outcomes other than death. Furthermore, difficulty with common definitions and the ease of gaming the system with regard to nonfatal outcomes continue to produce substantial difficulty in the assessment of outcomes. Finally, the large number of outcomes that must be identified to discern differences in quality produces a fundamental limitation for the system.

Some have advocated that clinical trials should be used to establish efficacy and that outcome research should be used to determine the most effective way of delivering a diagnostic therapy or strategy. When these components have been evaluated in adequately sized studies, measurement of how often appropriate practices are used provides a method of measuring quality that is firmly based in empirical methodology and does not require adjustment for differences in baseline characteristics of patients seen by one practice compared with another.

Volume versus Outcome

The relationship between volume and outcome has been at the center of discussion because it is an easy structural measure to record and to assess in an aggregate manner. The fundamental observation that “practice makes perfect” seems to be a verifiable observation across multiple medical practices and procedures. This relationship seems to hold not only for individual practitioners, but also for institutions.

However, volume is not the only determinant of quality, and empirically, differences in volume account for only a modest amount of differences in outcomes observed. Nevertheless, almost all adequately sized studies indicate that focus on a particular medical problem or procedure as evidenced by high volume tends to be associated with better outcome; therefore, when all other factors are equal with regard to medical outcomes, one would prefer to be cared for by a high-volume clinician in a high-volume facility.

A particularly interesting issue in the volume-outcome relationship is the extent to which the proper environment can allow the low-volume clinician to achieve adequate or excellent outcomes. For example, interventional laboratories in which a high-volume operator is physically present may allow many low-volume operators to thrive with oversight and help from a more experienced person. Similarly, although cardiologists provide care for acute MI, which has a more consistent evidence base for appropriate use of therapies and better outcomes than what internists or family practitioners provide, it is also likely that a coronary care unit supervised by a cardiology intensivist can allow equal or better quality of care with multiple lower-volume generalists admitting patients.

Individual versus Institutional Assessment

Arguments can be made that oversight agencies should concern themselves with aggregate measures of performance of practice groups or institutions, allowing internal assessments to govern the behavior of individual practitioners. This approach has the advantage of providing adequate sample size to discern differences and of allowing for high-quality, low-volume operators to perform within groups that can monitor quality in groups of patients. It also seems apparent that holding groups responsible for outcomes will allow the natural selection process to occur, as groups will not want poor performers to drag down the overall group effort, and it is likely that gravitation toward development of shared expertise would occur. This approach is already being used in the assessment of managed care organizations by the NCQA and in the assessment of institutions by managed care organizations in the determination of which practices are awarded contracts.

Multifactorial Understanding of Outcomes

The science of determining the reasons for the variability in underlying risk that can affect outcome is in an early stage of development. In the past, this science was mostly limited by the inability to aggregate large amounts of data, but this restriction is no longer a problem. The most fundamental limitation remains difficulty accessing true clinical information, because little of it is recorded in a computerized format. Statistical methodology, including multivariable regression analysis and neural networking, continues to develop, but for the most part, an understanding of the empirical basis for reaching a conclusion remains elusive to most practitioners, and statistical concepts are even more foreign to most administrators and patients. Finally, an understanding of the biologic and clinical constructs that are critical to the prediction of outcomes generally falls far short of desired accuracy, even with the best statistical methodology and careful prospective data collection.

Low-Volume Operator

The low-volume operator or low-volume provider presents a special problem with regard to statistical assessment. In the absence of a sufficient number of cases, a few bad outcomes will give unreliably high point estimates of event rates. Additionally, practitioners with low volume may have the appearance of excellent outcomes due to chance. A useful rule of thumb is that when no complications have been observed, an approximation for the upper ninety-fifth percentile of the confidence interval is $3/N$, where N is the number of patients treated.

Fundamentally, the numbers demonstrate that determining complication rates or outcomes with confidence is nearly impossible in the low-volume situation. This conclusion limits the number of options. Because it is known that low-volume operators have worse outcomes, they could simply be banned; this approach is not likely to succeed in the current environment. A second option would be to allow low-volume operators to avoid statistical assessment until an adequate number of cases had been recorded. An alternate option would set up a “buddy,” or pairing, configuration of operators as long as the group volume was adequate for statistical assessment. This approach would promote peer review as the main method of controlling quality in the low-volume operator, with substantial motivation through peer pressure.

New Operator

In an environment focused on assessment of quality, the training of new operators requires special consideration. The lack of experience and volume would be expected to lead to less sufficient process and outcome measures. Teachers and teaching institutions put themselves at risk in this situation. An evaluation of this problem leads to the inevitable conclusion that special allowances need to be made for teaching institutions, but the measurement of process and outcomes provides a motivation for providing top-notch teaching rather than “laissez-faire” training programs.

Difficulty of Data Collection

Substantial information exists to validate the concept that a hierarchy of accuracy of clinical data exists. Prospective clinical databases provide the highest level of data reliability, followed by chart review, administrative reports, and self-audit. Several studies provide substantial insight into the difficulties with self-audit. A review of the literature on reported complications of carotid endarterectomy revealed that studies with only individual surgeon assessment of the patient found only a 2.3% rate of death or major complications, whereas multiauthored reports showed a 5.5% rate and reports with specific assessments by internists or neurologists revealed a 7.7% rate of death or major complications (152). Similarly, when cardiologists report rates of nonfatal MI after percutaneous intervention, much lower rates are observed with self-report than with individual assessment (43). Extensive data are available comparing self-report with core laboratory assessment of procedural anatomic results indicating a similar phenomenon: Practitioners have difficulty of bias when reporting on their own care (153). Administrative databases provide low-quality, but comprehensive data. In one report (45), agreement rates between clinical and claims databases varied from 0.83 for diabetes diagnosis to 0.09 for unstable angina, with a wide variety of values in between. All of these findings point to the fact that the ideal data system does not currently exist. The limitations of these systems should be acknowledged in quality reports, but too often this issue is forgotten.

Cost

The cost of collecting data specific for quality assessment is much higher than anticipated. For hospitals that are responsible to provide their data to multiple payers, this burden can be overwhelming. In Pennsylvania, where extensive data are required to submit for patients, the cost per case for specific data collection was estimated to be $17.43, or representing approximately $100,000 per year (51). In comparison, to participate in the Cleveland Health Quality Choice program of rating risk-adjusted mortality for five diagnoses, it costs The Cleveland Clinic Foundation more than $450,000 per year for chart abstractors, data management, and quality assurance. Thus, the cost of the collection of the data can be quite imposing and represents a major obstacle to the widespread use and acceptance of serial quality assessments. Efforts to reduce the costs by using electronic means of capturing the data, from both the administrative database and the laboratory, with avoidance of chart review, are under way (51).

Auditing

The difficulties with statistical modeling to adjust for differences in baseline characteristics have been reviewed elsewhere. Regardless of the method used, when the results in one practice differ from the results in another practice, whether the different outcomes resulted from differences in medical care, the play of chance, or a greater severity of underlying illness from one practice to another cannot be determined with certainty. Fortunately, it has been the experience of most outcome assessors that when major differences in outcomes occur, the differences in quality are measurable on multiple levels. Even when high-quality statistical models are available, the ability to game the system can be substantial. As reviewed for bypass surgery in New York State, concern exists about practices ensuring that maximum severity of illness is coded so that the observed versus expected numbers will be as favorable as possible (74).

Rewarding High Risk

Another special problem is the frequent inability of statistical models to account adequately for those who care for specially high-risk populations. Inner-city or extremely rural populations may have worse outcomes due to difficulty with compliance or resources. These sorts of variables are frequently not collected or accounted for. It has been proposed that special consideration should be given to practices voluntarily caring for identifiable high-risk populations. In the context of gaming the system, this approach would reduce the current incentive to steer high-risk patients away from practices undergoing substantial outcome scrutiny or financial pressures. Outcome models frequently neglect recording critical information about patients transferred from one institution to another.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The public entitlement for complete information on hospitals and physicians has been validated by the supreme court in New York, but the most important concern is that the public accesses quality information about the quality of care. Many clinical, statistical, and logistic problems, summarized in *e*Table 45.1.4, largely remain unresolved. Although public release of meaningful data can be supported, the most critical obstacle is whether and how such data can be generated. The public expectations of assessing the quality of care have been raised in the last few years. In a State of the Union address, former President Bill Clinton stated the following:

***e*TABLE 45.1.4** CLINICAL, STATISTICAL, AND LOGISTIC PROBLEMS OF RELEASING OPERATOR-SPECIFIC DATA TO THE PUBLIC

Clinical problems
Mortality, although easiest to track, may not be the most meaningful index (e.g., length of stay, readmission, functional status, recurrence of symptoms)
Difficult to establish the appropriate reference group for comparison
Incomplete data (e.g., lack of ejection fraction)
Statistical problems
Limited sample, with respect to number of patients, event rates, and time of assessment
Risk adjustment is difficult
Proper weighing of variables
Small differences that are not statistically significant on an individual basis can have a meaningful cumulative impact
“Reward” for high-risk patients
Cluster phenomenon and periodicity of release
Logistic problems
Collection and proper maintenance of the data, preserving authenticity
Cost of data management

From Topol EJ, Califf RM. Scorecard cardiovascular medicine. *Ann Intern Med* 1994;120:65–70, with permission.

> We have evidence that more efficient delivery of health care doesn’t decrease quality. . . . Pennsylvania discovered that patients who were charged $21,000 for coronary artery bypass surgery received as good or better care as patients who were charged $84,000 for the same procedure in the same state. High prices simply don’t always equal good quality” (49).

Clearly, the amalgamation of cost and quality into the “value” of health care has become a principal competitive concept, for one health care system to prevail against another. However, the data for the quality component are too often “soft,” with such components as patient satisfaction indices heavily relied on. Even for comparing cardiac services between hospitals or health care systems, it is very difficult to get an authentic quantitative evaluation of interventional cardiology, bypass surgery, electrophysiology and pacing, management of acute MI and heart failure, and all the other facets of a heart center. Paradoxically, in this world of a high density of information that is immediately electronically available for business, sports, and news, we are still lacking the critical data that would be necessary for decisions on health care.

Assuming that one can strive to generate worthwhile data, there is also the controversy about whether the data have an impact on improving the quality of care. With CABG the best-case scenario for measuring outcomes and assessing and adjusting risk, the debate continues as to whether the 40% reduction in mortality in CABG throughout New York State was a direct result of detailed quality assessment. Transfer of high-risk patients outside a particular medical system continues to be studied (154).

Operator- or physician-specific outcome data are perhaps most controversial of all because the inadequacies of sample size magnify the problems of interpreting these data. Nonetheless, such data have been used for cardiac surgeons in New York State and in Pennsylvania. Ultimately, for low-volume operators to assert their capabilities to deliver excellent care, it will be essential to demonstrate lack of complications on a risk-adjusted basis.

FUTURE DIRECTIONS

As was expressed by Nightingale more than a century ago, there is a need for better accountability in medicine. Via the study of quality parameters, it is hoped that health care systems, hospitals, and physicians will accept more responsibility for maintaining data and disclosing the data in suitable circumstances. Surely checks on process, such as monitoring the proportion of patients with proven coronary disease and hypercholesterolemia who are not getting secondary prevention therapy or the number of patients with heart failure not on an angiotensin-converting enzyme inhibitor, will be worthwhile. Internally, medical centers should consider developing risk-adjusted models for such procedures as CABG and percutaneous revascularization to monitor groups of physicians over an extended period, such that the number of operations or procedures is suitable for analysis.

Many factors suggest that the future of quality assessment will continue to be mired with controversy (155,156,157,158,159,160 and 161). The cost of information about quality care (162,163) and the cost of not delivering quality care (164) will remain contentious. The risks of risk adjustment (165,166 and 167) and release to the public of such data (168,169,170,171 and 172) remain unsettled issues. Fundamental issues such as defining the optimal way to measure quality (173,174,175,176,177 and 178), appropriateness of procedures (179,180), and physician competence (181,182) lie at the heart of debate and will continue to evolve over time. Without question, the effect of simply studying quality can have a salutary outcome (183), and as clinical trials continue to address major, unanswered dilemmas it becomes easier to judge whether evidence-based medicine is being practiced (184). A major, penetrating issue is individual physician and institution accountability. Kassirer, a former editor of the *New England Journal of Medicine*, claims we remain in a state of “pseudoaccountability” (185) and that hospitals need to heal themselves (186). Much of Iglehart’s review of the American health care system (187) and the insight of Shine, who directs the IOM (188) and the International Practitioners Data Bank (189), reinforce this perspective. The recent British Royal Infirmary Inquiry and Report underscored the nature of pseudoaccountability recounting the deaths of brain-damaged children (in 167 of 1,827 children undergoing cardiac surgery in a 12-year period) and the media characterized the “club” atmosphere with reluctance to accept criticism that allowed poor surgical standards to continue undetected for years (190,191 and 192). Certainly, in our quest to improve the quality of care and to avoid medical errors in cardiovascular medicine, there will need to be deep commitment for not only improving the data accountability and measurement instruments, but also the “teeth,” or active steps towards privileging, credentializing, and close surveillance of hospital and physicians.

THE FUTURE

Electronic data retrieval, ultimately via Internet entry, will greatly facilitate collection and analysis of data. There will be steady refinement of risk adjustment for each of the major diagnoses and procedures in cardiovascular medicine (e.g., acute MI, heart failure, atrial fibrillation, CABG, PCI). Ultimately, the goal of measuring quality and stepwise reduction of medical errors will be increasingly achieved over time.

OVERVIEW

Accurate imaging is essential to assess cardiac anatomy, function, perfusion, and metabolism, and revolutionary advances have been seen in the past 20 years, primarily because of improvements in computer technology and digital signal processing. The heart may be imaged using x-rays [radiography, angiography, computed tomography (CT)], gamma rays (radionuclide imaging, positron emission technology), sound waves (Doppler echocardiography), and the magnetic properties of the hydrogen nucleus [magnetic resonance imaging (MRI)]. Tests may be compared by their ability to detect and exclude disease (sensitivity and specificity, respectively), but the predictive value of the test depends largely on the prevalence of the disorder in the population being tested (Bayesian analysis). Computer processing is important both in generating images and in enhancing the images for display (smoothing and edge enhancement); Fourier transformation is commonly used to analyze the frequency content of images and data in Doppler echocardiography, MRI, and radionuclide ventriculography. Digital image storage is becoming feasible with reductions in computer costs and agreement on the Digital Imaging and Communications in Medicine (DICOM) Standard for medical image exchange. The massive storage requirements may be reduced by careful clinical editing of studies and with digital compression algorithms. All-digital storage and transmission will greatly enhance the value of cardiac studies and facilitate telemedicine.

GLOSSARY

Convolution: Altering a pixel based on the values of surrounding pixels.

DICOM: Digital Imaging and Communications in Medicine, a formatting standard to allow the exchange of medical images.

Digital compression: Recording an image to require less storage. *Lossless* compression does not change the appearance at all (but yields little compression), whereas *lossy* compression yields greater savings (but with some alteration of the image).

Doppler principle: Ultrasound signals have their frequency shifted in proportion to the blood velocity.

Fourier analysis: Analysis of the frequency content of an image or signal.

Gamma ray: High-energy photon produced by nuclear decay.

Nuclear magnetic resonance: Spinning or precessing of certain nuclei (typically the hydrogen proton) in the presence of a magnetic field.

Photons: "Particles" of electromagnetic radiation.

Piezoelectric: A property of matter that converts electricity into vibration and vice versa.

Point processing: Altering an image gray scale, pixel by pixel.

Positron: Positive electron (antimatter); when it encounters an electron, both are annihilated and two 511-keV photons are emitted in opposite directions, forming the

physical basis for positron emission tomography.

X-ray: High-energy photon produced by rearrangement of an atom's electron cloud.

INTRODUCTION

High-fidelity imaging is required to understand cardiovascular anatomy, function, metabolism, and blood flow more than any other organ system in the body. The fine structure and complex motion of the heart demand imaging modalities with high temporal and spatial resolution. Fortunately, intensive research in physics, pharmacology, and computer processing over the past 50 years has led to dramatic improvements in our ability to characterize and quantify disorders of the cardiovascular system. The next 11 chapters describe in greater detail the clinical aspects of the major cardiovascular imaging modalities: radiography, echocardiography, angiography, nuclear cardiology, and MRI. As a prelude, this chapter describes many of the concepts common to each of these techniques, including image generation, computer processing, assessment of diagnostic accuracy, and the emerging area of digital storage and transmission. An understanding of the physical background of these methods will help the reader to understand better the clinical applications described in later chapters.

Here we consider four broad ways to acquire images of the heart: x-ray transmission, radionuclide emission, ultrasonic reflection, and nuclear magnetic resonance. Although these techniques share many features, together they span virtually all of classical and quantum physics. This chapter can only touch on these topics, and the reader is referred to a number of excellent texts for greater detail (1,2,3,4,5,6,7,8 and 9).

What Is Imaging?

In a broad sense, imaging displays the differential interaction of energy with matter to discern structure or function. For instance, the printed page reflects fewer photons from dark letters, allowing them to be seen against the photon-rich white page. Similarly, radiography exploits the fact that more x-rays are absorbed by bone than by soft tissue, and echocardiography displays the reflection of ultrasonic energy from the border of two tissues with different acoustic impedances. Radionuclide techniques are slightly different in that they deliver an energy source (the radioactive compound) to the body, where it is concentrated in structures of interest and then localized by external detectors. MRI defines the differential distribution of weak magnetic characteristics within the body.

Basic Concepts

A number of terms and concepts are common to all imaging modalities.

Resolution

Resolution can have several meanings in imaging. *Spatial resolution* reflects the smallest separation that two objects can be distinguished. For example, in radiography, spatial resolution is measured with a grid of finely spaced lines. The densest packing of lines that can be distinguished is reported as the number of line pairs per centimeter. For radiography, resolution is relatively constant across the field of view. This is not true for echocardiography, which typically has greater resolution in the near field than in the far field, because of the divergence of the ultrasound beam. Furthermore, in echocardiography, resolution is *anisotropic*, that is, better in the axial direction (along a scan line) than in the lateral direction (across scan lines). One must also take care to distinguish the physical resolution of the imaging modality from the resolution of a video or computer display (commonly used in nuclear imaging, echocardiography, MRI, and digital angiography). The spacing of the picture elements (*pixels*) on the screen may be greater or lesser than the physical resolution. This screen resolution typically is stated in the number of pixels across the screen in the horizontal and vertical direction (640 × 480 is typical for low-end computer monitors; 1,024 × 1,024 for high-resolution digital angiography; and 2,048 × 2,048 or even higher for digital radiographic and mammographic images). The functional spatial resolution is always the lesser of the physical and screen resolutions.

Temporal resolution reflects the frequency with which an image is generated, usually stated in frames per second. Plain film radiographs are typically taken as single images, but temporal resolution may still be relevant because the *shutter speed* (the time the film is actually exposed to x-rays) determines whether rapid movements (such as prosthetic valve motion) can be "frozen" in the image. There often is a trade-off between temporal and spatial resolution. Echocardiograms can be generated more frequently, but this usually requires that the density of scan lines per image be reduced. The data for a multigated nuclear scan can be divided into shorter temporal "bins," but this reduces the amount of data available for each image, reducing the signal-to-noise ratio and spatial resolution.

Resolution issues are also important in the calculation of cardiac blood velocity (by Doppler echocardiography or MRI). Velocity resolution reflects the smallest difference in velocity that can be discerned, whereas temporal resolution is the frequency with which the velocity data are updated. Just as with images, there usually is a trade-off between velocity and temporal resolution. Increasing the frequency of display reduces the velocity resolution and vice versa.

Dimensionality

The heart is a four-dimensional structure, possessing three spatial dimensions of shape and one temporal dimension of motion. Most imaging modalities have two spatial dimensions (i.e., a picture, such as a radiograph or an echocardiographic image). M-mode echocardiography displays structures along a single line in the heart (like an ice pick), and so is a one-dimensional display. Magnetic resonance, CT, and some nuclear and echocardiographic studies are intrinsically three-dimensional (3-D), although the display may be on a two-dimensional (2-D) screen. Because motion is critical to many cardiac diagnoses, most modalities include the temporal dimension, typically with a series of 2-D or 3-D images. Plain film radiographs and some nuclear studies do not show motion.

Transmission versus Tomographic Imaging

Two-dimensional images of the heart can be generated by either *transmission* or *tomographic* techniques. In transmission imaging, the full thickness of the heart is projected onto a screen, whereas a tomogram displays structures lying within a single plane of the heart. For most applications, tomographic imaging (used in MRI, CT, echocardiography, and many nuclear tests) is preferable, because there is no interference from overlying structures. For angiography, however, transmission imaging is actually an advantage, because the full course of the vessel can be visualized, something no single tomographic plane could do. Indeed, in magnetic resonance angiography, the 3-D data set is projected onto a plane to generate a transmission image for easier diagnosis.

IMAGING WITH ELECTROMAGNETIC RADIATION: X-RAYS AND GAMMA RAYS

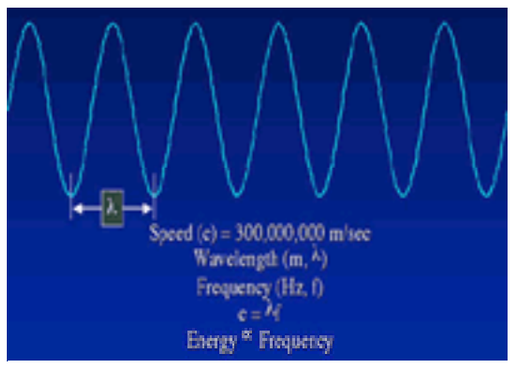
Radiography uses x-rays delivered externally to image the body, whereas nuclear imaging uses gamma rays produced inside the body. There is in fact no physical difference between x-rays and gamma rays, both being forms of high-energy electromagnetic radiation. The only distinctions are historic and etiologic: Gamma rays by definition are produced by radioactive decay within the atomic nucleus, whereas x-rays are produced by processes in the electron cloud surrounding the nucleus. As detailed in the CD-ROM and online versions of this chapter, electromagnetic radiation is characterized by frequency and wavelength, the product of which is equal to the speed of light (299,792 km per second) and an energy, which is proportional to the frequency. Table 46.1 shows typical values for a range of electromagnetic radiation.

Radiation	Frequency (Hz)	Wavelength (m)	Energy (eV)
AM radio	1.00×10^{6}	300	4.14×10^{-9}
^{1}H in 1T field	4.26×10^{7}	7.04	1.76×10^{-7}
FM radio	1.00×10^{8}	3.00	4.14×10^{-7}
Microwave oven	2.45×10^{9}	1.22×10^{-1}	1.01×10^{-5}
Infrared	4.29×10^{14}	7.00×10^{-7}	1.78
Green light	6.00×10^{14}	5.00×10^{-7}	2.48
Ultraviolet	1.00×10^{15}	3.00×10^{-7}	4.13
Diagnostic x-ray	1.45×10^{19}	2.07×10^{-11}	6.00×10^{4}
Technetium-99m gamma ray	3.38×10^{19}	8.87×10^{-12}	1.40×10^{5}
β+ β− gamma ray	1.23×10^{20}	2.43×10^{-12}	5.11×10^{5}
Therapeutic gamma ray	4.80×10^{21}	6.25×10^{-14}	2.00×10^{7}
Cosmic rays	6.00×10^{23}	5.00×10^{-16}	2.49×10^{9}

TABLE 46.1 ELECTROMAGNETIC RADIATION

Nature of Electromagnetic Radiation

Quantum mechanics has taught us that electromagnetic radiation can be thought of as eing made up of either waves or particles (10). Before the twentieth century, the classical perception was that of electrical and magnetic waves, propagating at the speed of light c, 299,792 km per second. Viewed this way (eFig. 46.0.1), electromagnetic radiation is characterized by a wavelength l and a frequency *f* related to c as



***e*FIGURE 46.0.1** Parameters of electromagnetic radiation. In the wave representation of electromagnetic radiation, key parameters are the wavelength and frequency, the product of which is the speed of light. In the particle representation, the key parameter is photon energy, which is proportional to frequency.

$$\lambda f = c$$

Table 46.1 displays the wavelength and frequency for some familiar forms of electromagnetic radiation. As can be seen, there is over a 10^{15}-fold range between AM radio waves and the highest frequency radiotherapeutic gamma rays, with visible light lying roughly in the middle.

The second representation of electromagnetic radiation, discovered in the early part of this century, is of discrete particles (*photons*), massless "billiard balls" propagating at the speed of light. These photons have an energy, *E*, associated with them given by the product of frequency multiplied by Planck's constant h, 6.625 × 10^{-27} erg-second (g-cm^2/s):

$$E = hf$$

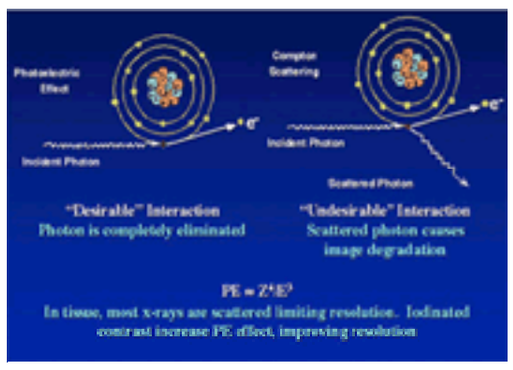
Because the erg is so large compared with typical photon energies, *E* frequently is expressed by the electron volt (eV), the energy acquired by an electron being accelerated by a 1-V electrical field: 1 eV = 1.602 × 10^{-12} erg. As Table 46.1 shows, photons of light have an energy of approximately 2 eV with typical x-rays in the 50- to 100-keV range.

It is important to remember that neither the particle nor wave nature of electromagnetic radiation is the "correct" representation. Both are correct all of the time, but in practice, one aspect or the other typically is more evident. Indeed, quantum mechanics has further taught us that particles such as the electron can sometimes have wavelike properties.

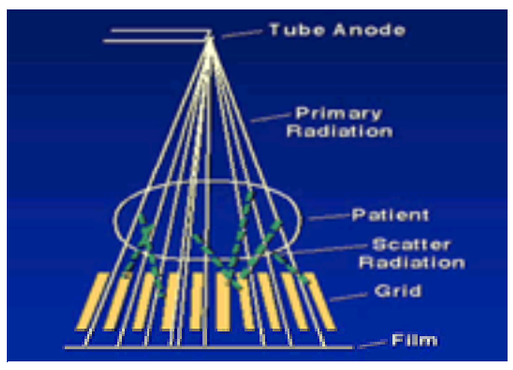
Interaction of X-Rays and Gamma Rays with Matter

Radiography depends on the differential absorption and scattering of photons by various types of tissue. In nuclear imaging, by contrast, nuclide distribution in the body is the primary determinant, although photon scattering is a major cause of image degradation.

Thus, understanding how x-rays and gamma rays interact with tissue yields insight into how both types of images are formed. For photons in the 50- to 500-keV range (those of principal diagnostic importance), there are two major interactions with matter to consider: the *photoelectric effect* and *Compton scattering* (eFig. 46.0.2). In the photoelectric effect, a photon is completely absorbed by an atom, which then emits a high-speed electron that is quickly stopped in the surrounding tissue, thus removing the photon completely from the image. In Compton scattering, a high-speed electron is also emitted, but the original photon is not completely absorbed but rather scattered at a lower energy and at a different angle from the original direction. This scattering can significantly degrade the image, since these photons may escape the body and strike the x-ray film in a random location. This scattering can be partially ameliorated by a collimating grid in front of the film to admit only photons traveling in a straight line from the x-ray source (*e*Fig. 46.0.3). In nuclear medicine, it is harder to exclude these scattered photons, leading to worse image degradation than in radiography.



***e*FIGURE 46.0.2** Interaction of x-rays and gamma rays with matter: the photoelectric effect (PE) and Compton scattering. In each case, a shell electron is emitted that quickly loses energy by ionizing adjacent atoms. With Compton scattering, however, a lower energy photon is also emitted, traveling in a different direction from the incident one, which leads to image degradation. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:627, with permission.)



***e*FIGURE 46.0.3** Exclusion of Compton-scattered photons by a collimating grid.

It would be better if all photons interacting with the tissue did so by the photoelectric effect, since photons are completely absorbed rather than scattered. Unfortunately, the likelihood of the photoelectric effect is inversely proportional to the third power of the photon energy *E* and directly proportional to the fourth power of the atomic number *Z* (number of protons) of the interacting atom: photoelectric effect $\approx Z^4/E^3$. For tissue (average $Z \approx 5$), virtually all attenuation is caused by Compton scattering above an energy of 80 keV (typical for a diagnostic x-ray or thallium decay). By comparison, the *Z*-dependence is exploited in iodinated contrast agents and sodium iodide detectors for nuclear medicine; because iodine has a *Z* of 53, the photoelectric effect is dominant up to photon energies of 300 keV.

Photon Attenuation

The net effect of Compton scattering and the photoelectric effect is to remove a certain percentage of the incident photons for each centimeter of tissue they pass through. This percentage is determined by the linear attenuation coefficient μ (cm^{-1}), which causes the intensity of an x-ray beam to decrease exponentially with distance traveled through the body. The critical factor for x-ray imaging is that the attenuation coefficient μ varies for different tissues in the body, being low for lung, intermediate for soft tissue, and high for bone and radiographic contrast media such as barium and iodine. The coefficient μ further varies inversely with photon energy (generally), yielding deeper penetration for higher energy photons.

As a beam of photons passes through the body, the rate of attenuation changes as they pass through tissue with variable attenuation coefficient μ. Figure 46.1 shows the photon intensity as a function of depth of travel into the tissue, which decays most rapidly when μ = 5 (arbitrary units). The 2-D image that results from the passage of x-rays thus has lost all information about the distribution of matter along the x-ray path. CT techniques (see Computed Tomography) must be used to reconstruct the 3-D distribution of μ.

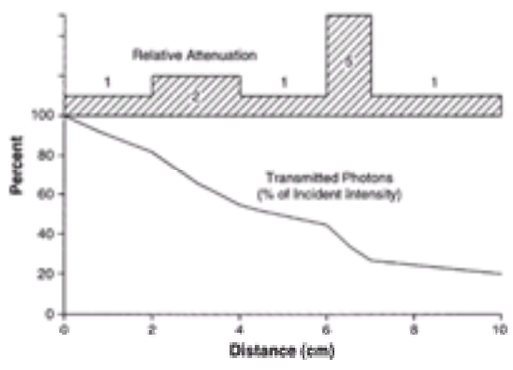


FIGURE 46.1 Impact of linear attenuation coefficient (μ) on the rate of photon intensity decay. A beam of photons (with 100% intensity) enters the tissue at 0 cm, losing intensity in proportion to μ (upper bar graph, units arbitrary). Only 21% of the incident photons traverse the entire tissue without absorption or scattering. Each of the segments is an exponential curve with a decay constant proportional to μ. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:628, with permission.)

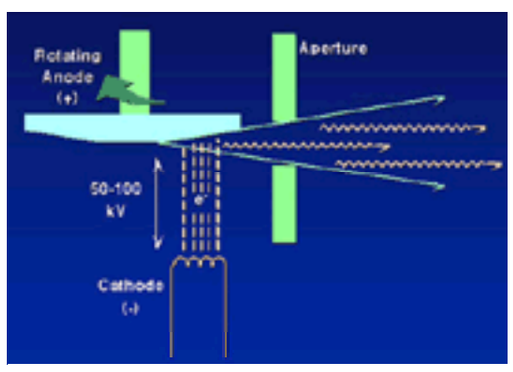
Note that attenuation has different implications for x-ray and nuclear imaging. In radiography, all diagnostic information results from differential attenuation of the x-ray beams passing through the body. In nuclear medicine, by contrast, the photons themselves are similar to x-rays, but it is their distribution *within* the body that is of interest. Ideally, there should be no attenuation at all to maximize the diagnostic information available at the surface, but short of this, attenuation should be as uniform as possible.

The distinctive features of radiography and nuclear medicine are discussed.

Imaging with X-Rays

Production of X-Rays

The basic method for generating energetic x-rays has changed little since the early part of this century (11,12). The cathode (negative electrode) of a vacuum tube is heated white hot, allowing electrons to “boil” from its surface (*e*Fig. 46.1.1). The electrons are then accelerated to roughly half the speed of light by a 50- to 150-kV gradient before they collide with the anode (positive electrode) made of tungsten or similar heavy metal. Most of these electrons collide with the shell electrons of the anode metal, dissipating their energy as heat. A small proportion of incident electrons actually pass close enough to an atomic nucleus in the target to “feel” the intense electric field surrounding the protons. This electric field abruptly decelerates the electron, bending its course and causing release of an x-ray, a process termed *bremsstrahlung* radiation, which occurs only approximately 0.5% of the time for 100-keV electrons striking tungsten, the remaining energy being wasted in heat. Because only a small percentage of x-rays will be emitted in the direction of the patient, the efficiency of the x-ray tube is further reduced by at least another factor of 10.



***e*FIGURE 46.1.1** Schematic diagram of x-ray production. Within a vacuum tube, electrons “boil” off of the heated cathode and are accelerated by the 50- to 150-kV potential difference before striking the rotating tungsten anode. There, a tiny fraction of the electrons interact with the tungsten nuclei and produce x-rays by the *bremsstrahlung* effect. These x-rays are collimated to produce a small cone of radiation. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:628, with permission.)

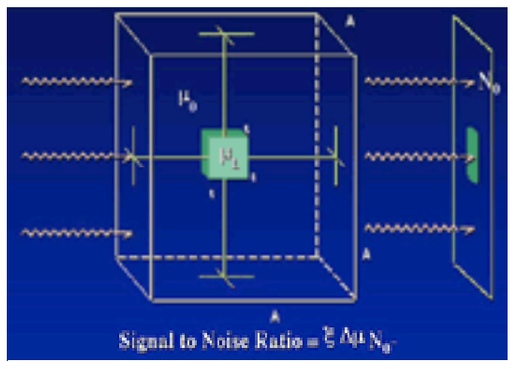
For instance, a typical x-ray tube used in cineangiography might have 100-kV potential and 500-mA current (50,000 W) and fire for 3 ms per pulse (150 J). If 0.5% of this (0.8 J or 8×10^6 ergs) is converted into 100-keV x-rays (1.6×10^{-7} erg each) then approximately 5×10^{13} x-rays will be produced, of which, perhaps 2%, or 1 trillion, ultimately strike the patient.

Statistical Limitations to X-Ray Image Resolution

Two major factors have an effect on overall x-ray image resolution: system noise and the geometry of the imaging system. System noise is related to the random variation in the number of photons striking any given area of the patient. Because the x-ray production obeys Poisson’s statistics, the standard deviation s in the number of photons striking any given area (noise) is approximately equal to the square root of the number of photons expected (signal). For the previous example, if the 1 trillion x-rays per pulse irradiate a 32 × 32-cm area on the patient (1,000 cm^2), this yields an x-ray density of approximately 1 billion photons per square centimeter, with a standard deviation of approximately 32,000, leading to a signal-to-noise ratio of 32,000:1. A 1-mm^2 patch will have one-hundredth of this number of

photons but one-tenth the variability, a reduction in signal to noise by a factor of 10 to 3,200:1.

For a structure to appear distinct from the background, it must attenuate the x-ray beam differently enough so that the change in the number of transmitted photons (D*N*) exceeds the natural variability s expected for a region of that size. eFigure 46.1.2 illustrates a cubic nodule, z cm on a side, nested inside an otherwise homogeneous cube of tissue from which it differs in attenuation coefficient by Dμ; the signal-to-noise ratio then is given (approximately) by |D*N*|/s:



***e*FIGURE 46.1.2** Diagram to illustrate statistical aspects of x-ray resolution. A uniform block of tissue A cm on each side has uniform linear attenuation coefficient = μ_1 except for a small x × x × x-cm block with $\mu = \mu_2$. Incident photon flux is F/cm^2 with N_0 striking an n × n patch on the surface and N_1 and N_2 exiting the tissue having passed and not passed, respectively, through the small block. The signal-to-noise ratio is given by the difference between N_1 and N_2 (D*N*) compared with the expected statistical variation in N_1, which is s = $(N_1)^{1/2}$. See text for details. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:628, with permission.)

$$\text{Signal-to-noise ratio} = \zeta\, \Delta\mu\, N_0^{1/2}$$

where N_0 is the number of photons that would pass through the tissue if the nodule were not there. Thus, the signal-to-noise ratio is reduced when small nodules are sought and when there is little contrast between the tissues. N_0 exerts a profound influence on signal-to-noise ratio; it relates directly to the intensity of the x-ray beam and inversely to the attenuation coefficient of the background tissue. If the x-ray beam is highly attenuated by the surrounding tissue, then signal-to-noise ratio will be poor regardless of the other factors. This explains why it is much easier to image a piece of lead suspended in air than to see a bubble of air inside a block of lead, even though the difference in attenuation, Dμ, is the same in each case.

The signal-to-noise ratio in an image is related to the difference in attenuation coefficient between the object of interest and the background, as well as the number of photons passing through the body. How may resolution be improved? An obvious solution is to do something to increase Dμ. If the nodule is actually a small vessel, infusing iodinated contrast medium dramatically improves resolution. Increasing the density of the incident photons (by increasing the current in the x-ray tube or lengthening the pulse) will help some but not much; it takes approximately a 16-fold increase in photon density to improve the resolution by a factor of 2. As an alternative method to improve photon transmission number, some catheterization laboratories may require obese patients to undergo weight reduction before study. One may also reduce attenuation by increasing the energy of the incident x-rays by raising the x-ray tube voltage. However, this effect must be balanced against the reduction in Dμ, which also typically occurs with increasing photon energy.

Geometric Limits to X-Ray Image Resolution

The second major determinant of x-ray image quality relates to the finite size of the x-ray source. Within the x-ray tube, the anode is beveled at a small angle (7 to 13 degrees), so that the x-rays, emitted at right angles to the electron beam, appear to arise from a small focal spot, perhaps 1 mm^2 in area. As shown in Figure 46.2, even this small spot may blur the image. For a focal spot *a* cm in diameter, positioned *A* cm from the patient with the film *B* cm from the patient, the width of blurring will be *aB*/*A*. To minimize this, one seeks as small a focal spot as possible, limited principally by anode heat. Similarly, *B* should be as small as possible, but this is usually dictated by patient size. Finally, resolution can be improved by positioning the focal spot as far from the patient as possible (large *A*), but since x-ray density declines as 1/*A*^{2}, a trade-off exists between signal-to-noise ratio and blurring.

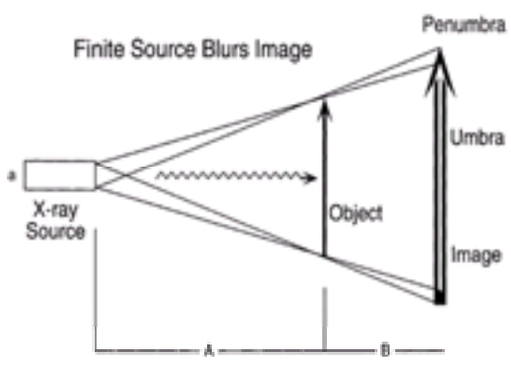


FIGURE 46.2 Geometric limits to x-ray resolution. The finite size of the x-ray source (a) leads to a penumbra around solid objects of *aB*/*A*. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:630, with permission.)

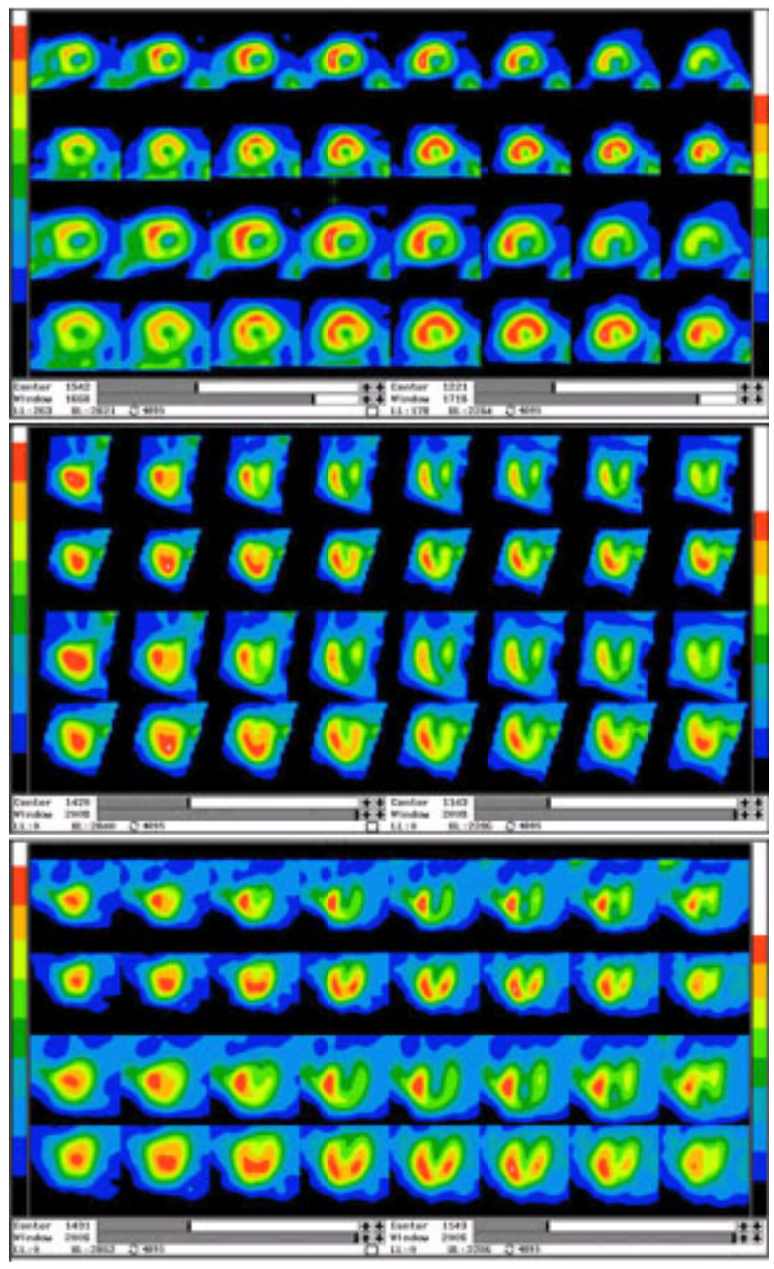
Recording X-Ray Images

In conventional radiography, images are recorded by exposing photographic film to the transmitted photons. To exclude Compton-scattered photons, a lead collimating grid is placed in front of the film to absorb all photons arriving more than approximately 5 degrees out of line with the x-ray source (eFig. 46.0.3). The relationship between film exposure and darkening is complex, but there generally is only a rather narrow exposure range over which the film responds linearly; at very low and high exposures, the film response is flat and shows little contrast.

Alternatively, the x-ray image may be intensified by video techniques and then recorded on light-sensitive film or on videotape, or digitized for computer storage and analysis, a method used in cineangiography and digital radiography. Key to this is the *image intensifier*, which converts a weak x-ray image into a bright visual image. In this device, transmitted x-rays (after collimation) strike a cesium iodide screen from which visible photons impinge on a negatively charged photocathode, which in turn emits electrons; these electrons are focused and accelerated to approximately 30 keV and cause a second, smaller output phosphor to display a much brightened visible version of the original x-ray image. This image can then be directed either to a cinefilm camera (typically 35 mm) or to a TV camera for display, video recording, or digitization. Because the details of digitization and image processing have much in common with the other imaging techniques of the chapter, these are discussed below.

Nuclear Imaging

Nuclear imaging uses trace quantities of radioactive isotopes to produce high-energy photons inside the body. The internal distribution of the radioactive compound is based on its *chemical* properties, giving it affinity for specific anatomic or pathologic structures (bone, blood, myocardium, for example). Localization and quantification of photon production gives diagnostic information about these structures.



Dual isotope resting thallium-201/stress technetium-sestamibi single-photon emission computed tomography transverse (*first image*), sagittal (*second image*), and coronal (*third image*) plane images demonstrating anterolateral, lateral, mid to distal inferolateral, distal inferior, and apical ischemia. Moderate transient left ventricular chamber dilation is seen in stress images. In the same patient, the left anterior oblique cranially angulated view (*first video*) illustrates severe obstruction of the mid left anterior descending, second diagonal, and proximal left circumflex and the left anterior oblique cranially angulated view (*second video*) illustrates severe disease in the posterior descending, posterior ventricular, and posterior lateral branches of the right coronary artery.

In general, the isotopes of nuclear medicine can be divided into two broad types, those that produce single photons when they disintegrate and those that produce pairs of oppositely directed photons. Table 46.2 lists the decay mechanism and photon energy of several important isotopes, the details of which are provided on the CD-ROM and online versions of this chapter.

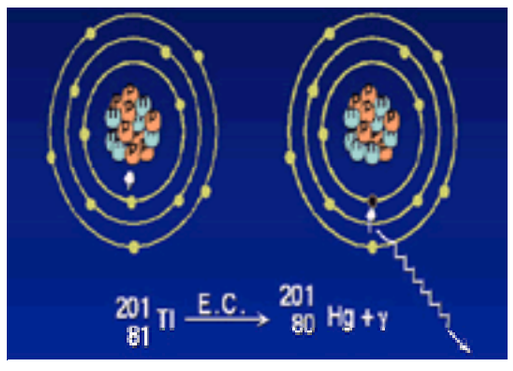
Isotope	Decay mode	Half-life	Photon energy (keV)*
^{99m}Tc	Isomeric transition	6.0 h	140
^{201}Tl	Electron capture	73.0 h	69–83
^{133}Xe	β–	5.3 d	81
^{82}Rb	β+	1.25 min	511 (2)
^{11}C	β+	20.5 min	511 (2)
^{15}O	β+	2.0 min	511 (2)
^{18}F	β+	1.8 h	511 (2)

β–, beta-emission; β+, positron emission; (2), 2 photons of 511 keV are emitted.
*Photon energies are for the principal decay mode. There usually are other emissions of lesser frequency.

TABLE 46.2 CHARACTERISTICS OF DIAGNOSTIC RADIOISOTOPES

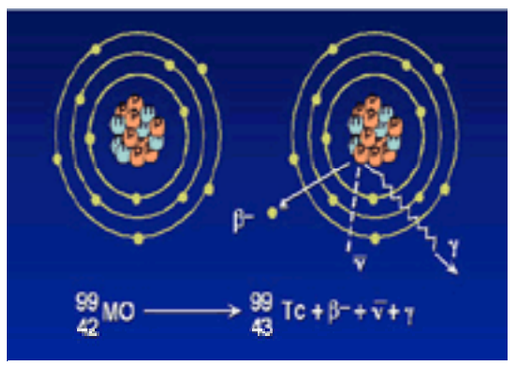
Single Photon Production

One common process by which single photons are produced is electron capture (eFig. 46.2.1), whereby a nuclear proton captures an inner shell electron, converting the proton to a neutron and reducing the atomic number by one, while leaving the atomic mass unchanged. Typical of this class of decay is thallium, $^{201}_{81}$Tl, which captures an electron to become mercury, $^{201}_{80}$Hg. As an outer electron falls to fill the vacancy in the lower energy inner shell, it releases the difference in energy as a characteristic x-ray, usually one of 80 keV.



***e*FIGURE 46.2.1** Photon emission by electron capture (E.C.). See text for details. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:632, with permission.)

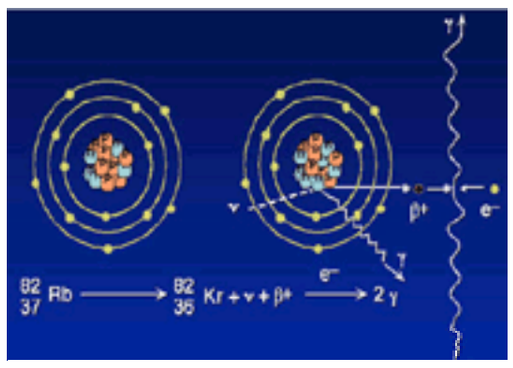
Another single photon scheme is beta decay (eFig. 46.2.2), in which a nuclear neutron becomes a proton with the emission of an electron (beta particle) and an antineutrino. This leaves the nucleus in an excited state, and when the nucleons "reshuffle," a gamma ray is emitted. The nucleus may remain in a metastable state, however, releasing its gamma ray after some time. This *isomeric transition* is the decay process for the important cardiac imaging isotope technetium-99m where the *m* stands for metastable.



***e*FIGURE 46.2.2** Photon emission by beta decay. See text for details. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:632, with permission.)

Dual-Photon Production

All dual gamma-ray isotopes decay by a process called *positron emission*. In this transition, a nuclear proton turns into a neutron with the emission of a positive electron (positron) plus a neutrino (eFig. 46.2.3). This positron travels only a short distance before it collides with an electron, leading to the annihilation of both. The mass of the two particles is completely converted into energy (by $E = mc^2$) and results in two 511-keV photons being emitted in opposite directions.



***e*FIGURE 46.2.3** Positron emission, which is similar to beta decay except that a positively charged electron is emitted, which is rapidly annihilated, producing two high-energy (511 keV) photons directed in opposite directions. See text for details. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:632, with permission.)

Radioactive Decay Rates

The number of disintegrations per second in an isotope is proportional to the amount of the isotope and to a decay constant l, which expresses the likelihood of a given atom decaying per second. Another common way to characterize the decay rate is the half-time $t_{1/2}$, the time required for half of the isotope to decay. It is related to l by

$$t_{1/2} = 0.693/\lambda$$

The half-time of an isotope has important practical and safety impacts. If $t_{1/2}$ is too long, then a large dose of the isotope will have to be given to the patient to get adequate images, leading to excessive long-term exposure unless the compound is cleared from the body chemically (e.g., via the kidneys). If $t_{1/2}$ is too short, however, the isotope may be impossible to transport: Many positron emitters have a $t_{1/2}$ measured in minutes and must be generated by an on-site cyclotron.

Imaging the Emitted Gamma Rays

The Anger gamma camera uses a large sodium iodide (NaI) crystal that emits light by the photoelectric effect in proportion to the energy of an impinging high-energy photon. This provides a means of not only counting the photons, but also of identifying the isotopes from which they arise. When a scintillation event occurs, it is “seen” by several photomultiplier tubes behind the NaI crystal, triangulating the position of the discharge before computer storage (Fig. 46.3).

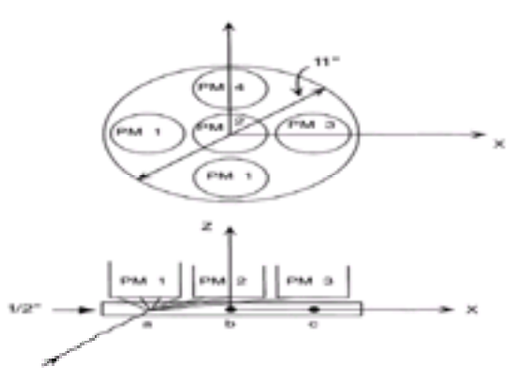


FIGURE 46.3 Schematic diagram of the Anger camera. The different output magnitudes from the photomultiplier (PM) tubes allow localization of the impinging gamma ray.

Unfortunately, reconstructing the internal distribution of the nuclide is hampered by several factors, the first of which is attenuation. Unlike radiography, in which photon attenuation is essential to diagnosis, in nuclear imaging it only causes image degradation. This problem is compounded by photon divergence, which causes photon flux to fall (in the absence of attenuation) as $1/r^2$ where r is the distance from the source. In x-ray imaging, the source is far enough from the patient that this divergence is slight over the width of the body. For a gamma-ray source producing N_0 photons per second at the center of a sphere with radius R and linear attenuation coefficient μ, the photon flux F decreases dramatically:

$$\Phi = \frac{N_0 e^{-\mu R}}{4\pi R^2}$$

Photon Scatter

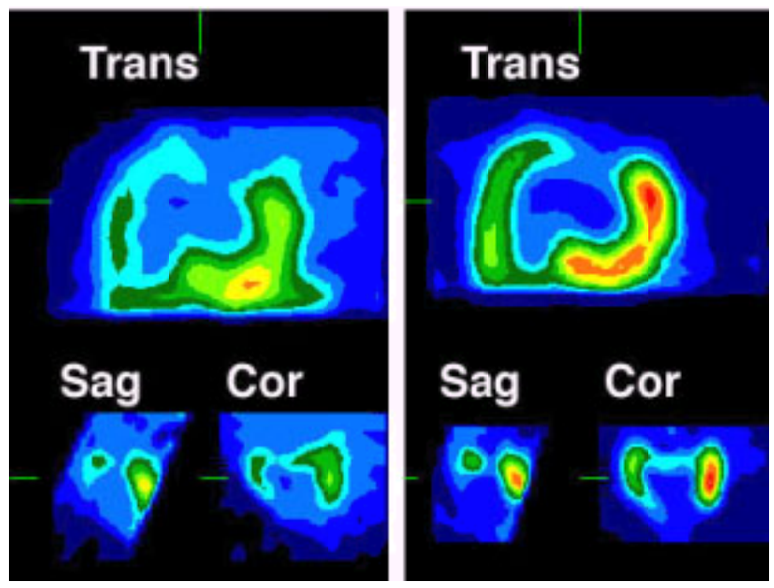
As with x-ray imaging, photon scattering significantly degrades nuclear images. Because diagnostic gamma rays are in the 80- to 500-keV diagnostic range, most photon interactions are by Compton scattering, which changes the energy and direction of the photon. As many as half of the photons escaping the body may be scattered and thus give false localizing data. One way to exclude these scattered photons is with a collimator, the simplest of which is just a small hole drilled in a sheet of lead, which causes an inverted image of the heart to be projected on the gamma camera. While giving reasonable image resolution, such a collimator is extremely inefficient and may image only 1 photon in 10,000 produced in the heart. Multihole collimators address this problem to some degree, although there is usually a trade-off between resolution and sensitivity in nuclear imaging.

Scattered photons may also be excluded on the basis of their energy. If the primary photon radiation from an isotope is in a narrow range, it should be possible to ignore lower energy Compton photons because they produce a dimmer scintillation in the NaI crystal. Unfortunately, in the 80- to 150-keV range, there is little energy change even for significant scattering. For example, a 100-keV photon scattered by 30 degrees loses only 1.5% of its energy. The 511-keV photons of positron

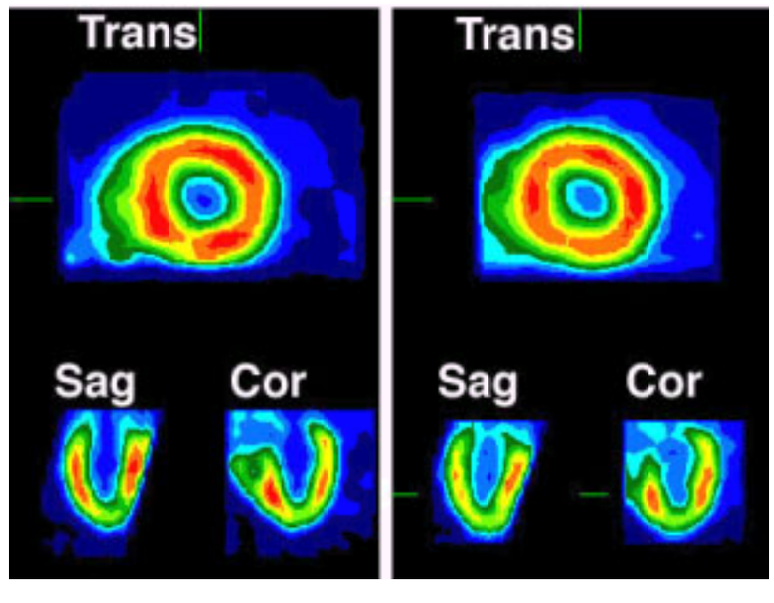
annihilation have a narrow spectrum and also transfer much more energy on scattering, so this method is more useful for them.

Positron Emission Tomography

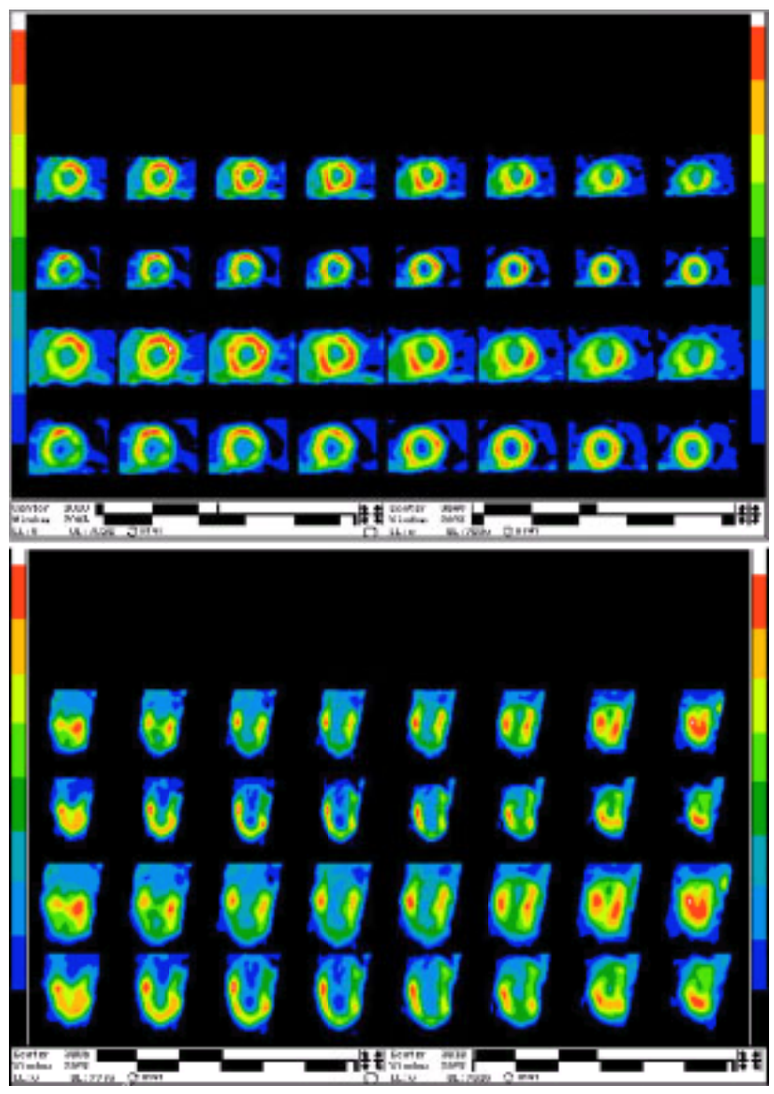
Imaging with positron emitters offers both advantages and disadvantages over single-photon imaging. The major disadvantage is that most positron sources have very short half-lives and thus must be made at the imaging site by a nearby cyclotron. An exception to this is rubidium-82, which can be eluted from a generator similar to technetium-99m and thus stored for some time.

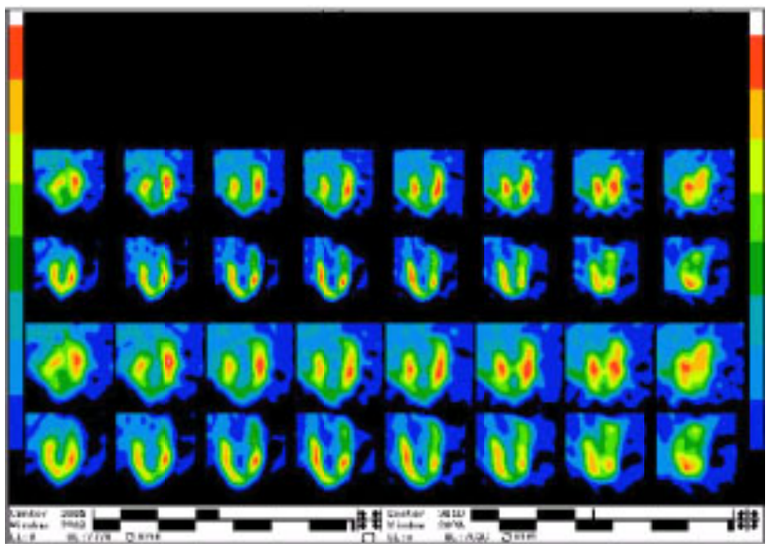


Matched resting rubidium (*left*) and radiolabeled fluoro-deoxyglucose (*right*) positron emission tomographic images. Transverse, sagittal, and coronal positron emission tomographic images demonstrating extensive scar in the left anterior descending and right coronary artery territories with evidence of myocardial hibernation in the left circumflex artery territory and right artery territory (including the right ventricle).



No fixed or transient changes in between stress (*left*) and resting (*right*) rubidium-82 positron emission tomographic images on transverse, sagittal, and coronal slices, demonstrating a dilated left ventricular cavity and a lack of myocardial scar or ischemia in a patient with nonischemic dilated cardiomyopathy.





Resting rubidium-82 with fluorinated deoxyglucose viability positron emission tomographic scanning in a 63-year-old patient in the transverse (*first image*), sagittal (*second image),* and coronal (*third image*) plane images demonstrating hibernating myocardium involving the mid and distal anterior, mid and distal anteroseptal, and distal septal segments. Matched perfusion and metabolic defects are seen involving the apical and inferoapical segments. The right anterior oblique left ventriculogram (*first video*) also shows the presence of hibernating myocardium, due to occlusion of a "wrap around" left anterior descending coronary artery. The mid and distal anterior, apical, and inferior apical walls are akinetic. The anteroposterior cranially angulated angiogram (*second video*) demonstrates subtotal occlusion of a large "wrap around" left anterior descending coronary artery in the same patient with a dominant left coronary artery.

The major advantage of positron imaging is that each decay event generates two high-energy photons (511 keV) directed 180 degrees from each other (Fig. 46.4). Using a ring of gamma cameras surrounding the patient, these photons will be detected simultaneously by two cameras, and the disintegration must have occurred on a line between them, allowing truly tomographic images to be obtained (13). Further refinement is possible by measuring the tiny difference in reception time for the two "simultaneous" photons, localizing the disintegration event along the line connecting the detectors. Unfortunately, the incredible speed of light (30 cm per nanosecond) and the finite temporal resolution of the simultaneity circuits (approximately 300 picosecond) limits localization to approximately 5 cm. Although this alone is not sufficiently accurate, it does aid in the statistical reconstruction from multiple events (14). Further refinement in electronic hardware may improve this performance in the future.

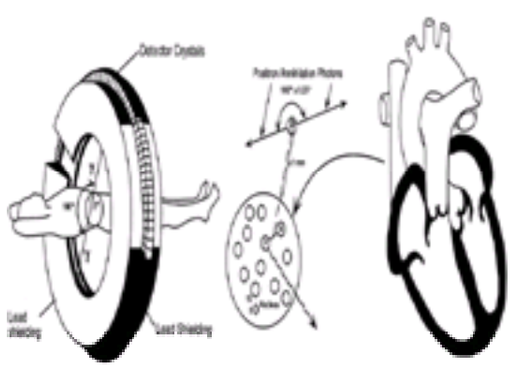

FIGURE 46.4 Positron emission tomography. The simultaneous detection of two photons localizes the disintegration to a line connecting the two detectors.

IMAGING WITH ULTRASOUND

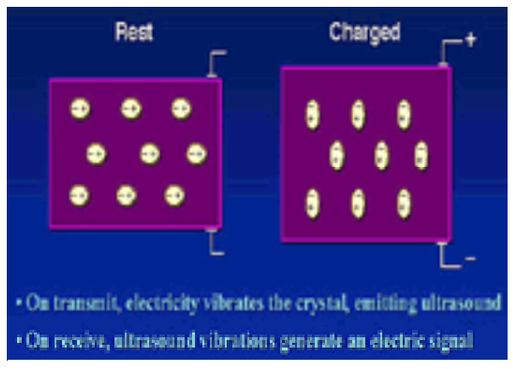
We now turn from imaging modalities that use high-energy photons to the use of high-frequency sound waves, which have a much longer wavelength and slower propagation than the photons considered previously. In addition, the speed of sound *c* is not constant like the speed of light, but rather varies with the medium through which it is passing. For typical soft tissue, this speed is approximately 1,540 m per second or 1.54 mm per μs (Table 46.3), and, as with electromagnetic radiation, there is an inverse relationship between wavelength l and frequency *f*: l = *c*/*f*.

Tissue	Velocity (m/sec)	Attenuation (cm^{-1})	Impedance (10^4 kg/m^2 sec)
Blood	1,580	0.0198	1.6
Bone	2,240	3.01	3.8–7.4
Fat	1,450	0.100	1.4
Muscle	1,580	0.193	1.7
Lung	—	—	0.26
Plasma	—	0.0069	1.5
Water	1,480	—	—

TABLE 46.3 ULTRASONIC PARAMETERS

Production of Ultrasound

Typical ultrasonic transducers have frequencies from 2.5 to 15.0 MHz, corresponding to wavelengths from 0.6 to 0.1 mm, respectively. They produce ultrasonic vibrations by the piezoelectric effect, in which a ceramic crystal vibrates when a high voltage is applied across it (eFig. 46.4.1). The size of the crystal largely determines the frequency of the vibrations, which propagate through the body as a longitudinal traveling wave, displacing the tissue to and fro by microscopic amounts in the direction parallel to the sound propagation. Wave energy exists as kinetic energy of particle motion and potential energy of tissue compression and rarefaction, which generally are 90 degrees out of phase with each other.



***e*FIGURE 46.4.1** Piezoelectric crystal. When a voltage is applied across the crystal, the highly polarized ovoid structures rotate, causing the crystal to thicken and produce ultrasound. Conversely, when ultrasound is received, the mechanical vibration of these structures produces an output voltage. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:635, with permission.)

Interaction of Ultrasound with Matter

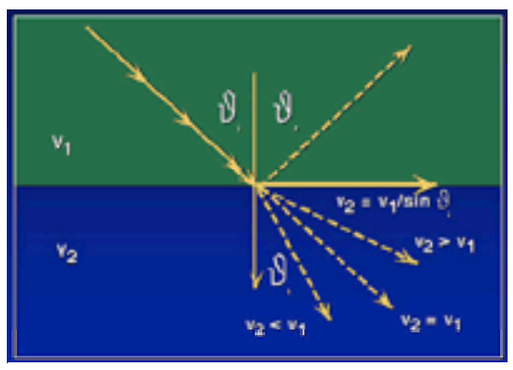
The important interactions to consider are attenuation, reflection, refraction, and scattering. Like electromagnetic radiation, ultrasound suffers an exponential decrease in amplitude as it passes through homogeneous tissue. Attenuation varies with tissue type (Table 46.3) and is faster at higher frequencies, limiting the frequency that can be used clinically in echocardiography (15).

Whenever a sound wave encounters a boundary between two types of tissue, the energy partially reflected with the remainder transmitted into the second tissue, the proportion being determined by the difference in acoustic impedance Z of the two tissues, defined as the product of sound velocity and tissue density, $Z = rc$. For relatively large, flat boundaries, the amount of reflected energy I_R is given by

$$I_R = I_i\,[(Z_2 - Z_1)/(Z_2 + Z_1)]^2$$

where I_i is the incident intensity and Z_1 and Z_2 are the impedances for the two tissues (16) (Table 46.3). Boundaries with a large difference in impedance reflect much more energy than those between tissues with similar acoustic properties. For instance, the heart–lung interface reflects 54% of the incident ultrasound, whereas the blood–myocardium boundary reflects less than 0.1%.

The unreflected portion of the wave passes into the second tissue but is refracted to travel in a different direction if the velocity of sound differs in the two media (eFig. 46.4.2). Since blood and most tissue have similar sound velocity, this is not a prominent effect in echocardiography.



***e*FIGURE 46.4.2** Snell's law. Ultrasound is reflected at the angle of incidence ($q_r = q_i$). The transmitted wave is bent to an angle q_t such that $\sin q_t = (v_2/v_1) \sin q_1$. If $(v_2/v_1) \sin q_1$ is greater than 1, then no transmission can occur. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:636, with permission.)

For interactions with structures that are smaller than the wavelength of sound, *scattering* occurs, the small object radiating sound outward as 3-D spherical waves. Scattering intensity varies approximately with the sixth power of particle radius and the fourth power of ultrasound frequency, strongly favoring larger particles and higher frequency. Scattering occurs within tissue at inhomogeneities between cellular and matrix elements that are not simple point scatterers. Further, these sources are so close to each other that the reflected waves interfere with each other producing a complex ultrasound pattern, *speckle*.

Echocardiographic Imaging

In echocardiography, short pulses of ultrasound are attenuated, scattered, and refracted as they pass through tissue, with a small amount of energy reflected from deep structures to the transducer. Assuming the velocity of sound c to be constant in soft tissue (1,540 m per second), the depth d of a reflector is given by the time

delay D*t* between transmission of the ultrasound pulse and receipt of the echo: $d = c\mathrm{D}t/2$, the factor of 2 entering because D*t* includes time *to* and *from* the object, approximately 13 µs per cm of depth (Fig. 46.5).

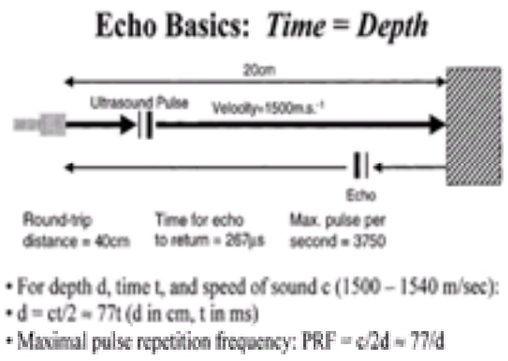


FIGURE 46.5 Basics of echocardiographic imaging. Because of the relatively fixed speed of sound in tissue, the delay in echo return can be translated into the distance to the reflection.

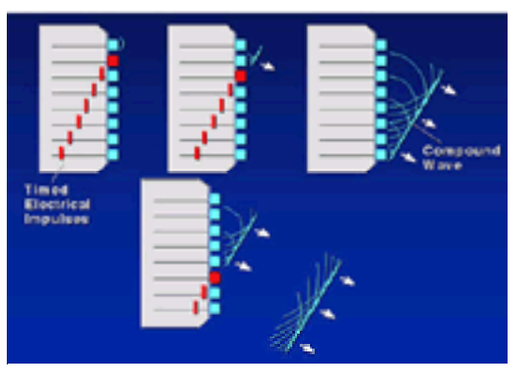
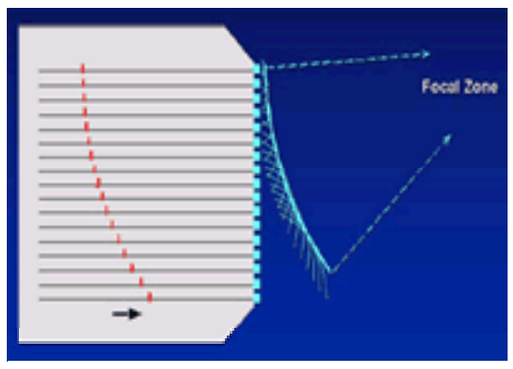
Echocardiographic Transducers

The original ultrasound transducers were single, flat crystals that produced approximately planar waves. For circular crystals, the wave front initially converges to approximately half its original width at a focal distance r^2/l from the transducer (*r* is crystal radius and l the wavelength), thereafter diverging to its original width at twice the focal depth. Acoustic lenses or curved crystals may give tighter focus in the near field at the expense of more rapid divergence in the far field.

Most current transducers are linear arrays of 64 to 256 narrow piezoelectric crystals. By precisely timing their firing, it is possible to direct the ultrasound in any direction within a wide sector coplanar with the array (eFig. 46.5.1) and to adjust the focal zone both on transmission and receiving (eFig. 46.5.2). Furthermore, by the principle of superposition of sound waves, it is possible to stimulate the array to send out multiple ultrasound pulses simultaneously in different directions, dramatically improving ultrasound frame rate by processing multiple scan lines in parallel. Finally, transducer technology has been expanded to 2-D arrays of crystals, allowing ultrasound pulses to be directed anywhere in a pyramid-shaped volume below the transducer, facilitating real-time 3-D imaging.



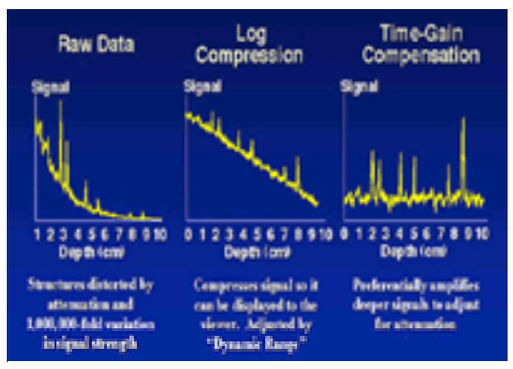
***e*FIGURE 46.5.1** Phased array echo transducer. By changing the timing of transmission from a linear array of crystals, it is possible to steer a planar ultrasound wave in different directions.



***e*FIGURE 46.5.2** Focused phased array echo transducer. If the time delay between adjacent crystals is not constant, it is possible to focus the wavefront at a specific depth.

Ultrasound Reception

When a reflected echo strikes the transducer, the piezoelectric crystal produces a minuscule voltage in response to the vibrations from the returning ultrasound. Because of attenuation within the tissue, the returning echoes from shallow structures are much stronger than those from deeper layers. To adjust for the significantly weaker echoes from deep structures, *time-gain compensation* applies greater amplification to echoes returning at longer intervals from the echo pulse. This may be adjusted by the user for individual variation in attenuation. Even with this depth compensation, echo signals may vary in intensity by a factor of 10^9 or more, while the human eye can only appreciate approximately 500 gray levels on a television screen. Thus, the echo signal must be compressed to this smaller dynamic range by *logarithmic amplification*, which amplifies weak input signals much more than strong ones, in effect converting an exponential distribution of voltages into a linear one (eFig. 46.5.3).



***e*FIGURE 46.5.3** Scan-line processing. To normalize the billion-fold variation in signal strength with depth, logarithmic compression and time-gain compensation must

be applied to the returning echoes.

The amplified signal now consists of the radiofrequency wave of the transducer, modulated in time by the reflective structures in the body. In most echo instruments, these lower frequency (100 to 500 kHz) modulations are extracted from the multimegahertz carrier by full-wave rectification and low-pass filtration, leaving only the *amplitude* of the ultrasonic reflections. More recently, however, it has become possible to use the *phase* information to improve the lateral resolution of the ultrasonic image, allowing objects to be localized, even if they fall between scan lines.

Display Modes

As discussed in Chapter 49, echo signals can be displayed in various formats. In M-mode echocardiography, repeated echo pulses are made along a single scan line, and the processed envelope is drawn vertically on the output video with subsequent envelopes displaced rightward, so that the horizontal axis of the display corresponds to time while the vertical axis relates to distance from the chest wall (Fig. 46.6).

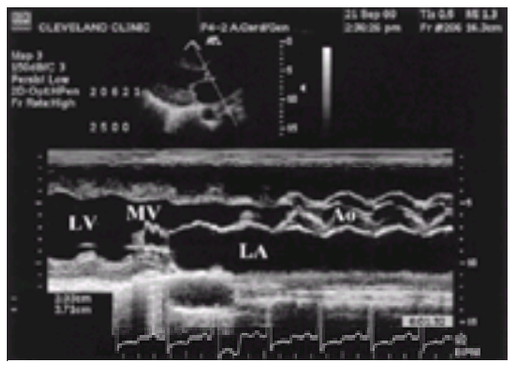


FIGURE 46.6 M-mode echocardiographic imaging. The M-mode display shows depth vertically and time horizontally. Ao, aorta; LA, left atrium; LV, left ventricle; MV, mitral valve.

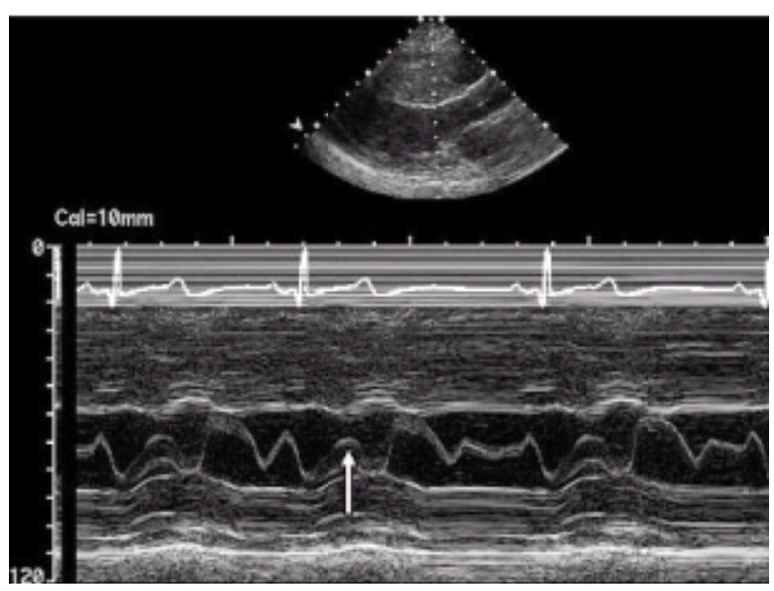

M-mode tracing of hypertrophic cardiomyopathy with severe septal hypertrophy seen at the top of the trace and systolic anterior motion (SAM) of the mitral valve in systole seen in the middle of the trace (designated by the arrow).

In 2-D or sector scanning, echo interrogations are made sequentially throughout a 60- to 90-degree sector, fanning out from the transducer, typically approximately 100 scan lines per frame. For a 20-cm imaging depth, pulses can be emitted every 260 µs, allowing a 100–scan-line frame to be formed in 26 ms, and a display rate of over 38 frames per second. With parallel processing, up to four scan lines can be displayed simultaneously, allowing frame rates over 150 per second (Fig. 46.7).

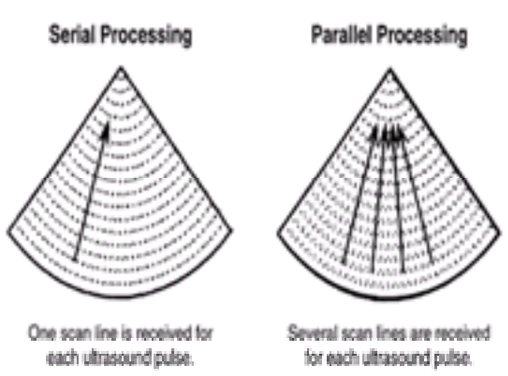

FIGURE 46.7 Serial versus parallel processing. By analyzing several scan lines simultaneously through parallel processing, frame rate can be significantly improved.

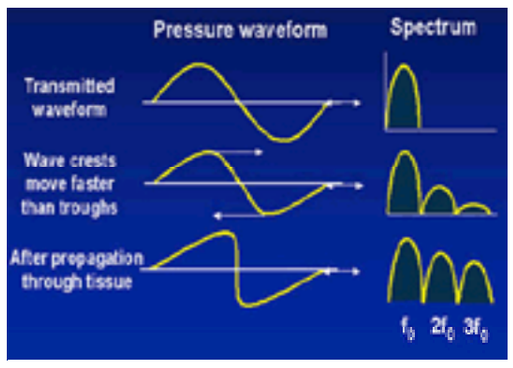
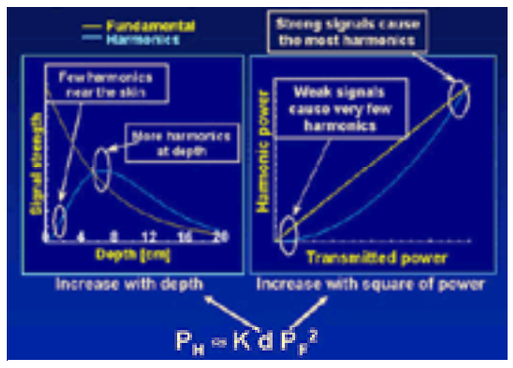
Tissue Harmonic Imaging

One of the greatest advances in echocardiographic image quality in the past years has been the development of tissue harmonic imaging. When ultrasound waves propagate through tissue, their frequency content does not remain constant, but rather shifts to increasing amounts of higher frequencies (17).

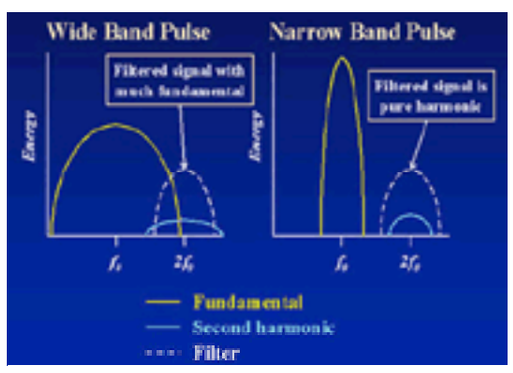
*e*Figure 46.7.1 illustrates how this happens: Because the peaks of the sound waves propagate a little faster than the troughs, with distance the waveforms transform from simple sinusoids (pure frequency content) to asymmetric waves containing a significant quantity of energy at multiples of the original frequency, termed *harmonics*. An approximate formula for the development of these harmonics is $P_H \approx K\, d\, P_F^2$, illustrating that harmonic power (P_H) grows linearly with the distance of propagation (d) and nonlinearly with the square of the power in the original fundamental wave (P_F). As shown in *e*Figure 46.7.2, these two features determine the key utility of harmonics: (a) There are few harmonics in the near field, so distortion from the chest wall is eliminated; and (b) only the strongest fundamental echoes (resulting from the central beam of the transducer) are likely to generate harmonics, whereas artifactual signals (reverberations and beam width and side lobe artifacts) generate few harmonics. To take advantage of these harmonic echoes, an instrument needs three key features: (a) a wide dynamic range so that the weak harmonic echoes can be detected with adequate signal-to-noise ratio, (b) a narrow output spectrum so that the dominant fundamental energy falls outside the second harmonic band, and (c) a sharp receive filter so that only the harmonic signal is passed through to the amplifier. *e*Figure 46.7.3 (left panel) shows the impact of too wide a transmit spectrum that cannot be separated from the harmonic signals, while the narrow spectrum in the right panel can be separated by use of a sharp receive filter.



***e*FIGURE 46.7.1** Nonlinear acoustic propagation. Because blood and tissue are not completely incompressible, the peaks of ultrasound waves propagate slightly faster than the troughs, leading to a gradual change in the shape of the wave with distance due to the shift of energy to second and higher order harmonics.



***e*FIGURE 46.7.2** Determinants of harmonic generation. As shown by the equation, harmonic energy (P_H) grows with distance *d* from the skin surface (*left panel*) and varies with the square of the incident fundamental energy (P_F). This means that the most common echo artifacts (near field distortion and scattering, side lobe, or beam width artifacts) do not produce significant harmonic signals, resulting in a cleaner image at the harmonic frequency.



***e*FIGURE 46.7.3** Instrument requirements for tissue harmonic imaging. If the transmitted pulse has too broad a frequency spectrum (*left panel*), it will be impossible to separate it from the much weaker harmonic signal. In contrast, a narrow transmit signal can be separated from the harmonics with a sharp receive filter, provided the other instrument has very high signal-to-noise ratio (*right panel*).

Figure 46.8 shows the impact of harmonic imaging in a patient with mitral stenosis, demonstrating improved endocardial definition and imaging of the subvalvular apparatus. Clinical tests on this modality have shown improved contrast between the wall and cavity (18) without adverse effect on valve thickness (19).

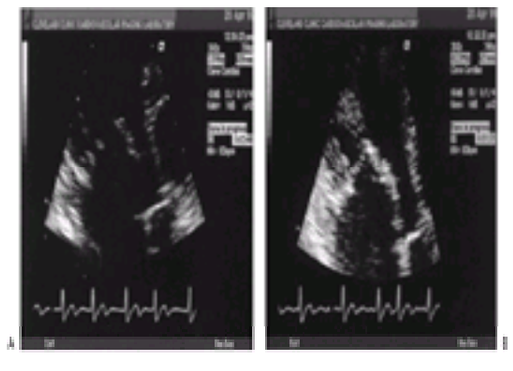


FIGURE 46.8 Impact of harmonic imaging in a patient with mitral stenosis. **A:** Fundamental. **B:** Harmonic.

Doppler Echocardiography

Exploitation of the Doppler principle to define intracardiac blood velocity adds enormous value to echocardiographic imaging (20,21). It is based on the observation that sound reflected from moving objects is frequency shifted in proportion to the ratio of object velocity *v* and sound velocity *c*: $f_d = 2vf_0/c$, where f_0 is the transducer frequency and f_d is the amount of the Doppler shift. The factor 2 occurs because the frequency is shifted when the sound hits the moving particle and again when it is reradiated by scattering. Only the component of particle velocity parallel to the ultrasound beam affects the Doppler shift (Fig. 46.9). For a particle moving at an angle q to the scan line, the Doppler shift is proportional to the cosine of q: 30-degree misalignment leads to a 13% velocity underestimation.

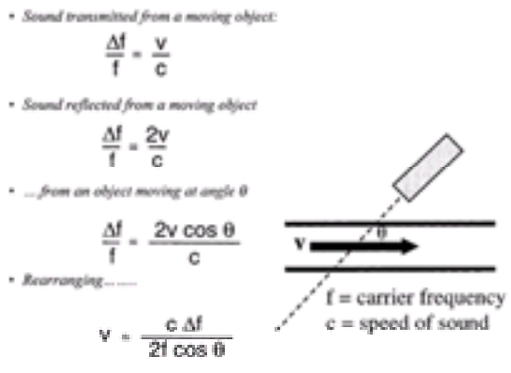

FIGURE 46.9 Determinants of the Doppler shift. When sound is emitted from a moving object, the frequency is shifted in proportion to the velocity. For reflected sound, the factor 2 occurs because this shift occurs on absorption and reflection. Only the component of velocity parallel to the sound wave contributes to the Doppler shift.

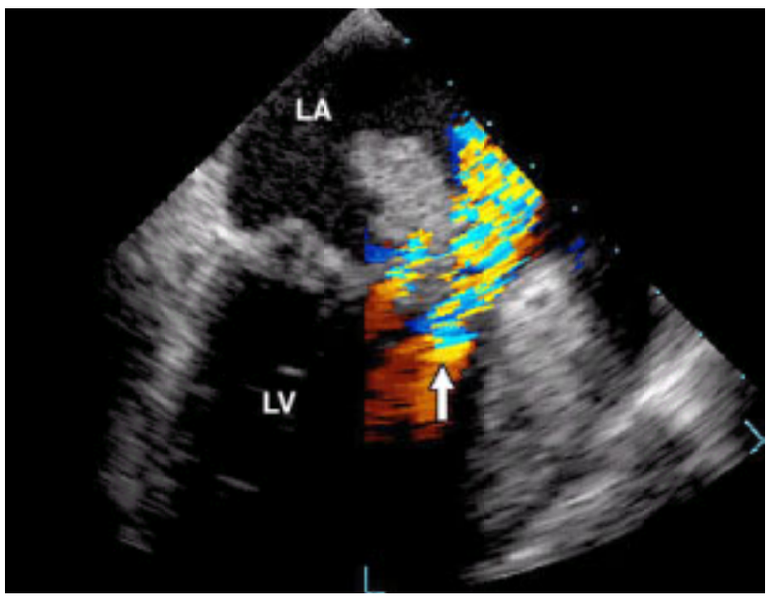
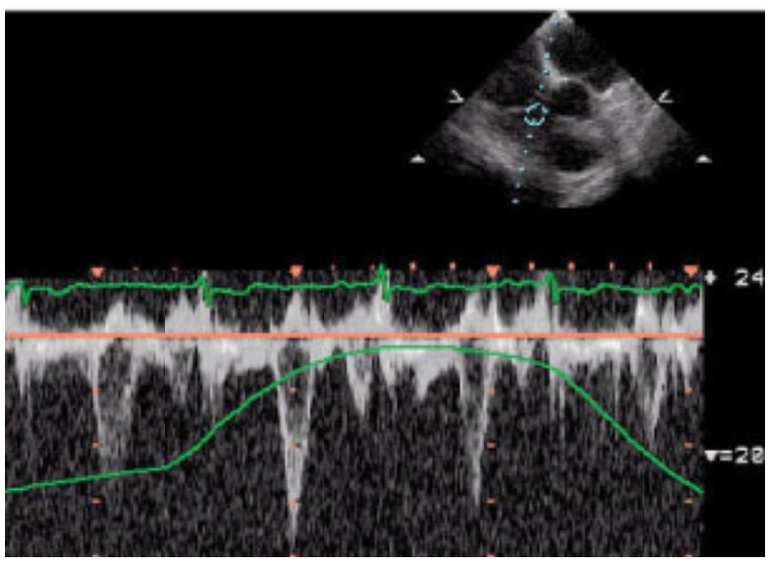
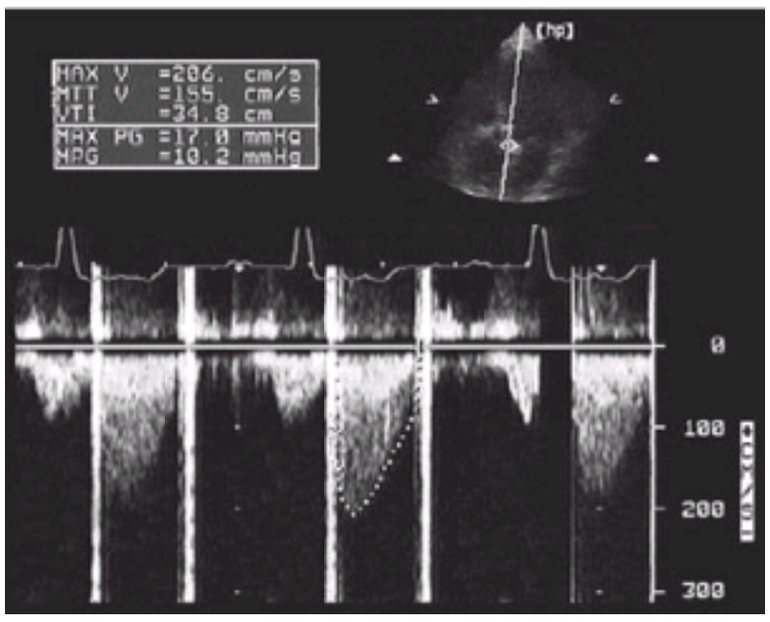


Color Doppler showing a perforation of the base of the anterior mitral leaflet from *Streptococcus* endocarditis. The patient's underlying pathology was myxomatous mitral valve disease with mitral valve prolapse. The proximal flow convergence of the mitral regurgitation jet is demonstrated by the arrow at the orifice of the large perforation.

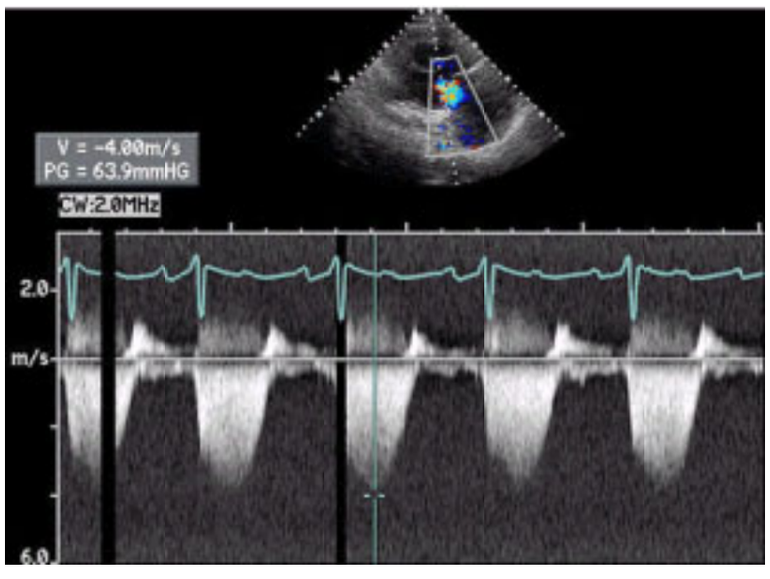


Pulsed wave Doppler through the tricuspid valve of a patient with constrictive pericarditis. Note the decrease of the E wave with inspiration due to interventricular dependence.

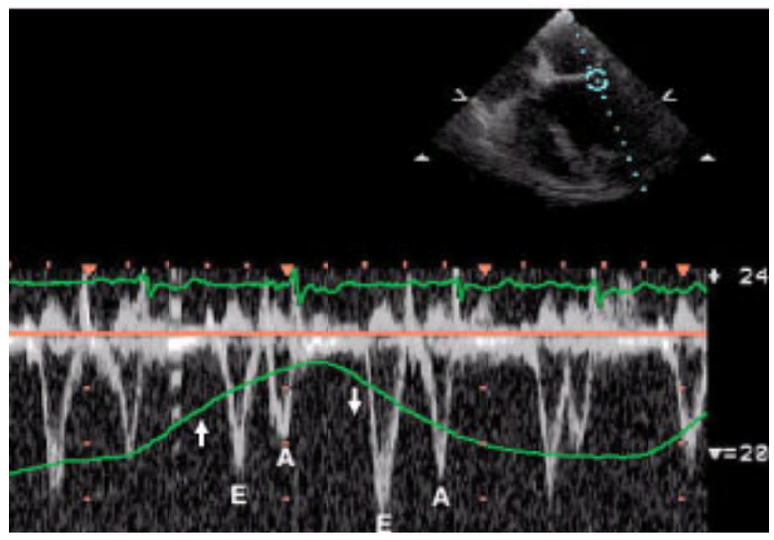
In general, three different types of Doppler processing are available on contemporary echocardiographic equipment: continuous wave Doppler, pulsed Doppler, and Doppler flow mapping ("color Doppler"). Each is processed differently and discussed in detail on the CD-ROM and online versions of this chapter.



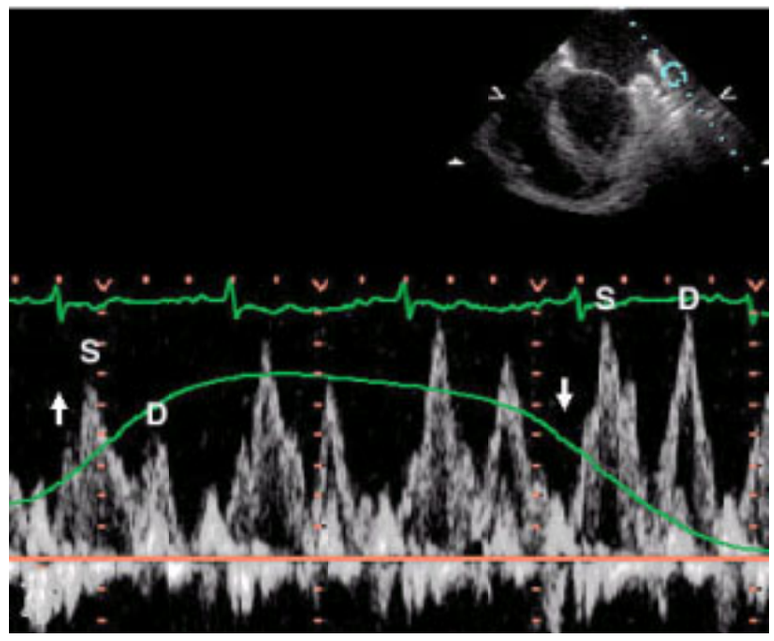
Continuous wave Doppler spectrum of mechanical prosthesis in the aortic position. Note opening and closing clicks and calculation of mean and maximal pressure gradients.



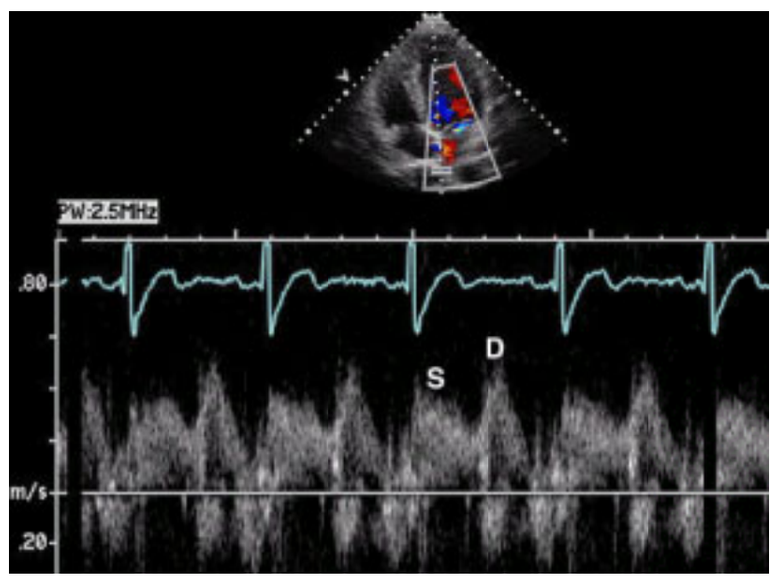
Continuous wave Doppler trace through the tricuspid valve of a patient with pulmonary hypertension. The maximal jet velocity of 4 m/sec corresponds to a pressure gradient of 64 mm Hg or a PA pressure of approximately 80 mm Hg.



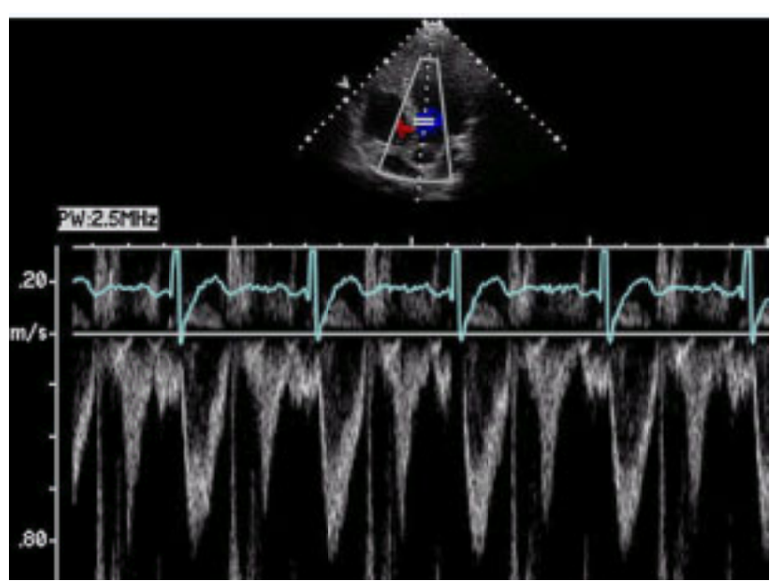
Pulsed wave Doppler of the mitral valve inflows of a patient with constrictive pericarditis. Note the decrease of the E wave during inspiration (*upward arrow*) due to interventricular dependence, and the increase in the E wave during expiration (*downward arrow*) for the same reason.



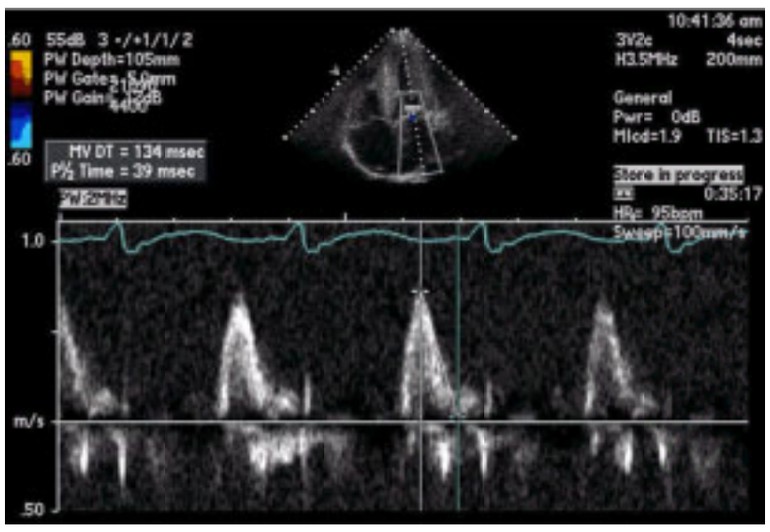
Pulsed wave Doppler of the pulmonary veins of a patient with constrictive pericarditis. Note the inspiratory decrease of the S and P waves and the expiratory increase due to interventricular dependence. (Inspiration is denoted by the upward arrow and expiration by the downward arrow).



Pulmonary vein pulsed wave Doppler flow. Note the S (systolic) wave and the D (diastolic) wave.



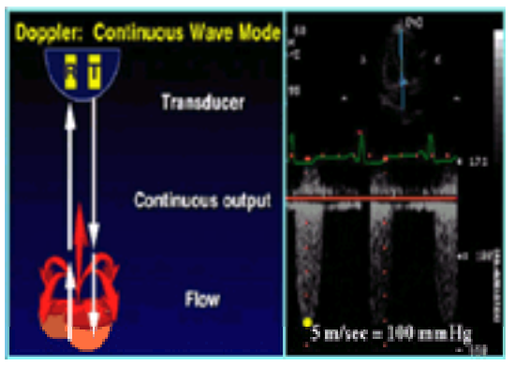
Normal pulsed wave Doppler signal from the left ventricular outflow tract. Note the maximal velocity is only 80 cm per second.



Pulsed wave Doppler of the mitral valve inflow in a patient with amyloidosis demonstrating a short deceleration time (134 ms) consistent with restrictive physiology.

Continuous Wave Doppler

In continuous wave Doppler, the transducer contains two crystals, one to send and the other to receive ultrasound continuously (eFig. 46.9.1). The returning signal is compared with the original carrier frequency by quadrature demodulation, and the frequency-shifted echoes are quantified by Fourier analysis. Because Fourier analysis plays a pivotal role in many types of cardiac imaging, a section of this chapter describes it in greater detail, particularly its role in Doppler processing (see Application of Fourier Analysis in Cardiac Imaging, later in this chapter).

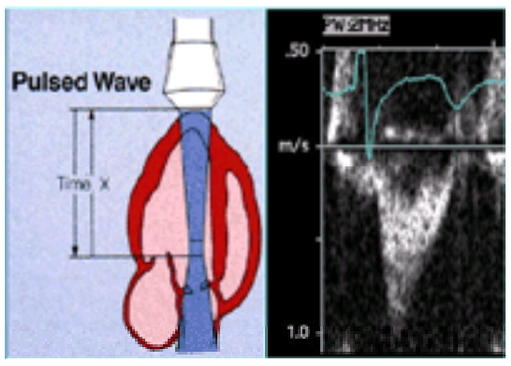


***e*FIGURE 46.9.1** Continuous wave Doppler. By continuously transmitting and receiving Doppler-shifted echoes, it is possible to quantify velocities of any magnitude, although at the cost of not having range information as to the specific depth of that velocity. A common application is quantification of aortic stenosis (*right panel*), using the simplified Bernoulli equation, $Dp = 4v^2$.

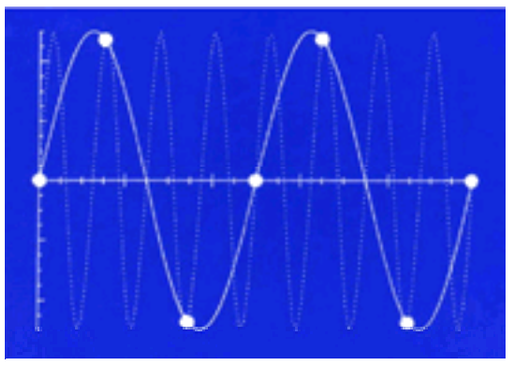
A limitation of continuous wave Doppler is its lack of range information about the signals it displays. Because the ultrasound is continuously emitted and received, the detected Doppler shifts may have arisen from any depth along the scan line. This disadvantage is countered by the ability of continuous wave Doppler to quantify high intracardiac velocities as might be encountered in stenotic or regurgitant lesions.

Pulsed Doppler

In pulsed Doppler echocardiography, brief (1 to 4 µs) bursts of ultrasound are transmitted into the patient, with the receiver timed to “listen” to the returning signal at a specific time delay, Dt, after the pulse transmission, corresponding to reflections from depth $d = cDt/2$, where c is the velocity of sound (eFig. 46.9.2). The advantage of recording blood velocity from a specific location within the heart is balanced by limitations on the maximal velocity that can be unambiguously displayed. This limitation arises because, to fully reconstruct a Doppler shift frequency f_d, it must be sampled by pulses at twice this rate, $2f_d$, and signals that are undersampled will appear misdirected much as wagon wheels may appear to turn backward in motion pictures, an effect termed velocity *aliasing* (eFig. 46.9.3). To record signals at a depth d, pulses can be emitted at a maximal pulse repetition frequency (PRF) of $c/2d$, so the maximal resolvable Doppler shift is half this, or $c/4d$. Applying the fundamental Doppler equation shows that the peak recordable velocity is $c^2/8df_0$, inversely related to both transducer frequency and sample volume depth. For example, the maximal unambiguous velocity from a 3-MHz transducer at 10-cm depth is approximately 100 cm per second (if flow is known to be in one direction, this velocity can be doubled by shifting the baseline of the display). To reconstruct the Doppler spectrum in detail, the instrument typically sends out 128 or 256 pulses, then analyzes them by a fast Fourier transform, updating the velocity information approximately every 10 ms.



***e*FIGURE 46.9.2** Pulsed wave Doppler. By transmitting a brief pulse of ultrasound and “listening” for returning echoes from a specific depth, it is possible to localize velocities within the heart, though at the cost of not being able to quantify very high velocities.



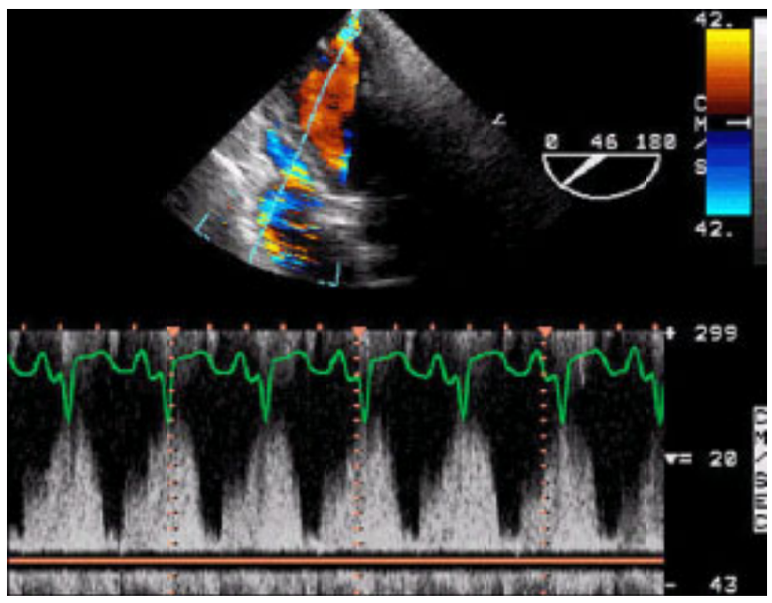
***e*FIGURE 46.9.3** Impact of aliasing in Doppler echocardiography. If the actual Doppler waveform (*dotted line*) is undersampled (*white dots*), the reconstructed

waveform (*solid line*) will be at a falsely low frequency (and thereby velocity).

Doppler Velocity Mapping

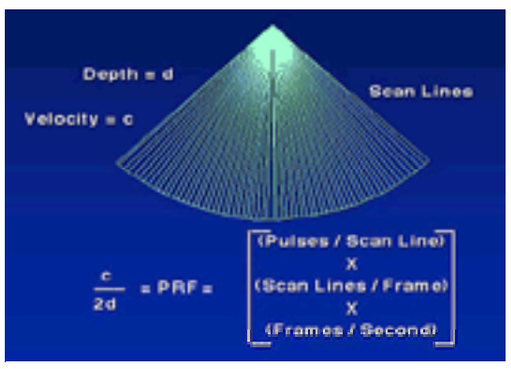
Doppler velocity mapping superimposes color on an echo sector scan to show the distribution of blood velocity throughout the heart, allowing the dynamic display of normal flow patterns and those associated with valvular regurgitation, stenosis, and various shunt lesions (eFig. 46.9.4). Color Doppler shares many limitations with pulsed Doppler such as limited PRF (to allow pulses from the deepest part of the sector to return before another is emitted) and velocity aliasing, but differs in that all the returning echoes from the entire scan line are analyzed, not just those from a specific depth. Furthermore, whereas in pulsed Doppler a given point may be interrogated over 100 times before velocity is calculated, in color Doppler the complete sector must be swept many times a second to capture the dynamic nature of intracardiac blood flow (22), imposing fundamental limits on the spatial, temporal, and velocity resolution of the system.

***e*FIGURE 46.9.4** Color Doppler echocardiography. By processing successive ultrasound pulses with autocorrelation techniques, it is possible to map velocity throughout the imaging sector.



Doppler recording of flow through an ischemic ventricular septal defect before surgical repair.

To understand how these resolutions relate to each other, recall that the fundamental data limitation in Doppler is the PRF, fixed (inversely) by the depth of the sector. This limits the displayable velocity range and the detail with which the velocity map can be reconstructed and updated (eFig. 46.9.5). Three key parameters enter into this trade-off, the product of which cannot exceed the PRF: the number of interrogations per scan line N_i, the number of scan lines per frame N_s, and the number of frames per second N_f. The N_f should be at least 15 frames per second for a smooth display, and for brief intracardiac events or fast heart rates, a more frequent update is desirable. The second factor, N_s, is determined by the width of the color sector and the density of interrogation within the sector, so that reducing the sector width to concentrate on the region of interest (such as a regurgitant jet) allows higher frame rates. The final factor, the number of interrogations per scan line, largely determines the accuracy with which the velocity is measured, since the more a scan line is interrogated, the finer the velocity resolution. For example, a scan depth of 10 cm translates into a PRF of approximately 7,700 Hz. If eight bursts are used per scan line (a typical value, in contrast to the 128 used in pulsed Doppler) and the sector is narrowed to 50 scan lines, then just over 19 frames per second can be reconstructed. The emerging technology of parallel processing allows this frame rate to be increased considerably (Fig. 46.7).

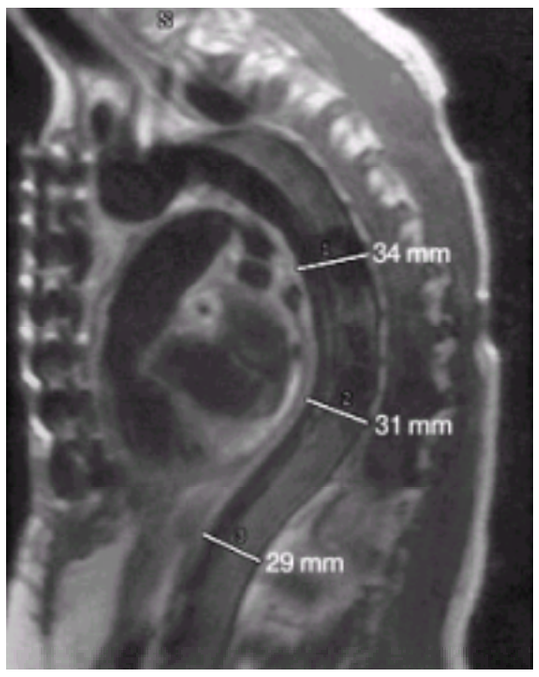


***e*FIGURE 46.9.5** Temporal, spatial, and velocity trade-offs in Doppler flow mapping. The pulse repetition frequency (PRF, number of interrogations per second) is fixed by the depth of imaging and the velocity of sound: PRF = $c/2d$. This PRF must be divided between the number of pulses per scan line (which determines velocity resolution), the number of scan lines per frame (which determines spatial extent and resolution of the flow map), and the number of frames per second (which is temporal resolution). (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:638, with permission.)

To show velocity, blood moving toward the transducer is typically displayed in red, whereas reverse flow is colored blue. Additionally, velocity variability may be estimated from the scatter in individual velocity measurements from the multiple scan line interrogations. This velocity “variance” is typically coded in green, although its physical connection with true turbulence is not precise.

MAGNETIC RESONANCE IMAGING

The third physical principle used in cardiac imaging, nuclear magnetic resonance, is less familiar than electromagnetic and sonic radiation, but its physical basis has been well defined in the last half-century, an understanding of which helps in the appreciation of clinical MRI. Pauli first suggested the existence of microscopic magnetic moments within atomic nuclei in 1924. Studies of this phenomenon in the presence of external magnetic and electromagnetic fields by Purcell and Bloch in 1946 were landmarks and led to the two sharing the Nobel Prize for physics in 1952.



Magnetic resonance scan of the thoracic aorta in Marfan syndrome. There is dilation of the descending aorta with an average diameter of approximately 3 cm.

Video 46.7 Post–myocardial infarction true aneurysm (long-axis). Dyskinesia and thinning of the left ventricular apex due to an occlusion of left anterior descending artery. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 46.8 Aortic stenosis and insufficiency (long-axis). A systolic signal-void jet of aortic stenosis is visible extending from the aortic valve into the ascending aorta. In addition, a diastolic signal-void jet of aortic insufficiency is seen extending from the aortic valve into the left ventricular cavity. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 46.9 Aortic insufficiency associated with annuloaortic ectasia of aortic root (oblique-coronal). An “onion-bulb” dilatation of the proximal ascending aorta and the sinuses of Valsalva is observed. A signal-void jet of aortic insufficiency is seen extending from the aortic valve into the left ventricular cavity during diastole. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 46.10 Subaortic poststenotic flow in hypertrophic cardiomyopathy (long-axis). Asymmetric hypertrophy is noted, resulting in dynamic narrowing of the left ventricular outflow tract with a signal-void jet in the subaortic region. In addition, a signal-void jet in the left atrium is also seen, representing mitral regurgitation due to systolic anterior motion of the anterior leaflet of the mitral valve. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 46.11 Arrhythmogenic right ventricular dysplasia (transaxial). Thinning the right ventricular wall with dyskinesia of the right ventricular free wall during systole is due to fibrous replacement of the myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Physical Principles

Although many nuclei are magnetic, by far the most important to medical imaging is the single hydrogen proton (^{1}H), both because of its abundance and its high sensitivity to external influences. An individual proton in an external magnetic field of strength B_0 spins or *precesses* about the magnetic field at the *Larmor frequency*, f, proportional to the strength of the external field B_0 and the magnetogyric ratio g, a constant specific to each nuclear species: $f = gB_0/2p$. For the hydrogen proton, g/2p is 42.58 MHz per Tesla (Fig. 46.10), where Tesla is a standard unit of magnetic field strength, equivalent to 10,000 Gauss, an older unit. Typical MRI magnets have field strengths from 0.5 to 4.0 T. By way of comparison, the earth’s magnetic field strength is approximately 0.3 Gauss or 3×10^{-5} T, and thus a proton in the Earth’s magnetic field will precess at approximately 1,280 Hz.

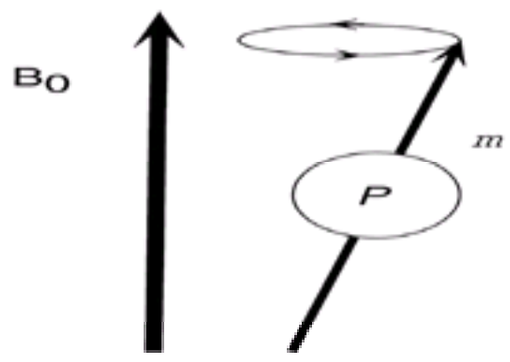

FIGURE 46.10 Precession. Nuclei with odd numbers of protons and neutrons are weakly magnetic with magnetic moment μ, ^{1}H being most important. In a strong magnetic field (strength B_0), a few protons line up; in a 1T field (3,000 × earth), <0.001% are aligned. If these "aligned" protons are tipped out of alignment, they will precess like a wobbling top at 42.6 MHz per Tesla. This Larmor frequency is proportional to the magnetic field, critical to magnetic resonance imaging. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:639, with permission.)

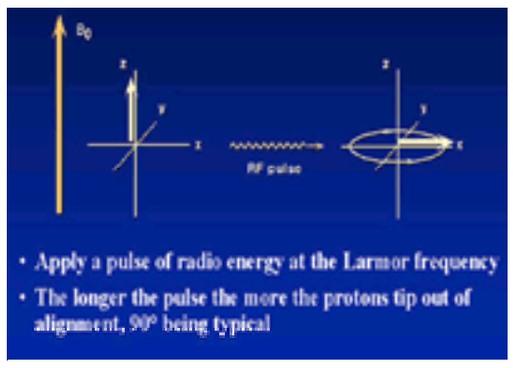
Production and Control of the Magnetic Moment

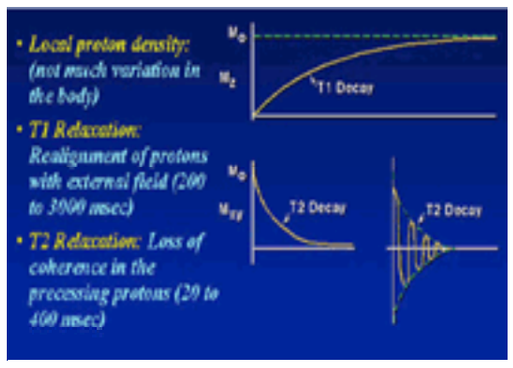
Any magnetic field that changes its strength or direction in time radiates electromagnetic radiation outward at the precessional frequency, which can be received by an antenna and amplified electronically. This radiated signal forms the basis for MRI. Normally, however, the proton moments in the body are oriented randomly in space, and the radiation from their precession cancels out. Only if these magnetic moments can be made to line up, by application of a strong external magnetic field, will there be a net magnetization vector whose precession will cause radiation of energy to the outside. Actually, only a tiny fraction of the protons will be aligned by the magnetic field, fewer than 0.001% in a 1-T field, as a result of thermal energy randomizing atomic orientation. Nevertheless, this is enough to give a net magnetization vector to the substance as a whole, which can be exploited by MRI.

Tissue Relaxation Parameters

Producing a net magnetization vector is only the first step in MRI. This vector must next be tipped away from the direction of the main magnetic field so that it will precess within that field, emitting radiation that can be detected. This is done with a pulse of electromagnetic radiation at the precessional frequency [termed a *radiofrequency* (RF) *pulse*], which exerts a torque on the magnetization vector. The longer the duration of the RF pulse, the more the magnetization vector is tipped away from the main magnetic field, say 90 degrees. When the RF pulse is removed, the tipped magnetic moment precesses about the main magnetic vector, emitting electromagnetic radiation at the Larmor frequency, which can be detected externally (eFig. 46.10.1). The initial strength of this signal depends primarily on the local proton density, but this does not vary enough within the body to give sufficient contrast to distinguish tissues. Fortunately, there are several other magnetic properties that can be exploited to enhance contrast (eFig. 46.10.2), the first of which is the rapidity with which the tipped magnetization vector realigns itself with the external magnetic field. This time constant, termed *T1*, the longitudinal relaxation time, or the spin-lattice relaxation time, typically is of the order of 200 ms to 3 seconds (eTable 46.3.1). The second time constant, T2, refers to the rapidity with which the precessing vector loses coherence in the transverse plane because of the interaction of adjacent magnetic moments. For this reason, it is also called the transverse or spin-spin relaxation time. It usually is shorter than corresponding T1 values, typically 20 to 400 ms. By delaying the signal reception for a certain period after the RF pulse, it is possible to highlight either T1 or T2 differences between tissues of interest. The subject of pulse sequencing to contrast magnetic properties is highly complex and is discussed in detail elsewhere (23,24). Cardiac imaging involves several additional difficulties because of the periodic contraction of the heart and the motion of blood within it. Gated nuclear magnetic resonance (to avoid motion artifact) and pulse sequencing to highlight blood flow are discussed in Chapter 54.



***e*FIGURE 46.10.1** Tipping the magnetic moment. Delivery of radio-frequency (RF) energy at the Larmor frequency causes the mean magnetization vector to tip away from the *z*-axis. Precise timing of the pulse tips the vector by precisely 90 degrees into the *x-y* plane where it will precess about B_0, emitting electromagnetic radiation (again at the Larmor frequency), which can be detected externally. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:640, with permission.)



***e*FIGURE 46.10.2** Relaxation parameters used in magnetic resonance imaging. T1 represents the realignment of the magnetic moment with the external field (directed along the *z*-axis), whereas T2 reflects the loss of coherence in the *x-y* plane of the precessing protons.

***e*TABLE 46.3.1** MAGNETIC RESONANCE IMAGING PARAMETERS

Tissue	^{1}H density (% H_2O)	T1 (ms)	T2 (ms)

Localizing the Signal

The final issue to contend with is localizing a particular magnetic signal within the body. Because all protons in a magnetic field B_0 will precess with the same frequency $f = gB_0/2p$ (except for minuscule variations related to the local chemical environment and exploited in magnetic resonance spectroscopy), there is no way for an external receiver to distinguish where the signals are arising. It is possible, however, to make the precessional frequency a function of position by varying the magnetic field across the patient during the readout period. If a magnetic gradient G_x is applied across the region of interest in the *x*-direction, the precessional frequency will be $f = g(B_0 + xG_x)/2p$, and protons at high *x* values will ring at a higher frequency than those at low *x* values. By analyzing the frequency content of the received signal, it is possible to distinguish regions with different *x*-coordinates (in much the same way that it is possible to tell whether the right or left end of the piano keyboard has been struck simply by listening to the pitch of the emitted note; Fig. 46.11). This process is intimately involved with Fourier transform theory (see Application of Fourier Analysis in Cardiac Imaging, later in this chapter).

FIGURE 46.11 Localizing the magnetic resonance imaging signal. By varying the strength of the magnetic field across the image, the proton precessional frequency varies, allowing them to be localized by Fourier analysis, much like a piano note can be localized.

COMPARISON OF TECHNIQUES

The preceding physical descriptions and the subsequent chapters show there are a host of diagnostic tests available for most cardiovascular disorders. To choose among them in the workup of a given patient, one may apply any of several criteria, such as cost, safety, accuracy, and availability of the test. Also of critical importance is the likelihood that a particular disease is actually present in the patient.

Sensitivity and Specificity

Two key parameters for the accuracy of a test are its sensitivity and specificity. In general, *sensitivity* refers to the likelihood that a patient with a given disease will have a positive test result, whereas *specificity* is the likelihood that a patient without that disease will have a negative test result. We can divide patients into four general classes: true-positive results (TP, patient with disease has a positive test result), true-negative results (TN, patient without disease has a negative test result), false-positive results (FP, patient without disease has a positive test result), and false-negative results (FN, patient with disease has a negative test result). Sensitivity then is defined as TP/(TP + FN), whereas specificity is TN/(TN + FP). Closely related to these concepts are the positive and negative predictive values for a test. The positive predictive value is the proportion of patients with positive test results who, in fact, have the disease: TP/(TP + FP), whereas the negative predictive value reflects patients with a negative test result who are free of the disease: TN/(TN + FN). Overall accuracy of the test is given by the percentage of patients who have the proper test result: (TP + TN)/(TP + TN + FP + FN).

Critical to rational use of sensitivity and specificity figures is knowing the prevalence of disease in the test population. For example, a test with a specificity of 95% sounds very accurate, but in a population whose prevalence is only 1:1,000, there will be 50 false-positive test results for every patient who actually has the disease.

Bayesian Analysis

To determine the true value of a test in a given patient population, one uses Bayesian analysis. If the prevalence of a finding in a given population is *p*, then the likelihood of being free of that disease is 1 – *p*. Sensitivity and specificity data can then be used to derive the positive and negative predictive value for a given *p*:

$$\text{Positive predictive value} = Se \cdot p/[Se \cdot p + (1 - Sp)(1 - p)]$$

$$\text{Negative predictive value} = Sp \cdot p/[Sp \cdot p + (1 - Se)(1 - p)]$$

Thus, when the prevalence of a disease is low, a test must have extraordinarily good specificity for most of the positive test results not to represent false-positive results. Alternatively, one may solve for the prevalence of disease at which the predictive value positive for a test is 0.5 (equal odds of disease vs. false-positive result), given by $p = (1 - Sp)/(1 + Se - Sp)$. Thus, for a test with equal sensitivity and specificity, this break-even point for predictive value positive is given by a prevalence of $1 - Sp$. It is often unwise to perform tests in populations with either a very low prevalence of disease (high proportion of false-positive test results) or a very high prevalence (most negative test results are false negative).

Receiver-Operator Curve Analysis

Often a test may produce a continuum of parameter values, and it is unclear what threshold should be used to determine whether a disease is present. If the threshold is set too low, this results in an unacceptable number of false-positive readings, whereas a threshold set too high will miss many patients with disease. A receiver-operator curve is useful for determining the optimal test threshold as well as judging the overall value of the test. In receiver-operator curve analysis (Fig. 46.12), one specificity is plotted along the *x*-axis, while sensitivity is plotted along the *y*-axis with various points plotted corresponding to alternative test thresholds. A test that is entirely without value (such as flipping a coin) produces a diagonal line between (0,0) and (1,1). There is always a trade-off between sensitivity and specificity of a test as the threshold is altered, but generally the optimal point is the one that is closest to the upper left-hand corner of the receiver-operator box (0,1). The area under the receiver-operator curve (or between the receiver-operator curve and the line of identity) is a measure of the overall worth of the test, and tests that approach the ideal are those that are skewed strongly to the upper left-hand corner.

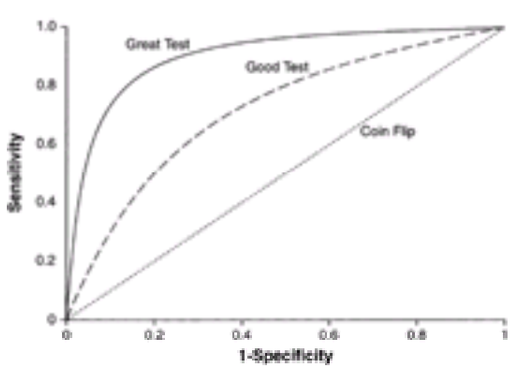

FIGURE 46.12 Receiver-operator curve analysis. For tests with continuous output parameters, there is a trade-off between sensitivity and specificity based on the choice of the cutoff to declare a test result positive. The closer a test result approaches the ideal of 100% sensitivity and specificity (*upper left corner*), the better the test.

Economic Analysis

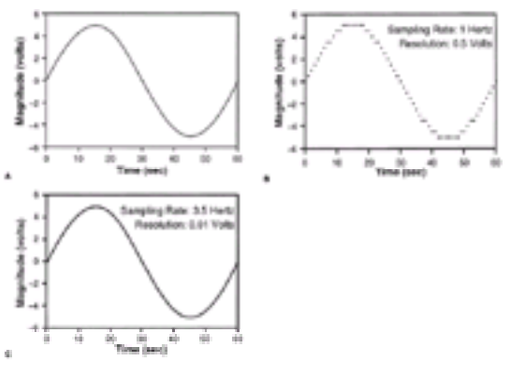
With the current restraints on health care expenditures, the cost of a diagnostic test must be considered in judging its overall worth. Unfortunately, determining the cost-effectiveness of a diagnostic test (in terms such as the cost per additional quality year of life) is more difficult than a therapeutic maneuver (25). With a therapeutic intervention, there is a discrete encounter with a well-defined cost and an outcome that can be tracked from that point forward. With a diagnostic test, however, a physician must act on the test, putting a cloud of therapeutic uncertainty between the diagnostic test and the outcome. Furthermore, this evaluation does not in any way account for the significant reassurance that a patient may feel by having a negative test outcome.

DIGITAL DATA PROCESSING

We now discuss digital imaging and image processing, the hallmark of which is that parameters of interest (such as x-ray attenuation or Doppler shift) are measured at discrete time or space intervals and quantized into a limited number of values. This contrasts with *analog processing*, in which these parameters are handled as continuous functions of space or time. Digitized signals are easier to process, because digital amplifiers need only distinguish whether a voltage is on (i.e., above a certain level) or off (i.e., below this voltage threshold). Furthermore, to change the analysis requires only a modification of the computer program, not a change in the physical components of the system, a flexibility that has allowed the development of complex CT and MRI algorithms, which could not even be attempted on an analog system.

Analog versus Digital Representation of Signals

*e*Figure 46.12.1A displays a sine wave in analog format, varying smoothly between +5 volts and –5 volts. Since this is a *continuous* function, every point in time (*x*-axis) has a corresponding voltage (*y*-axis), without intrinsic resolution limitation: The signal is 2.5 V at 5 seconds and 2.500037 V at 5.0001 seconds. In practice, however, analog equipment seldom has this accuracy.



***e*FIGURE 46.12.1** Analog versus digital representation of data. The same physical signal (a slowly varying voltage ranging between ±5 volts and described mathematically as 5 sin p*t*/30) is represented in analog fashion in **A** and digital format in **B**. **A:** Both time and voltage are *continuous* quantities, the quality of the data determined by the intrinsic accuracy of the measuring equipment. **B:** The data are sampled only once per second (1 Hz), and no information is available between these points. Furthermore, the magnitude of the voltage is stored in 0.5-V increments, leading to a less accurate representation than the analog signal. **C:** There is improved digital representation of the signal, with a sampling rate of 3.5 Hz and a resolution of 0.01 V, leading to a much more faithful rendering of the data, indistinguishable in this reproduction from the original analog representation. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:653, with permission.)

In contrast, a digital representation of the same voltage wave is shown in *e*Figure 46.12.1B, differing from *e*Figure 46.12.1A in that the signal is measured and displayed only at *discrete* 1-second time intervals; the measured voltage can take on values that are multiples of 0.5 V. *e*Figure 46.12.1C, however, shows that digital signals may be as accurate as needed by measuring the voltage more frequently and storing it more precisely.

Digital signals are stored as a series of binary bits, which can represent only 0 or 1. The more bits stored per value, the more precisely it is represented and the wider the dynamic range. Four-bit numbers have only 16 levels, whereas 6-bit may represent 64, 8-bit 256, 10-bit 1,024, 12-bit 4,096, 16-bit 65,536, and 24-bit may take on 16,777,216 values. Compared with the data in *e*Figure 46.12.1B, the data in *e*Figure 46.12.1C has 3.5 times as many numbers to store (because of the more frequent sampling), and each number requires 10 bits rather than 4 to get the 50-fold finer resolution, and thus almost nine times as many data must be stored. In general, it pays to use a digital representation of a signal with a precision roughly equivalent to the accuracy of the original analog signal from which it was derived.

Image-Processing Hardware

Analog-to-Digital Conversion

The interface between the computer and the outside world is the analog-to-digital converter, which converts the analog value of a signal (e.g., the magnitude of a reflected echo) into a binary representation. Two figures of merit characterize the performance of analog-to-digital converters: *resolution* (the number of bits per datum discussed previously) and *throughput* (the number of samples digitized per second). The resolution should be carefully matched to the intrinsic accuracy of the signal being digitized: 6 to 8 bits for visual gray-scale data and 12 to 16 bits for pressure or flow data. Throughput should be at approximately twice the maximal frequency component of interest.

Digital-to-Analog Converters

The human eye is a fundamentally analog system, so the processed, digitized signal must be converted back to analog format for displaying on a monitor or plotting on a graph. This digital-to-analog conversion is characterized by the same resolution and throughput concerns of the analog-to-digital converter.

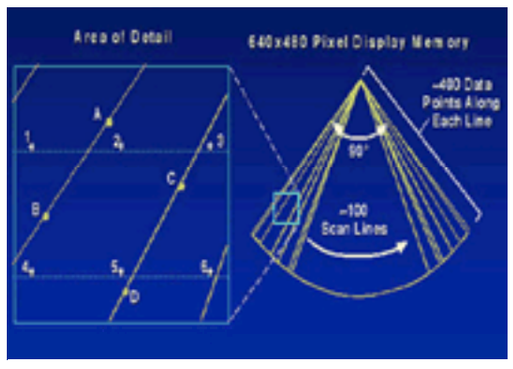
Analog and Digital Representation of Video

The analog television image is formed by sweeping an electron beam across and down the screen 30 times a second to form a video *frame*. In actuality, each frame is composed of two *fields*, containing (respectively) the even- and odd-numbered scan lines (called *raster lines*), interlaced to form 60 video fields per second, which reduces image flicker. The video standard in the United States, National Television Standards Committee (NTSC) has 525 raster lines in a frame (26). Computer monitors typically use *progressive* scanning (noninterlaced) and may have true frame rates over 80 Hz and resolution from 640 × 480 pixels to over 2,000 × 2,000 pixels. Color on such monitors may be represented by 8 bits (256 colors), 16 bits (thousands of colors), or 24 bits (8 bits for each primary color, red, blue, and green), producing photographic quality of millions of colors.

Digital Scan Conversion

The digital scan converter (DSC) changes the image data from its internal representation (in this example, the polar representation of ultrasound) to the rectangular video format (*e*Fig. 46.12.2) (27). A typical sector has approximately 100 scan lines, each of which has approximately 400 discrete echo amplitude points. The DSC

maps the ultrasonic intensity at each of these sampled points onto the video memory *buffer* (storage area), which is arranged in Cartesian (rectangular) format. Near the top, several scan lines overlap each pixel, and the DSC uses the polar point falling closest to the center of the pixel. At the periphery, many pixels are not crossed by a scan line, and interpolation from adjacent data points is therefore necessary (28). Because the data are in digital format, it is simple to shift images on the screen to show Doppler or M-mode information and to insert calibration marks and patient identification. Finally, every 16.7 ms, the memory buffer is scanned, and analog signals are calculated corresponding to the horizontal raster lines, first the odd lines, then the even ones for NTSC output. These writing and reading tasks need not be synchronized; thus, the transducer scan rate may be different from the video output rate. Commonly the video buffer may have many frames from which cardiac motion from echocardiographic, MRI, and nuclear data may be displayed as a cine loop.



***e*FIGURE 46.12.2** Digital scan converter. The data from each sector sweep consist of approximately 100 scan lines, each of which is digitized at several hundred points. These data form a fan radiating out from the scan head. The digital scan converter maps these data, which are in a *polar* geometry, onto a rectangular array of memory pixels. This output buffer is then scanned 60 times a second to generate the analog video output signal. In the close-up, it is evident that the rectangular grid points do not in general line up with the polar data points. Simple algorithms assign the value of the nearest polar point to a given rectangular point, whereas more sophisticated techniques interpolate among the four nearest neighbors to yield a smoother video output. (Adapted from Weyman AE, et al. *Principles and practice of echocardiography*, 2nd ed. Philadelphia: Lea & Febiger, 1994:60, with permission.)

On-Screen Data Analysis

The digital memory buffer allows on-screen analysis since placing a cursor on the screen simply requires writing the value for bright white (usually 255) to form a cross in video memory, which is displayed on the screen. Knowing the location in video memory and the calibration for the screen, the computer may compute dimensions, circumferences, and areas for various structures identified by the operator on the screen.

Image Processing

Although the mathematics of image processing may be daunting for the average reader, even a cursory knowledge of this technique will facilitate understanding of the edge-enhancing techniques of angiography, echocardiography, and others. A more detailed description of the mathematics of image processing may be found in standard texts (29).

Overview

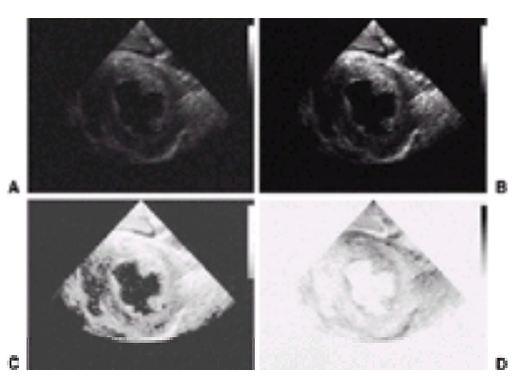
Image processing can be loosely divided into low-level and high-level components. Low-level processing deals with the individual points or pixels that make up an image, which are smoothed, sharpened, and edge-enhanced to yield a collection of *features* on which high-level processing operates to render an interpretation. By analogy, the retina and optic nerve act like a low-level processor, reducing the billions of photons per second impinging on the rods and cones to a smaller list of edges, corners, movement, and texture, which are passing to the high-level processor, the occipital cortex. Low-level processing may be subdivided into four steps: (a) *analog-to-digital conversion*; (b) *reduction of noise*, both within (spatial noise) and between (temporal noise) video frames; (c) *enhancement of edges* and other key features of the image; and (d) *extraction* of the location and characteristics of these features, which may then be passed along to a high-level processor for interpretation by template matching and pattern recognition. Despite intense research in artificial intelligence, the high-level processor usually remains the interpreting physician.

Low-Level Processing

Once a sequence of images has been digitized, processing algorithms can be applied to individual points (point processing), to single image frames (*spatial convolution*), and to a sequence of frames (spatiotemporal convolution).

Point Processing

Point processing alters each pixel value individually and is typically used to optimize image brightness and contrast. For example, *e*Figure 46.12.3 shows the effect of several pixel remappings on a B-mode echocardiogram. The ultimate contrast stretch is thresholding, in which pixels above a certain value become white, and those below that value become black.

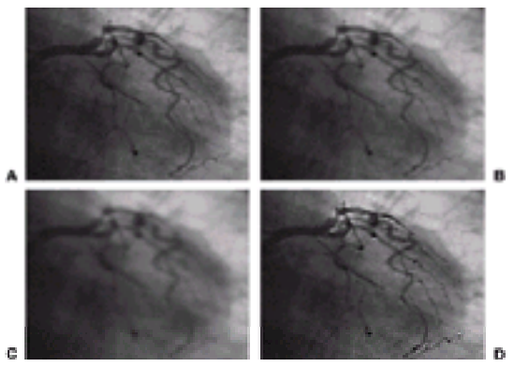


***e*FIGURE 46.12.3** Remapping of pixel values within an image. **A:** The original parasternal short-axis echocardiographic image is shown. **B:** The image is brightened and the contrast enhanced. **C:** The contrast is optimized by histogram equalization (spreading pixel values across all 256 potential values). **D:** Image inversion (white becomes black and vice versa).

Spatial Convolution

In spatial convolution, the output value of a pixel is determined by its own input value and those of its neighbors within a single frame. If these pixels are averaged together, random noise is reduced (30,31), although at the expense of some blurring of edges and other sharp features (32,33). *e*Figure 46.12.4 shows the effect of slight (B) and severe (C) noise reduction. In contrast, if the difference of pixel values is calculated, then edges are highlighted. *e*Figure 46.12.4D shows the effect of unsharp masking, which increases the contrast at edges. The simplest convolution requires nine multiplications and one addition, so that processing a 512 × 512 image at 30 frames per second requires almost 80,000,000 operations per second, previously requiring dedicated computer hardware to convolve video in real-time. With the dramatic increase in computer speed, however, such processing can now be implemented in software. More complex convolutions may apply an asymmetric mask to the image, recognizing that axial and lateral resolution may differ (34). In addition, different filtration masks may be applied on a pixel-by-pixel basis to smooth *along* the

edges but not *across* them. Such filters are nonlinear in character and thus computationally more intense.



***e*FIGURE 46.12.4** By adjusting a pixel based on the value of its neighbors, noise reduction and edge enhancement can be accomplished. **A:** The unprocessed angiogram. **B,C:** Moderate and severe smoothing using a Gaussian (bell-shaped) averaging scheme. **D:** The effect of unsharp masking that increases contrast at edges.

Temporal Noise Reduction

Because there is some randomness in the data arising from a single point over time, *temporal noise* is introduced, which must be minimized for subsequent edge and motion analysis to be accurate. Two general approaches to temporal noise reduction have been described. First, a given pixel may be averaged with the same location on previous and subsequent frames (12,35), which may blur out rapidly moving valve structures, but appears acceptable for the slower endocardial motion. The second general approach is *gated averaging* of corresponding video fields from successive cardiac cycles, taking advantage of the natural periodicity of cardiac movement, commonly done in nuclear cardiology and MRI (36,37). Averaging *N* images together should decrease the random noise by a factor of $(N)^{1/2}$, though image misalignment and ultrasonic “speckle” noise limit its use in echocardiography.

It is also possible to combine spatial and temporal operations into a single 3-D convolution encompassing three (or more) video fields. With faster hardware, it should be possible to use nonlinear filters, such as those described in this chapter, to preserve and highlight moving as well as static edges.

Edge Extraction

To actually extract the edges themselves from an image, one may threshold a gradient image to select points with strong edge characteristics. These candidate edges may be serially thickened and thinned to form a single closed contour and eliminate extraneous “edge” pixels. Once in this form, the boundaries may be output, for example, to a computer for automated quantification of regional wall motion or quantitative coronary angiography. Motion analysis may follow edge enhancement. The optical flow algorithm tracks edges on successive frames to quantify their perpendicular motion (38); one group has used this technique with echocardiographic images (39,40) to identify regions of convergence (contraction), divergence (dyskinesis), translation, and distortion. If one has an accurate sequence of edge maps, the convected activation algorithm can calculate perpendicular edge motion at the video frame rate (41). However, such a technique is critically dependent on the continuity and accuracy of the input edge maps.

Practical Experience with Edge Detection

Critical to the success of any edge-detection scheme is the quality of the raw data. Data with high signal-to-noise ratio and highly defined edges, such as contrast ventriculography, are most amenable to automated border detection (42). Image enhancement by digital subtraction of a noncontrast image further improves this process (43). Automated and semiautomated methods for tracking contrast-filled coronary arteries have been used to assess hydrodynamic severity of stenosis (44,45).

Nuclear Imaging

In nuclear cardiology, despite the low signal-to-noise ratio, it has been possible to enhance endocardial borders by a combination of thresholding with first and second spatial derivative operators (46,47). An advantage of radioventriculography is the ability to measure ventricular volume directly from the photon count without geometric assumptions, from which rates of filling and ejection can be measured. Because these calculations require temporal differentiation, which amplifies noise, Fourier analysis is commonly used to reconstruct the ventricular volume curve using only the low-frequency harmonics (48). By mapping the phase and amplitude of the first harmonic for all the pixels in the image, it is possible to assess regional function (from the amplitude image) and time and location of ventricular activation (from the phase image) (49,50).

Magnetic Resonance Imaging

Because magnetic resonance images are of such high quality, they are good candidates for image processing and automated edge detection. This is especially so because edges may be detected within one plane and tracked to adjacent planes at the same point in time, or projected forward and backward in time to yield a full four-dimensional data set of cardiac anatomy. Such a reconstruction presents formidable challenges for surface modeling and display (51).

Echocardiography

An early approach to echocardiographic edge extraction used either the Sobel or Laplacian operators applied to an entire ventricular image, with either a user-specified (9) or automated (52) threshold declaring a pixel to be an edge, but it is difficult to exclude extraneous edge points and fill in regions of echo dropout. A fundamentally different approach assumes a priori that the short-axis left ventricular endocardium is a closed, nearly circular, curve (53). After the user specifies a point within the ventricular cavity, the ventricular centroid is defined and a radial search performed for points of maximal gradient, presumed to represent the endocardium and epicardium, with points rejected if they cause too sharp a discontinuity in the border. Efforts have also been made to use the position of the endocardium in one frame to guide the subsequent border search (54). Like the earlier serial methods (17), these search radially from the ventricular centroid but use pixel intensity, spatial gradient, and local variance in combination to assign a probability that a pixel is on an edge. Some methods have also allowed the user to correct computer errors on a single frame (for instance, to include or exclude the papillary muscles) and then extrapolate this correction throughout the cardiac cycle (55).

Artificial Intelligence Techniques

Many analytic methods are quite specific in their application: They require data from specific imaging views in a particular format. The long-term goal is a much more robust system, one that could accept data from the low-level processor from a variety of views (perhaps nonstandard) and fit this information into a 3-D model of how a normal heart should appear, judging abnormality as a discrepancy from this normal model. Ideally such a system should interact with the low-level processing algorithms to optimize the features extracted and perhaps cue the examiner for additional views. Although such a system is far in the future, the use of artificial intelligence modeling has been described to guide ultrasonic data acquisition (56). In this preliminary work, the size and shape of a balloon were reconstructed by sequential input of border information together with 3-D positioning data from sonic spark gaps mounted on the transducer. The computer used previously provided information concerning the typical appearance of a balloon to build a 3-D model of the object being imaged and request additional views as needed.

APPLICATION OF FOURIER ANALYSIS IN CARDIAC IMAGING

Fourier analysis is a technique for extracting the frequency components from a signal or image (57,58 and 59), a powerful mathematical tool that has achieved a prominent role in diagnostic cardiology. Most familiar is its use in Doppler echocardiography to convert the frequency-shifted signal into blood velocity. Fourier analysis is also integral to image formation in nuclear magnetic resonance and CT and is gaining utility in wall motion analysis in nuclear cardiology and echocardiography. Although the mathematical details are daunting, it is hoped that the graphic description here will give all readers insight into the principles and limitations of Fourier

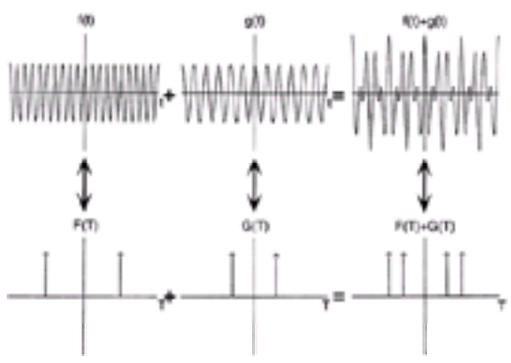
analysis.

Notational Conventions

Functions of time, space, or both have lowercase names and variables, $y(t)$, $f(x)$, $s(q)$, and so forth, while the corresponding Fourier transforms will be capitalized, $Y(T)$, $F(X)$, $S(Q)$, and so forth, related by $\leftrightarrow$: $y(t) \leftrightarrow Y(T)$. The variables $t \leftrightarrow T$ are reciprocal to each other: if t is time in seconds, then T is temporal frequency in sec^{-1} or Hertz. It is critical to appreciate that $y(t)$ and $Y(T)$ are simply different representations of the same thing, with a flexible interrelationship. Sometimes it is more convenient to consider the individual values of a signal [use $y(t)$], whereas at other times it is more informative to display its component frequencies [use $Y(T)$].

Fourier Transform Properties

The Fourier transform theorem states that any function of time, $f(t)$, can be duplicated by adding together sine and cosine waves of different frequencies. eFigure 46.12.5 shows how two cosine waves of different frequencies can be added together to produce a complex waveform (top row). The corresponding Fourier transforms on the lower row demonstrate several features. First, the higher frequency signal (10 Hz, left) has the broader Fourier transform with data present at ±10 Hz (the presence of negative frequencies is a mathematical artifact); second, just as the waveforms can be added together, the two transforms can be added together (right panels). This linearity property is critical for the utility of the Fourier transform. We can either add two signals together and take the transform of the result or take the transform of the two signals separately and add these together. The result is the same.

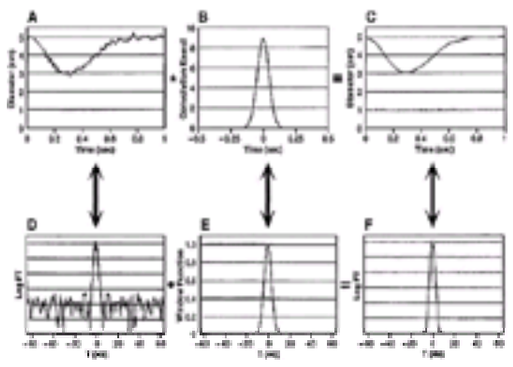


***e*FIGURE 46.12.5** Fourier transformation is a linear process. $f(t)$ is a cosine wave with frequency 10 Hz, whereas its transform $F(T)$ is nonzero only at 10 Hz; similarly, $g(t)$ is a lower frequency wave, with $G(T)$ positive at 6 Hz. The Fourier transform of the sum $f(t) + g(t)$ is simply the sum of the two component transforms $F(T) + G(T)$ (*right*). (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:643, with permission.)

Applications

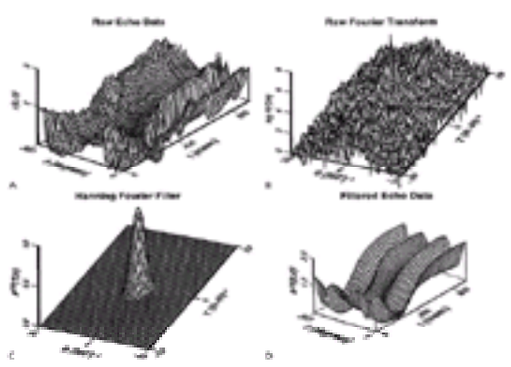
Data Smoothing

eFigure 46.12.6 illustrates an important application of Fourier analysis, smoothing a noisy signal. In A, a ventricular diameter curve is seen with random measurement error of approximately ±0.2 mm superimposed. The transform below shows that this noise is mostly contained in the higher frequencies of the signal, with the true signal concentrated below 10 Hz. By multiplying the transform in D by the windowing curve in E, we can eliminate all frequencies over 10 Hz (F), and when this is inverse transformed, we obtained a smoother rendition of ventricular contraction in C. Note that exactly the same result would result from computing the moving average of the signal in A with the smoothing curve in B, using a complex process termed *convolution*. It is often more efficient to smooth a signal by the Fourier filtration approach (A→D→E→F→C) than to do the computationally more difficult convolution (A→B→C).



***e*FIGURE 46.12.6** Fourier filtration to smooth a noisy signal. The noisy signal in **A** (analogous to an M-mode left ventricular diameter) is Fourier transformed in **D**, showing that most of the noise is in higher frequencies. Multiplying this by the windowing curve in **E** eliminates these high frequencies **(F)**, which, on inverse transformation, reveals the smoothed curve in **C**. Alternatively, the noisy signal can be convolved with the Gaussian function in **B** to yield the smoothed curve in **C**, but this is often more computationally difficult than using the Fourier transform. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:646, with permission.)

This efficiency is even more obvious as one moves beyond the one-dimensional data set of eFigure 46.12.6 to a 2-D data set as shown in eFigure 46.12.7, showing the traced endocardial borders from a short-axis echocardiogram throughout a complete cardiac cycle (60). This data set has both a temporal dimension (the t-axis) and a spatial one (the q-axis, representing the angular distance around the border). The radial distance of the endocardium from the ventricular centroid is shown as a height, $r(t,q)$. Although one can discern in A gross systolic contraction (between 0 and 300 ms) and the location of the papillary muscles (at approximately 45 and 300 degrees), much is lost in the random noise of the traced contours. The 2-D Fourier transform of these data (eFig. 46.12.7B) shows physiologic information at low frequencies (center of the graph) with a noise spectrum in the high frequencies. These noisy frequencies are eliminated by multiplying eFigure 46.12.7B by the filter function in eFigure 46.12.7C. Performing the inverse Fourier transform on these filtered data yields the smoothed profile in eFigure 46.12.7D in which cardiac structure and function are much more evident.

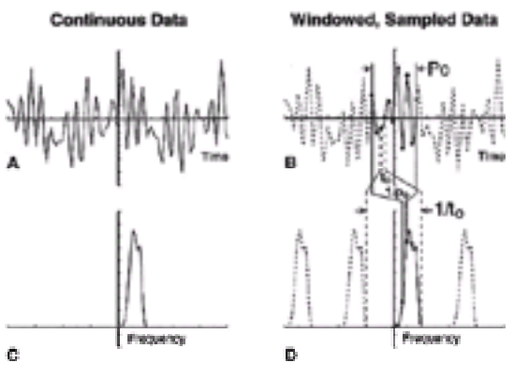


***e*FIGURE 46.12.7** Spatiotemporal Fourier filtration. The noisy data in **A** (traced endocardial borders) is Fourier transformed in **B**, which is multiplied by the filter function in **C**, and then inverse transformed to yield the smoothed data set in **D**. See text for discussion. (Reprinted from Thomas JD, Hagege AA, Choong CY, et al. Improved

accuracy of echocardiographic endocardial borders by spatiotemporal filtered Fourier reconstruction: description of the method and optimization of the cutoffs. *Circulation* 1988;77:415–428, with permission.)

Doppler Processing

Fourier analysis helps to appreciate the limitations of pulsed Doppler echocardiography. Consider eFigure 46.12.8 showing the actual Doppler-shifted signal from a region of the heart, whose transform is shown in C. Pulsed Doppler processing imposes two fundamental changes on this picture (right panels). First, since blood velocity changes throughout the cardiac cycle, the Doppler signal must be analyzed in discrete windows of duration p_0 (typically 2 to 20 ms). Alternatively, analysis of the whole cycle would simply yield the mean velocity without any phasic information. The second limitation is imposed by the pulsed nature of the interrogation: The Doppler signal is not sampled continuously but rather at the PRF, represented by intervals of t_0 (typically 0.1 to 0.5 ms). These impose limitations on both the maximal and minimal velocities resolvable by Doppler. The discrete sampling interval dictates that the maximal resolvable frequency is $1/2t_0$ (actually, twice this, $1/t_0$, if the Doppler baseline is shifted maximally), manifested physically as Nyquist's velocity. The window period p_0 dictates the *minimal* resolvable frequency, $1/p_0$, leading ultimately to the velocity resolution. This kind of trade-off is ubiquitous throughout Fourier analysis: Longer observation periods lead to finer frequency resolution but worsen the temporal resolution of phasic velocity changes. Such changes in velocity can be tracked more closely by decreasing the window internal p_0, but only at the expense of worsened velocity resolution. eFigure 46.12.8 shows this graphically, where t_0 is related inversely to the width of the resolvable frequency spectrum and p_0 is related inversely to the minimal resolution of the spectrum.



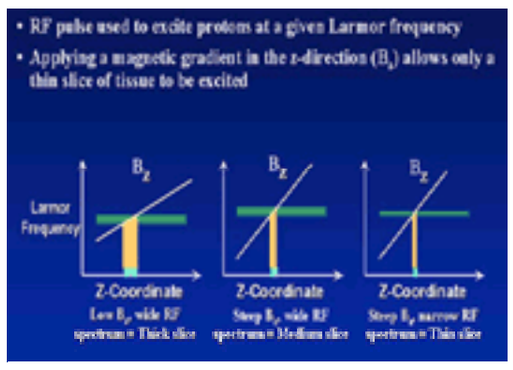
***e*FIGURE 46.12.8** Effect of sampling and windowing of the Doppler waveform on its frequency representation. The "true" Doppler signal in time **(A)** and frequency (Fourier) domains **(C)** are shown on the left. The continuous temporal data are sampled at intervals of t_0 for a period of p_0 (a total of p_0/t_0 readings, **B**); in effect, it is multiplied by d($t_0 \pm nt$) and convolved with d($t \pm np_0$). In the frequency (velocity) domain **(D)**, these effects are reversed and inverted: The data sampling leads to repetition of the velocity waveform at frequencies $1/t_0$ (i.e., convolving it with d[$T \pm n/t_0$]), whereas convolving the window leads to multiplication of the velocity profile by the repeating delta function, d($T \pm n/p_0$). Thus, unambiguous frequency data are available only for p_0/t_0 frequencies between $\pm 1/2t_0$ at intervals of $1/p_0$. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:648, with permission.)

Magnetic Resonance Imaging

Fourier processing has a critical effect on the initial magnetization and subsequent extraction of spatial information from magnetic resonance signals (61). Recall that delivery of an RF pulse at the Larmor frequency will tip the mean magnetization vector out of alignment with the external magnetic field, after which it rotates, emitting radiation at the Larmor frequency. MRI exploits this frequency dependence both to excite part of the imaging field selectively and to separate signals from different locations within that field.

Slice Selection

Before a magnetic resonance image can be formed, a slice of tissue must be localized by changing the orientation of the magnetic moment. This is done by applying an RF pulse at the Larmor frequency, given by $gB_0/2p$, where g is the gyromagnetic ratio and B_0 is the strength of the external magnetic field. If the sample is irradiated by RF at anything other than the Larmor frequency, nothing occurs, a frequency dependence that allows selection of a specific slice by varying the strength of B_0 along the axis of the body. The more rapidly B_0 varies along the body, the thinner the excited slice will be, as shown in the left and middle panels of eFigure 46.12.9. Also affecting slice thickness is how well defined the frequency of the RF is, and here Fourier theory enforces a trade-off between this frequency definition and the speed with which the magnetization can occur. The shorter the RF pulse, the more rapidly images can be obtained, but short pulses have more spectral broadening and thus excite a slice of tissue less precisely. The right panel of eFigure 46.12.9 shows how a longer, weaker RF pulse excites a thinner slice but at the price of slower data acquisition.



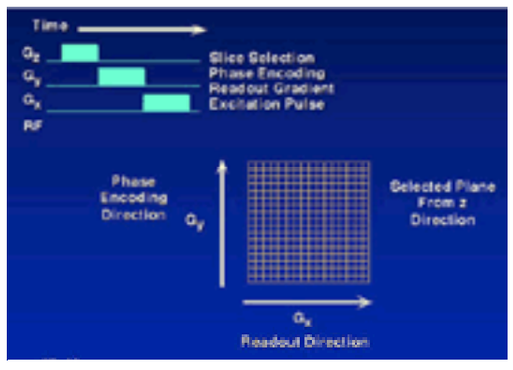
***e*FIGURE 46.12.9** Slice selection in magnetic resonance imaging by selective excitation. The thickness of the plane excited by a radiofrequency (RF) pulse (*yellow bar*) depends on the steepness of the magnetic gradient (*diagonal line*) and the spectral width of the RF pulse (*green bar*). (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:649, with permission.)

Spatial Resolution within the X-Y Plane

Following selective excitation of a slice of tissue, features within the plane are localized by varying the strength of the magnetic field across the plane to make the protons "ring" at a frequency specific to their location. Fourier analysis is then used to recover position from these frequencies. If the only challenge were to localize a structure in one direction (say the *x*-direction), one could simply change B_0 linearly along that direction, yielding a spectrum at which frequency is directly related to position (not unlike the keyboard of a piano; Fig. 6.11). The faster the rate of change in B_0, the finer the potential resolution along that axis, but the greater the risk that frequency shifts on the periphery of the image may exceed the capacity of the instrument, leading to the MRI equivalent of aliasing, folding over of structures into the incorrect location.

To resolve features in the perpendicular (*y*) direction requires processing a series of signals that are frequency encoded in the *x*-direction, each of which is additionally encoded by a brief gradient of varying duration or strength applied in the *y*-direction (eFig. 46.12.10) (62). These phase-encoding steps highlight different spatial

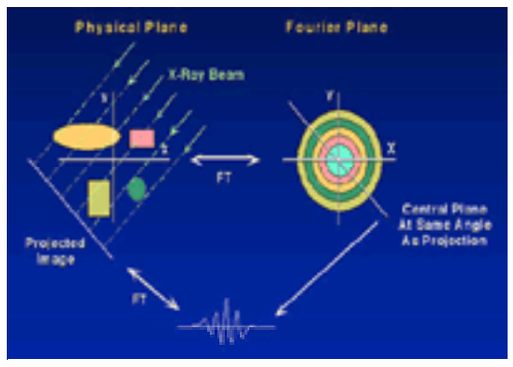
frequencies in the *y*-direction. The net effect of this is to perform a 2-D inverse Fourier transform on the structural anatomy within the plane (an inverse transform because position in the slice is equivalent to frequency, which is converted into a temporal signal). To recover the positional data, the many digitized induction signals are arranged mathematically into an array, where time within each signal is along one axis and degree of *y*-phase encoding is along the other axis. A 2-D Fourier transform then yields the desired anatomic data. The number of phase-encoding sequences applied along the *y*-axis determines the resolution of the image in this direction. A more detailed description of the pulsing necessary for cardiac gating and multislice imaging is included in Chapter 54.



***e*FIGURE 46.12.10** Nuclear magnetic resonance Fourier zeugmatography. After selectively exciting a single slice of tissue (with the *z* gradient), a phase-encoding gradient is applied in the *y*-direction followed by a frequency-encoding *x* gradient during the signal readout period. By combining data from multiple phase-encoding steps (which highlight specific Fourier components in the *y*-direction) one is left with a two-dimensional Fourier transform of the tissue slice from which one can reconstruct the original anatomy. RF, radiofrequency. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:650, with permission.)

Computed Tomography

Fourier analysis also plays a pivotal role in the theoretical underpinnings and practical implementation of computed x-ray tomography (63,64 and 65). Similar to MRI, a CT scan is built from a series of slices, but in contrast, each slice is generated from a number of x-ray projections across the slice. The difficulty is obtaining information across the depth of the slice from these projections, which (as in standard radiography) blur all details along the path of the beam. If it were possible to derive the 2-D Fourier transform of the anatomy of the slice, $F(X,Y)$, inverse transformation would yield the actual structure, $f(x,y)$. Fortunately, the 2-D Fourier transform can be built up a slice at a time as shown in eFigure 46.12.11. This is because the Fourier transform of a projection at angle q is precisely the same as the 2-D transform sampled along a line passing through the origin of the 2-D Fourier plane and inclined at an angle q. Thus, by gathering projections from a variety of qs, the complete 2-D transform $F(X,Y)$ can be filled in by interpolation. In actual implementation, a related numeric approach of filtered back projection is used, but the overall principle is the same, illustrating again how much of contemporary cardiac imaging depends on facile movement of data from real space to Fourier space and back again to simplify complex calculations.



***e*FIGURE 46.12.11** Physical and Fourier representations of an image: application to computed tomography. The projected image is obtained by integrating image density along the direction of the x-ray beam (just as a standard x-ray does). The central slice theorem states that the Fourier transform (FT) of the projection is precisely the same as the plane of the full FT passing through the Fourier origin at the same angle as the image projection. (Adapted from Fozzard HA, et al. *The heart and cardiovascular system*, 2nd ed. New York: Raven, 1992:651, with permission.)

PRACTICAL ASPECTS OF DIGITAL IMAGING

The foregoing indicates that much of contemporary cardiac imaging relies on digital acquisition and processing, but until relatively recently, the final image was usually stored in analog format: 35-mm film for angiography, videotape for echocardiography, and cut film for radiography and nuclear cardiology. Increasingly, however, images are being stored in digital format for review, analysis, and archiving. Among the advantages of digital storage are the following (66,67): (a) individual components of an examination (e.g., cine runs in angiography, echocardiographic views) can be quickly reviewed without needing to search through the entire study; (b) prior examinations are available for side-by-side comparison with the current study; (c) studies can be reviewed by clinicians throughout the hospital; (d) images can be transferred instantaneously to other institutions for consultation or referral (68,69); (e) spatial, temporal, and other calibration data can be stored with the study, facilitating quantitative off-line analysis; (f) sophisticated image-processing algorithms can be readily applied to the original data; (g) images can be duplicated without degradation; (h) long-term archiving can be accomplished without loss of quality; and (i) costs may be lower than with analog techniques. To accomplish this goal has required agreement on formatting standards, dramatic improvement in the cost-effectiveness of computers and networks, and agreement within the clinical community as to the degree of data compression that will be allowable.

Digital Imaging and Communications in Medicine Image Format Standard

Until fairly recently, commercial digital archiving systems for medical applications typically used proprietary, closed technology for image storage, so a study recorded using one manufacturer's system could not be viewed on another vendor's equipment. To head off this coming "tower of Babel" in medical imaging (70), the American College of Radiology and the National Electrical Manufacturers' Association organized in the early 1980s to standardize the exchange of digital images. Initial versions were published in 1985 and 1988 but had little effect on cardiology because angiography and echocardiography (beyond single-frame gray-scale images) were not addressed. The scope was further limited to point-to-point communications, meant to allow American College of Radiology/National Electrical Manufacturers' Association–compliant radiographic machines to exchange images, with no provision for storage of these images on exchange media, whether floppy disk, hard disk, or magnetic tape. Furthermore, the protocol was extremely limited, requiring the use of a unique 50-pin connector, which did not conform to any emerging networking standards in the computer industry. By contrast, version 3 of the American College of Radiology/National Electrical Manufacturers' Association Standard, now specified as DICOM, to emphasize its role in the general field of medical imaging as well as the inclusion of many other professional organizations (including the American College of Cardiology, the American Society of Echocardiography, and the Society for Nuclear Cardiology) in its formulation, has addressed many of the prior limitations. It now specifies a much wider range of image types, including ultrasound, MRI, CT, and x-ray angiography. In particular, color images are now enabled as are moving images and physiologic data. It specifies both network exchange of images as well as media storage, and the network interface is now an industry standard.

Overall Structure of Digital Imaging and Communications in Medicine

DICOM is simply a set of rules to specify how images and other data should be exchanged between compliant pieces of equipment. Individual image files are stored with information on the patient, the purpose and technique of the examination, interpretation of the image, and, of course, the pixel data themselves. Each modality (echo, CT, MRI, nuclear, angiography) has specified which data elements are required and which are optional in the file and the exact nature of the pixel storage, including any possible digital compression. Images may be exchanged either by network or by disk. For network communications, a process of negotiation goes on

between equipment to determine the most efficient format for the image data to be exchanged (as a lowest common denominator, all must be able send and receive uncompressed images). For disk exchange, the format must be agreed to in advance (termed *application profiles*, specific to each modality); this made up the bulk of the DICOM efforts from 1994 to 1996. It should be emphasized that DICOM is not an archival standard, but rather a communication and exchange standard. Within an institution, images may be stored on whatever media are most appropriate.

Digital Imaging and Communications in Medicine for X-Ray Angiography

The initial application profile approved for angiography specifies the writable CD-ROM (CD-R, 680 MB in capacity) as the storage medium. Studies are to be stored as 512 × 512 pixel images with 8 bits used for the gray-scale information. Lossless compression must be obtained with the Joint Photographic Expert Group (JPEG) algorithm, which reduces storage needs by 50% to 60% (see Digital Compression of Images, later in this chapter). With these rules, approximately 4,800 cine frames can be stored on a disk, sufficient for over 95% of the diagnostic and interventional studies performed in the United States. The recent progress in CD player speed allows images to be reviewed at full speed (15 frames per second). A large trial demonstrated that *lossy* compression will not be acceptable for angiographic storage, as even minor degrees of degradation resulted in a quantifiable loss in interobserver agreement (71).

Digital Imaging and Communications in Medicine for Echocardiography

In echocardiography, the needs for image interchange are more diverse. Accordingly, several interchange media are supported by the standard. Gray-scale, color, and spectral Doppler images can be exchanged over a network or stored on 1.44-MB floppy disks, 3.5-and 5.25-in. magneto-optical drives, and CD-R disks. Calibration factors may be stored for linear, temporal, and velocity measurements and 3-D registration. Images may be stored either uncompressed or with lossless or lossy compression (72).

Digital Imaging and Communications in Medicine for Nuclear Cardiology

The DICOM nuclear standard has been updated to encode the complex studies of nuclear cardiology. Truly multidimensional data sets may be stored, reflecting the four-dimensional, multistage, multinuclide nature of contemporary protocols. Because the size of the actual data sets is small in comparison with echocardiography and angiography, nuclear studies are stored without any compression.

Digital Compression of Images

Cardiac images are voracious consumers of disk storage and network bandwidth. Even a relatively low-resolution angiographic run (512 × 512 × 8 bits × 30 frames per second) will consume 7.5 MB per second, as much as 1 GB in a complex study. Full-color echocardiography (640 × 480 × 24 bits × 30 frames per second) requires 30 MB per second, up to 20 GB for a typical 10-minute study. Such requirements outstrip contemporary, affordable computer systems, highlighting the need for data reduction in cardiac imaging.

Clinical Compression

Much efficiency can be obtained through judicious editing of images on clinical grounds. In echocardiography, for example, single cardiac cycle loops can be stored for repetitive display rather than long acquisitions, a 20- to 30-fold saving. In stress echocardiography, images have been stored in quad screen format, saving only the systolic frames, a further eightfold savings. However, for both echocardiography and angiography, in which such clinical editing is not advocated, there remains a need for digital compression of the images themselves, both for storage efficiency and for speed in network and telemedicine transmission.

Digital Compression

Digital compression of images falls into two broad categories, *lossless* and *lossy*. As the name implies, lossless algorithms allow the original image to be recovered in every detail, removing all concern that such compression might affect the clinical content of the image. For lossless encoding, the echocardiographic DICOM standard uses a scheme called *packbits*, in which repetitive blocks of same-valued pixels are coded efficiently (termed *run-length encoding*). The angiographic standard currently allows only lossless encoding, using the lossless version of the JPEG algorithm. A disadvantage of all lossless techniques is relatively poor compression ratios, typically 2:1 or 3:1.

To gain more efficient compression (often beyond 100:1) *lossy* algorithms must be used, which distort the recovered image in a slight (and inapparent, it is hoped) fashion. The DICOM echocardiography standard allows the use of the lossy JPEG algorithm in which 8 × 8 pixel blocks are in essence Fourier-transformed and only the significant, mostly low-, frequency components are stored. Quantitative image analysis has shown little degradation of echocardiographic images at compression ratios as high as 20:1, whereas images stored on super VHS (SVHS) videotape show degradation equivalent to 26 to 30:1 compression (73,74). In a blind comparison, a large group of observers overwhelmingly selected digital echocardiograms over videotape equivalents, with no impact of 20:1 JPEG compression (75). Other studies have shown that 20:1 JPEG compression has no adverse effect on edge-detection algorithms and allows accurate extraction of velocity from color Doppler maps. Thus, 20:1 JPEG compression appears acceptable in clinical echocardiography; a major trial is under way to determine the effect of 7 to 14:1 JPEG compression on angiographic images. Other trials have shown the acceptability of lossy compression for CT (76) and nuclear medicine (77).

Higher degrees of compression are available from other algorithms, although these have not yet been standardized within DICOM. The Motion Pictures Expert Group (MPEG) approach extends JPEG by exploiting redundancies between frames, achieving compression ratios beyond 100:1 with excellent fidelity. MPEG is attractive because it is emerging as the standard for multimedia computing and entertainment, and prior concerns that it was more difficult to encode than decode and did not allow crisp stop frames appear to have been alleviated. It has been demonstrated that MPEG encoding has diagnostic content equivalent to videotape (78), while even higher quality can be obtained by transmitting echoes over high-speed digital networks (5 MB per second) using MPEG-2 encoding (79). Among other algorithms being evaluated are wavelet compression, which uses a continuum of frequencies to compress the image rather than the discrete frequencies of the Fourier transform (80), and H.261, a multiframe precursor of MPEG widely used in videoconferencing.

Digital Imaging at The Cleveland Clinic Foundation

The year 2000 marked the time that digital storage became a reality in the echocardiography and catheterization laboratories. Figure 46.13 shows the current architecture in use for digital echocardiography in our laboratory. All echo machines in the inpatient and outpatient laboratories, operating rooms, and regional satellite facilities are capable of digital output of still images and loops in the DICOM format using a standard TCP/IP network (100 MB per second for the local machines, 1.54-MB per second T1 lines for the regional facilities). For portable studies performed outside the high-speed network, studies can be stored temporarily on the machine's hard disk for later network export or stored on a magneto-optical disk for "sneaker netting" onto the archive. Within the echo laboratory, all image traffic is handled over a network that is isolated by switches so as not to degrade performance of the remainder of the cardiology network. A typical study in our laboratory contains 30 to 80 single-cycle cine loops with an additional 10 to 20 still frames of spectral Doppler and M-mode tracings, yielding an average study size of approximately 60 MB. With 160 studies performed daily, this requires 10 GB of storage daily or approximately 2.5 TB of storage annually. To handle this enormous storage need while providing rapid review of recent studies (access times less than 30 seconds), data sets are initially stored on a local hard drive with almost 1 TB of storage, where they remain for 30 to 60 days. Simultaneously, data are also copied to a long-term digital tape archive providing 160-TB storage with 2- to 3-minute access time. All of this is controlled by a dedicated software program running on several viewing stations in the laboratory. A similar architecture is used in the catheterization laboratory with a dedicated network providing access to up to 60 angiographic studies performed daily and stored using the DICOM standard and lossless JPEG encoding.

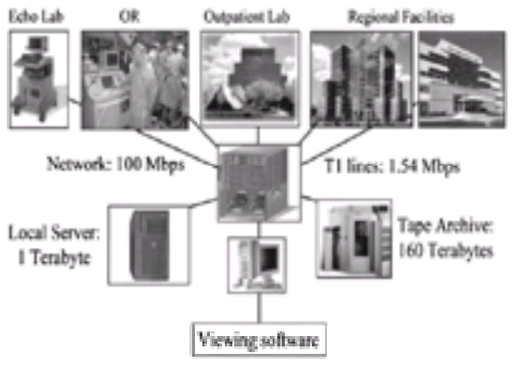


FIGURE 46.13 Implementation of digital echocardiography at The Cleveland Clinic Foundation in 2001. High-speed networks connect more than 30 echocardiographs to a central server and archive. See text for details. OR, operating room.

SUMMARY

The theory underlying cardiac imaging techniques spans a wide range of physical principles, from low-energy photons (magnetic resonance) to high-energy photons (radiography and nuclear medicine) to acoustic energy (ultrasound). With each of these methods, there are fundamental trade-offs to be made in terms of spatial resolution, temporal resolution, acquisition time, and radiation exposure, trade-offs that often become clearer when studied in terms of the spectral content of signals using Fourier analysis. Finally, combining data from any of these imaging modalities with techniques of digital image processing may provide new ways for automated image analysis and understanding.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Each year brings dramatic new developments in cardiac imaging. Since the physical interaction of photons, ultrasound, and magnetism with matter has changed little, most of these improvements result from enhancement in the computer processing of these data. Extrapolating to the future, we can only expect this to continue. Moore's law states that, over the past 50 years, computer processing power (per unit cost) doubled every 18 months. Had the auto industry shown similar productivity gains, the cost of a new car would be less than 1 cent. Since the mid-1990s, the trend toward all-digital acquisition and storage for radiography, angiography, and echocardiography has become reality, with practical solutions available from several vendors. For the most part, however, these solutions are isolated from each other and are not generally available throughout the hospital. If we are to achieve true intervendor, intermodality utility, the medical community must insist on adherence to both the letter and spirit of DICOM: DICOM should be output (by disk, network, or both) by each imaging machine and read by all information management systems. In this way, the end-user can choose components based solely on quality and price performance without concern for interoperability. In the next 5 years, we can expect solutions to emerge that can read multiple modalities and deliver these quickly to the practitioner's screen, allowing the easy integration of echo, nuclear, catheterization, and MRI data to guide management of the patient.

Digital storage and transmission should also make health care more economical by reducing the need for duplicate studies. Patients will carry their medical records and images with them, initially on compact disk but perhaps soon on a small holographic card. Images will be transmittable via telephone, satellite, or the Internet, allowing remote consultation and timely referral. Equally important is extracting as much data as we can from any given study. In this regard, several modalities (ultrasound, MRI, and nuclear imaging) are touting themselves as "one-stop shopping" for cardiac structure, function, and perfusion. Of the three, ultrasound permits the least expensive assessment of chamber size, global and regional ventricular function, and valvular stenosis and regurgitation. With the development of stress echocardiography and novel contrast agents, myocardial perfusion may similarly be measurable. Unfortunately, echocardiography has been used traditionally in a largely qualitative fashion; it is hoped that the trend toward quantitative processing of color Doppler velocities and regional wall motion will continue. Nuclear imaging has seen great improvement in the last two decades and represents the current gold standard for myocardial perfusion and metabolism. Positron emission tomographic scanning is uniquely informative, but so expensive as to be confined to a few large medical centers. In this era of cost containment, it is hard to imagine widespread dissemination of this technology. MRI provides high-resolution isotropic 3-D data throughout the body without the restriction of echocardiographic windows. With improvements, the large epicardial coronary arteries may be routinely imaged, contrast may assess myocardial perfusion, and spectrographic techniques may detect ischemia. Like positron emission tomography, though, the large capital investment and operating expense of MRI will likely limit it to specialized applications in major medical centers. More recently, computed tomography with spiral scanning techniques has allowed rapid acquisition of gated cardiac images, allowing excellent visualization of the aorta and proximal coronaries at considerably lower cost and complexity than MRI.

THE FUTURE

The next decade will see continued technical progress in all cardiac imaging modalities, but economic forces will increasingly force clinicians to choose between examinations. Those tests that provide the most comprehensive assessment of the heart at the least cost will prosper, whereas others may see diminished use. A great challenge is the routine exchange of digital studies both within and between institutions. Vendors and professional societies have agreed on the DICOM standard for this exchange, but implementation remains incomplete. The medical community must insist on adherence to standards if global interoperability is ever to be achieved.

OVERVIEW

The value of plain film examination of the heart and lungs lies in its availability, long history of clinical utility, and ability to display acute and chronic changes in a safe and convenient manner. Diagnosis is based on identification and characterization of variance in the appearance of structures on chest film from their expected normal appearance. Interpretation of the chest radiograph involves systematic evaluation of the quality of the examination, the position of the patient undergoing examination, as well as the radiographic changes encountered in the examination. The validity and significance of observed abnormalities depend on a belief in the physiologic or technical basis for their presence. Attention to these factors allows extraction of pertinent, reliable evidence of pathophysiologic mechanisms that allows the observer to make cardiovascular diagnoses, as well as to assess the instant physiologic status of the patient at the time of examination.

GLOSSARY

Cardiac contour: The borders of the cardiac silhouette are formed by portions of the cardiac chambers and aorta and pulmonary artery; in oblique view, different border-forming chambers are accentuated or brought into view. Analysis of chamber and great artery abnormality is based on systematic estimation of the appearance of these contours. Evaluation begins by dividing the cardiac silhouette into the left and right heart borders. The left heart border is composed of the aortic arch, main pulmonary artery, left atrial appendage, and left ventricular portion. The right heart border is composed of the superior vena cava, ascending aorta, and right atrial portion.

Cardiac position: This describes the position of the heart within the chest. In general, it is determined by estimating where the bulk of the cardiac silhouette resides. We expect the cardiac apex and bulk of the ventricular myocardium to lie just slightly off the midline, toward the left (levocardia). Thus, *mesocardia* and *dextrocardia* describe the heart as straddling over toward the right with respect to an imaginary line drawn in the chest midline. *Dextrocardia* refers to the presence of a heart in the right chest resulting from an abnormality of embryologic cardiac rotation. It is frequently associated with congenital heart disease. *Dextroposition* describes a heart in the right chest, caused by noncardiac abnormalities that affect the normally formed heart.

Cardiac rotation: The heart and proximal great arteries are contained by the pericardium and fixed in the superior mediastinum and at the diaphragm. Right atrial, ventricular, or both atrial and ventricular dilatation produces (looking from below) clockwise rotation of the heart and great vessels, so that the appearance of the left heart border in postero-anterior view is altered. The superior mediastinal silhouette is narrow as the superior vena cava rotates toward the midline, and the mid-left heart border becomes more convex as the dilated right ventricular outflow forms the left heart border.

Left ventricular configuration: Hearts that appear unusual may be morphologically normal. However, many abnormal hearts share a common appearance: The contour of the left ventricular portion of the left heart border appears greater in curvature than expected. This appearance of the left-sided heart contour is found in a variety of congenital and acquired forms of heart disease. It is a sensitive "case finder" or indicator of cardiac abnormality. However, it is nonspecific and requires appreciation of other radiographic or clinical findings for more precise cardiac diagnosis.

Pulmonary edema: This term refers to the characteristic inhomogeneous appearing infiltrates found with alveolar edema. It represents the severe end of the spectrum of the radiographic changes of pulmonary venous hypertension. The earliest radiographic finding in elevated left atrial pressure is indistinct lower lobe pulmonary vessels.

Pulmonary vascularity: The radiographic appearance of the pulmonary arteries and veins closely correlates with left atrial pressure and the regional distribution of water in the lungs. This general term refers to the caliber of the larger pulmonary arteries and veins in a chest radiograph. Comparison of left-sided vessels with those on the right, upper with lower vessels, and central with peripheral vessels is commonly used to differentiate failure from pneumonia and shunt from pulmonary hypertension.

Shunt vascularity: This subcategory of pulmonary vascularity refers to the status of the pulmonary arteries in individuals with left-to-right shunts. In particular, it refers to increase in the caliber of the entire pulmonary arterial tree, from main pulmonary artery segment, to peripheral subsegmental pulmonary arterial branches. Vessels are sharp, demonstrate normal peripheral branching, and extend further toward the pleura.

INTRODUCTION

Plain film examination of the chest is nearly always employed to determine the presence of heart disease and to help establish its etiology and severity. The development and use of angiographic, nuclear, and tomographic cardiac imaging technologies (echocardiography, computed tomography, and magnetic resonance imaging) have changed but not excluded the role of plain film radiography in the management of these patients. Characteristic changes in the atrial and ventricular portions of the cardiac contour reflect change in their chamber volume and myocardial mass. Similarly, changes in the contours formed by the great arteries and veins of the chest reflect altered pressure and blood flow. Evaluation of these changes provides the substrate for constructing a differential diagnosis or to assess the severity and often etiology of the cardiac dysfunction.

This chapter is designed to assist clinicians in the use of plain film examination of adult patients with acquired and congenital heart disease. Conventionally, chapters describe radiographic abnormalities in an organized list of cardiovascular conditions. This format can be excellent if the reader knows the answer before asking the question (i.e., if you know the patient has mitral stenosis, then reference to such a chapter provides a source for review of the literature concerning radiographic diagnosis and so on). However, as is more often the case, one does not know the plain film diagnosis; rather, one has acquired a list of positive (and negative) radiographic findings and is in need of an outline of differential diagnoses. In other words, the role of the chest film examination has changed in the management of patients with cardiovascular disease. The examination is performed more to evaluate the instant physiologic status of the patient. This change in use is not surprising, considering the rapid advance in noninvasive cardiovascular imaging. On the other hand, there remains a great deal of diagnostic information contained in plain film examination that can and does benefit the clinician.

This chapter is organized based on radiographic abnormality [i.e., the cardiac silhouette in the postero-anterior (PA) chest film is divided into left and right heart borders and the pulmonary vascularity]. The left heart border contains the aortic arch, pulmonary artery, left atrial appendage, and left ventricular contours. The right heart border contains the superior vena cava, ascending aorta, and right atrial contours. The parenchymal pulmonary vascularity is described in terms of the appearance of the pulmonary vessels. Thus, entrée into cardiovascular diagnosis and differential diagnosis is based on identification of an abnormality or constellation of abnormalities. This approach is useful, especially if one does not know the diagnosis before interpretation of the examination.

After describing the normal appearance of the cardiopulmonary structures, the range of abnormalities of that portion of the chest film is characterized and the differential diagnosis of congenital and acquired cardiovascular disease based on those specific changes is presented. That is, many different diseases may produce individual specific changes in the chest film, but more specific diagnosis may be made or a differential diagnosis ordered by evaluation of the particular constellation of findings present. In other words, rather than review the radiographic findings of a series of cardiovascular lesions, I describe particular radiographic abnormalities, explain how these changes may represent the effect of a congenital abnormality or acquired pathophysiologic mechanism, and then use these findings to construct a differential diagnosis. This is a clinically relevant approach, and it more effectively demonstrates the utility and limitations of chest film examination.

As the reader will appreciate, the utility of plain film examination in the evaluation of adult patients with congenital heart disease is emphasized. This is an important area of rapid growth. This chapter should aid clinicians who encounter such a patient or have an established practice containing many such individuals. Few non–plain film images are included in this chapter; only a few relevant images are included to reinforce mechanisms of radiographic changes in the plain film. One final note on the interpretation of plain chest films. In many cases, one may observe major “obvious” findings that form the basis for an anatomic diagnosis. Further careful analysis of the image, however, often reveals other subtler observations that correlate with the major findings. The constellation of all findings allows the observer to assess not only the disease and its severity, but also to assess the confidence the individual has in that diagnosis.

HISTORY OF CHEST RADIOGRAPHY IN CARDIAC DISEASE

Wilhelm Conrad Roentgen discovered x-rays on November 8, 1895 (1). Immediately after his discovery, physicians around the world began using this new tool in the evaluation of bone fractures and abnormalities of the gastrointestinal tract. Within months of the discovery, application of the “new photography” to chest examination was reported. Williams (2) reported fluoroscopic examination of a patient with cardiomegaly and described the findings for pericardial effusion. Early examinations were crude and dangerous by today’s standards. For example, Walsh (3) published a text that included a chest film demonstrating the position and dimensions of the heart. The exposure required 20 minutes and was obtained using a 30-in. focus-film (x-ray tube–to-film) distance.

A report of heart size in healthy individuals (4) was published in 1902; by 1909 (5), a review of the normal appearance of the heart, the size and appearance of the heart in patients with aortic and mitral valvular disease, and a thoracic aortic aneurysm was published. The measurement of the cardiothoracic ratio (the quotient of the transverse diameter of the heart divided by the greatest transverse chest diameter) was introduced by Danzer (6) in 1919. In his paper, he also noted that the normal ratio is probably greater in children. Radiographic demonstration of pericardial calcification (7) and rheumatic valvular calcification (8) were reported in the early 1920s. Evaluation of changes in cardiac size, as determined by computation of the area of the cardiac silhouette in PA chest film examinations of patients with valvular heart disease, myocarditis, systemic hypertension, and hyperthyroidism (9,10) became routine during the latter half of the decade.

Seeking to gain improved insight into the sensitivity of chest film examination for detecting cardiac disease, Ungerleider and Gubner (11) reviewed the PA chest films of 1,460 healthy individuals and published nomograms for normal transverse diameter and radiographic area of the heart, an indicator of cardiac volume.

The clinical value of plain film examination of the heart was pointed out by Paul Dudley White in an address to the American Roentgen Ray Society in 1929 (12). He emphasized that radiographic examination of the heart provided the most accurate available means of estimating cardiac size and detecting unsuspected pericardial calcification and aortic aneurysms. Furthermore, he praised the technique for its ability to estimate atrial and ventricular chamber enlargement and to provide clinical information in patients too obese or emphysematous for accurate physical examination of the heart. Although there are other imaging modalities, the value of plain chest film examination remains high, and in terms of clinically relevant information obtained, the cost to perform, and patient risk, it remains an integral means of cardiac diagnosis.

THE CHEST FILM ITSELF: IMAGE QUALITY

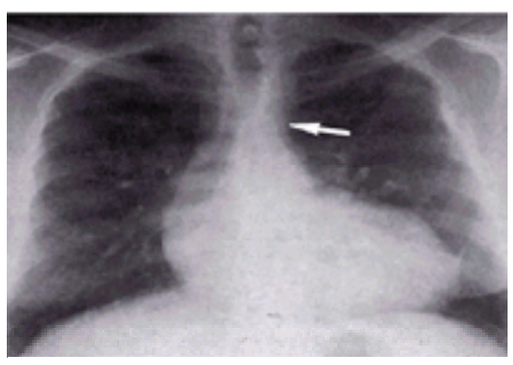
Estimation of the radiographic technique helps the observer to assess the severity of pulmonary vascular changes. A properly penetrated chest examination should allow differentiation of the four basic radiographic densities: air, bone, soft tissue, and fat. Radiographic exposure factors should be chosen so that the resultant examination permits faint visualization of the thoracic spine and the intervertebral disks so that the lung markings behind the heart are clearly visible. Proper radiographic technique allows evaluation of the sharpness of the pulmonary vascular markings and fluid status of the parenchyma. Standard high kilovoltage technique (13,14) radiographs are obtained with a fixed 145 kVp, varying mA between 400 and 600; exposure is controlled by phototimer. Exposure times of between 10 and 60 ms establish an exposure range of between 5 and 30 mA. This method produces clearer visualization of the pulmonary vasculature and better penetration of the mediastinum. However, this technique produces diminished visibility of intrathoracic calcium. Ideally, the lungs should appear gray. Radiographic underexposure (“light films”) generally result in overestimation of the unsharpness of vessels, leading to overinterpretation of pulmonary vascular congestion. Conversely, overpenetration (“dark films”) may produce better visualization of the mediastinal structures, but it prevents detailed observation of the pulmonary parenchyma, leading to underestimation of congestion or the belief that pulmonary blood flow is diminished.

Conventional chest film examination of the heart and lungs is performed using a 6-ft PA beam (i.e., the upright patient faces the film screen combination), and the radiographic exposure comes from behind (the view is named by the course of the beam, hence *PA*). Using this method, the x-ray beam is nearly parallel (nondiverging). The ventrally located heart is close to the film screen and is therefore not (minimally) magnified. Emergency room or intensive care chest radiography is typically performed from in front of the patient who leans against the film cassette. Thus, in this antero-posterior radiograph, the heart is away from the film screen combination, and the x-ray beam is not parallel and therefore diverges. These factors result in magnification of the heart.

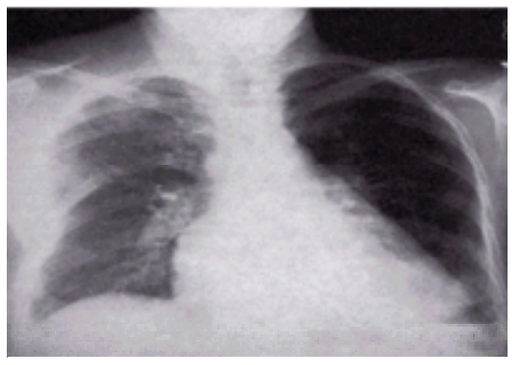
If chest radiographs are obtained with the patient upright, we see a reasonable representation of the distribution of interstitial lung water and pulmonary blood flow. When supine, the lower lobe pulmonary vessels lose their gravity dependence, and the upper lobe pulmonary veins become dependent. In the supine chest radiograph, the lungs usually show some degree of pulmonary redistribution, even in an individual with normal cardiac function.

Minor degrees of patient rotation may result in distortion of normal cardiac structures. The degree of film rotation can be judged by evaluation of the trachea, the clavicular heads, and anterior ends of the ribs with the thoracic spine. The trachea is a midline structure, and in a straight PA view, it should be projected over the spinous processes of the cervical and upper thoracic vertebrae. In this view, the lengths of the two clavicles are equal. Furthermore, the distance between the ends of the anterior ribs and the lateral margins of the thoracic spine is equal. Displacement of these landmarks is a sensitive indicator of patient rotation.

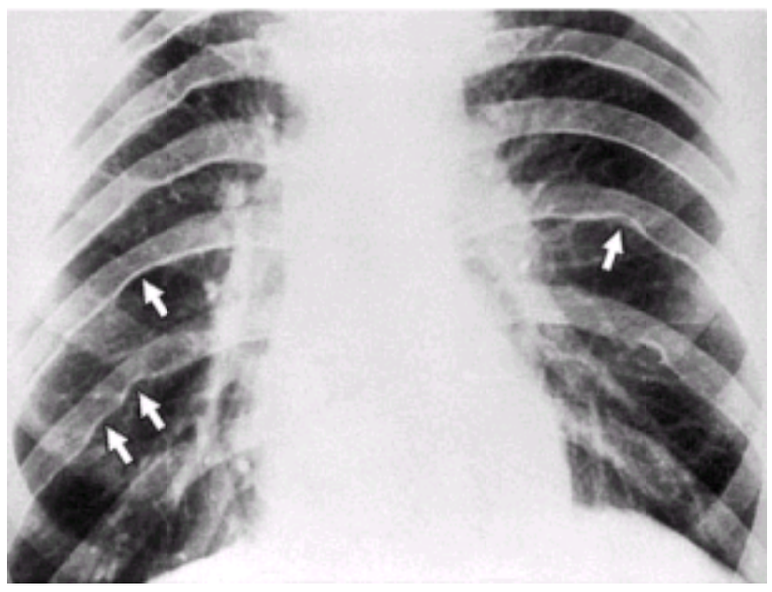
Radiographic signs of previous chest surgery include the obvious placement of midline sternal sutures and mediastinal clips or valvular prostheses as well as subtler findings such as the absence of a posterior rib or asymmetry of the intercostal spaces. Surgery in the more distant past may be evident by the appearance of a regenerating rib (eFig. 47.0.1). More recent surgery may be deduced by asymmetric chest wall edema (eFig. 47.0.2). In a manner analogous to rotation of the entire chest, scoliosis and chest wall deformity may distort cardiac structures, giving the impression of cardiac rotation or chamber enlargement. When scoliosis is present, changes of pulmonary hypertension and cor pulmonale (15,16) correlate with increasing angle of the scoliosis and patient age (17). Assessment of the size of the heart and state of pulmonary vasculature in these circumstances is difficult. Pectus excavatum (“funnel chest”) is a common deformity consisting of depression of the sternum such that the anterior ribs on each side protrude more anteriorly than the sternum itself. Some investigators have suggested (18) that the primary defect in this lesion is an anomalous position of the heart to the left of midline, leaving the retrosternal space “empty,” allowing the sternum and costal cartilages to fall posteriorly. In the PA projection the heart is rotated and displaced to the left (19). The parasternal soft tissues of the anterior chest wall are viewed in profile rather than *en face*, increasing their radiographic density, resulting in the appearance of a right middle lobe infiltrate.



***e*FIGURE 47.0.1** A 32-year-old man with a previously repaired coarctation of the aorta (the regenerating left fourth rib is irregular and faintly seen). The aortic arch segment (*arrow*) is inconspicuous. Left ventricular dilatation and mild pulmonary vascular congestion are caused by infection and subsequent insufficiency of his congenitally bicuspid aortic valve.



***e*FIGURE 47.0.2** A 48-year-old man with rheumatic mitral stenosis 4 days after right thoracotomy. The right sixth rib has been resected. Asymmetry between density of the right and left chest is caused by posttraumatic edema on the operated side. Note the mild pulmonary vascular congestion and straightening of the left atrial contour on the left heart border.



Chest x-ray in coarctation of the aorta. There is prominent rib notching (*white arrows*).

THE HEART AND GREAT ARTERIES

Cardiac Position

The heart lies just to the left of midline, and the bulk of the ventricular myocardium is in the left chest (Fig. 47.1). The position of the heart within the chest depends on cardiac looping and intrathoracic rotation, as well as the presence of skeletal, pulmonary, and diaphragmatic lesions. In situs solitus, a right-sided heart secondary to a noncardiac abnormality is called *dextroposition* (eFig. 47.1.1). This term implies an abnormal position of the heart in the absence of an intrinsic cardiac abnormality. Dextroposition may be caused by abnormalities of the bony thorax (scoliosis, deformities of the sternum or ribs), the lungs (pulmonary agenesis, pneumonectomy, right pneumothorax, chronic volume loss, scimitar syndrome), eventration, or diaphragmatic hernia.

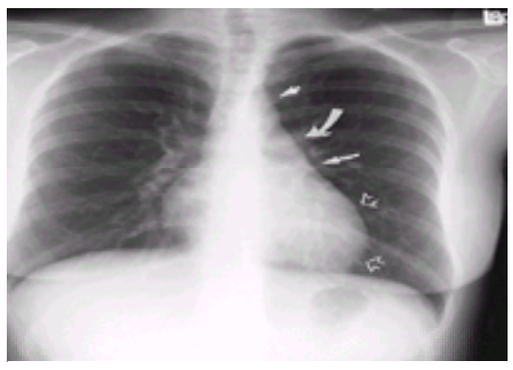


FIGURE 47.1 Normal postero-anterior chest film from a 35-year-old woman. The contours of the left heart border include the aortic arch (*short arrow*), the pulmonary artery segment (*curved arrow*), the concave left atrial appendage segment (*long arrow*), and the gentle curvature of the left ventricular segment (*open arrows*). The lower right heart border is derived from the lateral border of the right atrium.

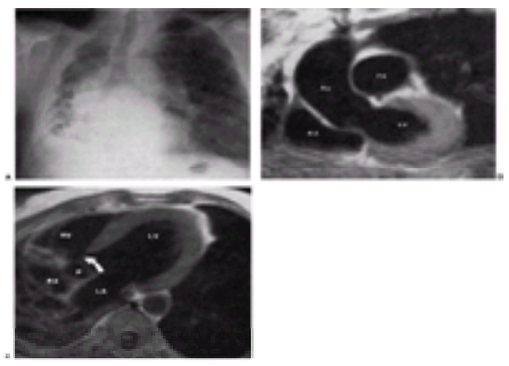

***e*FIGURE 47.1.1** A 63-year-old man with chronic tuberculosis. **A:** Postero-anterior chest film. The heart and mediastinal structures are displaced into the right chest. Notice the pleural thickening and right lower lobe pulmonary changes. **B:** Coronal spin-echo magnetic resonance image through the aortic root. The chronic pulmonary changes, volume loss, and displacement of the heart into the left chest are evident. The ascending aorta (Ao), main pulmonary artery (PA), right atrium (RA), and left ventricle (LV) are labeled. **C:** Axial spin-echo magnetic resonance image through the posterior right sinus of Valsalva (p). The heart is intrinsically normal but rotated slightly to the left. The thin, membranous interventricular septum (*curved arrow*) is seen. RV, right ventricle.

The diagnosis of pneumothorax is made by identification of the visceral pleural line. Only large pneumothoraces produce complete lung collapse and significant mediastinal shift. The roentgenographic density of the ipsilateral collapsing lung changes little until lung volume is greatly reduced (20). In a pneumothorax of any size, shift away from that side is inevitable because pressure in the normal hemithorax remains relatively more negative. Such a circumstance must be differentiated from a tension pneumothorax, in which there is a check valve mechanism, which allows air into the pleural space during inspiration, but prevents its egress during expiration. In tension pneumothorax, one finds inspiratory shift of the heart and mediastinum away from the side of the pneumothorax associated with ipsilateral diaphragmatic depression (Fig. 47.2). Eventration of the diaphragm is a congenital failure of the muscular development of one or both diaphragms (21). Unless occurring in neonates (21,22), this condition does not cause symptoms.

FIGURE 47.2 Tension pneumothorax in a 30-year-old man. The left ventricular contour is medial (*black arrows*) to the line of the pleura (*white arrows*) against the air-filled left chest. The heart and mediastinal structures are shifted toward the right. Notice the flattened left diaphragm.

The scimitar syndrome (23,24 and 25) is an unusual malformation consisting of partial or total anomalous pulmonary venous return of the right lung veins to the inferior vena cava just above or below the diaphragm. It is frequently associated with hypoplasia of the right lung and right pulmonary artery. Frequently, bronchial anomalies and anomalous arterial blood supply to the right lung from the aorta are found (26). PA chest films demonstrate a slight decrease in the size of the right bony thorax and a shift of the heart and mediastinal structures to the right. The characteristic anomalous vein, or scimitar (after the Turkish curved sword), shows a vertical course toward the right cardiophrenic angle, closely paralleling the right atrial border (eFig. 47.2.1). Depending on the degree of right lung hypoplasia, the scimitar may project through the heart or in the right pericardial area.

***e*FIGURE 47.2.1** Two patients with scimitar syndrome. **A:** A 26-year-old woman. The heart is displaced into the smaller right chest. The scimitar may be faintly visualized (*white arrows*) crossing the right atrial border. **B:** A 35-year-old woman. The scimitar (*black arrows*) increases in caliber as it curves inferiorly to cross the diaphragm and enter the inferior vena cava (not demonstrated).

Cardiac Situs

Cardiac atrial situs is assumed to be solitus in the presence of thoracoabdominal situs concordance and abdominal situs solitus. Thus, identification of a right-sided liver and left-sided gastric air bubble establishes normal abdominal situs (Fig. 47.1). Thoracic situs is reliably determined by analysis of the trachea and lungs (27). That is, the morphologic left lung has two lobes (and therefore no minor fissure) and a longer left main bronchus over which the morphologic left pulmonary artery passes proximal to the origin of the left upper lobe bronchus. The morphologic right lung has three lobes (and thus a minor fissure). The right bronchus travels a short course before the origin of the right upper lobe bronchus. The morphologic right pulmonary artery lies anterior and slightly inferior to the right bronchus. Under these circumstances, atrial situs solitus (i.e., morphologic right atrium on the right and morphologic left atrium on the left) can be assumed. The position of the aortic arch or cardiac apex cannot be used to ascertain thoracic situs. Patients with atrial situs solitus may have an isolated right aortic arch or the bulk of their myocardial mass in the right chest (situs solitus with dextrocardia, isolated dextrocardia) in the absence of any other abnormality (Fig. 47.3). Atrial situs inversus is deduced by concordance between inverted abdominal viscera and lung morphology (Fig. 47.4).

FIGURE 47.3 A 21-year-old man with isolated dextrocardia. The heart and lungs are normal. The cardiac apex is in the right chest. The trachea (*arrows*) is midline.

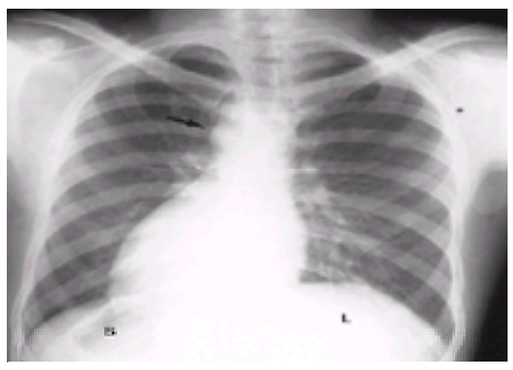

FIGURE 47.4 A 30-year-old man with complete situs inversus. The liver (L) is on the left, and the stomach bubble (S) is on the right. The aortic arch (*arrow*) and cardiac

apex are on the right.

Aortic Arch and Ascending Aorta

The normal aortic arch passes to the left, displacing the trachea toward the right (Fig. 47.1). Measurement of the true caliber of the aorta is difficult on plain chest examination because both contours are not visualized in frontal projection. The left border of the descending thoracic aorta is visualized in the PA radiograph, but the right border is not. The contour of the ascending aorta should not extend to the right beyond the vascular pedicle of the right hilum or shadow of the superior vena cava. Enlargement of the ascending aorta is characterized by increased curvature of the middle third of the mid-right heart border or by a forward bulge of the anterior border of the aorta, as viewed on lateral examination (Fig. 47.5). The aortic arch diameter (28) is the sum of the distances measured between the midline and the right-most ascending aortic contour and left-most aortic shadow, measured above the base of the heart. The diameter of the aortic arch may vary in healthy individuals between 1.8 and 3.8 cm but must not exceed 4.0 cm. However, the ascending aorta, for which there are no “normal” values, is most frequently enlarged in disease.

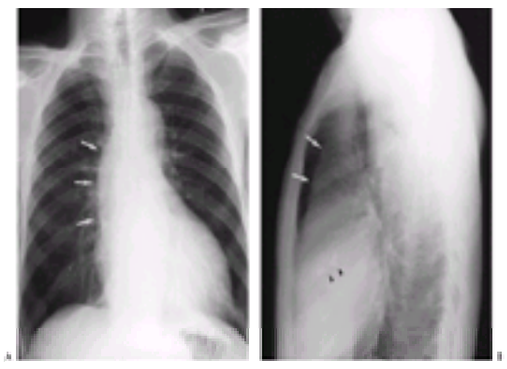

FIGURE 47.5 A 60-year-old man with degenerative calcific aortic stenosis. **A:** Postero-anterior examination shows increased rounding of the left ventricular portion of the left heart border and dilatation of the ascending aorta (*arrows*). **B:** Lateral examination shows aortic valvular calcification (*arrowheads*) in the center of the cardiac silhouette and filling of the retrosternal air space by the dilated, calcified (*arrows*) ascending aorta. The left ventricle is not dilated.

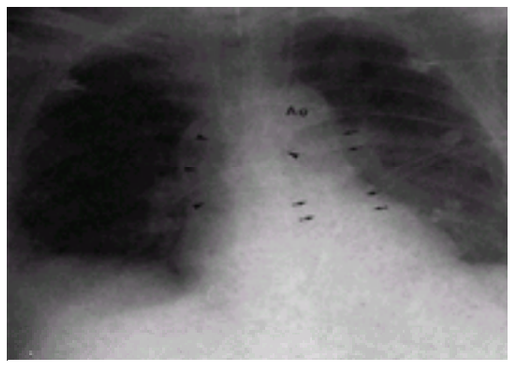
The proximal descending thoracic aorta may be identified as a straight line seen through the cardiac silhouette running parallel to the spine in continuity with the inferior, medial aspect of the aortic arch. Usually this line is to the left of the spine, but the proximal portion may be right-sided in cases of right aortic arch. Unless situs inversus is present, the aorta in cases of left and right aortic arch enters the abdomen through the left-sided aortic hiatus.

Discrete, rim-like calcification of the aorta and aortic arch is usually a sign of degenerative intimal change, most often resulting from atherosclerosis (eFig. 47.5.1). The distance between visualized calcification and the outer aortic contour is an estimation of aortic wall thickness; its measurement may be helpful in evaluating acute and chronic changes. If care is taken to consider the effects of supine versus upright examination, and the effects of tangential visualization of the heart and aorta in oblique or antero-posterior versus PA examination, then the distance between intimal calcification and the outer wall of the aorta should be no greater than 10 mm (29). This sign is valuable in the descending aorta but may be of limited value in analysis of the more proximal aortic arch as a result of technical problems described previously.



***e*FIGURE 47.5.1** A 60-year-old man with mild congestive heart failure. Antero-posterior intensive care unit examination shows an endotracheal tube in good position with its tip above the carina, and a Swan-Ganz catheter whose tip is in the right pulmonary artery. There is extensive calcification of the ascending aorta (*arrowheads*), the aortic arch (Ao), and descending aorta (*arrows*).

When there is a right aortic arch, the convex shadow of the aortic arch lies on the right side of the superior mediastinum, displacing the tracheal air column to the left (Fig. 47.6). Right aortic arches may be classified (30,31 and 32) by whether the arch is anterior or posterior to the esophagus. This distinction is important, because the heart is characteristically normal when a posterior arch is present. The presence of an anterior arch is almost universally associated with congenital heart disease. This distinction is made by evaluation of the lateral chest radiograph. In the posterior right aortic arch, found in approximately 0.1% of the population (33,34), there is a large retroesophageal defect produced by the junction of the posterior right aortic arch with the descending aorta, causing anterior bowing of the tracheal air shadow. This form of right aortic arch is usually asymptomatic and frequently associated with an aberrant left subclavian artery.

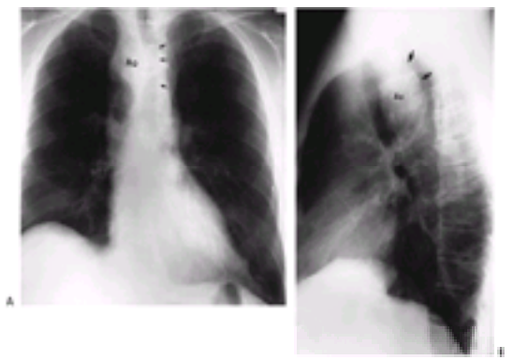


FIGURE 47.6 A 78-year-old man without cardiovascular complaints. **A:** Postero-anterior chest examination shows the convexity of the right aortic arch (Ao) displacing the trachea to the left (*arrows*). **B:** In lateral view, the trachea is bowed anteriorly by the calcified (*arrows*) arch (Ao).

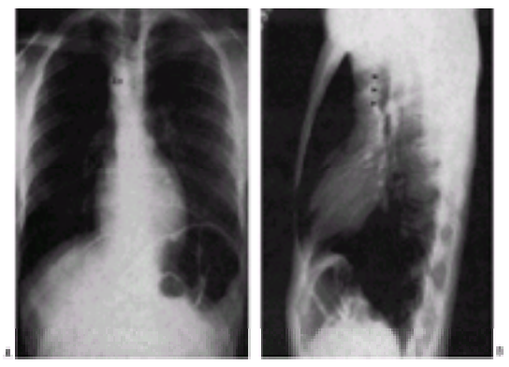
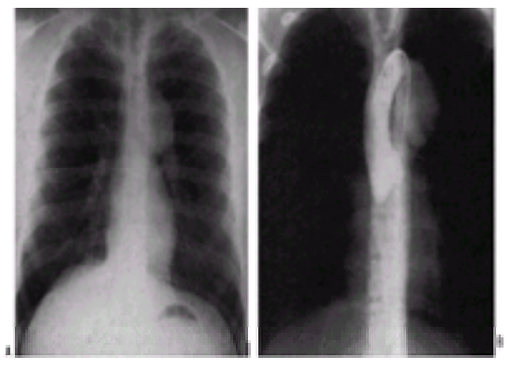
The anterior aortic arch is frequently associated with mirror-image branching. That is, the first branch from the aortic arch is a left-sided innominate trunk, followed by the right common carotid and right subclavian arteries. In this case, there is no retroesophageal component, and thus, no anterior bowing of the tracheal air column (*e*Fig. 47.6.1). There is a significant association between this form of right aortic arch and congenital heart disease. Between 18% (35) and 34% (33) of patients with tetralogy of Fallot (TOF), 33% (36) and 60% (33) of patients with truncus arteriosus, and 4.9% (24) and 6.7% (33,37) of patients with D-transposition of the great arteries have this form of right aortic arch. Unoperated survival of individuals with these lesions into adulthood is uncommon. However, differentiation among these lesions can be made based on the appearance of the superior mediastinum, the pulmonary artery segment, and the pulmonary vasculature. In patients with TOF one

finds a small pulmonary artery segment and decreased pulmonary vascularity; in D-transposition and persistent truncus arteriosus, the pulmonary artery segment is not found on the left heart border, and there is increased pulmonary vascularity.



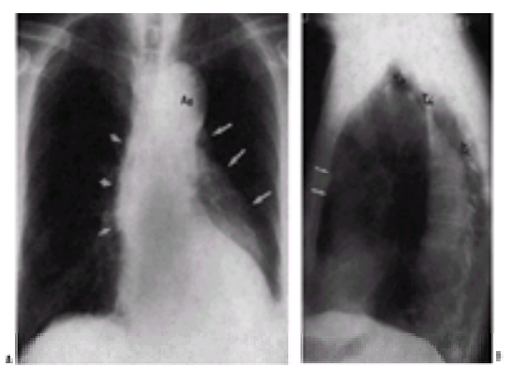
***e*FIGURE 47.6.1** A 32-year-old man with isolated anterior right aortic arch. **A:** Postero-anterior examination shows the aortic arch (Ao) on the right displacing the tracheal air column toward the left. **B:** Lateral view shows no anterior displacement of the tracheal air column (*arrowheads*).

Increase in the caliber of the aortic arch segment may be caused by changes in the aortic wall, often associated with more generalized changes in the aorta or by localized increase in vessel caliber. The former class of diseases includes atherosclerosis and systemic hypertension. They often result in a “prominent” appearing aortic arch, but one not necessarily dilated to pathologic size. Focal atherosclerotic aneurysms of the distal aortic arch or proximal descending aorta may present in association with other localized areas of increase in aortic caliber. Diseases resulting in focal dilatation of the aortic arch include aortic dissection and posttraumatic aortic pseudoaneurysm formation (*e*Fig. 47.6.2).

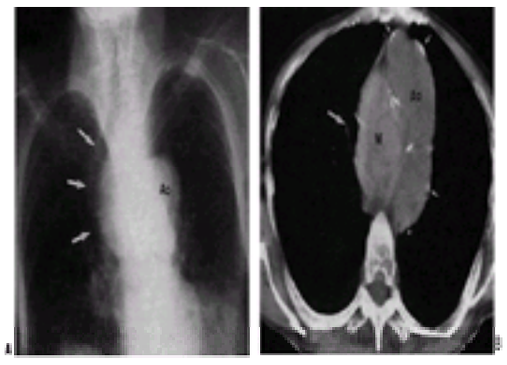


***e*FIGURE 47.6.2** A 26-year-old man with a history of an automobile accident 7 years ago. **A:** Postero-anterior chest examination shows marked dilatation of the aortic arch segment of the left heart border. The remainder of the examination is unremarkable. **B:** Antero-posterior image from an ascending aortogram demonstrates opacification of the dilated distal aortic arch segment.

Atherosclerosis is the most common cause of descending aortic aneurysm (38,39 and 40). These aneurysms are typically located just distal to the origin of the left subclavian artery and appear as fusiform enlargement of the aortic contour (*e*Fig. 47.6.3). Focal aneurysmal enlargement of the aorta may be difficult to differentiate from diffuse aortic ectasia or from focal mediastinal or pulmonary masses. Most often, however, these aneurysms project into the left chest. Displacement of the distal trachea is most often caused by increased caliber of the proximal portion of the aortic arch as well as by masses within the superior mediastinum, medially located with respect to the aortic arch (*e*Fig. 47.6.4).



***e*FIGURE 47.6.3** A 78-year-old man with an aneurysm of the entire thoracic aorta. **A:** The left ventricular contour is enlarged due to chronic aortic regurgitation. Dilatation of the ascending aorta (*short arrows*) and the aortic arch (Ao), as well as the descending thoracic aorta (*long arrows*), is significant. **B:** In lateral view, calcification of the ascending aorta (*closed arrows*) and the irregular contour of the proximal descending aorta (*open arrows*) are viewed.



***e*FIGURE 47.6.4** An 80-year-old man with lymphoma and a tortuous, calcified aorta. **A:** Postero-anterior chest examination shows the dilated aortic arch (Ao) and marked bowing of the trachea to the right (*arrows*). **B:** Computed tomography of the chest obtained at the level of the aortic arch. The trachea (*large arrow*) is displaced far to the right by the mediastinal lymph node mass (M) interposed between the left-sided aortic arch (Ao) and the trachea. Note the diffuse, mild aortic calcification (*small arrows*).

A high index of suspicion is the most important factor in diagnosing aortic dissection (29). In the appropriate clinical setting, an abnormal chest radiograph lends support to this diagnosis. However, the aortic arch, and in fact the entire chest film examination itself, may appear normal in the presence of an aortic dissection (41). When the aortic arch is involved, one frequently finds widening of the distal portion of the arch, beyond the origin of the left subclavian artery; the aortic arch is abnormal in 80%

to 90% of patients with dissection involving the arch (42). Intimal aortic calcification separated by more than 6 (29,43) to 10 (44,45 and 46) mm from the outer contour of the arch shadow is an excellent indicator of intramural hemorrhage and dissection. One must keep in mind, however, that calcification in a more proximal portion of the aortic arch may be projected medial to the outer contour of the distal arch, and that calcification of mural thrombus or inflammatory thickening of the aortic wall may produce a false-positive diagnosis. Any subtle or questionable finding becomes significant when a change in appearance from a previous examination is demonstrated (Fig. 47.7).

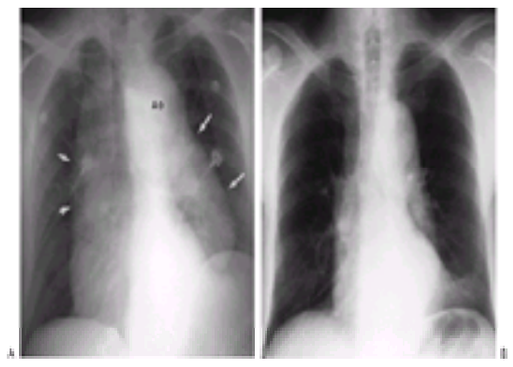


FIGURE 47.7 A 71-year-old hypertensive man awakened from sleep with midscapular back pain. **A:** Postero-anterior chest examination shows marked widening of the mediastinum, particularly involving the ascending aorta (*short arrows*), the aortic arch (Ao), and descending aorta (*long arrows*). **B:** Postero-anterior examination from 18 months earlier.

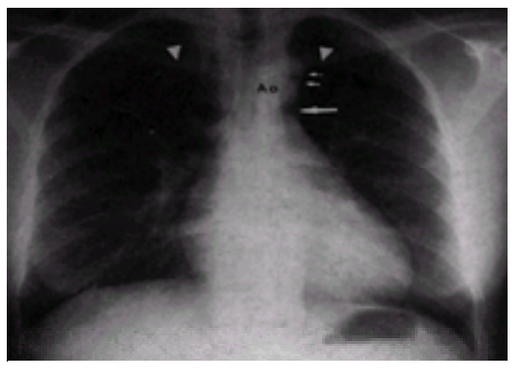
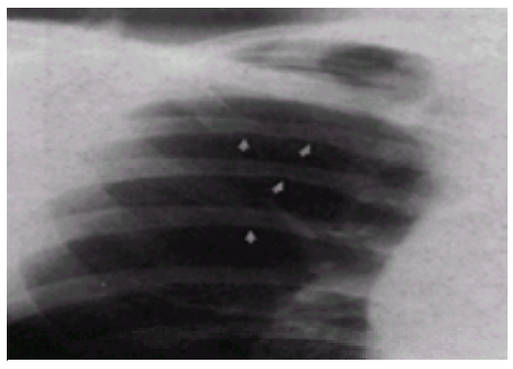
Diminution of the aortic arch segment may be real, as seen in patients with coarctation of the aorta, or apparent, as in the case of individuals with increased pulmonary blood flow in left-to-right shunts. In the former circumstance, there is tubular hypoplasia of the distal aortic arch proximal to the actual area of focal coarctation. The resulting narrow aorta presents as a small, inapparent aortic arch segment (eFig. 47.7.1). The focal coarctation presents as a concave (to the right) notch in the proximal descending aorta, immediately below the aortic arch. The descending aortic shadow can usually be followed from below in a cephalad direction just to the left of the spine, continuous with the aortic arch shadow. In patients with coarctation, the shadow of the descending aorta is interrupted caudad to its continuity with the aortic arch. Rib notching (eFig. 47.7.1 and eFig. 47.7.2) is a reliable sign of retrograde collateral flow to the postcoarctation aorta by dilated intercostal arteries.



***e*FIGURE 47.7.1** A 25-year-old woman with coarctation of the aorta. There is increased curvature of the left ventricular contour of the left heart border. The aortic arch (Ao) is inconspicuous, and the left subclavian artery (*small arrows*) is dilated. Note the break in the shadow of the descending aorta (*large arrow*) just inferior to the aortic arch at the site of the aortic narrowing. Irregular erosions (*arrowheads*) on the underside of the left and right fourth ribs (rib notching) are seen.

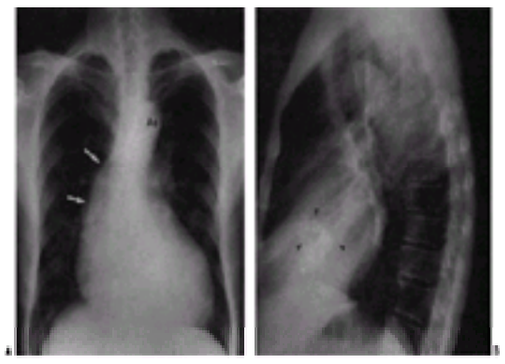


***e*FIGURE 47.7.2** Close-up from the postero-anterior examination of a 24-year-old man with coarctation of the aorta. The sclerotic margin along the superior border of the scalloped inferior erosions (*arrows*) characterizes rib notching.

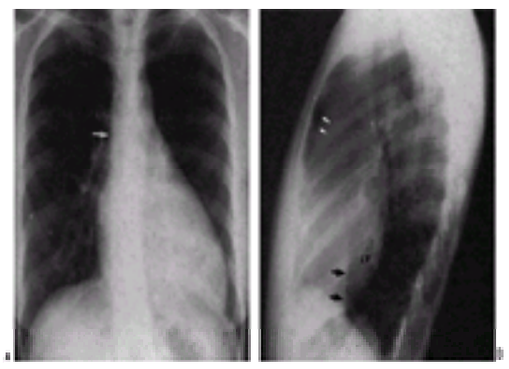
The hearts of patients with corrected transposition of the great arteries have discordant atrioventricular and ventriculoarterial relations. The systemic venous return is as expected, to the right-sided morphologic right atrium. Blood drains across a right-sided mitral valve to the right-sided morphologic left ventricle, which supports a right-sided main pulmonary artery. Pulmonary venous blood returns to the left-sided left atrium, across a left-sided tricuspid valve, and into the left-sided morphologic right ventricle, which supports a left-sided aortic valve and ascending aorta. The left-sided ascending aorta in these patients produces an aortic arch segment that is typically longer and more convex than that found in the normal segment (47,48 and 49). Furthermore, although the hilar pulmonary arteries may appear normal, the main pulmonary artery segment of the left heart border is not seen (eFig. 47.7.3). Mesocardia and dextrocardia are relatively common in corrected transposition of the great arteries. Mirror-image patterns of this anomaly occur in situs inversus (in which the convex upper right cardiac contour is produced by the ascending aorta).

***e*FIGURE 47.7.3** Two patients with corrected transposition of the great arteries. **A:** A 48-year-old woman. There is a left aortic arch (Ao). The superior left heart border (which extends down to the left ventricular portion of the contour) is formed by the left-sided ascending aorta. The left pulmonary artery (L) is seen passing over the left bronchus. However, no pulmonary artery segment is seen along the left heart border. **B:** A 32-year-old man. The liver (L) is on the right, the stomach (S) is on the left, and the cardiac apex is toward the right; situs solitus with dextrocardia. Although not nearly as pronounced as in **(A)**, the upper left heart border is formed by the left-sided ascending aorta, which obscures the pulmonary artery segment.

Increase in the prominence of the ascending aortic segment on frontal examination may be a sign of increase in aortic caliber or tortuosity of the aorta itself. Poststenotic dilatation of the aorta may be found in aortic stenosis (50) (eFig. 47.7.4). More generalized dilatation of the ascending aorta may be found in aortic insufficiency or in dissection of the aorta. In systemic hypertension, or in long-standing atherosclerosis, the aorta may become mildly dilated and “meander” through the mediastinum, causing increase in the curvature of the ascending aorta on frontal examination. Whether the aorta is dilated or tortuous, these changes may not always be readily apparent on the frontal examination. If the predominant direction of the aortic curve is anteriorly into the anterior mediastinum, then the retrosternal space on the lateral examination will become filled and reveal this abnormality (eFig. 47.7.5).



***e*FIGURE 47.7.4** A 64-year-old man with degenerative calcific aortic stenosis. **A:** Postero-anterior view. Notice the typical concavity of the pulmonary artery and left atrial appendage segments of the left heart border sandwiched between the convexities of the aortic arch (Ao) and the prominent left ventricular contour. The mid-right heart border contains the convexity (*arrows*) of the dilated ascending aorta. **B:** Lateral view. The aortic valve (*arrowheads*) is calcified. Despite the prominence of the left ventricular contour in the postero-anterior view, there is no left ventricular dilatation.



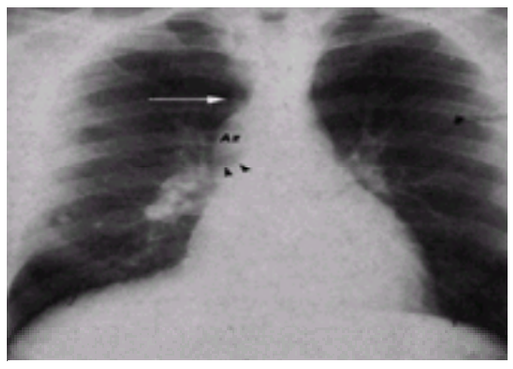
***e*FIGURE 47.7.5** A 39-year-old woman with aortic regurgitation. **A:** In postero-anterior view, the left ventricle contour is increased in curvature, extending toward the left chest wall. The ascending aorta is barely seen along the mid-right heart border (*arrow*). **B:** In lateral view, the retrosternal space is nearly filled by the dilated ascending aorta (*white arrows*). The shadow of the dilated left ventricle (LV) extends more than 18 mm behind the inferior vena cava (*black arrows*).

Superior Vena Cava

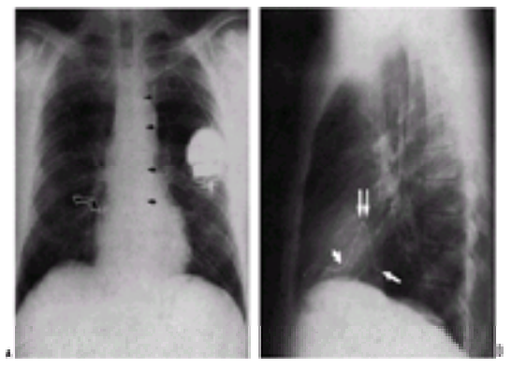
The superior vena cava is formed by the junction of the left and right brachiocephalic veins dorsal to the right first sternochondral articulation, behind the right border of the sternum. As it descends in the anterior mediastinum, it makes a slight curve convex to the right and dorsalward before emptying into the right atrium at the level of the third costal cartilage ventrally and the seventh thoracic vertebra dorsally. The superior vena cava forms the upper half of the right heart border on the frontal radiograph. The caval shadow is fairly straight and lies parallel to and to the right of the tracheal air column. It extends from the inferior edge of the clavicle to its insertion into the right atrium. At its inferior extension, its insertion into the right atrium, there is a break in the contour of the right heart border, representing the superior aspect of the curve of the right atrium.

The superior vena cava may be displaced to the right by a dilated or tortuous ascending aorta, giving the observer the impression of a widened superior mediastinum. Masses in the superior mediastinum cause extrinsic compression of the cava, resulting in the superior vena cava syndrome. In this circumstance, the cava may actually be displaced medially (to the left) by the mass. More distal caval obstruction (secondary to lymphadenopathy or mediastinal fibrosis) may result in dilatation of the cava and innominate veins, resulting in widening of the mediastinum with prominent curvature of the superior right heart border. Similarly, the functional obstruction and resulting elevation of caval pressure caused by pericardial constriction may present with a dilated superior vena cava. Because there is no obstructing valve in the superior vena cava, elevation of right atrial pressure—such as that found in severe tricuspid regurgitation or right ventricular failure of any etiology—is transmitted back, resulting in dilatation of the azygos vein, and if severe enough, the cava itself.

Dilatation of the azygos vein is found in patients with interruption of the inferior vena cava with azygos continuation. PA chest examination reveals a prominent rounded contour adjacent to the right hilum, at the junction of the distal trachea and origin of the right mainstem bronchus (eFig. 47.7.6). In individuals with isolated lesions, the chest film is otherwise unremarkable. This condition (27,51,52) is frequently associated with polysplenia and left isomerism (bilateral left-sidedness), but may be found as an isolated lesion in adults. Failure of development of the intrahepatic portion of the inferior vena cava results in passage of lower extremity and abdominal venous return to the heart via the dilated azygos vein. Persistence of the superior vena cava (eFig. 47.7.7) results from failure of the obliteration of the left anterior cardinal vein. It most frequently drains to the coronary sinus and right atrium, resulting in no hemodynamic insult. In approximately 15% of cases, the right superior vena cava may be absent.

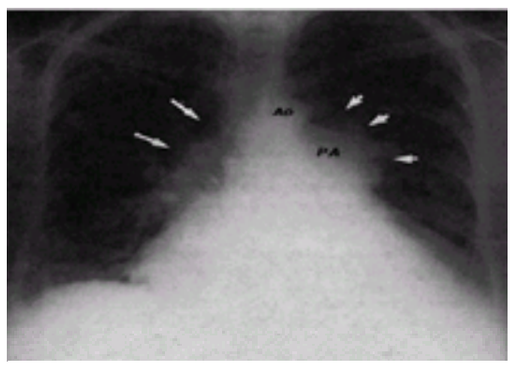


***e*FIGURE 47.7.6** A 36-year-old man with interruption of the inferior vena cava and azygos continuation. The abnormally convex, dilated azygos vein (Az) crosses above the right bronchus (*arrowheads*) and extends beyond the shadow of the superior vena cava (*arrow*).



***e*FIGURE 47.7.7** A 62-year-old man with persistence of the left superior vena cava draining to the coronary sinus. **A:** Postero-anterior examination shows the pacing wire descending to the left of the spine (*arrows*) and looping in the right atrium (*curved arrow*). **B:** Lateral view shows the descent of the wire through the left-sided superior vena cava and coronary sinus to enter the posterior aspect of the right atrium (*arrow*), looping in the right atrium (*double arrow*), and passing across the tricuspid valve (*curved arrow*). The tip of the wire is in the right ventricle.

Increased blood flow through the superior vena cava results in its dilatation and increase in the curvature of the superior right cardiomediastinal silhouette. This may be found in children with intracerebral arteriovenous malformations, or in individuals with total anomalous pulmonary venous connection above the heart. In the latter entity, both the left and right superior mediastinal contours are convex; the left contour is dilated by the draining vertical vein and the right by the dilated superior vena cava (*e*Fig. 47.7.8). These individuals have a characteristic “snowman” configuration of the heart and mediastinum and increased caliber of their pulmonary artery segment and parenchymal pulmonary arteries, evidence of left-to-right shunt.



***e*FIGURE 47.7.8** A 64-year-old woman with total anomalous pulmonary venous return. There is dilatation of the main pulmonary artery segment (PA) and the parenchymal pulmonary arteries. The vertical vein, draining pulmonary venous blood from both lungs (*short arrows*), extends to just inferior to the small appearing aortic arch (Ao). The convex, dilated superior vena cava (*arrows*) makes the superior right heart border.

In individuals with right-sided heart dilatation, the heart rotates (looking from below) in a clockwise manner, bringing the bulk of the cardiac mass into the left chest and causing the superior vena cava to come to lie over the spine, resulting in a narrow-appearing superior mediastinum. This is common in patients with atrial septal defect (ASD) or in patients with pulmonary hypertension and secondary tricuspid regurgitation.

Main and Central Pulmonary Arteries

The main pulmonary artery and pulmonary valve are supported by the right ventricular infundibulum and thus lie cephalad and to the left of the aortic valve. The pulmonary artery segment of the left heart border is composed of the main pulmonary and proximal portion of the left pulmonary artery (Fig. 47.1). The right pulmonary artery originates from the main pulmonary artery, passing over the roof of the left atrium to enter the right lung. The right hilum is slightly caudad with respect to the left hilum. The main pulmonary artery then passes over the left mainstem bronchus to become the left pulmonary artery. Because, in PA projection, a portion of the main pulmonary artery segment is derived from the proximal left pulmonary artery, accurate measurement of the caliber of the main pulmonary artery in this view is inaccurate. The main pulmonary artery is best viewed in shallow right anterior oblique projection (Fig. 47.8), which has the effect of rotating the proximal left pulmonary artery posteriorly, away from the cardiac contour. The pulmonary artery appears as a smooth convexity above the upper portion of the right ventricular contour, paralleling the distal trachea and left main bronchus. In individuals with normal pulmonary artery pressure and no left-to-right or right-to-left shunt [i.e., left ventricular output equals right ventricular output (Qp:Qs = 1.0)], the size of the pulmonary artery segment should be nearly the same side as the aortic arch segment on the PA radiograph. As the main pulmonary artery ascends and curves to become the left pulmonary artery, it runs away from the sternum to leave a retrosternal clear space behind (Fig. 47.9).

FIGURE 47.8 Normal right anterior oblique chest film of the same woman in Figure 47.1. The pulmonary artery (*arrow*) lies beneath the aortic arch (Ao). Left pulmonary artery branches (*arrowheads*) are seen projected through the heart.

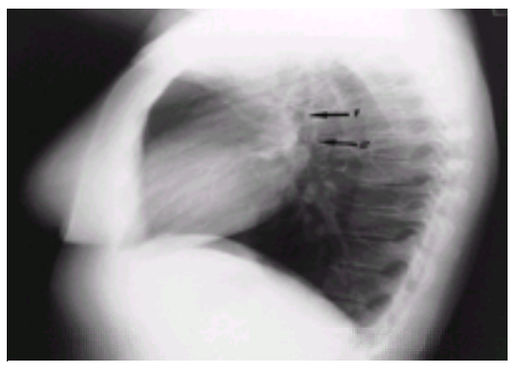


FIGURE 47.9 Normal lateral chest film of the same woman shown in Figure 47.1 and Figure 47.8. The retrosternal space is air filled. The right pulmonary artery lies anterior to the trachea. The right upper lobe bronchus (*arrow 1*) and left upper lobe bronchus (*arrow 2*) are labeled.

Often, both lateral and medial borders of the left pulmonary artery may be visualized through the heart, descending in the left chest. The right pulmonary artery shadow on lateral examination is identified as a round density anterior to the tracheal air column at the level of the carina. The left pulmonary artery is visualized in cross-section just as it passes over the left bronchus, behind and slightly superior to the right pulmonary artery.

On PA view, the right descending pulmonary artery is found running from the right hilum parallel to the right heart border. Its widest point is distal to the origin of the right middle lobe artery. At this level, the contour of the artery is sharply outlined against the air-filled lung on its right and by the air-filled right mainstem bronchus along its left border. In patients with pulmonary hypertension, the caliber of the artery is greater than 16 mm in men and 15 mm in women (53).

Pulmonary Vasculature

The majority of right and left hilar opacities is formed by the right and left pulmonary arteries, respectively. In the infant and adolescent, the left hilum may be obscured by the superimposed thymus and pulmonary trunk. Beyond each hilum, the intrapulmonary arteries extend in a tree-like branching pattern, gradually tapering with each division. It is abnormal for a pulmonary vessel to change caliber abruptly. The branching pulmonary arteries and veins should be identified nearly two-thirds the distance from the hilum to the pleural surface. Beyond this region, the spatial resolution of the chest film technique is inadequate to resolve individual vessels.

The distribution of the pulmonary vessels is uniform in both the left and right lungs, as well as between upper and lower lung zones. In general, the pulmonary arteries appear to converge at the hila, and the pulmonary veins course toward the left atrium to enter the cardiac silhouette at a level lower than the arteries. In healthy individuals, there is a normal, gravity-dependent perfusion gradient from pulmonary apex to base. Furthermore, alveolar air pressure in the upper lung segments narrows and collapses upper lobe capillaries and pulmonary veins, increasing upper lobe pulmonary resistance. In the upright position, therefore, lower lobe perfusion is four times that of the upper lobes. Thus, the intrapulmonary vessels of the lower lobes carry greater pulmonary blood flow and appear larger radiographically. When in the supine position, the normal apex-to-base gravitational gradient is lost; in its place, a similar gravitational anterior-to-posterior lung segment gradient develops. Therefore, when supine, the radiographic appearance of the pulmonary vessels is altered; one observes an increase in the caliber of the upper lobe pulmonary arteries (which lie relatively posterior) with respect to the lower lobe vessels (which are now relatively anterior).

The intrapulmonary arteries are sharply outlined by the air-filled lung and appear to branch in a relatively regular pattern as they extend toward the chest wall. The interstitial connective tissues of the lung invest the pulmonary arteries and veins, lymphatics, bronchi and bronchioles, and nerves. Connective tissue supports the alveolar spaces and forms the interlobar septa that delineate the pulmonary lobules. The pulmonary interstitium does not produce identifiable shadows on plain chest film examination but may be identified by an overall, faint homogeneous density to the space between parenchymal pulmonary arteries and veins. The normal pulmonary interstitium should not appear “busy” or filled with radiographic density not conforming to any vascular structure.

Increased Pulmonary Blood Flow

Because left ventricular output should equal right ventricular output, the main pulmonary artery and aortic arch segments of the left heart border should be approximately the same size. Patients experiencing hypermetabolic states, including fever, pregnancy (54,55), and hyperthyroidism (56,57) or those experiencing hyperkinetic, nonhypermetabolic conditions such as anemia (58,59), arteriovenous fistula (60,61), and beriberi (62,63) all exhibit increased preload with a reduction in afterload, resulting in cardiac chamber dilatation with increased caliber of the pulmonary vascular markings (*e*Fig. 47.9.1). If the increase in ventricular filling pressure is great enough, symptoms of congestive failure occur even though myocardial contractility is normal. Maintenance of increased cardiac output in the face of congestive heart failure is referred to as *high output cardiac failure*.

***e*FIGURE 47.9.1** A 29-year-old man with sickle cell anemia in high output failure. The lower left cardiac border is rounder in contour and extends toward the lateral chest wall. The central pulmonary arteries are increased in caliber, and the upper lobe veins (*arrows*) are as great in caliber as the lower lobe vessels, indicating increased pulmonary blood flow. The edges of the upper lobe vessels are sharper than vessels in the lower lungs, and the central hilar vessels are not sharp, all resulting from pulmonary interstitial edema caused by left atrial hypertension.

In circumstances of increased pulmonary artery blood flow, pressure, or both, the main pulmonary artery segment appears increased in size with respect to the aortic arch. In patients with left-to-right shunts, the difference in size is a function of the difference in blood flow carried by the two vessels. Therefore, small left-to-right shunts may not be identified by plain film examination. In patients with increased pulmonary artery pressure, the greater pulmonary artery caliber may be the result of increased distension. Differentiation between increased pressure and increased flow may be difficult, but in general, the two may be identified by further analysis of the pulmonary vascular tree (53).

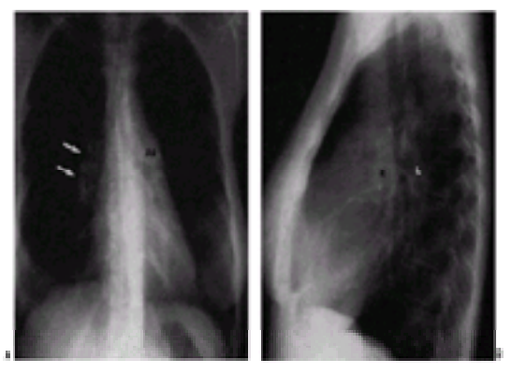
Shunt vascularity may be characterized by increase in the size of the entire roentgenographically visualized pulmonary tree (Fig. 47.10). That is, not only are the central main and proximal hilar left and right pulmonary arteries dilated, but the branch parenchymal vessels are increased in size. Furthermore, the pulmonary artery branches appear sharp and are visualized far beyond the usual two-thirds of the way between hilum and chest wall. The vessels in both the upper and lower lobes appear to be dilated to the same degree as well. Depending on the adequacy of roentgenologic technique, and the depth of the individual’s inspiratory effort, dilated, sharp, branching vessels may be seen far into the posterior pulmonary sulci and out to the lateral chest wall pleura on PA and lateral views. The increased arterial flow in shunt lesions is matched by an increase in the size of the draining pulmonary veins.

FIGURE 47.10 A 46-year-old woman with secundum atrial septal defect. Mean pulmonary artery pressure is 20 mm Hg. **A:** The heart lies in the left chest. The pulmonary artery segment (PA) is greater in caliber than the aortic arch (Ao). The pulmonary artery branches of both lungs are all dilated, sharp edged, and extend nearly to the pleura. The narrow superior mediastinum and decreased concavity in the middle of the left heart contour are caused by cardiac rotation secondary to right heart dilatation. Furthermore, as the heart rotates, the left bronchus no longer crosses the left heart border. **B:** In lateral view, the retrosternal space is filled by the dilated right ventricle and proximal pulmonary artery. The orifices of the right upper lobe bronchus (*arrow 1*) and left upper lobe bronchus (*arrow 2*) are in line with the tracheal air column (T), a sign of normal left atrial volume. The right (*long arrows*) and left (*arrowheads*) pulmonary arteries are dilated. Analysis of the relation between the inferior vena cava (*short arrows*) and the posterior left ventricular border reveals no left ventricular enlargement.

The differential diagnosis of increase in the caliber of the main pulmonary artery segment depends on associated cardiac and pulmonary vascular changes. Adolescents and young adults (especially women) under 30 years of age commonly have an isolated *prominence* or increase in caliber of the main pulmonary artery segment (eFig. 47.10.1) without any abnormality of the central or parenchymal pulmonary arteries, and without any cardiac chamber abnormality. These individuals, in fact, have no cardiac or pulmonary abnormality and thus represent a normal anatomic variant.

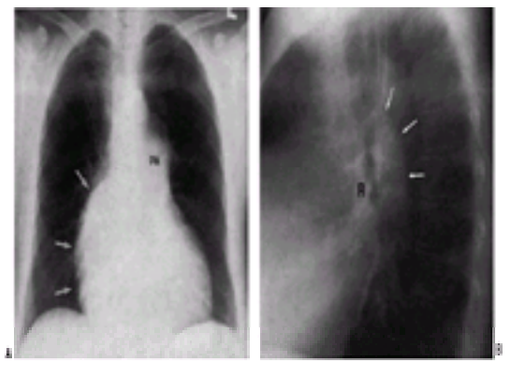
***e*FIGURE 47.10.1** A 26-year-old woman being treated for lymphoma. Postero-anterior examination reveals apparent enlargement of the pulmonary artery segment. The central pulmonary artery segments are normal, and there is no evidence of pulmonary vascular change.

Idiopathic dilatation of the pulmonary artery (64,65) (eFig. 47.10.2) is a benign condition that does not affect cardiac function. It is characterized by prominence of the pulmonary artery segment and proximal pulmonary arteries with normal or slightly increased heart size. In this lesion, pulmonary insufficiency is frequently associated, resulting in a typical murmur and dilatation of the right ventricle.



***e*FIGURE 47.10.2** A 39-year-old woman with idiopathic dilatation of the pulmonary arteries. **A:** Postero-anterior view of the chest reveals dilatation of the pulmonary artery segment (PA) of the left heart border as well as dilatation of the hilar right pulmonary artery (*arrows*). **B:** On lateral view, the dilated right (R) and left (L) pulmonary arteries are viewed.

If enlargement of the pulmonary artery segment is associated with shunt vascularity, then a left-to-right shunt should be considered. Disparity between the caliber of the central pulmonary arteries and the peripheral branches indicates pulmonary hypertension. Dilatation of the pulmonary artery in the face of normal pulmonary vascular markings should raise the possibility of valvular pulmonic stenosis. Valvar pulmonic stenosis is usually congenital in origin and frequently bicuspid in nature (66). It is a common congenital cardiac malformation in adult patients. In these patients, there is dilatation of the pulmonary artery segment and classically that of the proximal left pulmonary artery as well (eFig. 47.10.3). The caliber of the pulmonary artery segment does not correlate with the gradient across the valve. If right ventricular hypertension results in tricuspid regurgitation, then right atrial and ventricular dilatation occurs, and the heart rotates into the left chest. Otherwise, the heart usually appears normal in size. Long-standing turbulence in the main and left pulmonary artery may result in aneurysmal pulmonary arterial dilatation (Fig. 47.11). Identifying normal appearing parenchymal pulmonary arterial branches (the consequence of the normal pulmonary blood flow) helps differentiate the appearance of valvular pulmonic stenosis from pulmonary hypertension.



***e*FIGURE 47.10.3** A 49-year-old woman with valvular pulmonic stenosis. **A:** Postero-anterior view shows the dilated pulmonary artery segment (PA). The right atrial contour (*arrows*) is markedly convex, and the superior mediastinum is narrow, resulting from right atrial and right ventricular dilatation caused by tricuspid regurgitation. **B:** In lateral view, the retrosternal clear space is partially filled. Notice the dilatation of the left (*arrows*) and the normal appearance of the right (R) pulmonary artery.

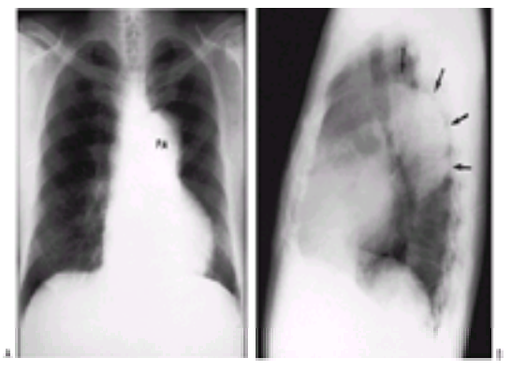


FIGURE 47.11 A 61-year-old man with valvular pulmonic stenosis. **A:** In postero-anterior view, the dilated pulmonary artery segment (PA) is apparent and obscures the proximal left pulmonary artery. The contour of the right atrium is normal. **B:** In lateral view, the aneurysmal dilation of the main and left pulmonary artery (*arrows*) is better viewed.

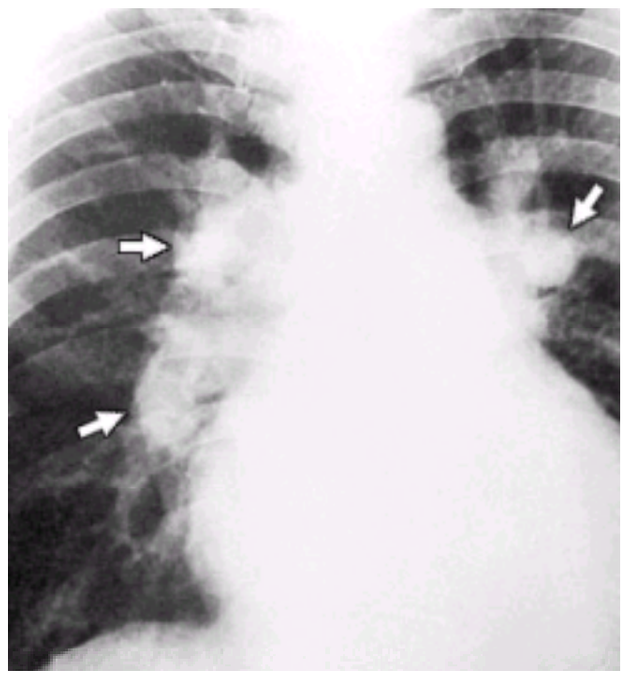
Shunt Lesions in Adults

Adult survival with secundum ASD is the rule. Secundum ASD is the most common congenital cardiac lesion diagnosed in adult patients. In a review of 412 patients with ASD, 45% were more than 20 years old at the time of diagnosis (67). Sixty-five percent of these patients were female; 35% were male. The radiographic appearance of uncomplicated secundum ASD is characterized by normal or near normal overall cardiac size, changes in the heart contours secondary to cardiac rotation, and pulmonary arterial changes caused by the increased pulmonary blood flow. In these patients, right atrial and ventricular dilatation rotates the heart and shifts it into the left chest. The superior mediastinum is relatively narrow, and the lucency of the left bronchus runs parallel to the convex curve of the mid-left heart border. The pulmonary artery segment and both central left and right pulmonary arteries are dilated. Furthermore, the parenchymal branch pulmonary arteries are sharply defined, dilated, and visualized further toward the pleura than in normal individuals. Both the left ventricle and left atrium are typically normal in size.



Chest x-ray in atrial septal defect. There is plethora of the pulmonary vasculature with prominent main pulmonary arteries (*white arrows*).

Changes in myocardial compliance and pulmonary vascular resistance play an important role in the radiographic appearance of adults with ASD. The decreased compliance of older ventricular myocardium, especially if further reduced by superimposed myocardial ischemia, results in decreased myocardial compliance, resulting in elevation of left atrial pressure, further increasing the left-to-right shunt across the atrial septum. This causes progressive elevation of pulmonary arteriolar tone, resulting in increased pulmonary vascular resistance and the radiographic appearance of pulmonary hypertension. In a review of 311 patients with ASD who underwent cardiac catheterization (67), 31% had pulmonary hypertension (mean PA pressure greater than 20 mm Hg). Pulmonary hypertension was found to increase in incidence with increasing age; from 14% of patients under 20 years of age to 53% of patients greater than 30 years of age had pulmonary hypertension.

The chest radiograph of patients with ASD and pulmonary hypertension displays relative paucity of peripheral pulmonary artery branches and abrupt change in caliber of the central pulmonary arteries, typical of the generalized changes of pulmonary hypertension. However, careful inspection reveals that although sparse, upper lobe as well as lower lobe vessels are enlarged, and that branching vessels often may be identified farther out toward the pleura than in other patients with non–shunt-related causes of pulmonary hypertension. The size of these vessels reflects the sequelae of the increased blood flow of the shunt. Their number is an indication of the reduced cross-sectional area of the pulmonary bed (*e*Fig. 47.11.1).

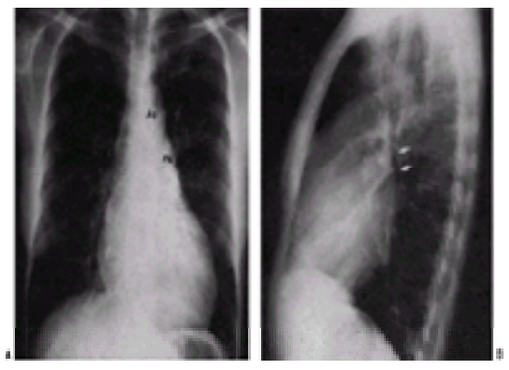
***e*FIGURE 47.11.1** A 55-year-old woman with atrial septal defect and pulmonary hypertension. The pulmonary artery is dilated. The dramatic difference between the caliber of the hilar and lobar pulmonary arteries and the segmental branches is typical of pulmonary hypertension. However, these segmental arteries branch and extend toward the pleura, which is typical of shunt vessels.

Progressive, severe mitral regurgitation is found in 15% of patients with ASD (68,69 and 70). In these patients, left atrial (and left ventricular) dilatation (71) confuses the picture, making it difficult to radiographically differentiate ASD from other shunts. An unusual cause of left atrial enlargement in adult patients with ASD is Lutembacher's syndrome (ASD with coexisting rheumatic mitral stenosis). The picture may be complicated further in cases in which left atrial pressure is elevated, resulting in radiographic changes of pulmonary venous hypertension and left atrial enlargement superimposed on shunt vascularity (*e*Fig. 47.11.2).

***e*FIGURE 47.11.2** A 45-year-old woman with secundum atrial septal defect and rheumatic mitral stenosis, postero-anterior view. Findings of marked pulmonary hypertension and left atrial outflow obstruction characterize the picture. The marked dilatation of the pulmonary artery segment (PA) and central PAs is striking against the small aortic segment (Ao). There is abrupt change in the caliber of the segmental and subsegmental pulmonary artery, but branching vessels may be seen out toward the pleural edge (*arrows*).

Most patients with patent ductus arteriosus (PDA) present early in childhood. Those who survive their first year of life are generally asymptomatic. Among 804 patients with PDA seen in one series (72), 37 (4.6%) reached 50 years of age. Of these, 35 had exclusively left-to-right shunts, and 28 of the 35 (80%) were women. The mean

age at diagnosis in this group was 49 years (range, 19 to 73 years). PDA may rarely be diagnosed in patients more than 50 years old (73,74). If the shunt is small, the heart may appear normal. The right ventricle dilates if there is pulmonary hypertension or heart failure. The central pulmonary arteries are dilated, and occasionally, one may see aneurysmal dilatation of one pulmonary artery or another (75). In adult patients with shunt vascularity, the radiographs of individuals with PDA often exhibit dilatation of the ascending aorta (*e*Fig. 47.11.3), an indication of the extracardiac shunt. Calcification of the ductus arteriosus itself is of limited value; it does not necessarily indicate whether the duct is patent or occluded (75). Calcification of the ligamentum arteriosus, however, implies closure of the duct.



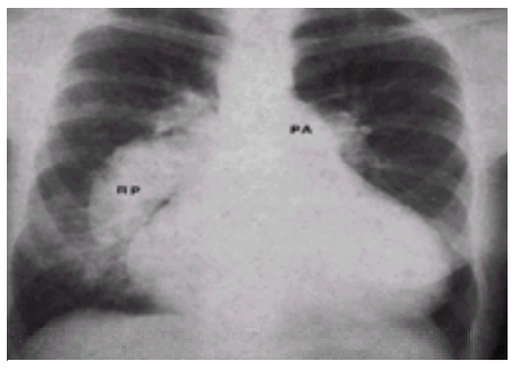
***e*FIGURE 47.11.3** A 48-year-old man with a patent ductus arteriosus and moderate pulmonary hypertension. **A:** The aortic arch (Ao) and pulmonary artery segment (PA) are both enlarged. However, the parenchymal pulmonary arteries are decreased in caliber and barely visible. The left ventricular contour is enlarged. **B:** In lateral view, the left bronchus is posteriorly displaced (*arrows*), indicating left atrial enlargement, and the retrosternal space is filling by the dilated ascending aorta and main pulmonary arteries.

If pulmonary hypertension persists, the chest film reflects changes in the appearance of the heart. Signs of right ventricular hypertrophy and pulmonary hypertension (dilatation of the central pulmonary arteries with diminished caliber of the peripheral vessels) dominate the film. Reversal of the shunt results in a decrease in cardiomegaly.

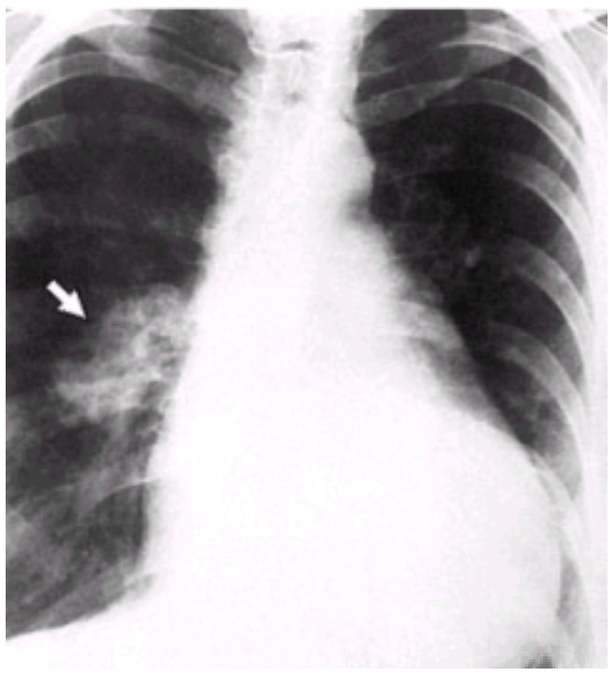
Spontaneous closure or surgical repair in childhood both decrease the prevalence of ventricular septal defect (VSD) in the adult population. VSD is found in 0.5% of adults (76,77) and 10.0% of adult patients with congenital heart disease (78). Adult patients with VSD may be classified (79) based on the size of their defects. Patients with small defects (with mean pulmonary arterial pressure less than 20 mm Hg) are usually treated medically and appear not to develop progressive pulmonary vascular changes. Patients with larger defects (mean PA pressure greater than or equal to 20 mm Hg) are more likely to undergo surgical repair, as well as develop Eisenmenger's syndrome (79). Patients with Eisenmenger's syndrome have four times the risk of death compared with patients with normal pulmonary artery pressure (80).

There is marked variation in the chest film appearance of individuals with VSD, depending on the size of the defect and the pulmonary resistance. An adult with a small VSD may have a nearly normal examination, with only a suggestion of dilatation of the pulmonary artery segment (*e*Fig. 47.11.4). Individuals with larger defects have the typical appearance of shunt vascularity, with dilatation of the left atrium and both right and left ventricles. In the face of cardiac rotation secondary to right ventricular enlargement, left ventricular dilatation may be difficult to assess. The right atrial contour should appear normal as it is not dilated. The aorta should appear normal or slightly decreased in size (*e*Fig. 47.11.5). If pulmonary resistance exceeds systemic resistance and the shunt reverses, then the heart may appear normal or small or demonstrate rotation resulting from right atrial and ventricular dilatation. The typical appearance of pulmonary hypertension—dilated central pulmonary arteries and constricted peripheral vessels—is expected.

***e*FIGURE 47.11.4** A 26-year-old man with a small membranous ventricular septal defect. The heart is slightly rotated to the left. The pulmonary artery segment is just barely greater in caliber than the aortic arch, and the left atrial appendage portion of the left heart border is straightened. All visualized pulmonary artery branches have sharp edges, are dilated, and extend far out toward the pleura.



***e*FIGURE 47.11.5** A 32-year-old woman with a moderate-sized ventricular septal defect. The heart is markedly enlarged. Dilatation of the pulmonary artery segment (PA) and descending right pulmonary artery (RP) is marked. Abrupt change in caliber of the parenchymal pulmonary artery branches indicates pulmonary hypertension.



Chest x-ray in patient with a congenital ventricular septal defect. There is fullness in the hilum secondary to an enlarged pulmonary artery (*white arrow*).

Pulmonary Hypertension

In patients with pulmonary arterial hypertension, the more distal pulmonary artery branches are vasoconstricted. Therefore, not only are the visualized parenchymal pulmonary artery branches smaller in caliber than normal, but fewer (of the more peripheral pulmonary artery branches) are visualized. There is an apparent disparity between the appearance of the dilated central and hilar pulmonary arteries and the more peripheral vessels (Fig. 47.12). Not only is the appearance of gradual taper in caliber between the central and peripheral vessels lost, but the space between peripheral vessels appears to be increased. Thus, the “ratio” of central pulmonary artery to peripheral branch pulmonary artery caliber is greatly increased, and the lungs appear “blacker.”

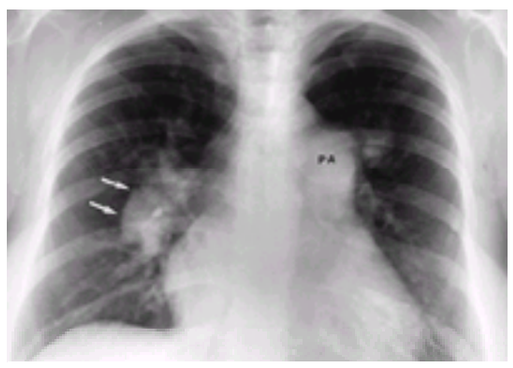


FIGURE 47.12 A 45-year-old woman with unexplained pulmonary hypertension. The pulmonary artery segment (PA) and descending right pulmonary artery (*arrows*) are markedly enlarged. Note the abrupt change in caliber of the peripheral pulmonary arterial branches beyond the right hilum. Right atrial and ventricular dilatation are indicated by the pronounced contour of the lower right heart border and rotation of the heart into the left chest.

The chest films of patients with pulmonary hypertension secondary to left-to-right shunts present an interesting hybrid picture. Their predominant vascular appearance is that of central pulmonary arterial enlargement with constricted peripheral vessels (i.e., that of pulmonary hypertension). However, close inspection of the vasoconstricted peripheral parenchymal pulmonary artery branches reveals that sharply defined branches are identified going far out into the periphery of the lung (i.e., findings of both shunt and hypertensive constricted vessels are evident).

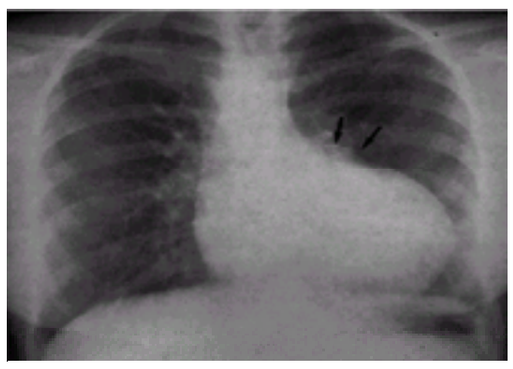
Decreased Pulmonary Blood Flow

Diagnosing decreased pulmonary blood flow may be difficult. When right ventricular cardiac output is decreased, the size of the main pulmonary artery and the pulmonary arterial segment of the left heart border appear decreased in caliber. The caliber of the central and hilar pulmonary arterial branches, as well as the parenchymal pulmonary arterial segments, is decreased. The parenchymal pulmonary arterial segments appear normal, but the overall appearance of the lung is that of greater spacing among the arterial segments, and increased “blackness” of the pulmonary parenchyma. Regions of the lung distal to a focal branch pulmonary artery stenosis may appear focally darker, resulting from the focal perfusion defect. Without good data describing the normal caliber of pulmonary arterial branches, objective plain film changes may be hard to detect and differentiation between normal caliber and mild to moderately decreased blood may not be reliable.

The limited differential diagnosis of adult patients with decreased pulmonary blood flow includes TOF, pulmonary atresia with VSD (PAVSD), Ebstein’s anomaly, and tricuspid atresia.

Most patients with TOF die before the end of their second decade. Only 11% are alive at 20 years, 6% at 30 years, and 3% at 40 years (81,82). Survival to adulthood in patients without prior surgical palliation or repair appears to be associated with early development of collateral circulation to the lungs and progressive narrowing of an initially mild infundibular stenosis with age (83). Decreased pulmonary blood flow results in a small main pulmonary artery segment with commensurate decrease to normal caliber of all visualized pulmonary arterial branches (*e*Fig. 47.12.1). Systemic-to-pulmonary arterial collaterals appear as unusually shaped radiographic densities among the normally distributed arterial branches. Not uncommonly, collateralization is asymmetric, so that the pulmonary arterial branches in one lung are greater in caliber than in the other. Generalized cardiomegaly is frequently found in adult patients with TOF. Cardiomegaly was found in 25% (83) of adult patients without previous surgical intervention. Among patients followed after surgical repair, postoperative cardiomegaly was reported in 85% (84) and 42% (85). Aneurysm of the right ventricular outflow after patch repair is uncommon, but may be associated with residual distal obstruction (86) or pulmonary insufficiency leading to right ventricular enlargement (*e*Fig. 47.12.2). Right aortic arch was the most frequently reported anomaly (83,84). PAVSD may be regarded as a severe variant of TOF. However, in PAVSD, pulmonary blood flow is maintained via systemic-to-pulmonary artery collaterals. Thus, radiographically, these patients may differ from those with TOF (Fig. 47.13). In the former, the main pulmonary artery segment of the left heart border is smaller and often concave, as opposed to only diminished in caliber in patients with TOF. Furthermore, collateralization to the lungs in patients with TOF is usually only from the bronchial arteries, and that in PAVSD is via larger systemic-to-pulmonary artery collaterals (87,88 and 89). Hence, asymmetry in pulmonary blood flow as well as the radiographic appearance of larger collateral vessels is usually found in patients with PAVSD. The incidence of right aortic arch is approximately 40% in these patients (90), greater than the expected 33% in patients with TOF.

***e*FIGURE 47.12.1** A 35-year-old woman with unrepaired tetralogy of Fallot. Kyphoscoliosis causes the unusual orientation of the ribs and asymmetric density between the right and left chest. The pulmonary artery segment is small, and the pulmonary vascular markings are decreased in caliber. The apical curvature of the left heart border is elevated (*coeur en sabot*).



***e*FIGURE 47.12.2** A 28-year-old woman with repaired tetralogy of Fallot. The heart is enlarged and rotated into the left chest. The main pulmonary artery remains concave, but the pulmonary vascular markings are nearly normal. Note the thin calcified rim (*arrows*) along the aneurysmal right ventricular outflow patch.

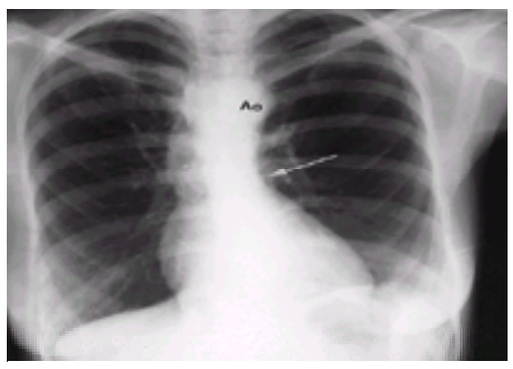


FIGURE 47.13 A 28-year-old woman with pulmonary atresia with ventricular septal defect. There is a left aortic arch (Ao). The pulmonary artery segment is concave (*arrow*), and the parenchymal pulmonary artery segments are decreased in caliber.

In patients with Ebstein's malformation, the tricuspid valve is displaced into the right ventricle, resulting in "atrialization" of a portion of the right ventricle (91,92 and 93). Tricuspid regurgitation dilates the "true" right atrium as well as the "atrialized" right ventricle, causing right-sided enlargement and cardiac rotation (*e*Fig. 47.13.1). The right atrium may become markedly enlarged, filling the retrosternal space on lateral examination. The main pulmonary artery segment is normal to small, and the parenchymal pulmonary artery segments are normal to decreased in caliber (94). Left atrial size is generally normal, but, depending on the amount of right-to-left shunting across the atrial septum, there may be evidence of mild pulmonary vascular congestion.

***e*FIGURE 47.13.1** A 22-year-old woman with Ebstein's malformation. **A:** Postero-anterior examination shows the concave pulmonary artery segment (*long arrow*) and cardiac rotation. The superior mediastinum is narrow, and the left cardiac border (*short arrows*) is filled by the remaining functional right ventricular chamber. Notice how the left bronchus (*arrowheads*) parallels the left heart border of the rotated heart. **B:** In lateral view, severe right atrial dilatation results in posterior displacement of the inferior vena caval shadow (*arrows*).

The chest film appearance of the heart in patients with tricuspid atresia depends on the relationship of the great arteries, the presence or absence of a VSD, and the state of the pulmonary valve (95,96). In patients with normally related great arteries with associated pulmonic stenosis, the main pulmonary artery segment appears small, and parenchymal pulmonary artery branches are decreased in caliber (*e*Fig. 47.13.2). In the presence of transposition of the great arteries or in patients with normally related great arteries and a large VSD without pulmonic stenosis, pulmonary blood flow may appear increased. Right-to-left shunting across the interatrial septum causes left atrial dilatation with or without evidence of left atrial hypertension. Left ventricular enlargement is characteristic in these patients.

***e*FIGURE 47.13.2** A 40-year-old woman with tricuspid atresia, normally related great arteries, and no ventricular septal defect, after Potts and Glenn shunts. Postero-anterior view of the chest demonstrates the small pulmonary artery segment (*arrowhead*) over which the markedly dilated left pulmonary artery is superimposed (*long arrows*). The superior vena cava (*short arrows*) is mildly dilated. The right atrial contour is increased in curvature, there is left atrial and left ventricular enlargement, and the pulmonary arteries in the right lung are small in caliber.

Left Atrium and Left Atrial Appendage

The left atrial appendage is a long, finger-like extension of the left atrium. It wraps around the left side of the base of the heart to form the left heart border between the main pulmonary artery segment and the superior portion of the left ventricular contour. When left atrial pressure and volume are normal, this segment of the left heart border is concave.

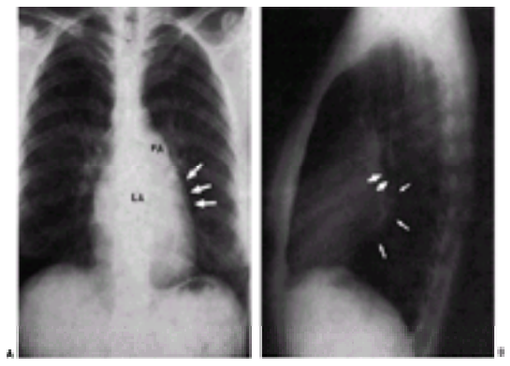
The body of the left atrium lies in the midline, superior and posterior to the left ventricle, and beneath the tracheal bifurcation. In lateral view, the superior posterior border of the heart is formed by the left atrium. Early or mild enlargement of the left atrium may be detected as enlargement of the left atrial appendage (i.e., straightening of this segment of the left heart border). Subsequent enlargement of the atrium results in convexity of the left atrial appendage portion of the left heart border and development of a double density in the midportion of the cardiac silhouette (representing the dilated, blood-filled left atrium). The double density is characterized by identification of its right lateral border medial to the right atrial portion of the right cardiac border. Displacement of the left bronchus can be recognized by analysis of the lateral examination. The right upper lobe bronchus originates just after the tracheal bifurcation. The left main bronchus travels for several centimeters before the origin of the left upper lobe bronchus. The plane of the tracheal bifurcation is nearly parallel to the coronal, so that when viewed in lateral, the ostia of the right and left upper lobe bronchi have a directly superior-inferior relationship. Thus, if one can draw a straight line passing through the distal tracheal air column and the centers of the right and left upper lobe bronchi, then the left atrium is not enlarged.

Left Atrial Enlargement

Analogous to the left ventricle, the left atrium is a muscular cardiac chamber, albeit thinner. Therefore, smaller increases in volume and pressure manifest as changes in the shape of the left atrium and, therefore, its radiographic appearance. Increased left atrial pressure or volume increases the size of the left atrium. Radiographically, this is manifested by change in the contour of the left atrium, extrinsic compression of adjacent structures, and change in the radiographic appearance of the chamber. Furthermore, depending on the severity and chronicity of the disease processes resulting in the elevation of left atrial pressure and volume, characteristic pulmonary vascular findings may exist.

Straightening of the left atrial appendage segment between the level of the main pulmonary artery and left ventricular segments on the left border of the heart is the earliest and most sensitive radiographic sign of elevated left atrial pressure or volume (Fig. 47.14). Continued left atrial enlargement results in convexity of this segment beyond the lower, left ventricular contour, and then identification of a double density to the right of the spine on the PA examination (*e*Fig. 47.14.1). This represents displacement of the right inferior border of the left atrium caused by enlargement of the left atrial body. This is associated with a discrete convex bulge to the superior posterior cardiac contour below the carina on the lateral examination. The distance between the midpoint of the double density and the midpoint of the left mainstem bronchus (the left atrial dimension) is less than 7.5 cm in the adult man and less than 7.0 cm in the adult woman. Enlargement is a good sign of previous rheumatic disease. Enlargement of the left atrium results in posterior displacement of the left bronchial tree (97), and in chronic cases of left atrial enlargement, elevation of the left main bronchus (98). On the frontal radiograph, the normally observed carinal angle of approximately 75 degrees may be increased to 90 degrees or more. However, care must be taken in considering this observation. Without a previous PA chest examination for comparison, it is difficult to judge small differences from normal. In the lateral view, a sensitive marker of left atrial enlargement is posterior displacement of the left bronchus. Normally, a straight line constructed by connecting the centers of the right and left upper lobe bronchi, when extended superiorly, should pass within the main tracheal air column. In cases of left atrial enlargement, this line extends outside of the trachea. Care must be taken to make this observation only in true lateral radiographs. When the left atrium is enlarged, it produces a superior, posterior mass behind the heart and under the tracheal carina. Often the mass extends inferiorly, producing a second contour along the posterior aspect of the heart. Although no longer in common practice, barium esophagography is a sensitive technique for demonstrating the extrinsic compression of the esophagus by the dilated left atrium. Severe left atrial enlargement results in merging of the left atrial contour with the right atrial contour on the right border of the heart on PA examination.

FIGURE 47.14 A 37-year-old woman with rheumatic mitral stenosis. **A:** Postero-anterior examination demonstrates straightening of the left atrial appendage portion of the left heart border (*arrows*). The right border of the left atrium (*arrowheads*) appears to approach the right cardiac contour. There is indistinctness of the pulmonary vessels, including the descending right pulmonary artery. The caliber of the upper lobe vessels is greater than that in the lower lung zones. The pulmonary artery segment (PA) is larger than the aortic arch segment. The left ventricle is normal. **B:** There is fullness in the superior posterior cardiac space, but no displacement of the left bronchus.



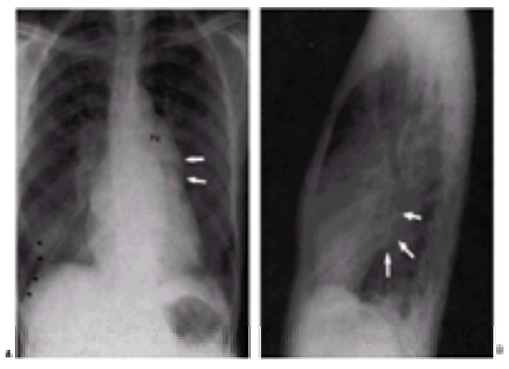
***e*FIGURE 47.14.1** A 41-year-old woman with rheumatic mitral stenosis. **A:** The left atrial appendage segment is convex (*arrows*). The double density of the left atrium (LA) extends to the right cardiac border. Dilatation of the pulmonary artery segment (PA) and decreased caliber of the peripheral vessels indicates pulmonary hypertension. **B:** Lateral view demonstrates fullness of the superior posterior cardiac space (*thin arrows*) and posterior displacement of the left bronchus (*thick arrows*).

Pulmonary Venous Hypertension

In the normal lung, there is a gravity-dependent perfusion gradient between the apex and base (99,100). In the upright position, upper lobe alveolar pressure narrows the upper lobe capillaries and pulmonary veins, causing their collapse and therefore relatively poor visualization on chest films. Furthermore, the lower lobe veins contain a hydrostatic pressure gradient, distending them and increasing their radiographic caliber. This decreases lower lobe pulmonary resistance, resulting in increased lower lobe blood flow. There is nearly four times as much blood flow to the lower than to the upper lobes.

The pulmonary veins are valveless. Therefore, increased left atrial pressure is freely transmitted through the pulmonary veins to the pulmonary bed, resulting in chest film changes in the appearance of the parenchyma and pulmonary vascular markings. Mild elevation of left atrial pressure stretches the intracellular pores of the capillary endothelium, allowing leakage of large molecules from the vascular compartment into the pulmonary interstitium. Migration of edema fluid into the interstitium is mediated, in part, by the pulmonary lymphatics. The lymphatics remove large (protein) molecules as well as provide a route for return of excess fluid to the mediastinal veins, helping to maintain low interstitial fluid pressure. Capillary leakage in prolonged left atrial hypertension may overwhelm these lymphatics, causing increased interstitial fluid volume and an increase in interstitial pressure. Eventually, fluid begins to collect away from the thin alveolar septa, separating the capillary from alveolar endothelium. Continued passage of fluid from the pulmonary parenchyma into the pulmonary lymphatics results in lymphatic engorgement, further

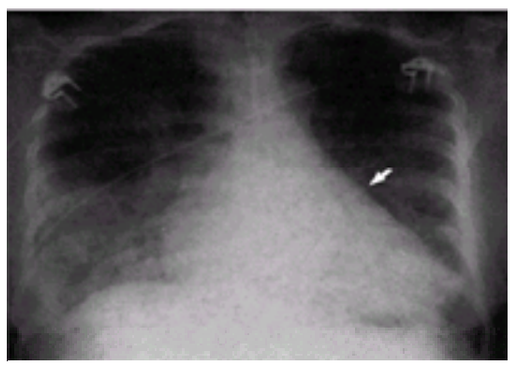
resulting in fluid accumulation in peribronchial sheaths, edema of bronchial walls, and thickening of the subpleural interlobular septa. The interstitial fluid volume may increase by nearly sixfold before development of clinical symptoms or radiographic changes (101). Eventually, the summation of the thickened, edematous interstitial tissues overlaps, blurring the shadows of the lower lobe pulmonary vessels, making them appear indistinct (102) (Fig. 47.14, eFig. 47.14.1 and eFig. 47.14.2). Similarly, edematous swelling of the bronchial walls and peribronchial connective tissues results in peribronchial cuffing (103) and Kerley B lines (104,105), distinct, parallel opacities in the lung bases, oriented perpendicular to the pleural surface (eFig. 47.14.2). B lines are often followed by A and C lines, as the pulmonary lymphatic system increases in caliber to handle the increased parenchymal edema. A and C lines are the radiographic manifestation of more deeply situated lymphatic segments and appear as randomly distributed linear densities found in the mid-lung fields.



***e*FIGURE 47.14.2** A 45-year-old woman with rheumatic mitral stenosis. **A:** Postero-anterior examination shows convexity of the left atrial appendage (*arrows*), which appears to blend into the dilated pulmonary artery segment (PA). The central right pulmonary artery is indistinct. Kerley lines are visible in the right lower lung zone (*arrowheads*). **B:** In lateral view, the dilated left atrium extends inferiorly (*arrows*), the left ventricle is normal, and the retrosternal clear space is filled by the dilated right ventricle.

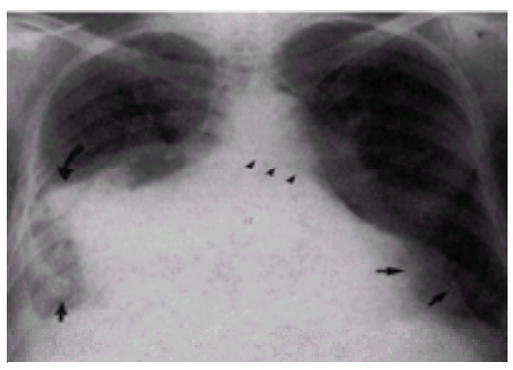
Edema fluid passing from the vascular compartment into the lung parenchyma first obscures the edges and then causes silhouetting of the lower lobe pulmonary vascular markings, making them more difficult to identify on the plain chest. The continued migration of water increases the space between the pulmonary capillary bed and the alveolar compartment of the lung, causing local arteriolar hypoxemia, a potent vasoconstrictive stimulus. This and the decreased compliance of the mildly edematous lung parenchyma cause local increase in the lower lobe pulmonary resistance (106), which induces an intrapulmonary shunt of pulmonary arterial blood flow from the lower lobes to the upper lobes. Normally, the upper lobe pulmonary veins are collapsed (alveolar pressure is greater than pulmonary venous pressure). The intrapulmonary change in blood flow causes increased upper lobe blood flow, and thus increased venous return from the upper lobe segments. These changes result in further impairment in the ability to identify lower lobe vessels as well as increase in the caliber of the upper lobe vessels, referred to as redistribution or “cephalization” of blood flow. In these cases, the caliber of an upper lobe pulmonary vessel is greater than that of another vessel measured an equal distance from the pulmonary hilus in the lower lobe. The pulmonary hila in these individuals may become dense and appear enlarged, similar to findings in shunt lesions. Convergence of the shadows of engorged pulmonary septa in the region of the pulmonary hila causes accentuation of background density, producing an indistinct and fuzzy hila and an especially indistinct descending right pulmonary artery (“perihilar haze”) (107). The hila and central pulmonary arteries in patients with shunt lesions, on the other hand, are sharp and distinct.

Elevation in left atrial pressure to greater than 25 mm Hg (thus exceeding colloid oncotic pressure) results in eventual flooding of the alveolar space, producing frank pulmonary edema. Radiographically, this has an appearance similar to but differentiable from other air space consolidation or infiltrates. In pulmonary edema, the alveolar air is replaced by edema fluid. It is uncommon for all alveoli in a geographic region to be filled with fluid. Therefore, the average radiographic density of the lung is composed of the increased density of the filled alveoli mixed with the low-density regions of air-filled alveoli. Thus, the infiltrates of pulmonary edema are generally less dense in appearance than the more uniformly dense infiltrates of many forms of pneumonia (eFig. 47.14.3). Furthermore, in pulmonary edema the infiltrates are more often bilateral, change in geographic distribution over short periods of time (“fleeting infiltrates”), and are associated with rapid changes in severity associated with changes in the patient’s functional cardiac status. The confluent, patchy infiltrates of pulmonary edema usually involve the medial two-thirds of the lungs and expand outward from the mediastinum, giving the appearance of wings (108). The most frequent presentation of acute pulmonary edema is that of bilateral, fluffy pulmonary infiltrates. Occasionally, the pulmonary edema may be unilateral (109), but within a day or so, the other lung is found to be involved. In patients with acute or chronic mitral regurgitation, focal right upper lobe pulmonary edema may be found (110). This finding may be the result of the jet of regurgitant blood directed toward the right upper lobe pulmonary vein, accentuating the forces for edema formation in the right upper lobe. The known diagnosis or suspicion of mitral valvular disease, as well as the presence of interstitial edema in the remainder of the lung, is helpful in differentiating this condition from pneumonia.



***e*FIGURE 47.14.3** A 72-year-old woman in pulmonary edema. The left ventricle is enlarged. The left atrial appendage portion of the left heart border is nearly convex (*arrow*). The upper lobe vessels are dilated and indistinct. The diffuse and inhomogeneous infiltrates involve the lower lungs, sparing the upper lobes.

Chronic left atrial hypertension is associated with elevated pulmonary vascular resistance and the radiographic changes of pulmonary hypertension, including enlargement of the pulmonary artery segment as well as central left and right pulmonary arteries with marked decrease in peripheral pulmonary arterial caliber. Eventually, chronic left atrial hypertension results in right ventricular dilatation and failure. In long-standing and severe left atrial hypertension, hemosiderosis and pulmonary ossification may be observed. The latter processes are the sequelae of microvascular bleeding and passage of formed blood products into the alveolar space and pulmonary interstitium (eFig. 47.14.4).



***e*FIGURE 47.14.4** A 55-year-old man with chronic rheumatic mitral stenosis. The left atrium is markedly enlarged. It splays the tracheal bifurcation, elevating the left bronchus (*arrowheads*), and forms part of the lower right heart border. The central pulmonary arteries are enlarged. However, upper lobe vessels are greater in caliber than the lower lobe vessels, an indication of chronic left atrial hypertension rather than shunt. Numerous small and punctate calcified nodules (*arrows*) are distributed mostly to the lower lobes. Fluid loculated in the minor fissure (*curved arrow*) appears as a pseudotumor.

Differential Diagnosis of Left Atrial Enlargement

Left atrial enlargement is most frequently caused by left atrial obstruction in chronic rheumatic mitral stenosis. Early roentgenologic changes in these patients may be limited to left atrial enlargement. With time and progressive increase in the mitral valvular gradient, signs of pulmonary venous hypertension and eventually pulmonary hypertension are seen. Untreated, mitral stenosis may cause chronic parenchymal pulmonary hemorrhage, resulting in hemosiderosis, nodular calcific (predominately lower lung zone) densities. The pulmonary hypertension associated with mitral stenosis may eventually result in right ventricular failure. Left atrial and left atrial appendage calcification is frequently associated with chronic mitral stenosis. Calcium deposits are most often found within the endocardial or subendocardial layers of the myocardium, but may also be found in organized thrombus adherent to the atrial wall (111), appearing as a curvilinear circumferential calcific shell (112,113). Left atrial enlargement may also be found in other forms of left atrial obstruction, including left atrial myxoma and congenital mitral stenosis.

Increased left atrial volume results in left atrial enlargement. Chronic mitral valvular regurgitation often results in massive left atrial enlargement. Increased pulmonary blood flow, as seen in VSD and PDA, results in left atrial dilatation. It is important to remember that increased pulmonary blood flow does not necessarily result in left atrial enlargement. The left atrium is of normal size in patients with ASD. In these individuals, the increased pulmonary blood flow reaching the left atrium divides between flow across both the mitral valve and atrial defect, resulting in increased blood flow through the left atrium, but normal atrial volume.

The etiology of left atrial enlargement can be distinguished by analysis of associated findings in the chest examination. Left atrial enlargement associated with left atrial outflow obstruction is associated with a normal-appearing left ventricle and findings associated with chronic pulmonary venous hypertension (i.e., interstitial edema, redistribution, and evidence of pulmonary hypertension). Atrial tumors often calcify. Left atrial enlargement resulting from mitral regurgitation is associated with left ventricular enlargement and a conspicuous absence of significant pulmonary venous changes. Most notably absent is any sign of pulmonary hypertension, nearly always found in patients with chronic mitral stenosis. Shunt lesions resulting in left atrial enlargement present most notably with shunt vascularity and enlargement of the central and peripheral pulmonary arterial segments.

Left Ventricular Free Wall and Left Ventricle

In a normal heart (situs solitus, D-loop, normally related great arteries), the left ventricle lies posterior to and slightly to the left of the right ventricle. The plane of the tricuspid valve (and thus, the right ventricular inflow) lies to the right of the plane of the mitral valve (the left ventricular inflow). The shape of the left ventricle is best approximated by a prolate ellipsoid (114,115) or football. The ventricular long axis is rotated approximately 25 to 30 degrees clockwise from the coronal plane, and 10 to 20 degrees caudal to the axial. The apex of the normal left ventricle points down, anteriorly, and to the left. Thus, in PA, the inferior portion of the left heart border is formed by the anterolateral wall of the left ventricle, the portion of the left ventricular myocardium lateral to the interventricular sulcus. In lateral view (Fig. 47.9), the lower one-half of the posterior border of the heart is formed by the free wall of the left ventricle. When the right ventricle is not enlarged, the shadows of the inferior vena cava and the posterior border of the heart intersect approximately 2 cm above the level of the diaphragm (Fig. 47.9 and Fig. 47.14B) (116).

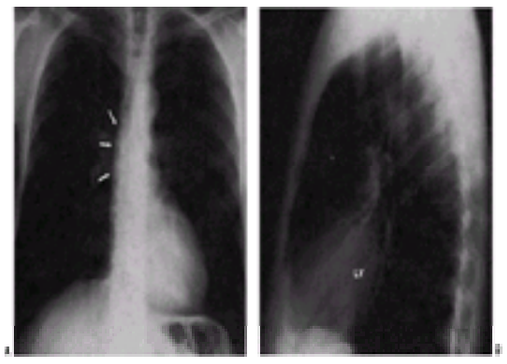
Left Ventricular Enlargement and the Left Ventricular Configuration

In adults, the appearance of the left heart border may change in the absence of left ventricular dilatation. In this circumstance, the heart assumes in the PA view a so-called left ventricular configuration (117); i.e., there is an increase in the curvature of the left ventricular contour and aortic arch segment of the left heart border, between which are sandwiched normal (and thus relatively concave appearing) left atrial appendage and pulmonary artery segments (eFig. 47.14.5). Although this configuration may be found in individuals with healthy hearts, its recognition may be helpful in identifying patients with subtle and significant heart disease.

***e*FIGURE 47.14.5** A 59-year-old man with chronic stable angina. The contour of the left ventricular portion of the left heart border is enlarged. The left atrial appendage and pulmonary artery segments are concave and normal in appearance. The upper lobe pulmonary veins are greater in caliber than vessels in the lower lung zone.

The left ventricular configuration is associated with increased left ventricular wall stress, including volume-loaded, pressure-loaded, ischemic, and cardiomyopathic left ventricular myocardium. In the absence of a lateral chest examination, identification of the left ventricular contour is useful as a case finder or entry point into a differential diagnosis. Left ventricular obstruction, whether caused by asymmetric subaortic septal hypertrophy, congenital or acquired aortic stenosis, coarctation of the aorta, or essential hypertension (Fig. 47.15), may present with this configuration. Associated other observations will help to differentiate among these lesions. For example, the ventricular appearance associated with a small aortic arch segment, with or without the presence of rib notching, may be diagnostic of coarctation of the aorta. If the aortic arch segment appears prominent or enlarged, one might consider the diagnosis of systemic hypertension. When the ascending aorta is volume loaded, its lateral contour is directed toward the right. When this is associated with a left ventricular configuration, then aortic regurgitation (eFig. 47.15.1) is a likely diagnosis. Calcification of the aortic valve (118) is almost always found on plain chest film examination in patients with clinically significant degenerative calcific aortic stenosis. In patients with congenitally bicuspid aortic valve, calcification is almost universally present but may not be apparent on plain chest films. Patients with rheumatic aortic stenosis may not have the calcification found in cases of nonrheumatic disease.

FIGURE 47.15 A 69-year-old man with essential hypertension. In postero-anterior view, the left ventricular contour is rounder and extends farther toward the left chest wall than is normal. Visualization of more than half the circumference of the aortic arch segment (Ao) increases its apparent size, accentuating the concavity of the pulmonary artery and left atrial appendage segments. The lateral view (not shown) demonstrates normal left ventricular volume.

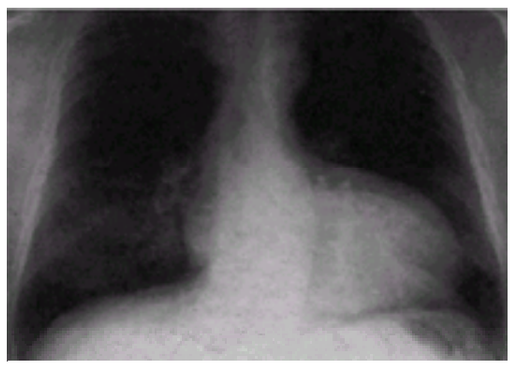


***e*FIGURE 47.15.1** A 40-year-old man with aortic regurgitation. **A:** Postero-anterior view. The left ventricular contour is prominent, and the left atrial appendage and pulmonary artery segments are concave. The ascending aorta (*arrows*) forms the mid-right heart border. **B:** In lateral view, the left ventricle (LV) is dilated.

In some patients with ischemic heart disease, the only morphologic abnormality identifiable on PA chest examination may be the left ventricular configuration. However, in most of these individuals, elevated left ventricular filling pressure manifests radiographically as elevation of pulmonary venous pressure. Depending on the severity and chronicity of the ischemia, one may find only subtle signs of indistinctness of lower lobe vessels or mild redistribution. The left atrium may be normal in size, allowing the chest film to retain a typical convex-concave-convex appearance. Similarly, patients with other abnormalities that result in abnormal left ventricular diastolic compliance, including cardiomyopathy, may present with the left ventricular configuration, with or without evidence of pulmonary venous hypertension.

The addition of the lateral view aids in differentiation between a dilated and nondilated (and potentially hypertrophied) left ventricle and adds information about the presence or absence of intracardiac (aortic) valvular calcification. The left ventricular configuration with a normal-sized heart may be found in patients with aortic stenosis. If calcification of the aortic valve is found in the presence of a left ventricular configuration and a normal-sized heart, then the diagnosis of valvular aortic stenosis is assured. The left ventricular configuration with left ventricular dilatation, as determined from the lateral view, is often associated with aortic regurgitation. The ascending aorta usually dilates toward the right in PA view. However, if the aorta dilates in an anterior direction, then the ascending aortic segment of the right heart border on PA view may appear normal, but on lateral view, the retrosternal air space fills, confirming the presence of a dilated aorta.

Left ventricular dilatation increases the roundness of the lower left cardiac border (eFig. 47.15.2). The apex of the heart may appear to be displaced in a downward direction. In films obtained during deep inspiration, the left ventricular apex may not be separated from the left diaphragm. In both oblique and lateral examination, the inferior posterior cardiac border extends posterior to the inferior vena caval shadow filling the retrocardiac space, and the heart appears to increase in size inferiorly, causing extrinsic compression of the superior aspect of the gastric air bubble. Hoffman and Rigler (116) found that the relationship between inferior vena cava and left ventricle on lateral chest film may provide important information concerning left ventricular size. If the posterior border of the left ventricle extends more than 1.8 cm posteriorly to the border of the inferior vena cava when measured at 2 cm cephalad to the crossing of the right hemidiaphragm and inferior vena cava, then one may presume with certainty that the left ventricle is enlarged. Care must be taken, however, to perform this measurement in true lateral views; measurement in oblique chest examinations results in erroneous interpretation (119).



***e*FIGURE 47.15.2** A 53-year-old man with dilated cardiomyopathy. The curvature of the left ventricular portion of the left heart border is exaggerated, and the overall heart size is increased. However, the left atrial appendage and pulmonary artery segments are concave and normal.

Global left ventricular enlargement is commonly found in patients with left ventricular ischemia, aortic or mitral regurgitation, or cardiomyopathy. This appearance may be mimicked by a pericardial effusion. In patients with ventricular ischemia, the left ventricle dilates to maintain wall stress, and left atrial pressure increases to maintain ventricular filling at increased end diastolic pressure. Depending on the duration and severity of the ventricular ischemia and the compliance of the left atrial myocardium, one might expect to find patients with myocardial ischemia in whom there is left ventricular dilatation with left atrial hypertension in the absence of left atrial dilatation. Chronic left ventricular ischemia results in dilatation of the left atrium as well as the left ventricle.

In patients with chronic aortic regurgitation, left ventricular dilatation becomes pronounced and progressive (120). In these individuals, the volume-loaded left ventricle unloads into the ascending aorta, resulting in the typical picture of left ventricular and ascending aortic dilatation (eFig. 47.15.1). The dilatation of the ascending aorta may appear as an increase in the curvature of the ascending aortic segment of the mid-right heart border, or in the lateral view, present as filling of the retrosternal air space by the dilated ascending aorta (Fig. 47.5B). Generally, these individuals have normal left ventricular filling pressures and, therefore, present with a normal-sized left atrium and no evidence of left atrial hypertension.

In acute mitral regurgitation, the left ventricle and left atrium do not dilate in the face of the rapid increase in volume. Rather, these individuals present radiographically with normal-sized hearts and marked left atrial hypertension, caused by the systolic emptying of the left ventricle through the left atrium and into the pulmonary veins, with the resultant dramatic increase in pulmonary venous pressure (Fig. 47.16). However, in chronic mitral regurgitation, both the left atrium and left ventricle adapt to the increased volume load and dilate. Increased left atrial volume results in near normal left atrial and thus pulmonary venous pressure. The chest radiographs of patients with chronic mitral regurgitation demonstrate dilatation of both the left atrium and left ventricle in the absence of significant pulmonary venous hypertension (Fig. 47.17). In fact, although the left atrium in chronic mitral regurgitation is generally the largest encountered radiographically [greater in size than that found in mitral stenosis (120)], the disparity between the size of the left atrium and the paucity of pulmonary venous change is most pronounced.

FIGURE 47.16 A 52-year-old woman experiencing an acute myocardial infarction. **A:** The heart is not enlarged. The left atrial appendage segment of the left heart contour (*arrows*) is straightened. Notice the moderate to severe bilateral interstitial edema obscuring the pulmonary vascular markings and the increase in caliber of upper lobe vessels. **B:** In lateral view, all vascular markings are indistinct, and the interlobar fissures are thickened (*arrowheads*), containing edema fluid. The left ventricle is not dilated. Although the left atrial appendage segment is straightened on the postero-anterior view, the left bronchus is not posteriorly displaced in lateral, indicating the mildness of left atrial enlargement.

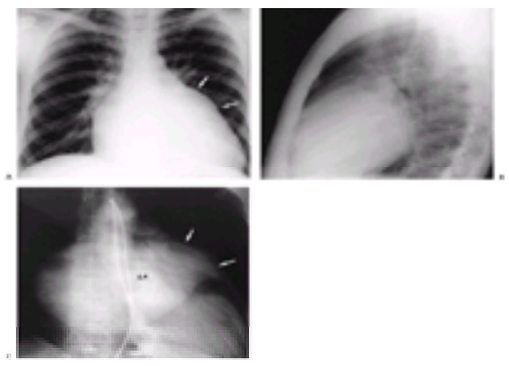


FIGURE 47.17 A 34-year-old man with rheumatic mitral regurgitation. **A:** Postero-anterior examination shows convexity of the dilated left atrial appendage segment (*arrows*) and displacement of the left ventricular contour toward the left chest wall. The pulmonary vascular markings are only mildly indistinct. **B:** Lateral view shows filling of the retrocardiac space by the dilated left atrium and ventricle. **C:** Postero-anterior image from a retrograde left ventriculogram demonstrates the dilated opacified left atrium (LA) and left atrial appendage (*arrows*).

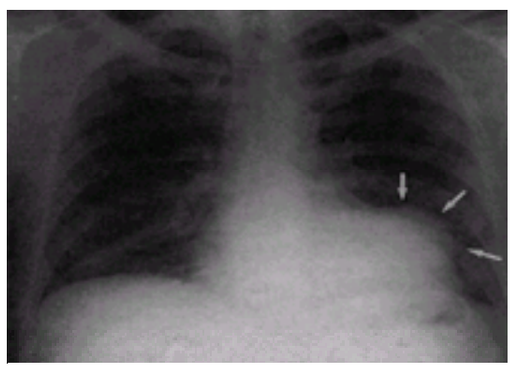
Left Ventricular Aneurysm

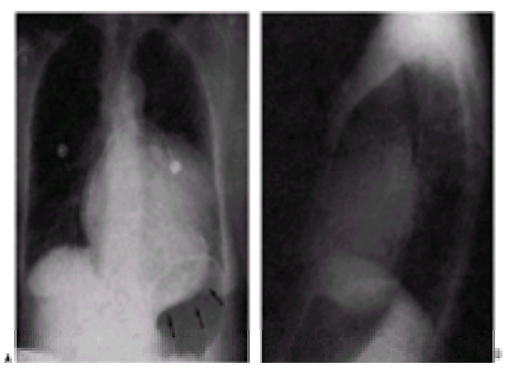
Focal aneurysmal dilatation of a portion of the ventricular wall is found in between 8% and 12% of patients who sustain an acute myocardial infarction (121). The overwhelming majority of left ventricular aneurysms is caused by ischemic heart disease (*e*Fig. 47.17.1). Ventricular aneurysms are localized, permanent, blood-filled dilatations of the left ventricle (122). Gradual bulging (expansion) of the involved (thinned) portion of the LV wall (123,124 and 125) results in a true aneurysm with a wide mouth. Nearly all anterolateral and apical aneurysms are true aneurysms (126) (*e*Fig. 47.17.2). False aneurysms (pseudoaneurysms) are the result of contained cardiac rupture. The wall of a false aneurysm is fibrous, containing blood clot, but without myocardium present. Nearly 50% of false aneurysms are posterior in location.



***e*FIGURE 47.17.1** A 44-year-old man 4 years after acute myocardial infarction with left ventricular aneurysm. Postero-anterior examination shows a focal convexity (*arrows*) along the mid-portion of the left ventricular contour, which itself is pronounced. The lower lobe vessels are indistinct, indicating mild left atrial hypertension.

***e*FIGURE 47.17.2** A 58-year-old man with a complex anterior left ventricular aneurysm. **A:** Postero-anterior view of the chest shows left ventricular enlargement and mild pulmonary vascular congestion. A focal convexity (*arrows*) formed by a portion of the aneurysm is seen protruding from the mid-left ventricular contour. In addition, faint calcification of an inferior portion of the aneurysm (*arrowheads*) is seen medial to the left ventricular contour. **B:** On lateral view, the superior portion of the aneurysm is superimposed on the heart (*arrows*). Calcification (*arrowheads*) takes the course of the distal interventricular septum.

Occasionally, the inferior border of the heart appears abnormal (*e*Fig. 47.17.3). When the aneurysm is large, it can be identified in more than one projection. Whether they appear as focal or global contour abnormalities, left ventricular aneurysms frequently have curvilinear, rim-like calcifications (*e*Fig. 47.17.2, *e*Fig. 47.17.3, and Fig. 47.18) immediately subjacent to their abnormal curvature, resulting from dystrophic calcification of the underlying infarcted ventricular myocardium (111). On occasion, a ventricular aneurysm may be detected on the lateral radiograph (127) as a retrosternal or superior soft tissue border (*e*Fig. 47.17.2B) produced by the wall of the aneurysm silhouetting against the midline cardiac shadow. False ventricular aneurysms may not be directly differentiated from true aneurysms on plain film examination. Location is not an absolute means of differentiating between true and false aneurysms.



***e*FIGURE 47.17.3** A 34-year-old woman with a huge inferior left ventricular aneurysm. **A:** In antero-posterior view, the left ventricle and left atrium are markedly enlarged. The calcified inferior aneurysm extrinsically compressed the gastric cardia (*arrows*). Note the near normal pulmonary vascular markings. **B:** Lateral view further defines the size of the aneurysm and compression of the stomach.

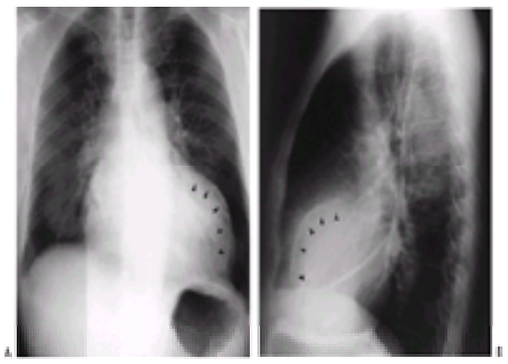


FIGURE 47.18 A 53-year-old man with chronic stable angina. **A:** Postero-anterior view of the chest shows mild pulmonary venous hypertension and enlargement of the left ventricular contour. Curvilinear calcification of the distal interventricular septum (*arrowheads*) defines the extent of a previous myocardial infarction. **B:** In lateral view, the calcification (*arrowheads*) is superimposed on the cardiac mass.

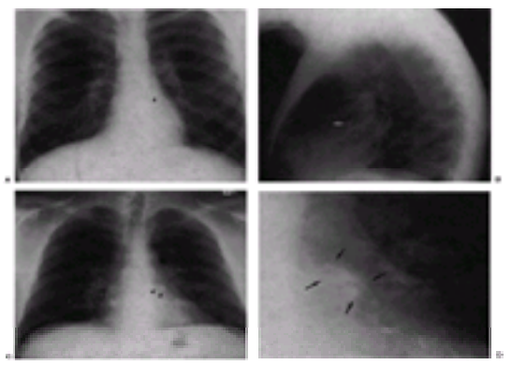
A close relationship between the presence and extent of coronary arterial calcification and the presence and severity of coronary atherosclerosis (128,129,132,133) has been known for years. However, the only reasonably sensitive means of detection of coronary calcification had been cardiac fluoroscopy (130,131,134), a decidedly operator-dependent technique. Thus, investigation of coronary calcification as a detector of coronary atherosclerosis and quantitation of the degree and distribution of calcification as a function of clinical status and prognosis were severely limited. Although limited in its sensitivity, coronary calcification may be detected on plain chest film examination by evaluation of a triangular area located on the left mid-heart border, bordered medially by the vertebral column, inferiorly by a horizontal line drawn from the vertebral column to the top of the left ventricular portion of the left heart border, and diagonally by connecting the former two borders (135). These authors found coronary calcification or a strong suspicion of coronary calcification within this triangle in 42% of patients with fluoroscopically detected coronary calcification (*e*Fig. 47.18.1).



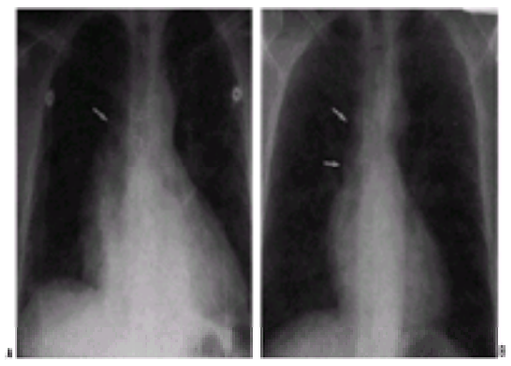
***e*FIGURE 47.18.1** Two patients with coronary arterial calcification. **A:** An 18-year-old man with a history of Kawasaki's disease, postero-anterior view. Calcification is faintly seen (*arrowhead*) medial to the mid-left heart border. **B:** In lateral view, the ring calcification of a coronary artery aneurysm (*arrow*) is seen. **C:** A 59-year-old man with coronary atherosclerosis and chronic stable angina, postero-anterior view. Irregular calcification of the proximal anterior descending coronary artery (*arrowheads*) is found just beneath the lucency of the left bronchus. **D:** Enlargement of the mid-portion of the left heart border, better displaying the calcification (*arrows*).

Pericardial Effusion

Nonspecific change in the appearance of the lower left heart contour may be an indication of pericardial disease, most commonly pericardial effusion. Small pericardial effusions may not be detected by plain film examination. The greater the accumulation of fluid, the more apparent the change in cardiac contour, and the greater the confidence one has in making the diagnosis. The pericardium is an Erlenmeyer flask–shaped fibrous bag consisting of the visceral pericardium, the parietal pericardium, and the normally occurring 20 to 60 mL of fluid collection between them. The normal visceral pericardium (or epicardium) covers the external surface of the heart. Beneath the visceral pericardium is either myocardium or epicardial fat. This layer extends for short distances along the pulmonary veins, the superior vena cava below the azygos vein, the inferior vena cava, the ascending aorta to a point 20 to 30 mm above the root, and the main pulmonary artery as far as its bifurcation. It then reflects on itself to become the parietal pericardium, which is a 1-mm-thick outer fibrous layer composed of dense collagen lined on the inside by a monolayer of mesothelial cells.

On the lateral chest radiograph, the normal pericardium may occasionally be seen as a 1- to 2-mm-thick curved stripe anterior to the heart set between more radiolucent mediastinal fat anteriorly and epicardial fat posteriorly. The visceral pericardium is normally thin and is therefore not visualized separately by any imaging modality.

An abrupt asymmetric increase in the dimension of the cardiac silhouette without specific chamber enlargement suggests the diagnosis of pericardial effusion. Frequently, the asymmetric change in configuration occurs along the right atrial contour of the right heart border (*e*Fig. 47.18.2), suggesting loculation of fluid about the right atrium. Filling of the retrosternal space, effacement of the normal cardiac borders, development of a "flask" or "water-bottle" cardiac configuration, and bilateral hilar overlay are characteristic of a larger pericardial collection (Fig. 47.19). The epicardial fat pad "sign" is positive when, visualized in the lateral projection, an anterior pericardial stripe (bordered by epicardial fat posteriorly and mediastinal fat anteriorly) is thicker than 2 mm. This sign is diagnostic of pericardial disease (136) (Fig. 47.20). Because there is abundant fat between the pericardium and the pleura at the cardiac apex, a positive epicardial fat pad may also be seen in the frontal projection. This is usually seen as an elliptical stripe internal to and paralleling the lower left heart border. This radiolucent line may migrate toward or away from the cardiac border with changes in the amount of pericardial fluid (137,138). Although diagnostically valuable in many patients, reliance on the plain film diagnosis of pericardial effusion has been largely supplanted by echocardiography and other cross-sectional imaging techniques.



***e*FIGURE 47.18.2** A 38-year-old woman recently reoperated to replace an aortic valve prosthesis. **A:** Postero-anterior examination shows a broad lower right heart contour extending cephalad to the carina (*arrow*). **B:** Postero-anterior examination obtained immediately before the recent surgery. Although the right heart border appears prominent, the curvature does not extend as far cephalad and does not obscure the curve of the ascending aorta (*arrows*).

FIGURE 47.19 An 87-year-old woman with chronic renal failure. The silhouette of the heart is globular in shape. The density of the fluid collection is defined by the attachments of the pericardium to the ascending aorta (*thick arrows*) above the azygos vein (a) and to the top of the pulmonary artery (*thin arrows*). The pulmonary hila are hidden.

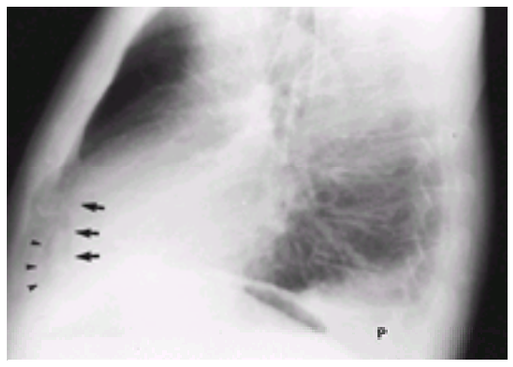


FIGURE 47.20 A 52-year-old man with pericardial and pleural effusion, lateral view. The lucency of the epicardial fat (*arrows*) is separated from the lucency of the pericardial fat (*arrowheads*) by the density of fluid in the pericardial space. A small left pleural effusion (P) silhouettes the posterior left hemidiaphragm.

Pericardial Calcification

Constrictive pericarditis is usually the result of a chronic pericardial insult. The greatest number of cases are of unknown etiology, presumably secondary to an inapparent viral pericarditis (139). Outside the United States, the most common cause is probably tuberculosis or fungal etiology (140). Other causes of nontuberculous disease include connective tissue disorders such as rheumatoid arthritis (141) and systemic lupus erythematosus (142), hemodialysis-treated chronic renal failure (143,144), and neoplastic infiltration of the pericardium, most commonly secondary to carcinoma of the lung or breast, lymphoproliferative malignancies, and melanoma (145). Pericardial constriction may occur months to years after mediastinal irradiation, usually performed to treat Hodgkin's disease (127) or breast carcinoma. Constrictive pericarditis had been considered a rare complication of cardiac surgery (146), especially in those cases in which the pericardium was left open. However, more recent experience (147) has shown a 0.2% incidence of constrictive pericarditis following cardiac surgery (148).

Pericardial calcification is not pathognomonic for pericardial constriction. However, extensive calcification is found in nearly one-half of patients and strongly suggests pericardial constriction of infectious etiology (149,150) (*e*Fig. 47.20.1). Pericardial calcification appears as irregular, large loci, distributed on both the left and right of the midline, reflecting the distribution of the pericardial space (151). Although the heart in most patients with constrictive pericarditis is usually enlarged, it is not unusual for the heart size to be normal (152). Coexisting pericardial effusion may increase the apparent heart size, but indirect findings associated with increased right-sided pressure (i.e., dilatation of the superior vena cava and azygos vein) help suggest the diagnosis. These radiographic findings are common to both constrictive pericarditis and restrictive cardiomyopathy.

***e*FIGURE 47.20.1** A 76-year-old woman with progressive shortness of breath. Thick, irregular calcification is seen along the right atrial contour of the right heart border (*arrows*) and the anterior interventricular groove (*arrowheads*).

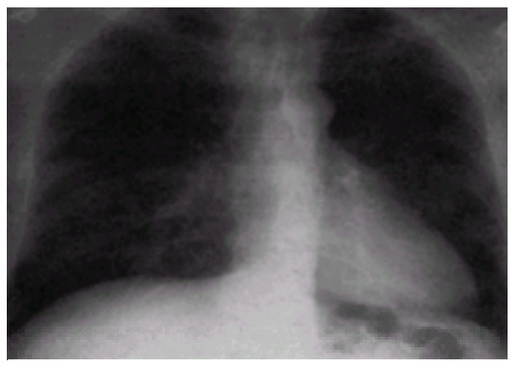
Pericardial Cyst

Most pericardial cysts appear as sharply demarcated masses near the right cardiophrenic angle (*e*Fig. 47.20.2). They may be found in other mediastinal locations, including at the left cardiophrenic angle. The borders of the cysts are usually round, but a pointed upper border may also be seen. This is thought to be due to drooping of the cysts originating higher in the mediastinum into the cardiophrenic region (153). Pericardial diverticula can be suggested on plain films and fluoroscopy by their change in contour and size during deep inspiration (154,155).

***e*FIGURE 47.20.2** Asymptomatic 77-year-old woman with a pericardial cyst. The left ventricle is enlarged. Pericardial effusion obscures the lower left heart border. A large pericardial cyst increases the curvature in the right atrial contour of the right heart border (*arrows*).

Congenital Partial Absence of the Pericardium

As described previously, the heart is fixed within the middle mediastinum by the pericardial attachments. Any interruption of this fixation results in distortion of the normal cardiac silhouette. The characteristic plain film findings (156) are usually present in complete absence of the left pericardium and include displacement of the left ventricle and pulmonary arteries toward the left side (*e*Fig. 47.20.3). The individual cardiac segments that make up the left heart border may be more clearly defined and separated than usual. Both the medial and lateral borders of the main pulmonary artery may be visualized more clearly because of an absence of the anterior pericardial reflection between the aorta and the pulmonary artery. In partial pericardial defects, varying degrees of prominence of the pulmonary artery or left atrial appendage or both may be seen, whereas the heart retains its normal position in the thorax (156).



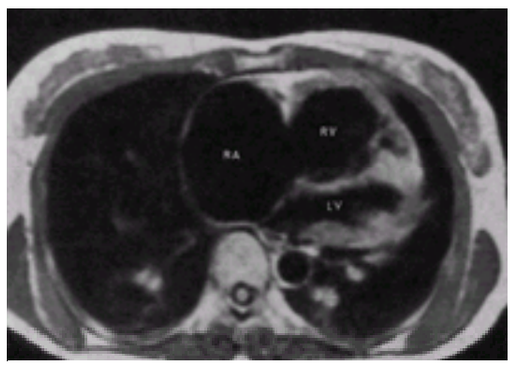
***e*FIGURE 47.20.3** Asymptomatic 59-year-old man with partial absence of the left side of the pericardium. The heart is rotated and shifted into the left chest. The right heart border is displaced toward the left and is projected over the spine. The pulmonary vascularity is normal.

In an asymptomatic patient the characteristic plain film findings may be sufficient to make the diagnosis. However, because plain film findings are frequently subtle and nonspecific, the condition often goes unrecognized (157). In a series of six patients only two had the diagnosis suggested on plain chest radiography (157). None of the 15 patients diagnosed with congenital absence of the pericardium during unrelated cardiac or thoracic surgery reported in the Mayo Clinic series had the diagnosis suggested on preoperative chest radiography (158).

Right Ventricle

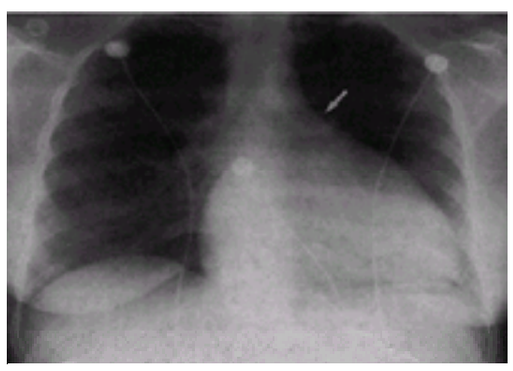
The right ventricle is an anterior, midline structure. The right medial border is limited by the anterior atrioventricular ring containing the tricuspid valve. To the left, the ventricle is limited by the anterior interventricular sulcus containing the left anterior descending coronary artery. Thus, in PA projection, the right ventricle does not form a cardiac border. In lateral projection, the right ventricle fills the inferior retrosternal air space; the free wall of the right ventricle lies directly subjacent to the inferior half of the sternum (Fig. 47.9).

Right ventricular hypertrophy may alter the appearance of the lower left cardiac contour and cardiac apex on PA view. The cardiac apex may be lifted from the diaphragm, and the curvature of the left ventricular contour may become more rounded. In the absence of another associated lesion (such as induced tricuspid regurgitation), right ventricular hypertrophy does not cause right ventricular dilatation. In PA projection, right ventricular dilatation causes (as viewed from below) clockwise rotation of the heart (*e*Fig. 47.20.4). This has the effect of altering the superior portion of the lower third of the left heart contour. As the heart rotates, the relative concavity of the left atrial appendage segment is rotated posteriorly and medially, and the right ventricular outflow tract and anterior interventricular sulcus are displaced laterally and come to form that portion of the left heart border. This portion of the left heart border appears fuller than in the healthy heart. This change can be differentiated from left ventricular and left atrial enlargement by recognition of the increased distance between the left main bronchus (which itself does not appear elevated on frontal examination or displaced on lateral examination) and the left heart border itself. In addition, in cases of right ventricular dilatation, other signs of heart and mediastinal rotation usually occur. The most important of these is medial displacement of the superior vena caval shadow; this results in disappearance of the vertical line of the superior vena cava over the spine. In lateral view, changes in the size of the right ventricular chamber manifest as filling of the retrosternal clear space and posterior displacement of the left ventricle, as manifested by posterior displacement of the inferior posterior heart border toward the spine.



***e*FIGURE 47.20.4** A 26-year-old man with cystic fibrosis, pulmonary hypertension, and secondary tricuspid regurgitation. Axial spin-echo magnetic resonance image demonstrates the clockwise rotation of the heart into the left chest. The right ventricle (RV) is dilated and moderately hypertrophied. Notice that the left ventricle (LV) is rotated into a posterior position and that the lateral border of the heart is formed by the right ventricle. The right atrium (RA) is dilated as well.

Right ventricular dilatation may be observed in patients with left-to-right shunts or malformations of the tricuspid valve or primary abnormalities of the right ventricular myocardium (159,160) (*e*Fig. 47.20.5). More commonly, however, they result from right ventricular dysfunction caused by left-sided heart problems, pulmonary disease, and primary or secondary right ventricular myocardial disease. The most common cause of right-sided heart failure is chronic left-sided heart failure (161). The common denominator of this and other left-sided heart problems causing right ventricular dysfunction is chronic left atrial hypertension transmitted back to the pulmonary veins, capillaries, and arteries. Similar cardiac changes may be found in cor pulmonale, the syndrome of right ventricular hypertrophy, dilatation, and failure resulting from pulmonary hypertension secondary to lung disease (162). Although the condition may be acute, as seen in sudden massive pulmonary thromboembolism (163,164), it most often develops chronically, resulting from hypoxia-induced pulmonary arteriolar vasoconstriction or fibrosis of the pulmonary vascular bed (165,166).



***e*FIGURE 47.20.5** A 24-year-old woman with Uhl's anomaly. The heart is rotated into the left chest. The dilated left heart contour is formed by the dilated right ventricle.

Notice the small pulmonary artery segment (*arrow*), indicating the decreased pulmonary blood flow in this lesion.

Right Atrium

The convexity of the lower right heart border on PA examination is formed by the lateral wall of the right atrium. Estimation of right atrial enlargement is difficult on plain films of the chest. Few linear measurements of the radiographic size of the right atrium have clinical significance. There is no good way to reliably differentiate patients with right atrial enlargement from those without (167). The chamber overlaps the right ventricle, and when the right ventricle is enlarged (which is the case in most conditions causing right atrial enlargement), determination of right atrial size can be difficult. On lateral examination, posterior displacement of the inferior vena caval shadow is a very specific finding.

Isolated enlargement of the right atrium is uncommon. Enlargement secondary to volume loading is most often the case, usually caused by tricuspid regurgitation (eFig. 47.20.4 and Fig. 47.21). The most common cause of tricuspid regurgitation is pulmonary hypertension of any etiology. In these cases, the diagnosis is made by observation of associated evidence of changes in the central and peripheral pulmonary arteries. Until right ventricular failure supervenes, right atrial dilatation in the absence of right ventricular dilatation is found. By the time the right ventricle has failed, clockwise rotation of the heart has occurred, and other findings associated with right atrial hypertension are found, including dilatation of the azygos vein and the presence of pleural or pericardial effusion or ascites.

FIGURE 47.21 A 56-year-old woman with rheumatic mitral stenosis and secondary tricuspid regurgitation. The pulmonary artery segment is enlarged. The right atrial contour of the right heart border is increased in convexity. Convexity of the left atrial appendage section of the left heart border and pulmonary vascular redistribution are evident. Visualized lower lobe vessels are acutely smaller in caliber than the hilar pulmonary arteries. The left ventricle is normal.

Marked dilatation of the right atrium may be found in congenital tricuspid regurgitation or Ebstein's anomaly. More severe tricuspid regurgitation is found in individuals with more severe tricuspid valvular malformations. Depending on how much of systemic cardiac output is derived from right-to-left shunting across the interatrial septum, varying degrees of left ventricular enlargement may be found.

In patients with tricuspid atresia, there is no antegrade filling of the right ventricle from the right atrium. Furthermore, in nearly 75% of patients there is pulmonic stenosis or a restrictive VSD, resulting in decreased pulmonary blood flow and an overall normal-sized heart (eFig. 47.21.1). The tricuspid valve obstruction and obligatory right-to-left shunt across the atrial septum results in right atrial dilatation (increased curvature of the right atrial border) and a normal-appearing to slightly enlarged left atrium. Depending on the size of the shunt and left atrial compliance, mild pulmonary venous hypertension may be evident. The left ventricle in these patients is dilated (it receives both systemic and pulmonary blood flow). The dilated ascending aorta increases the curvature of the right upper cardiac border directly and by lateral displacement of the superior vena cava. In approximately 25% of patients with tricuspid atresia, there is associated transposition of the great arteries, resulting in a less specific radiographic picture of increased pulmonary circulation and left atrial and ventricular enlargement without the characteristic increase in right atrial convexity.

***e*FIGURE 47.21.1** A 44-year-old man with tricuspid atresia and Pott's anastomosis. The left pulmonary artery is dilated, although the pulmonary artery segment (PA) is small. The right pulmonary artery branches are diminutive. The right atrial portion of the right heart border is increased in contour.

CONTROVERSIES AND PERSONAL PERSPECTIVES

There is little that is controversial about chest film examination of the heart. The role of the chest film has shifted in the past half century from a central role in cardiac diagnosis and patient management to more of a barometer of patient physiologic status. This reflects the increase of more sensitive and accurate imaging modalities, rather than the limited accuracy of plain film examination. In an era of advancing invasive means of monitoring physiologic status, the role of the chest film for assessment of cardiac chamber pressure will wane. However, there is still no better means than the plain chest film for displaying the presence and location of the myriad devices used for the monitoring of an intensive care unit or recovery room patient.

The form of image obtained from chest examination has begun to change. The evolution in electronic imaging that began in the 1970s and 1980s has produced reliable means of acquiring high-resolution imagery, high-volume means of archiving these images, and tools for distributing the data to sites around the hospital and community. As institutions have felt the pinch for space, the cumbersome radiology film library has evolved into an electronic library for examinations obtained with filmless systems. These studies arrive at the library via network and are archived for the short- or long-term on magnetic or optical disc. The file room now serves as the distribution center for direction of collected imagery to reading terminals, where algorithms may be applied to manipulate image data, and for the purpose of enhancing the appearance of the heart and pulmonary vascularity. The era of the 14-in. × 17-in. plain film is nearly over. Although the electronic revolution in radiologic imaging and archiving always raises the issue of automated image evaluation, we still have not reached that level of sophistication. The wide variation in physiologic statuses of individuals, as well as the potential artifacts and overlying hardware in and around an acutely ill individual in an intensive care unit, has confounded attempts to automate image evaluation. For the foreseeable future, humans will probably continue to interpret and report the results of these examinations.

THE FUTURE

This is the future. Over the past 25 years, a revolution in the practice of cardiac imaging has occurred. It is becoming mainstream practice for chest radiography to be acquired and archived in digital format and displayed electronically on a video monitor. In a post-future era, we can expect to see better interconnectivity among imaging devices and their networks, as well as among cardiac imagers themselves. This will increase the availability of previous examinations and allow easier comparison of current examinations with other imaging modalities. Along with a more sophisticated approach to the issues of privacy and broad public access, access to diagnostic imagery will be broadened, increasing network volume and maintaining pressure for network growth and evolution. Credit card–based access to all medical imagery and the means of transferring image studies, supporting the availability of rapid second opinions, will change the manner in which we manage patients with cardiovascular disease. As society becomes wired for broadband cable as well as ground-based and satellite-based Internet services, expect to see rapid growth in the use of distant reviewing stations for interpretation of centrally obtained diagnostic imagery. The film library will continue its evolution from storage facility to networking hub for distribution of electronic imagery.

OVERVIEW

Exercise electrocardiography (ECG) is the most widely used method for assessment of the presence and severity of coronary artery disease. Clinical confidence in the exercise ECG has been eroded by the limited sensitivity and predictive value of standard ST-segment depression criteria and by the overapplication of Bayesian principles to interpretation of the exercise ECG in comparison with other noninvasive modalities. However, the development of new approaches to analysis of the ST-segment response to exercise, including the heart rate (HR)–adjusted indices of ST-segment depression (the ST/HR slope and ST/HR index) and treadmill exercise scores, has led to a resurgence of clinical and research interest in the exercise ECG. These methods improve the accuracy of the exercise ECG for the identification and quantification of coronary artery disease and improve risk stratification in both asymptomatic low-risk subjects and symptomatic patients with coronary artery disease. Application of HR-adjusted techniques has been supported by theoretical and experimental evidence that relates the magnitude of ischemic ST depression at peak exercise to both the area of ischemic territory and the degree of myocardial oxygen supply-demand mismatch as reflected by changing HR. Novel approaches to analysis of the ECG during exercise, including changes in QRS complex duration and high-frequency content and assessment of HR responses during both exercise and recovery, hold promise for future improvements in test performance.

GLOSSARY

Bayesian analysis: Relation of test performance to the prevalence of disease in a population.

Chronotropic response index: Fraction of HR reserve achieved with exercise, adjusted by the fraction of metabolic reserve achieved.

ETT: Exercise tolerance test or exercise electrocardiogram.

J-point: Junction of the end of the QRS complex and the beginning of the ST segment.

Rate-recovery loop: Plots of ST-segment depression as a function of HR during both exercise and recovery.

ST/HR index: Maximal change in ST-segment depression with exercise, divided by the total change in HR.

ST/HR slope: Linear regression–based calculation of maximal rate of change in ST-segment depression as a function of change in HR during exercise.

INTRODUCTION

Exercise ECG, or the exercise tolerance test (ETT), is the most widely used and widely available technique for the investigation of known or suspected coronary artery disease. It has been estimated that 6 to 8 million treadmill tests are performed annually in the United States. Nonetheless, clinical confidence in the simple ETT has been eroded by the limited sensitivity and predictive value of standard ECG criteria. However, new approaches to analysis of the ETT have been developed over the past 15 years that improve the accuracy of the exercise ECG to levels found with use of more expensive and less widely available imaging methods. This chapter reviews the development of exercise ECG; gives a brief review of the pathophysiologic basis for exercise-induced ST-segment depression; provides detailed information on the performance, interpretation, and applications of the ETT; and addresses the controversies and future directions in exercise ECG.

HISTORICAL PERSPECTIVE

The development of exercise ECG was based on the empiric observation that ST-segment depression occurs after exercise in patients with coronary artery disease. In 1928, Feil and Siegel (1) reported ST-segment depression after exercise in patients with angina. They demonstrated that the ECG changes resolved after the pain subsided or after administration of nitroglycerin and ascribed the ST-segment depression to a decrease in blood flow to the heart. These observations and conclusions were supported by the subsequent studies of Hellerstein and Katz (2) that described the direction of the vector associated with subendocardial injury in various regions of the left ventricle and, using direct current electrograms, demonstrated that ST-segment depression is primarily a diastolic injury current.

In 1929, Master and Oppenheimer (3) published their first description of an exercise test, the standardized step method that was to become popular for several decades. However, they did not recognize the value of the ECG for the identification of ischemia until 1941, when Master and Jaffe (4) proposed that an ECG could be performed before and after the exercise test to detect coronary insufficiency. Before this, Wood and Wolferth (5) and Katz and Landt (6) had demonstrated the value of ST-segment changes after exercise for the diagnosis of angina and reported that the precordial leads were more useful than the standard limb leads for the identification of ischemic changes. In 1940, Riseman and colleagues (7) first described the use of continuous monitoring during exercise and reported that ST-segment depression usually appeared before the onset of angina and persisted for some time after the symptoms resolved. In 1952, Yu and Soffer (8) reported that the appearance of 1 mm (0.1 mV) of ST-segment depression on the ECG after Master's stair test was consistent with ischemia, and by 1955, the Master's test had

become widely accepted as a result of its simplicity and presumed accuracy.

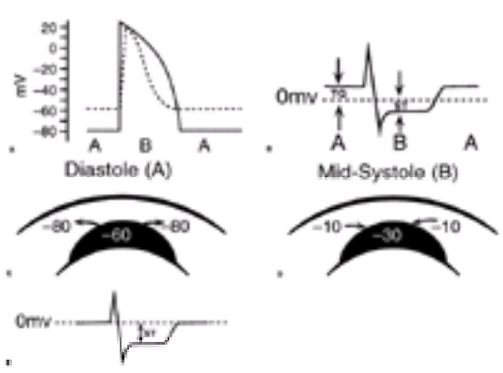
Modern stress testing can be dated from the mid-1950s, when Bruce (9) described a treadmill exercise protocol that provided a more adequate stress than the Master's test and allowed stratification of patients according to the New York Heart Association classification. Although numerous additional treadmill exercise protocols have subsequently been developed, many, if not most, of the protocols currently in use clinically are modifications of the original protocol of Bruce. The next two decades were marked by continued refinement of ST-segment depression criteria (10), with particular attention paid to the number and types of leads used for exercise testing (11), and by the application of exercise ECG for risk stratification (12,13). This period also marked the introduction of computers for the processing of exercise ECGs and measurement of ST-segment changes (14,15) and the subsequent development of quantitative scores based on computer-measured ST-segment depression in combination with other exercise test variables (16).

During the late 1970s and early 1980s, the relation of test performance to the pretest likelihood of disease, or "Bayesian analysis" (17,18 and 19), was brought to bear on the ETT, leading to an era for the exercise ECG that could best be called the "period of Bayesian paralysis" (17). Numerous studies were published that examined the predictive value of the ETT according to population probability of coronary artery disease (18,19), demonstrating the low positive predictive accuracy of the method when it was used for patients who had a low pretest likelihood of disease and the high positive predictive accuracy of the test when it was used for patients who had a high clinical likelihood of having disease. Even though the same principles apply to other noninvasive methods for the detection of coronary artery disease, these effects were particularly emphasized with respect to the ETT. Partly as a consequence of these findings, clinicians lost faith in the routine ETT, leading to more widespread use of newly available imaging modalities during exercise testing.

The past decade has seen a resurgence of interest in the exercise ECG. ETT research has focused on new ECG markers for ischemia, such as the HR-adjusted indices of ST-segment depression [the ST/HR slope, ST/HR index, rate-recovery loop, and ST/HR hysteresis (20,21,22 and 23a)] that significantly improve the accuracy of the exercise ECG. Additional work has led to a greater appreciation of the importance of an attenuated HR response both during and after exercise in the recognition of coronary artery disease in patients and in risk stratification (24 and 25a), brought about the incorporation of ST depression and other exercise parameters into treadmill scores that can improve performance of the ETT (26), and examined changes in QRS prolongation and QT dispersion during exercise as a marker for myocardial ischemia (27,27a).

PATHOPHYSIOLOGY OF ST DEPRESSION

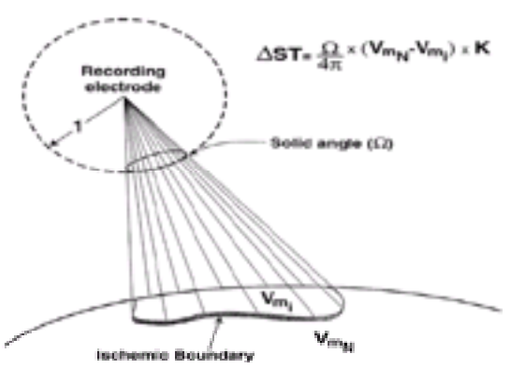
Diagnostic exercise ECG is predicated on the concept that the resulting tachycardia produces subendocardial ischemia, which in turn reverses the normal transmural gradient of ventricular repolarization properties to produce ST-segment depression on the surface ECG (28). The putative mechanism for ST-segment depression that is seen during subendocardial ischemia and the primary electrophysiologic events thought to occur in normal and ischemic myocardium underlying a surface electrode are illustrated in *e*Fig. 48.0.1 (29,30). As is shown in *e*Fig. 48.0.1A, during ischemia, the transmembrane potential of the ischemic cells is altered in comparison with that of normal cells. During diastole, ischemic cells have a lower (less negative) transmembrane potential than do normal cells; as a result, current flows from ischemic tissue to normal tissue (*e*Fig. 48.0.1C). During systole, the transmembrane potentials of the ischemic cells become negative earlier than those of the normal cells, and as a consequence, current flows from the normal to the ischemic tissue (*e*Fig. 48.0.1D). Thus, the current flow during diastole produces TQ-segment elevation in leads overlying the ischemic area, and the current flow during systole produces ST-segment depression in the same leads (*e*Fig. 48.0.1B). As a result, the phenomenon commonly referred to as *ST-segment depression* reflects the sum of TQ-segment elevation and true ST-segment depression. However, because of the manner in which clinical ECGs are recorded, the sum of the true TQ-segment elevation and ST-segment depression (*e*Fig. 48.0.1B) is displayed only as ST-segment depression (*e*Fig. 48.0.1E).



***e*FIGURE 48.0.1 A:** Transmembrane potentials of ischemic (*broken line*) and normal (*solid line*) tissue. **B:** Electrocardiogram recorded by an electrode overlying the ischemic tissue. The TQ segment is located above the isoelectric line (*broken line*), and the ST segment is located below the isoelectric line. **C:** Potential gradients existing at the boundary between normal and ischemic tissue during electrical diastole. **D:** Potential gradients existing at the boundary between normal and ischemic myocardium at mid-systole. **E:** The electrocardiogram shown in **B**, when recorded on a typical electrocardiograph, shows the sum of TQ elevation and ST-segment depression seen in **B** as only ST depression. Arrows in **C** and **D** indicate the direction of current flow (positive to negative) at the boundary. A, diastole; B, mid-systole. (Adapted from Holland RP, Brooks H. Precordial and epicardial surface potentials during myocardial ischemia in the pig: a theoretical and experimental analysis of the TQ and ST segments. *Circ Res* 1975;37:471, with the permission of the American Heart Association.)

The relationship between reduced subendocardial blood flow and consequent subendocardial ischemia, and ST-segment depression in the presence of coronary artery stenoses has been well documented (28,31). Numerous studies have demonstrated that tachycardia in the presence of coronary artery obstruction produces a decrease in subendocardial blood flow with essentially no change in epicardial flow, and a resulting decrease in the endocardial/epicardial flow ratio. If HR and the area (extent) of the tissue that is becoming ischemic are held relatively constant, a linear relationship between the decrease in subendocardial blood flow and the magnitude of ST-segment depression can be shown (28). Further evidence for the relationship of ST-segment depression to subendocardial ischemia is found in the study of Wilson and associates (32), which demonstrated a strong correlation between reduced coronary flow reserve and both the ST segment and HR response to exercise in patients with angiographically proven coronary artery disease. The similar linear relationship between changing HR and endocardial/epicardial flow ratio and resultant direct linear relationship between HR and the magnitude of subendocardial ischemia has important implications for the development of HR-adjusted ST-segment depression criteria (20,21,22 and 23,33).

Theoretical and experimental evidence (28,29,30,31,32 and 33) demonstrates that the determinants of the ST-segment response to exercise can also be mathematically modeled based on solid-angle theory (*e*Fig. 48.0.2). Based on a distributed dipole model of electrical activation of the heart, solid-angle theory indicates that the magnitude of ST-segment depression recorded at a surface (DST) can be related to the product of spatial and nonspatial determinants as defined by the relationship



***e*FIGURE 48.0.2** Mathematical and pictorial representation of solid-angle theory**.** The TQ-ST–segment voltage (DST) recorded at the electrode is given by the equation. The solid angle (W) is defined as the area of spherical surface cut off a unit sphere (inscribed about the recording electrode) by a cone formed by straight lines extending between the recording electrode and every point along the ischemic boundary. The ischemic boundary is a source of current flow established by differences in the transmembrane potentials of the normal (V_{mN}) and ischemic (V_{mi}) cells during diastole and systole. *K* is a term correcting for differences in intra- and extracellular conductivity and the occupancy of much of the heart muscle by interstitial tissue and space. (Adapted from Holland RP, Brooks H. TQ-ST segment

mapping: critical review and analysis of current concepts. *Am J Cardiol* 1977;40:110, with the permission of Excerpta Medica, Inc.)

$$\Delta ST = (\Omega/4\pi)\ (\Delta V_m)K$$

where W is the solid angle subtending the boundary of the ischemic territory, DV_m is the difference in transmembrane voltage between the ischemic and the adjacent nonischemic regions, and *K* is a term correcting for the differences in intracellular and extracellular conductivity and changes in gap junctional conductance. As a consequence, during the transient ischemia associated with exercise, the magnitude of ST-segment depression recorded by a surface electrode is proportional both to the area of ischemic territory subtended by the recording electrode and to the local transmembrane potential difference, which reflects the electrical consequences of the metabolic severity of ischemia at the level of the myocardial cell. This relationship remains proportional under conditions in which major changes in gap junctional conductance do not occur.

It is clear that during exercise the severity of ischemia is directly proportional to changes in myocardial oxygen demand and the ratio of endocardial/epicardial blood flow (31), which in turn can be linearly related to increasing HR (DHR) in experimental studies (31,34). As an arithmetic consequence of this relationship, the ratio DV_m/DHR should remain constant as ischemia develops (33). Dividing the solid-angle relationship in Equation 1 by DHR and making the appropriate substitution for a constant DV_m/DHR reveals that, under conditions in which changes in conductance are proportional or small,

$$\Delta ST/\Delta HR = (\Omega/4\pi)(c)$$

where *c* is a new constant of proportionality. Thus, during exercise-induced transient subendocardial ischemia caused by increased workload, the instantaneous ratio of changing ST-segment depression to changing HR should be directly proportional to the area of ischemic boundary. Furthermore, this ratio should remain independent of the metabolic effects of ischemic severity on transmembrane potential differences across the ischemic boundary. The relationships inherent in Equation 2 provide a strong theoretical basis for the practical application of HR adjustment to analysis of the ST-segment response to exercise, whereas Equation 1 offers further insight into the poor performance of traditional exercise test criteria that are based solely on the magnitude and configuration of ST-segment depression (10,11).

As seen in Equation 1, the ability of standard exercise test criteria to detect coronary artery disease is dependent on the product of both spatial and nonspatial factors reaching a threshold magnitude of ST-segment depression. However, this threshold may not be met when the voltage difference across the ischemic boundary is small, even when disease is anatomically extensive. Thus, sensitivity of standard criteria for the detection of coronary artery disease (= 0.1 mV horizontal or downsloping ST depression) depends on the achievement of a sufficiently high augmentation of myocardial oxygen demand by means of exercise-induced change in HR to produce a threshold amplitude of ST-segment depression (10,11,33). As a consequence, the high prevalence of false-negative standard test responses that can occur during submaximal testing can be both physiologically and mathematically related to reduced ST-segment depression associated with lower HRs and the lower voltage difference that results at the ischemic boundary. HR correction can overcome this fundamental limitation of standard test criteria by adjusting smaller amounts of ST-segment depression for the smaller increases in myocardial oxygen demand that are associated with submaximal exercise.

It is important to recognize that several factors may potentially limit application of this theoretical construct (33,35,36,37 and 38). The traditional view that exercise-induced myocardial ischemia primarily reflects fixed supply and varying demand inadequately describes a more complex pathophysiology. Variability in the functional significance of obstructive coronary artery disease, caused by variable collateral supply, variable differential transmural perfusion, and variable loading conditions in patients who have compromised flow reserve, should make correlation of the anatomic extent of disease with the rate-related change in ST-segment depression imperfect (35). The effects of variable luminal obstruction due to changes in coronary vasomotor tone, the effects of abnormalities of vasodilator reserve, and the effects of serial lesions in diseased vessels should also reduce this correlation (36). In patients who have normal coronary arteries, both exercise- and pacing-induced tachycardia may produce dilatation of epicardial vessels with a concomitant increase in coronary blood flow seen with pacing (37,38). Patients who have nonstenotic atherosclerotic vessels may fail to dilate or to increase coronary blood flow under similar circumstances, whereas patients with stenotic coronary arteries may exhibit epicardial coronary artery vasoconstriction that can be associated with a reduction in coronary blood flow (37,38).

Although these findings may alter the relation of this model of exercise-induced ST-segment depression to all types of ischemic responses, they do not appear to significantly affect the clinical utility of HR-adjusted methods in most cases of typical effort-related ischemia, in which the end-exercise ST-segment and HR responses are indeed quite strongly linear. Moreover, these findings may offer insight into the lower specificity of both the standard and HR-adjusted ST-segment depression criteria in patients who have “nonsignificant” coronary obstructions, in whom exercise-mediated failure to vasodilate (37) could play a role in the development of apparently ischemic ST-segment responses. The findings may also shed light on the relatively incomplete correlation of ST-segment depression criteria with the extent and severity of coronary artery disease, in which varying degrees of exercise-provoked epicardial coronary artery vasoconstriction might be expected to alter the severity of ischemia (37,38).

PERFORMING AN EXERCISE ELECTROCARDIOGRAM

Indications and Contraindications

The most widely accepted indications for ETT are in patients with known or suspected coronary artery disease, in whom ETT is used to determine the likelihood of coronary artery disease, to assess the likelihood of anatomic or functionally severe disease that may be of prognostic importance, to determine functional capacity, and to assess the effects of therapy (39,40). Although indications for the exercise ECG continue to evolve, a joint committee of the American College of Cardiology and American Heart Association has published categories of indications for the ETT based on published literature (39). Their classification includes conditions that are generally accepted as indications for exercise testing, conditions for which the test may be indicated, and conditions for which the ETT is generally considered to have marginal value (Table 48.1). Clinical contraindications to performing diagnostic exercise ECG include acute myocardial infarction, unstable angina before a period of stabilization, uncompensated severe congestive heart failure, advanced atrioventricular (AV) block or life-threatening arrhythmias, acute myocarditis or pericarditis, severe aortic stenosis, severe resting hypertension, and any medical condition that precludes the patient’s walking safely on the treadmill. The presence of left bundle branch block, left ventricular hypertrophy with strain, ventricular preexcitation (Wolf-Parkinson-White syndrome), or permanent ventricular pacing on the ECG is a contraindication to use of the exercise ECG for diagnostic purposes, because of the uncertain diagnostic value of additional ST-segment changes in these settings, but these factors do not preclude use of the ETT to assess exercise performance or to evaluate the risk of arrhythmia, when indicated.

Clearly indicated
Diagnosis of CAD in men with atypical symptoms
Patient has known CAD; assess prognosis and functional capacity
Symptomatic, recurrent, exercise-induced arrhythmias
Patient has experienced an uncomplicated myocardial infarction; evaluate prognosis and functional capacity
Patient has undergone coronary artery revascularization; evaluation recommended
Possibly indicated
Diagnosis of CAD in woman with typical or atypical angina
Diagnosis of CAD in patient taking digitalis
Diagnosis of CAD in patient with complete right bundle branch block
Patient has CAD or heart failure; evaluate functional capacity and response to therapy
Patient has variant angina; evaluation recommended
Patient has known CAD; serial evaluation recommended
Asymptomatic man who is older than 40 yr and in a high-risk occupation, who has two or more risk factors for CAD, or who is sedentary and plans to begin a vigorous exercise program; evaluation recommended
Asymptomatic patient after coronary revascularization; annual evaluation recommended
Selected patients with valvular heart disease; evaluate functional capacity
Probably not indicated
Asymptomatic patient with isolated ventricular ectopy; evaluation recommended
Patient is enrolled in a cardiac rehabilitation program; serial evaluation recommended
Diagnosis of CAD in patient with left bundle branch block or ventricular preexcitation (Wolff-Parkinson-White) syndrome on resting electrocardiography
Asymptomatic man or woman; evaluation recommended
Man or woman with chest pain of noncardiac etiology; evaluation recommended

TABLE 48.1 INDICATIONS FOR EXERCISE ELECTROCARDIOGRAPHY

Patient Preparation and Technique

The American Heart Association has published guidelines for clinical exercise testing laboratories that provide recommendations regarding the performance of clinical ETTs (41). All patients should be instructed not to eat, drink caffeinated beverages, or smoke for at least 3 hours before the test and to wear comfortable clothes and rubber-soled shoes or sneakers. Physicians should instruct patients on whether to continue or discontinue cardioactive medications before the ETT, depending on the indication for the test and the relative safety for the patient of exercising while not receiving medications. In a patient referred for testing, a brief history should be obtained to confirm the indication for the test and to determine cardiac risk factors and whether cardioactive medications are being taken. A directed physical

examination should be performed to exclude the presence of significant valvular or myopathic disease that might preclude exercise evaluation. The risks and benefits of the procedure should be carefully explained, and informed consent should be obtained before the study is begun.

Attention to adequate skin preparation before electrode placement is the most important technical aspect in obtaining high-quality ECG recordings. The areas where electrodes are to be placed should first be cleaned with alcohol to remove surface oils and then abraded with a scouring pad or other rough material to remove the most superficial layer of skin. Abrasion should be performed to reduce resistance at the skin-electrode interface to 5,000 ohms or less. Silver–silver chloride electrodes should be used to produce high-quality tracings.

Before exercise, a supine 12-lead ECG should be obtained with the limb electrodes on the extremities in the normal positions; this tracing should be carefully examined for any signs of active ischemia, for interval myocardial infarction, and for abnormalities that would prohibit performance of the ETT. Limb electrodes should then be shifted to the more proximal positions recommended by Mason and Likar (42) to reduce motion artifact during exercise, and additional ECG tracings should be obtained while the patient is in the supine and standing positions. Notably, because the Mason-Likar modification results in significant changes in QRS axis and amplitudes, the modified lead positions should not be used for interpretation of the resting ECG. Blood pressure should be measured while the patient is in the standing position, the patient should be instructed on how to perform the test, and walking on the treadmill should be demonstrated before the ETT is begun.

A 12-lead ECG should be obtained each minute during exercise, at peak exercise, and every minute during the postexercise recovery period. Rhythm strips and additional 12-lead ECGs should be recorded as needed. Blood pressure should be measured immediately before exercise while the patient is in the standing position, immediately before the end of each stage of exercise, and for each minute of recovery until the blood pressure has returned to baseline. Patient position in the postexercise recovery phase varies between laboratories. Many labs have the patient assume the supine position immediately after peak exercise; this will increase venous return and increase end diastolic volume and may augment ST-segment changes that are present at end-exercise. In our laboratory, we have the patient remain in the upright position, if possible, and have used a cool-down phase of 3 minutes immediately after peak exercise, during which the patient continues to walk at 1.7 miles per hour at a 0% grade. This allows patients a more gradual decrease in HR after exercise and appears to decrease the incidence of postexercise vagally mediated hypotension. In other laboratories, the patient remains in an upright seated position immediately after exercise.

Equipment and Personnel

Although excellent-quality stress tests can be obtained using standard 12-lead cardiographs that conform to the recommendations of the American Heart Association, most ETTs currently performed use equipment specifically designed for exercise testing. These computerized systems combine a cardiograph with a display monitor for continuous rhythm analysis and are capable of controlling treadmills and bicycle ergometers according to specific exercise protocols. The lead systems should be lightweight but strong and well shielded. In case of emergency, the stress lab should be equipped with a defibrillator that has the ability to perform synchronous cardioversion, an Ambu-bag and oxygen supply, and a cardiac arrest cart.

Exercise tests should be performed under the supervision of a physician who has been trained to conduct exercise tests. The degree of supervision required is primarily dependent on the type of patient being tested and can range from direct performance of the test for patients who are at higher risk of complications (e.g., those who have unstable angina after stabilization, who have congestive heart failure, or who have a high risk of arrhythmias) to assigning the performance of the test to an appropriately trained exercise physiologist or a specialist in patients at lower risk. In all cases, a physician should be immediately available during the exercise test.

Treadmill Protocol

Most exercise ECG laboratories in the United States use a treadmill rather than a bicycle ergometer for stress testing. The advantages of the treadmill lie in the greater familiarity of most people in this country with walking and the ability to increase both speed and grade of the treadmill to increase workload. Although a number of excellent treadmill protocols are available for use, by far the most commonly used protocols are the original protocol of Bruce (43) and modifications of this protocol. The Cornell protocol, originally developed in our laboratory to produce the smaller HR increments between stages that are necessary for calculation of the ST/HR slope (44), is a more graded modification of the Bruce protocol that divides each standard stage into 2-minute half-stages. To allow adequate warm-up time and to allow more patients to be able to exercise for a period of time adequate for calculating the ST/HR slope, the protocol begins with a 2-minute stage 0 at 1.7 miles per hour and 0% grade, with a 2-minute stage 0.5 at 1.7 miles per hour at a 5% grade, before reaching the usual starting point of the Bruce protocol (1.7 miles per hour and a 10% grade) (*e*Table 48.1.1).

***e*TABLE 48.1.1** COMPARISON OF STANDARD BRUCE PROTOCOL AND THE CORNELL PROTOCOL

		Bruce protocol		Cornell protocol	
Walking speed (mph)	**Grade (%)**	**Stage**	**Elapsed time (min)**	**Stage**	**Elapsed time (min)**
1.7	0			0	2
1.7	5			0.5	4
1.7	10	1	3	1.0	6
2.1	11			1.5	8
2.5	12	2	6	2.0	10
3.0	13			2.5	12
3.4	14	3	9	3.0	14
3.8	15			3.5	16
4.2	16	4	12	4.0	18
4.6	17			4.5	20
5.0	18	5	15	5.0	22

Lead Systems

The number and types of leads used in exercise ECG vary widely, but with the advent of modern recording devices, most stress laboratories monitor and record at least three leads during the test. Although the use of all 12 conventional leads is becoming more common, almost all of the useful diagnostic ST-segment information from these leads is present in limb leads II, III, and aVF and precordial leads V_3 to V_6. Bipolar lead systems that include one electrode in the V_5 position provide additional diagnostic information; bipolar lead CM_5 is the most sensitive for ST-segment changes (11) and is particularly important in optimal recording of the ST/HR slope (45). Orthogonal XYZ leads or Frank vector leads have also been widely used and analyzed, and there is general agreement that lead X (equivalent to a bipolar lead from right to left axilla) provides the most useful information. This lead set continues to be widely used in Europe. Preliminary results in 245 patients suggest that incorporation of ST-segment depression and elevation in right precordial leads may improve sensitivity of the ETT with no apparent decrease in specificity (45a). Further validation of these findings will be necessary before routine use of right precordial leads can be recommended.

Indications for Test Termination

The general indications for terminating an exercise test are outlined in Table 48.2. In the absence of symptoms or signs that warrant termination of the exercise ECG, patients should exercise with 100% of age-predicted target HR as the goal. Although use of 100% of the age-predicted target HR as an indication for terminating an exercise test may prevent the accurate assessment of functional exercise capacity in patients able to exercise beyond this point, in general, achievement of greater than 85% of target HR provides an adequate level of stress for diagnostic exercise ECG (10). Various equations have been used to relate target HR to age, but the simplest and most commonly used are 220 – age and 200 – (age/2). Although angina alone is not an absolute indication for test termination, progressively worsening typical anginal symptoms are a reason to stop the test, as are any other symptoms that limit further walking on the treadmill.

Achievement of target heart rate (see text for definitions)
Progressive angina
Other limiting symptoms (dyspnea, fatigue, lightheadedness, claudication)
ST-segment elevation >2 mm (in leads without a resting Q wave)
Severe ST-segment depression (see text)
Nonsustained ventricular tachycardia (three or more sequential ventricular premature contractions)
New onset of atrial fibrillation, atrial flutter, or of a supraventricular tachycardia
Development of second- or third-degree atrioventricular block
Development of a new left bundle branch block
A 10-mm Hg drop in systolic blood pressure
Extreme elevation of systolic or diastolic blood pressure
A progressive drop in heart rate with continued exercise
Equipment problems, such as loss of electrocardiographic signal

TABLE 48.2 GENERAL INDICATIONS FOR TERMINATING AN EXERCISE TEST

ST-segment elevation in the absence of Q waves is consistent with possible transmural injury and a reason for immediate termination of the ETT. In contrast, ST-segment depression alone is rarely an indication for cessation of the exercise test. Indeed, only marked ST depression (>3 mm of additional ST depression compared with baseline) would warrant test termination in the absence of other findings. New sustained tachyarrhythmias are clearly an indication for stopping the test, as is the development of second- or third-degree heart block. Routine diagnostic stress tests should also be halted if nonsustained ventricular tachycardia is seen, unless the patient is undergoing the test expressly for evaluation of the possibility of exercise-induced ventricular tachycardia with the extra precautions taken of having a second physician in attendance, intravenous access, and additional leads to a synchronous cardiodefibrillator. Other relative indications for terminating the ETT include development of a new left bundle branch block that precludes further evaluation of ST-segment changes, a 10–mm Hg or greater drop in systolic blood pressure, an extreme elevation of systolic or diastolic blood pressure, a progressive decrease in HR with exercise, or significant equipment problems, such as loss of the ECG signal.

Other Applications of Stress Testing

Performance of an exercise test for indications other than routine assessment of the presence or severity of coronary artery disease or evaluation of functional capacity deserves comment. After uncomplicated myocardial infarction, exercise testing is frequently performed to assess functional capacity and to help stratify risk (46). When exercise testing is performed early after myocardial infarction (i.e., before discharge or within 2 to 3 weeks of the infarction), submaximal symptom-limited testing is recommended (40), to a target HR of 140 beats/min or a metabolic equivalent of 7 in patients younger than 40 years and to a maximum HR of 130 beats/min or a metabolic equivalent of 5 in patients 40 years and older. A full symptom-limited maximal test is appropriate more than 3 weeks after myocardial infarction. Exercise ECGs are also commonly performed to evaluate the risk of exercise-induced tachyarrhythmias in patients who have exercise-related presyncope or syncope. Because of the risk of inducing a hemodynamically significant arrhythmia in these settings, the ETT should be performed with at least one (and preferably two) physicians present, with intravenous access, and with leads connected to a defibrillator.

Exercise ECG is also frequently used after percutaneous transluminal angioplasty to stratify risk and aid in the assessment of restenosis and appears to be well tolerated (47,48). However, reports of acute stent thrombosis associated with exercise testing soon after stent placement (49) raise the question of whether exercise testing should be performed in the immediate post-stent period. Until further data become available, caution should be used in the performance of exercise testing soon after the placement of intracoronary stents, with strong consideration given to the use of pharmacologic stress if early noninvasive assessment is indicated (49).

INTERPRETATION OF THE EXERCISE ELECTROCARDIOGRAM

ST-Segment Depression Criteria

To fully appreciate the ST-segment excursions that occur during the transient ischemia associated with exercise in patients with coronary artery disease requires some understanding of the ST-segment changes that occur during exercise in healthy subjects (Fig. 48.1). At baseline, most healthy subjects will have ST segments that are either at the isoelectric level or slightly elevated as a result of physiologic early repolarization of the J-point. As HR increases, progressive J-point or junctional depression occurs, with resultant rapidly upsloping ST segment (50,51). After exercise is terminated, the J-point depression tends to resolve quickly (usually within the first 2 minutes), as does the rapidly upsloping ST-segment depression. In contrast, the ST-segment depression associated with subendocardial ischemia is more likely to be horizontal or downsloping but may also be slowly upsloping (Fig. 48.2) (10,51). With progressive exercise, increasing HR, and the resulting increasing myocardial oxygen demand, the magnitude of ischemic ST-segment depression will increase, and the ST depression is more likely to be horizontal or downsloping. Placing the patient in the supine position immediately after exercise may accentuate ischemic ST-segment depression. However, ischemic ST depression may occur during exercise only, emphasizing the importance of adequate skin preparation before electrode placement. In a small percentage of cases, ischemic ST-segment depression will be seen during recovery only (52), especially when the patient is placed in the supine position, but isolated recovery-phase ischemic ST-segment depression is less common when patients remain in the upright position after exercise. In rare instances of exercise-induced transmural ischemia or injury, ST-segment elevation similar to that seen during the acute injury of myocardial infarction may also occur.

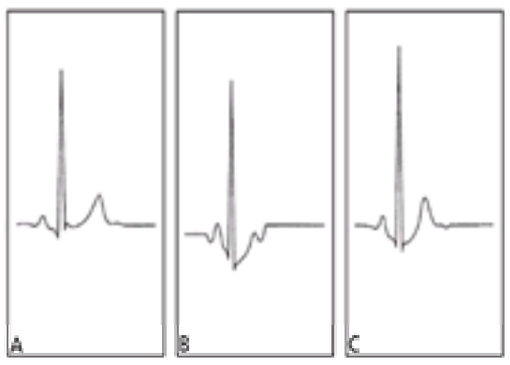

FIGURE 48.1 Progression of ST-segment changes that occur in healthy subjects from isoelectric at baseline **(A)** to J-point depression with rapidly upsloping ST-segment depression at peak exercise **(B)** and rapid resolution of the ST changes in recovery **(C)**.

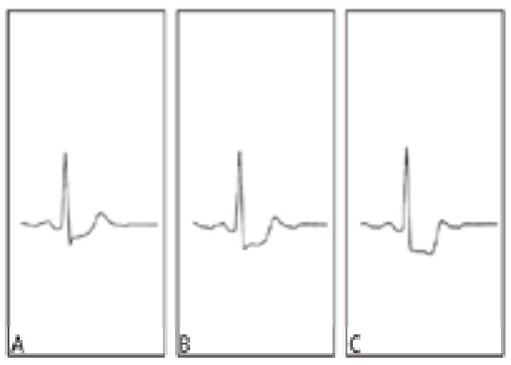

FIGURE 48.2 Comparison of the different patterns of ST depression. **A:** Slowly upsloping ST-segment depression. **B:** Horizontal ST-segment depression. **C:** Downsloping ST-segment depression.

Differences in the patterns of ST-segment depression in healthy subjects and in patients with coronary artery disease highlight the importance of choosing the correct point on the ST segment at which to measure the magnitude of ST-segment depression (15,50,51). Recommendations for the measurement of ST-segment depression have varied from the J-point (53) to between 60 and 80 ms after the J-point (10,39). Performance of standard ST-segment depression criteria varies with the timing of ST-segment measurement relative to the J-point, but measurements made at 60 ms after the J-point have generally outperformed J-point measurements for the identification of coronary artery disease (15,50,51). We have previously found that performance characteristics of HR-adjusted ST depression criteria are optimized when ST-segment depression is measured at 60 ms after the J-point, whereas use of J-point depression reduces performance of HR-adjusted criteria to the level of standard criteria (51). Thus, we currently recommend that ST-segment depression be measured at 60 ms after the J-point (45).

The actual measurement of ST-segment deviation on the exercise ECG is most accurately performed by the computerized systems that are widely in use today, but accurate ST-segment measurements can be performed by hand if careful attention is paid to proper selection of the correct measurement points. In measurement of

ST deviation, the PQ segment is usually chosen as the isoelectric point, which some computerized systems choose by scanning before the QRS complex for the 10-ms interval with the lowest slope, and ST-segment depression should be measured at 60 ms after the J-point. Computer systems are capable of accurately measuring ST deviation to the nearest 10 µV, and careful hand measurements using calipers or a magnifying graticule can readily achieve a precision of 25 µV for ST measurements (54). However, when computer measurements are used, it is important to recognize that motion artifact, electrical interference, and changes in QRS or atrioventricular conduction can interfere with PQ segment and J-point determinations and introduce error into the computerized ST measurements. Therefore, physicians should routinely compare the raw ECG signal with the computer-averaged or median beats used to perform ST measurements before accepting the computer measurements as accurate.

Standard Test Criteria

Assessment of the magnitude and configuration of ST-segment depression on the exercise ECG provides the basis for the standard ST depression criteria that are commonly in use. A positive test result based on standard ST depression criteria has been routinely defined as the achievement of 0.1 mV (100 µV) or more of horizontal or downsloping ST-segment depression at peak exercise or in early recovery compared with the baseline pre-exercise ECG (10,39,40). However, as is discussed later, these criteria have only limited test sensitivity for the presence of coronary artery disease and variable performance for identification of anatomically severe disease and for risk stratification (10,11,12,13,14,15 and 16,20,21,22 and 23,45,55). Additional factors that can affect the likelihood that coronary artery disease or multivessel disease will be detected in the presence of traditional criteria include the magnitude, time of onset, duration, and number of leads with ST depression. Although inclusion of upsloping ST depression of greater than or equal to 0.1 mV or 0.15 mV has been suggested as an additional component of standard criteria, to increase sensitivity for the detection of coronary artery disease (56,57), the incorporation of upsloping ST depression also lowers test specificity (10,20,55,56). As a consequence, we consider the presence of upsloping ST-segment depression of 1 mm (0.1 mV) or more to be an “equivocal” test response by standard criteria.

Heart Rate–Adjusted Criteria

HR adjustment of the magnitude of ST-segment depression is a rational, physiologic approach to interpretation of the ETT. Two related but distinct methods of HR adjustment of ST-segment depression seen during exercise have evolved: the linear regression–based ST/HR slope and the simpler ST/HR index. The ST/HR slope method was originally developed in England (58) and Hungary (59) and has subsequently been applied to treadmill exercise, using computerized ST-segment measurements, and further refined in our laboratory at Cornell (20,21,22 and 23,25,44,45,51,54). The ST/HR slope is calculated from the maximal rate of change of ST depression relative to HR during the period of active ischemia that accompanies end-exercise (Fig. 48.3). The ST/HR index, originally described by Detrano and coworkers (60), represents the average change of ST depression relative to HR change over the entire course of exercise, which underestimates the maximal ST/HR slope because it includes a large change in HR before any ischemia occurs (Fig. 48.3). Both of these methods specifically do not consider any ST depression that occurs during the postexercise recovery period.

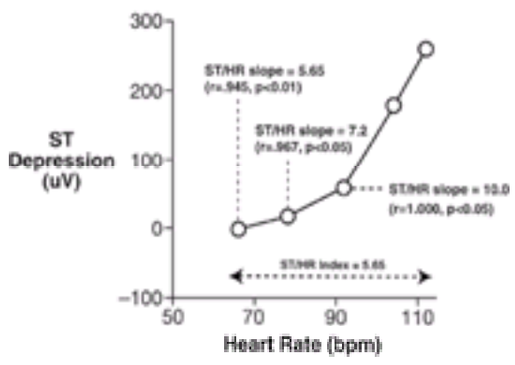

FIGURE 48.3 Calculation of the ST/heart rate (HR) slope. Progressive ST-segment depression in lead CM5 (shown as a positive magnitude on the vertical axis) is plotted against exercise HR in a patient with three-vessel coronary artery disease. This case illustrates the linear relation of ST-segment depression to HR as peak exercise is approached. As a result, the slope of the line relating the final three data points by linear regression is higher than the slope of lines incorporating earlier data points. When more than one linear correlation is statistically significant, the greatest value (in this case, 10.0) is taken as the test result for that patient. Note that the value obtained by simply dividing the total change in ST-segment depression by the total change in HR (the ST/HR index) markedly underestimates the true ST/HR slope. (Reprinted from Okin PM, Kligfield P. Heart rate adjustment of ST depression and performance of the exercise electrocardiogram: a critical evaluation. *J Am Coll Cardiol* 1995;25:1726, with the permission of Elsevier Science, Inc.)

Calculations of the ST/HR slope and ST/HR index are illustrated in Figure 48.3. Measurement of the ST/HR slope is determined by linear regression analysis to relate the measured amount of ST-segment depression in each lead to the HR at the end of each stage of exercise and at peak exercise. Because the maximal rather than the average rate of change is sought, linear regression analysis is performed from the end of exercise to progressively earlier intermediate stage data points, using HR as the independent variable and ST depression as the dependent variable. The highest ST/HR slope with a statistically significant correlation coefficient is taken as the test finding for that lead (in µV per beat per minute). After calculation of the maximal ST/HR slope for each lead, the highest ST/HR slope among all the leads (including bipolar lead CM_5, but excluding aVR, aVL, and V_1) is taken as the final test result (45,54). The ST/HR index is derived by dividing the maximal change in ST-segment depression during exercise by the total change in HR from rest to peak effort (45,60). Initial studies from our laboratory (20) established partition values, with specificities of 95% in healthy subjects, of more than 2.40 µV per beat per minute for the ST/HR slope and more than 1.60 µV per beat per minute for the ST/HR index for the identification of coronary artery disease. Partition values of more than 6.0 µV per beat per minute (ST/HR slope) and more than 3.3 µV per beat per minute (ST/HR index) have been established for the identification of three-vessel, left main, and functionally severe coronary artery disease (45).

Analysis of the behavior of ST-segment depression as a function of HR during both exercise and recovery using the rate-recovery loop (21,22,45) can elicit additional diagnostic and prognostic information from the ETT. Physiologic correlates of rate-recovery loop patterns can be found in the initial observations of Detry and Bruce and associates (61,62), which compare myocardial ischemia during exercise and recovery. They found a close linear relation of ST-segment depression during exercise to myocardial oxygen demand, as reflected by the tension-time index, among patients with coronary artery disease. During recovery, however, this relation was nonlinear, with similar ST-segment depressions observed at lower tension-time indexes than those seen during exercise. Additional support for this approach is found in reports of cases of subendocardial ischemia that continue into the recovery period with persistent ST-segment depression that remains greater relative to HR during early recovery than during the development of ischemia (63,64). Rate-recovery loops are constructed by plotting ST-segment deviation, with reference to changing HR, throughout treadmill exercise and recovery (Fig. 48.4). Healthy subjects typically exhibit a clockwise loop of ST-segment depression as a function of HR during exercise and recovery, whereas patients with coronary artery disease commonly exhibit a counterclockwise loop. Quantification of the degree of abnormal rate-recovery loop behavior by integrating the difference in ST depression between exercise and recovery phases from peak-exercise to the end of 3 minutes of the recovery phase can further stratify the presence and severity of coronary artery disease (23a).

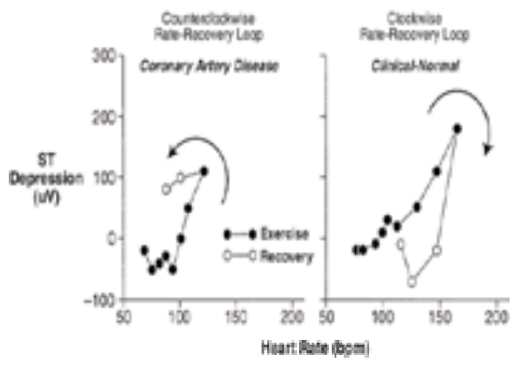

FIGURE 48.4 ST-segment deviation as a function of heart rate during exercise and recovery, with ST-segment depression shown in the upward direction and ST-segment elevation shown in the downward direction. Typical rate-recovery loops are shown for a clinically normal subject (*right*) and a patient with coronary artery disease (*left*). Despite a greater magnitude of ST-segment depression at peak exercise in the clinically normal subject, there is a clockwise pattern of ST-segment depression relative to heart rate during recovery; the patient with coronary artery disease has the opposite, counterclockwise pattern. Heart rate adjustment of ST depression and performance of the exercise electrocardiogram: A critical evaluation. *J Am Coll Cardiol* 1995;25:1726, with permission of Elsevier Science, Inc.)

Treadmill Exercise Scores

Numerous investigators have used either multivariate analyses or Bayesian theory to produce clinical scores in an attempt to improve the accuracy of the ETT (16,26,65,66,67 and 68). However, many of these methods incorporated clinical and catheterization data that make the contribution of the exercise test unclear. Two methods that have used data only from the ETT are the Hollenberg exercise score (16) and the Duke treadmill score (Table 48.3) (26,65). The Hollenberg exercise score quantifies the ECG response to exercise by measuring the cumulative area of ST depression and ST slope in leads V_5 and aVF during exercise and recovery, which is then normalized for R-wave height and workload (exercise duration and HR). The Duke treadmill score is a simple quantitative score, derived using a Cox regression model in a training sample of more than 1,400 patients, that includes exercise duration and weighted measures of ST-segment deviation and an angina score. The prognostic value of this score has been validated for ambulatory patients (26) and for patients undergoing angiography (65).

Hollenberg exercise score (16)
$\text{Exercise score} = \dfrac{\text{area (J-point + ST slope) } V_5 \times 12 \cdot RV_5 + \text{area (J-point + ST slope) aVF}}{\text{exercise duration} \times \text{fraction of maximal predicted heart rate}}$
(where exercise duration is in min and R-wave amplitudes are in mm)
Duke treadmill score (26)
Treadmill score = exercise duration − (5 × ST deviation) − (4 × TM angina index)
(where exercise duration is in min; ST deviation is in mm; and TM (treadmill) angina index = 0 for no angina, 1 for nonlimiting angina, or 2 for exercise-limiting angina)

TABLE 48.3 TREADMILL EXERCISE SCORES

ST Integral

Originally proposed by Sheffield and colleagues (14), the time-voltage integral of ST-segment depression (the ST integral) examines the total area of repolarization abnormality from the J-point to a terminal point late in the ST segment at which the ST segment crosses the isoelectric baseline. This method has primarily been applied in a series of population-based studies to assess risk (69,70), but the need for computer measurements and the lower accuracy of this method relative to standard ST-segment depression criteria (71) have limited its general applicability.

QRS Complex Criteria

An increase in R-wave amplitude that is seem during exercise has been proposed as a possible marker of myocardial ischemia and left ventricular dysfunction in patients with coronary artery disease (72). However, subsequent studies have demonstrated that R-wave amplitude changes associated with exercise are highly correlated with HR and that much of the discrimination between healthy subjects and patients with coronary artery disease thought to be due to R-wave amplitude changes actually reflects differences in the HRs achieved during exercise (73).

Changes in QRS complex duration and in intra-QRS amplitudes have also been suggested as possible markers of ischemia (27,74). Michaelides and company (27) demonstrated that QRS duration was more likely to shorten during exercise in healthy subjects than in patients with coronary artery disease, in whom, on average, QRS duration was more likely to increase. They further found that the magnitude of QRS duration prolongation in patients who had coronary artery disease was directly related to the number of obstructed coronary arteries and to the number of segmental wall motion abnormalities. Investigation of a more experimental nature, using signal-averaging of high-frequency ECGs during myocardial ischemia produced by balloon-catheter inflation in the catheterization laboratory, has demonstrated a reversible reduction in mid-QRS high-frequency signal strength during ischemia, with a sensitivity of 88% for acute coronary occlusion, which is significantly greater than the 71% sensitivity of standard ST elevation changes (74). These findings offer promise for increased use of QRS complex changes during exercise to improve the recognition of myocardial ischemia, but further work using computer measurements based on digital data recorded at high acquisition rates (500 to 1,000 Hz) during exercise will be necessary to clarify the role of these approaches in the diagnosis of coronary artery disease.

Chronotropic Response to Exercise

Independent of evidence of myocardial ischemia, an attenuated HR response to exercise, a measure of chronotropic incompetence, has been associated with the presence and severity of coronary artery disease (25,75) and has been shown to be a predictor of both coronary heart disease events and of total mortality (24,76,76a). Different measures of chronotropic response to exercise have been used to assess the adequacy of HR response, including simple measures such as peak exercise HR, percentage of target HR achieved, and change in HR during exercise. In addition, simple and HR-adjusted ST-segment depression criteria can be corrected for an attenuated HR response to exercise by adjustment of these measurements for the fraction of HR reserve achieved during exercise, which is the change in HR during exercise divided by the difference between 100% of age-predicted target HR and the HR at standing rest (25). A more complex measure is the chronotropic response index (24,25), which adjusts the fraction of HR reserve achieved for workload as measured by the fraction of metabolic reserve. HR changes during the recovery phase of the exercise test have also been demonstrated to provide prognostic information. A delayed decrease in HR after exercise, or abnormal HR recovery, predicts all-cause mortality among healthy adults and in patients referred for exercise testing, independent of evidence of inducible ischemia and beyond the predictive value of exercise-phase changes in HR (25a,76b,76c).

Blood Pressure Changes

Among patients with coronary artery disease, failure to increase systolic blood pressure to 120 mm Hg or higher and a sustained decrease in systolic blood pressure of 10 mm Hg or more both have been associated with an increased likelihood of anatomically extensive disease. However, other conditions can produce a blunted blood pressure response to exercise, such as obstruction of left ventricular outflow, hypovolemia, left or right ventricular dysfunction, cardioactive medications, and vigorous exercise. In contrast, although an exaggerated blood pressure response to exercise has been clearly associated with an increased risk of developing hypertension at rest and with a greater prevalence of left ventricular hypertrophy (77), the prevalence of coronary artery disease appears to be similar among patients who do and those who do not have exercise hypertension (210 mm Hg or higher in men and 190 mm Hg or higher in women) (78). Moreover, an exaggerated systolic blood pressure response to exercise appears to be associated with a lower likelihood of anatomically severe disease and with a lower 2-year overall mortality rate (78).

In the postexercise recovery phase, a progressive decline in systolic blood pressure is usually seen. Failure of systolic blood pressure to decline normally during early recovery, as measured by an increased ratio (greater than 0.90) of systolic blood pressure during the first 3 minutes of recovery to peak exercise systolic blood pressure, has been reported to be useful in the diagnosis of coronary artery disease (79). However, an increased ratio is also seen in patients who have hypertension and no significant coronary obstructions (79), and additional studies have not substantiated a high sensitivity of this ratio for coronary artery disease (80). Further study of the utility of blood pressure changes in improving the accuracy of the diagnosis of coronary artery disease by ETT is necessary before the routine application of these criteria can be recommended.

Rhythm and Conduction Changes

The ETT can be used to evaluate the risk for significant abnormalities of cardiac rhythm and conduction under appropriate conditions. Exercise-induced ventricular premature contractions (VPCs) are common, increase in prevalence with age, are more frequent, and may be associated with a somewhat worse prognosis in patients with coronary artery disease (81). In contrast, neither the abolition of VPCs with increasing exercise nor development of VPCs only during the postexercise recovery period appear to be of clinical significance, and the appearance of nonsustained ventricular tachycardia during exercise testing does not appear to convey an increased short-term risk (82). The development of sustained ventricular tachycardia during exercise testing in patients who have coronary artery disease is most commonly the result of myocardial ischemia and can be prevented by treatment of the underlying ischemia. Exercise testing can play an important adjunctive role to electrophysiologic studies in the evaluation of patients with exercise-induced ventricular tachycardia in whom the presumptive mechanisms are after-depolarizations or enhanced automaticity and who have no obvious structural heart disease. A left bundle branch block morphology and termination of ventricular tachycardia with vagal maneuvers or adenosine strongly suggest that delayed after-depolarizations are the cause of the tachycardia. Exercise-induced supraventricular arrhythmias occur in

4% to 8% of patients, increase in frequency with age, and do not reflect the presence of coronary artery disease.

Changes in AV and intraventricular conduction may occur during exercise. Rarely, exercise testing can elicit second-degree AV block in patients with exertional fatigue or dyspnea, but more commonly, AV conduction is enhanced with exercise as a result of increased sympathetic tone and increased circulating catecholamines. Exercise-induced, rate-related development of right or left bundle branch block is relatively rare; it is not associated with an increased incidence of underlying coronary artery disease in younger subjects (younger than 40 years), but it appears to be associated with coronary artery disease in older subjects. When right bundle branch block is seen on resting ECG, exercise-induced ST-segment depression in leads V_1 to V_4 commonly occurs and is not diagnostic for coronary artery disease; ST-segment depression in the inferior leads and leads V_5 and V_6 is consistent with ischemia. ST-segment changes in the presence of a left bundle branch block are best considered nondiagnostic for coronary artery disease.

The presence of preexcitation on the ECG invalidates the use of ST-segment depression criteria for the diagnosis of coronary artery disease, because abnormal repolarization frequently is associated with aberrant depolarization accompanying anterograde conduction over an accessory pathway. Exercise ECG may play a useful adjunctive role in the assessment of accessory pathway physiology in patients in whom preexcitation is seen at rest. The abrupt disappearance of a delta wave during exercise reflects a longer effective refractory period during anterograde conduction over the bypass tract and may be associated with a lower risk of ventricular fibrillation. Although a more gradual disappearance of preexcitation can occur when the enhancement in AV nodal conduction that accompanies increased sympathetic stimulation is greater than the increased conduction in the accessory pathway, this finding does not exclude the possibility that a shortening of an accessory pathway refractory period may be present that is associated with an increased risk of ventricular fibrillation when atrial fibrillation is manifest. Therefore, caution should be used before therapeutic decisions involving patients who have preexcitation are made solely on the basis of the results of exercise evaluation, and electrophysiologic testing should be used as indicated (see Chapter 62).

Drugs and Hormonal Effects

Cardioactive drugs and sex hormones can significantly affect interpretation of the ETT. Drugs that blunt the HR and blood pressure response to exercise, such as beta-blockers, diltiazem, and verapamil, may delay or diminish ST-segment depression during exercise and reduce the sensitivity of standard test criteria. Although the sensitivity of HR-adjusted criteria appears to be less affected by these medications (45), failure to produce ischemia during exercise that is the result of medication limits the diagnostic accuracy of any noninvasive modality. Conversely, digitalis preparations can produce ST-segment changes in the absence of heart disease, significantly decreasing the specificity of ETT criteria that are based on ST-segment changes. Similarly, both endogenous and exogenous estrogens and progesterones have been implicated in abnormal ST-segment responses that are seen in healthy women (83,84). Moreover, the administration of estrogens can increase the magnitude of ST-segment depression in men and women with ischemic disease (23,83,84), and consideration of estrogen status significantly improves the overall accuracy of the ETT in women (85). Although numerous investigators have reported lower accuracy when standard ST-segment depression criteria are used for women than when these criteria are used for men, whether these differences are better explained by lower test sensitivity or lower specificity in women remains controversial (23). Although the mechanisms of ST-segment changes in response to cyclic hormonal variations remain to be determined (23,83,84), notably, both the ST/HR index and ST/HR slope provide diagnostic accuracy that is similar in men and women, despite these potential limitations (23).

APPLICATIONS AND TEST PERFORMANCE OF THE EXERCISE ELECTROCARDIOGRAM

Identification of Coronary Artery Disease

The diagnosis of coronary artery disease remains the most frequent indication for exercise testing with standard ST depression criteria; achievement of at least 0.1 mV of additional horizontal or downsloping ST-segment depression is the most common diagnostic criterion. However, utility of the standard ETT for this purpose has been limited by the relatively low sensitivity and poor predictive accuracy of standard criteria (10,11,20,45,55). Although the exact performance of any test is difficult to determine because of the influence of study design, population selection, and referral bias (45,55,86,87 and 88), a metaanalysis assessing the sensitivity and specificity of the ETT in 24,074 patients evaluated in 147 consecutively published reports provides some important insights into the performance of standard ST depression criteria (55). Using 50% luminal obstruction at angiography as the diagnostic standard for coronary artery disease, the weighted mean sensitivity was 68% (range, 23% to 100%), and mean specificity was 77% (range, 17% to 100%); when upsloping ST depression was considered to be abnormal, test specificity was significantly reduced (from 80% to 73%), but sensitivity increased by a similar amount (8%). Predictably, use of these criteria for the identification of multivessel disease or left-main or triple-vessel disease was associated with higher sensitivity (mean, 81% and 86%, respectively) but also was associated with lower test specificity (mean, 66% and 53%) (89).

The results of this metaanalysis highlight the effects that differences in patient population can have on the sensitivity and specificity of standard ST depression criteria. Whereas sensitivity has been found to vary in accordance with the severity of coronary artery disease in the study population, specificity varies in accordance with the admixture of patients who have noncoronary heart disease that can produce ST-segment changes in the study population; both measures of test performance are affected by the degree of workup or referral bias (18,19,66,86,87 and 88). The combined effects of population selection are reflected in the results of one study from our laboratory (88), in which the 54% sensitivity of standard ST depression criteria when used to diagnose patients with clinical angina who had not undergone angiography was significantly lower than the 70% sensitivity seen when the criteria were used to diagnose patients with disease defined by angiography. Similar effects of population selection were observed on standard test specificity: the 97% specificity seen when the test was used for clinically normal subjects was significantly greater than the 74% specificity seen when the test was used for patients referred to angiography and found to have no significant coronary luminal obstruction greater than 50% (88).

Although some controversy persists over the value of HR-adjusted criteria (see the section Controversies and Personal Perspectives), the great majority of published studies that have adhered to proscribed requirements for ST-segment depression measurements have demonstrated that the ST/HR slope and the simple ST/HR index improve performance of the ETT as a tool for recognizing coronary artery disease. Early studies of the ST/HR slope by Elamin and colleagues (58), using an individually tailored bicycle ergometry protocol, demonstrated 100% specificity and 100% sensitivity for the detection of coronary artery disease; however, subsequent investigators have failed to reproduce this perfect test performance. Initial studies from our laboratory, using computerized ST measurements at 60 ms after the J-point and the Cornell modification of the Bruce protocol, derived criteria for the ST/HR slope and the ST/HR index that yielded a 95% specificity when used for clinically normal subjects, similar to the specificity of standard test criteria used for the same subjects (20). Test sensitivity of these criteria in separate groups of patients with clinical angina and with angiographically proven coronary artery disease were 94% and 95%, respectively, for the ST/HR slope and 88% and 93%, respectively, for the ST/HR index, all of which are significantly greater than the 68% sensitivity of use of standard ST-segment depression criteria for these populations (20). Moreover, these new criteria maintained similar specificity to standard criteria among patients in whom no significant obstruction was demonstrated by angiography (ST/HR slope, 72%; ST/HR index, 61%; standard criteria, 56%). Compared with standard test criteria, rate-recovery loops have demonstrated similarly high specificity in healthy subjects (95% vs. 93%), similar specificity in patients in whom no significant coronary obstruction was demonstrated by angiography (71% vs. 71%), and better sensitivity for the detection of coronary artery disease (93% vs. 74%) (21). Additional studies of the ST/HR slope from our laboratory and from investigators in Japan, Europe, and the United States have confirmed that the performance of this method in detecting coronary artery disease is superior (45). Improved accuracy for the detection of coronary artery disease has also been found in association with the simple ST/HR index in most but not all studies from other centers (45,53,60,68).

Detection of Anatomically and Functionally Severe Coronary Artery Disease

The poorer prognosis of patients with multivessel, and in particular three-vessel or left-main, coronary artery disease has made recognition of these patients a clinical priority. A metaanalysis of the cases of 12,030 patients that involved 60 consecutively published reports, comparing the ETT with findings at coronary angiography, found a weighted mean sensitivity of 81% (range, 40% to 100%) and mean specificity of 66% (range, 17% to 100%) for multivessel disease and mean sensitivity of 86% and specificity of 53% for three-vessel or left-main disease (89). In this metaanalysis, use of HR adjustment of ST depression was independently associated with improved specificity of the ETT for identification of three-vessel or left-main coronary artery disease (89). Factors that have been found to improve the performance of standard test criteria for these purposes include use of 2 mm or greater horizontal or downsloping ST-segment depression, early test positivity (Bruce stage 2 or earlier), and persistence of test positivity 8 minutes or more into recovery, all of which improve test specificity. In addition, both the Duke treadmill score and a consensus score that includes clinical variables have been shown to provide useful information for the recognition of anatomically severe coronary artery disease (89a,89b).

Studies from multiple investigators have demonstrated that both the ST/HR slope and the ST/HR index improve performance of the ETT for the identification of multivessel coronary artery disease. In early studies from our laboratory, standard test criteria identified multivessel coronary artery disease with a sensitivity of 76%, which is significantly lower than the 97% sensitivity associated with an ST/HR slope greater than 2.4 and than the 94% sensitivity associated with an ST/HR index greater than 1.6, with similar differences in test sensitivity for three-vessel disease (20). Similarly, when criteria that are specifically designed for the identification of three-vessel disease are used, the ST/HR slope significantly improves performance of the ETT for diagnosis of anatomically or functionally severe coronary artery disease, compared with standard test criteria. An ST/HR slope of more than 6.0 µV per beat per minute significantly improves ETT identification of three-vessel or left-main coronary artery disease and has been shown to be more accurate than standard criteria for assessment of the anatomic extent of coronary obstruction, as alternatively defined by high Duke jeopardy scores or Gensini scores (45,90,91 and 92). Further, as a functional consequence of extensive coronary obstruction, high ST/HR slopes have been found to correlate with large decreases in left ventricular ejection fraction during exercise and with abnormal results of thallium imaging

(91,92). However, the simple ST/HR index does not appear to consistently improve performance of the exercise ECG for identification of extensive coronary artery disease, compared with standard test criteria (45).

Risk Stratification and Assessment of Prognosis

Although the value of screening asymptomatic subjects for coronary artery disease remains controversial because of the poor predictive value of positive test findings in populations in which the prevalences of disease is low (18,19,22,93,94), numerous studies have documented the ability of the ETT to stratify risk in low-risk populations (12,13,22,69,70,95). An ischemic ST-segment response to exercise as judged by standard criteria was a significant predictor of cardiac morbidity and mortality in the overall population of the Seattle Heart Watch (13) and in a referred group of clinically normal male Air Force personnel (12). However, standard test criteria did not significantly concentrate risk among the large subset of asymptomatic healthy subjects in Seattle (13), did not concentrate risk in a nonreferred subset of healthy pilots and astronauts undergoing exercise testing as part of routine preflight assessment (12), was not predictive of coronary events in more than 3,000 asymptomatic men and women in the Framingham Offspring Study (Fig. 48.5) (22), and was not predictive of coronary heart disease mortality in 5,940 asymptomatic men from the usual-care arm of the Multiple Risk Factor Intervention Trial (MRFIT) (Fig. 48.6) (95).

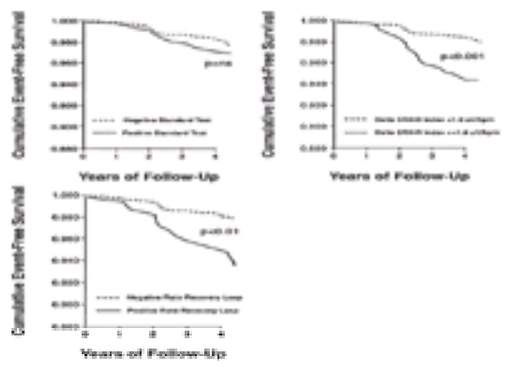

FIGURE 48.5 Kaplan-Meier plots of survival free of angina, nonfatal myocardial infarction, or coronary heart disease death according to exercise test criteria in the Framingham Offspring Study. Both the ST/heart rate (HR) index and the rate-recovery loop were predictive of outcome, with significantly lower event-free survival rates among subjects with positive than those with negative test outcomes. In contrast, no significant difference was seen in event-free survival between subjects with positive and with negative standard exercise tests, as defined according to traditional electrocardiographic criteria. ns, not significant. (Reprinted from Okin PM, Anderson KM, Levy D, et al. Heart rate adjustment of exercise-induced ST segment depression: improved risk stratification in the Framingham Offspring Study. *Circulation* 1991;83:866, with the permission of the American Heart Association.)

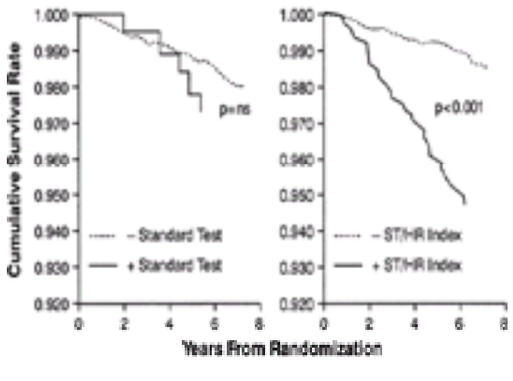

FIGURE 48.6 Kaplan-Meier plots of cumulative survival according to exercise test criteria in 5,940 asymptomatic men from the usual-care arm of the Multiple Risk Factor Intervention Trial. An abnormal ST/heart rate (HR) index identified a group of men with a significantly lower 7-year survival rate. In contrast, no significant difference was seen in survival rates between men with positive and with negative standard exercise test responses. ns, not significant. (Reprinted from Okin PM, Grandits G, Rautaharju P, et al. Prognostic value of heart rate adjustment of exercise-induced ST segment depression in the Multiple Risk Factor Intervention Trial. *J Am Coll Cardiol* 1996;27:1437, with the permission of Elsevier Science, Inc.)

In contrast, an ST/HR index greater than 1.60 µV per beat per minute significantly concentrated the risk of primarily nonfatal coronary events in asymptomatic men and women in the Framingham Offspring Study (Fig. 48.5) and stratified the risk of coronary heart disease death in MRFIT (Fig. 48.6) (22,95). In both studies, risk concentration by the ST/HR index was independent of age and additional cardiac risk factors and, in the Framingham Offspring Study, was similar in men and in women. An ST/HR index of more than 3.3 µV per beat per minute, previously demonstrated to be associated with anatomically extensive coronary artery disease (90,92), was associated with a nearly tenfold increase in risk of coronary death in MRFIT (95). In addition, an abnormal rate-recovery loop, both alone and in combination with the ST/HR index, and a blunted HR response to exercise, independent of ST depression findings, improved risk stratification by the ETT in the Framingham Offspring Trial (22,24). Perhaps most important, the decreased 7-year coronary mortality associated with an abnormal ST/HR index that was seen in the special-intervention group of MRFIT, compared with that in the usual-care group, suggests that this methodology can be used to identify men who are at increased risk of coronary death and will benefit from an aggressive risk factor–reduction program (95a).

The ETT can also be used to stratify risk among symptomatic patients who have known or presumed coronary artery disease (26,65,76,76c,96). In 4,083 medically treated patients from the Coronary Artery Survival Study registry, a high-risk subset with an annual mortality rate greater than 5% was identified when patients had positive results of standard testing and an exercise workload less than Bruce stage 1; a low-risk subset with an annual mortality rate less than 1% was identified by the ability to exercise to at least stage 3 of the Bruce protocol with a negative ST-segment response (96). The Duke treadmill exercise score (26,65,76c,96a) provides additional risk stratification to supplement that provided by ST-segment depression criteria among inpatients who have undergone angiography, outpatients who have suspected coronary artery disease, and patients who have resting ST-T–wave abnormalities. Further, among 1,300 symptomatic patients in whom coronary artery disease was demonstrated by angiography, the ST/HR index improved risk stratification by the Duke treadmill score and clinical variables and was an independent predictor of cardiac death in both men and women (97).

The prognostic value of standard ST-segment depression criteria after myocardial infarction has been well studied. In a metaanalysis of post–myocardial infarction exercise testing, Froelicher and coauthors (46) found exercise-induced ST-segment depression, poor effort tolerance, and an abnormal systolic blood pressure response to exercise to be associated with an increased risk of adverse outcome. The prognostic value of ST-segment changes after myocardial infarction in an era in which thrombolytic medications are available remains uncertain, because outcomes are similar in patients with and those without ischemic ST-segment changes (98). However, an inability to perform a predischarge low-level exercise test appears to be associated with a poor prognosis after myocardial infarction, independent of the use of thrombolytic agents (46,98). Independent of ECG, thallium imaging, or echocardiographic evidence of myocardial ischemia, attenuated HR changes, both during exercise and in the postexercise recovery phase, have been demonstrated to stratify the risk of all-cause mortality in asymptomatic subjects and in patients undergoing diagnostic exercise testing (24,24a,25a,76a,76b and 76c). An impaired chronotropic response to exercise, defined as failure to achieve 85% of target HR or a low chronotropic index, is associated with a 1.8- to 2.2-fold increased risk of all-cause mortality, after the analysis has been adjusted for confounding variables (24a). A delayed decrease in HR during the first minute of recovery provides similar risk concentration for overall mortality, even when exercise-phase HR responses were taken into account (25a).

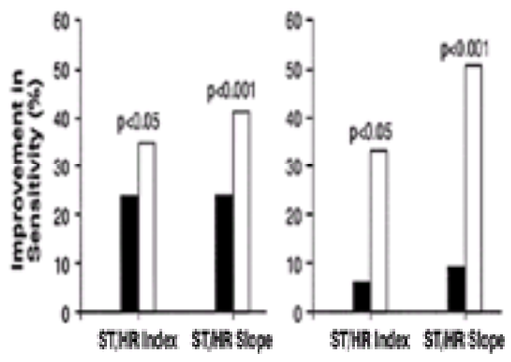
Test Performance in Women

Among the problems associated with use of the standard ETT is the lower overall test accuracy for the identification of coronary artery disease in women compared with that in men. However, it remains unclear whether the decreased test performance among women is a result of lower test sensitivity or of lower specificity. In a large subgroup of men and women from the Coronary Artery Survival Study who were matched for age, prevalence, and severity of coronary artery disease (99), no significant difference was seen in test sensitivity between women and men (76% vs. 78%), but specificity was significantly lower among women (64% vs. 73%). Barolsky and associates (100) reported similarly lower specificities when the test was used for women compared with its use for men (68% vs. 89%), with no significant gender differences in sensitivity (60% vs. 65%). However, when patients taking digitalis preparations were excluded from these analyses, standard ST-segment depression criteria had identical 95% specificity but lower sensitivity with use for women than with use for men (50% vs. 64%). We have found similar differences in

sensitivity of standard test criteria between women and men (51% vs. 67%), with matched specificities of 96% (23). Morise and colleagues (85) found lower overall test accuracy among women, which was the result of a combination of lower sensitivity and specificity associated with use for women than that associated with use for men.

It has been suggested that differences in the magnitude of ST depression between otherwise healthy men and women are a possible explanation for gender differences in test specificity. However, we found no significant difference in either standard test specificity or in the mean values or frequency distributions of ST-segment depression between clinically normal men and women (23). In contrast, the lower sensitivity of standard ST-segment depression criteria when they were used for women in our study (23) could be directly attributed to the lower magnitude of ST-segment depression found among women with coronary artery disease. Gender differences in the magnitude of ST-segment depression may be due in part to the effects of either estrogens or progesterones on the ST-segment response to exercise in women (83,84 and 85). The observation that consideration of estrogen status significantly improves the accuracy of the ETT in women (85) further supports this possibility. Last, solid-angle theory provides a basis for the theory that gender differences in ST-segment depression may in part reflect the effects of gender differences in left ventricular mass or chamber size on the projection of ST-segment changes to the body surface (29,30,33). However, this concept remains speculative.

Independent of these findings, adjustment or correction of ST depression by HR clearly improves test performance in women (23,68,101). In a study of 620 patients (23), we found that, compared with use of non-gender-specific test criteria in both sexes, use of gender-specific test criteria with high specificity improved sensitivity of the ST/HR slope for the identification of coronary artery disease in women from 84% to 91%, with no decrease in sensitivity in men. Compared with standard criteria, the increase in sensitivity provided by HR adjustment was significantly greater among women than among men, both for the detection of any coronary obstruction (40% vs. 21%) and for the identification of three-vessel coronary artery disease (50% vs. 9%) (*e*Fig. 48.6.1). Thus, at the present time, we recommend use of HR-adjusted criteria for improved test accuracy in women.



***e*FIGURE 48.6.1** Bar graphs showing sex differences in the improvement in sensitivity obtained using the ST/heart rate (HR) index and ST/HR slope compared with standard test criteria for the identification of coronary artery disease (*left*) and for the identification of three-vessel coronary artery disease (*right*). Solid bars represent men; white bars represent women. (Reprinted from Okin PM, Kligfield P. Gender-specific criteria and performance of the exercise electrocardiogram. *Circulation* 1995;92:1209, with the permission of the American Heart Association.)

CONTROVERSIES AND PERSONAL PERSPECTIVES

Although most studies performed to date suggest that HR adjustment improves performance of ST-segment depression criteria in diagnosis of coronary artery disease, some controversy remains (45,53). Initial reports from England reporting perfect test accuracy for the ST/HR slope (58) were met with well-deserved skepticism. These studies and other early reports documenting the expected imperfect performance of this technique severely hindered acceptance of HR adjustment of ST-segment depression, as did more recent studies that reported no improvement in sensitivity with use of the simple ST/HR index (53). However, these studies did not reproduce the methods previously used, and it has subsequently been shown that improved accuracy of HR-adjusted methods is strongly dependent on exercise protocol, number of ECG leads, the time of ST-segment measurement relative to the J-point, and the precision and accuracy of ST-segment measurement (44,45,51,54,71). Recent reports have demonstrated that HR adjustment improves risk stratification compared with standard test criteria in many different studies from various other centers (22,95,97), further highlighting the utility of these methods. Although final acceptance of these methods will require even further study in clinically more diverse populations, it should be emphasized that no study has demonstrated *lower* sensitivity of HR-adjusted ST depression criteria compared with standard test criteria, and numerous manufacturers have incorporated ST/HR slope calculation into their clinical ETT systems (54).

The diagnostic utility of the ETT in patients who have some resting ECG abnormalities and in patients who are receiving digoxin is variable, so caution must be used in applying ST-segment depression criteria under these circumstances. We have found that the high sensitivity and specificity of the HR-adjusted ST-segment depression criteria appear to be maintained in patients who have isolated ST-segment depression and in whom minor intraventricular conduction delays are seen on the resting ECG. In contrast, we have observed that administration of digoxin can produce marked ST-segment depression during exercise, even in healthy subjects with normal results of resting ECGs who have normal results of ETTs during exercise while they are not receiving digoxin. However, we do not have enough data to assess the performance of these criteria in patients with left ventricular hypertrophy (demonstrated by ECG or echocardiography); ongoing studies will help to address this gap in our knowledge. As a consequence, at the present time I would advocate the use of imaging modalities in conjunction with ECG criteria in diagnosis for patients who have left ventricular hypertrophy and patients who are receiving digitalis preparations.

My own perspective is that exercise ECG is not optimally used in current practice. In large part because of limited confidence in the accuracy of the simple ETT, the number of nuclear and echocardiographic imaging stress tests performed in the United States has increased dramatically. Although these methods provide important localizing information and are clearly indicated in situations in which performance of the exercise ECG is known to be poor, I believe that imaging stress tests are overused for the routine assessment of patients who have known or suspected coronary artery disease. It is also clear that exercise testing in general is inappropriately applied in large numbers of low-risk patients who undergo screening stress tests as part of annual physical examinations. The appropriate application of Bayesian analysis to these populations demonstrates that the large number of false-positive test responses (regardless of the test used) is a consequence of the extremely low pretest likelihood of disease and leads to further noninvasive and invasive testing at substantial cost and some risk to these patients. A better understanding of the limitations and indications of exercise testing and application of the more accurate HR-adjusted ST-segment depression criteria hold promise for improvement of the use and accuracy of the exercise ECG in clinical practice.

THE FUTURE

The development of new ECG criteria that have increased sensitivity at high specificity based on precise computer-based measurements is essential to improving the performance of the ETT. The increased accuracy seen with incorporation of measures of chronotropic incompetence in analysis of the ETT (24,25) suggests that further improvements in test performance may be achievable with better adjustment of ST-segment depression for HR changes that occur with exercise. Additional refinements in the ETT may be achieved by the combination of HR-adjusted ST-segment depression criteria with less-expensive imaging modalities, such as stress echocardiography, to increase accuracy and localize ischemia. Novel and interesting approaches to ETT analysis, based on examination of ECG findings that are distinct from the ST segment itself, also hold promise. These include measures of amplitude, duration, and frequency content of the QRS complex and measures of duration and dispersion of repolarization during exercise. Development and further refinement of computerized methods are needed before many of these new approaches can be adequately evaluated and used in clinical practice.

OVERVIEW

Since its development in the early 1950s to assess mitral valve (MV) motion, echocardiography has become the most commonly performed cardiac imaging test. It provides data with high spatial and temporal resolution while being noninvasive, portable, and inexpensive relative to competing technologies. Ultrasound images can be obtained along a single scan line (M mode) or swept along a two-dimensional sector through the heart, and extensions to three-dimensional imaging are in development. An echocardiographic examination should consist of a structured interrogation of all cardiac chambers and valves, with the quantitative data providing chamber size, stroke volume, and transvalvular flow. Systematic examination of the left ventricle localizes regional wall motion abnormalities and characterizes hypertrophic, dilated, and restrictive cardiomyopathies. Valve morphology is readily seen, although Doppler interrogation and often transesophageal imaging are necessary for quantifying stenosis and regurgitation. Cardiac tumors, thrombi, and vegetations are commonly diagnosed by transthoracic echocardiogram, although the transesophageal approach has a higher sensitivity. Evolving echocardiographic techniques include three-dimensional imaging, parallel computer processing to improve frame rate and resolution, contrast echocardiography for myocardial perfusion, and all-digital storage and transmission.

INTRODUCTION AND HISTORY

Echocardiography (cardiac ultrasound) is the most powerful diagnostic tool in cardiology. Although technically demanding, its diagnostic accuracy, cost effectiveness, availability, and noninvasive nature have made it the largest cardiovascular expense item in the Medicare budget.

As summarized by Feigenbaum (1), interest in sonic testing of materials spurred Hertz (an engineer) (2) and Edler (a clinical cardiologist) (3) to collaborate on the echocardiographic identification of normal and pathologic cardiac structures. The major initial contribution was identifying changes of the anterior mitral leaflet in rheumatic mitral stenosis (MS) (4,5), independently confirmed by Joyner et al. (6) and Feigenbaum (7), who did the most to popularize the technique in the United States (8).

An echocardiographic examination consists of three elements: M-mode and two-dimensional imaging (the subjects of this chapter) and Doppler interrogation (see Chapter 51). Echocardiography provides functional and anatomic information, with virtually no macroscopic feature of the heart inaccessible to visualization and quantitation. The physical and instrumentation principles of echocardiography are summarized in Chapter 46 and elsewhere (9,10 and 11).

MODALITIES OF ECHOCARDIOGRAPHY

M-mode echocardiography was the first form of cardiac ultrasound (Fig. 49.1), in which a single beam is directed toward the heart and reflected signals are displayed on a strip chart or oscillograph at high data rates (>1,000 Hz in early machines, 200 Hz in most contemporary machines). Two-dimensional echocardiography (Fig. 49.2) is created by sweeping an ultrasound beam back and forth through an arc either mechanically or by phased-array transducer. Minimizing the depth of interrogation or the width of the sector scan can enhance the frame rate. Structural resolution is dependent on imaging depth and transducer frequency. Transducer focus improves resolution in the focal zone, at the expense of greater divergence for deeper structures.

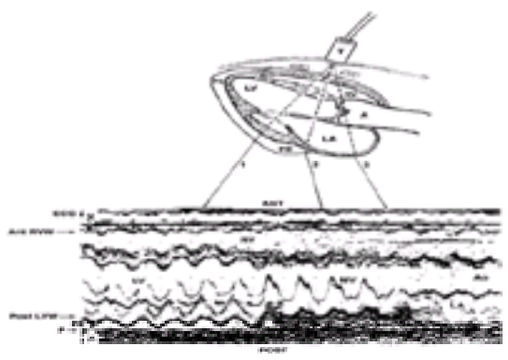

FIGURE 49.1 M-mode echocardiogram displaying motion along a single scan line within the heart. Here, the transducer (T) is swept from the left ventricular level (*left side of scan*) to the mitral valve level (*middle*) and up to the left atrial level (*right*). A, aorta; Ao, aorta; ANT, anterior; ECG, electrocardiogram; LA, left atrium; LV, left ventricle; MV, mitral valve; P, pericardium; PE, pericardial effusion; POST, posterior; RV, right ventricle; RVW, right ventricular wall. (From Cheitlin MD, Sokolow M, McIlroy MB. *Clinical cardiology*, 6th ed. Norwalk, CT: Appleton & Lange, 1993, with permission.)

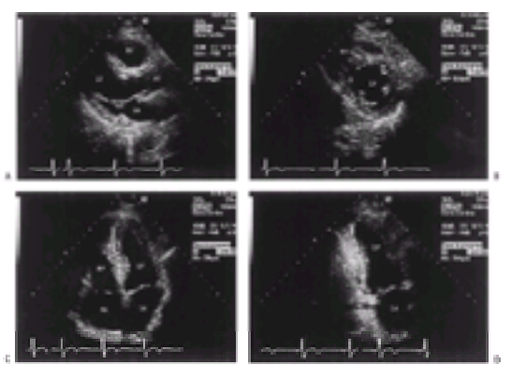

FIGURE 49.2 Two-dimensional echocardiography. Four standard views. **A:** Parasternal long axis. **B:** Parasternal short axis. **C:** Apical four chamber. **D:** Apical two chamber. AO, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

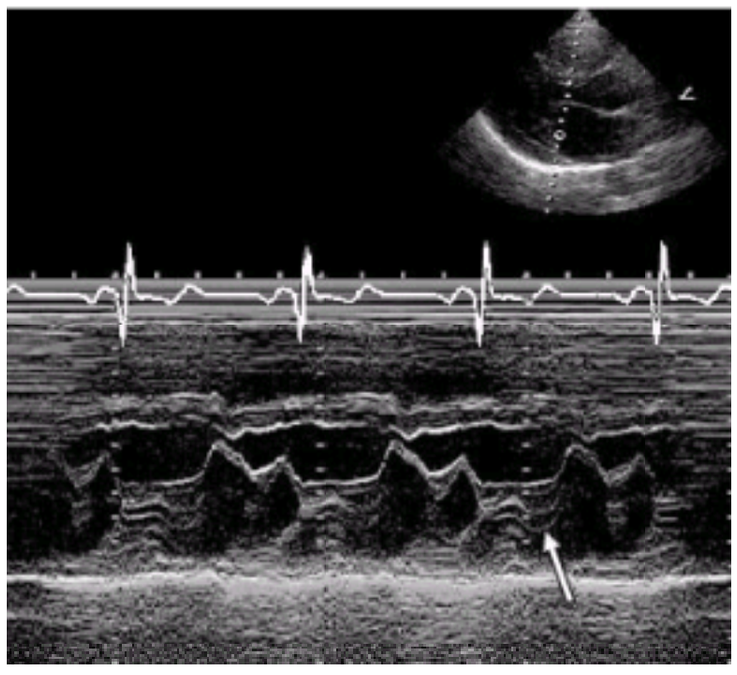

M-mode tracing of posterior leaflet mitral valve prolapse. Note the posterior displacement of the posterior mitral leaflet after the leaflets close in systole.

ECHOCARDIOGRAPHIC EVALUATION OF THE CARDIAC CHAMBERS

Left Ventricle

Left ventricular (LV) evaluation is probably the single most important clinical application of echocardiography. A combined M-mode, two-dimensional, and Doppler evaluation of the LV can provide reliable information about overall systolic function, regional wall motion, and ventricular mass and geometry.

Evaluation of Global Systolic Function of the Left Ventricle

Reliable determinations of LV function require the qualitative and quantitative evaluation of images taken from several standard windows. Typically, the LV is first viewed in the parasternal long-axis and short-axis planes (Fig. 49.2). From these, M-mode tracings are generated. If quantitation of M-mode tracings is used clinically, the American Society of Echocardiography recommends obtaining these from the parasternal short axis in the two-dimensional M mode (12,13) (Fig. 49.3).

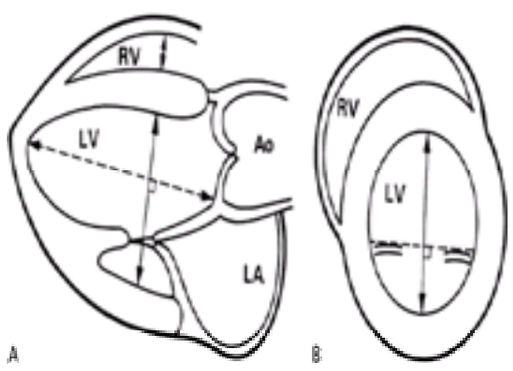

FIGURE 49.3 Quantitation of left ventricular size. Measurement sites recommended by the American Society of Echocardiography (12). **A:** Parasternal long-axis view. **B:** Parasternal short-axis view. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle. (Reproduced with permission of the American Society of Echocardiography.)

M-Mode Evaluation

Standard M-mode measurements are shown in Figure 49.4. Fractional shortening by M mode is given by left ventricular diameter at end diastole ($LVED_d$) – left ventricular diameter at end systole ($LVES_d$)/$LVED_d$ where ED_d is the LV minor axis in diastole and ES_d in systole. Normally, fractional shortening is approximately 50% and is considered clearly abnormal when it falls below 30% (8,14). Another M-mode measurement is the E-point septal separation (15,16) (a marker of LV dysfunction when it exceeds 7 mm).

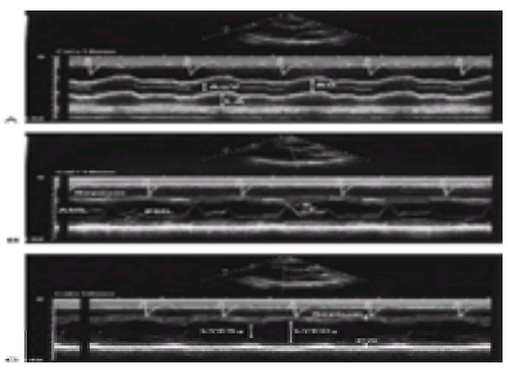

FIGURE 49.4 Standard measurements from M mode. Shown are sweeps at the aortic level **(A)**, mitral valve level **(B)**, and left ventricular level **(C)**. AML, anterior mitral leaflet; Ao, aortic root diameter; AoV, opening of aortic valve; EF, E to F slope (rate of closure of mitral valve); LA, end systolic left atrial diameter; $LVED_d$, left ventricular diameter at end diastole; $LVES_d$, left ventricular diameter at end systole; PML, posterior mitral leaflet; PW, posterior wall thickness; SEPTUM, septal thickness.

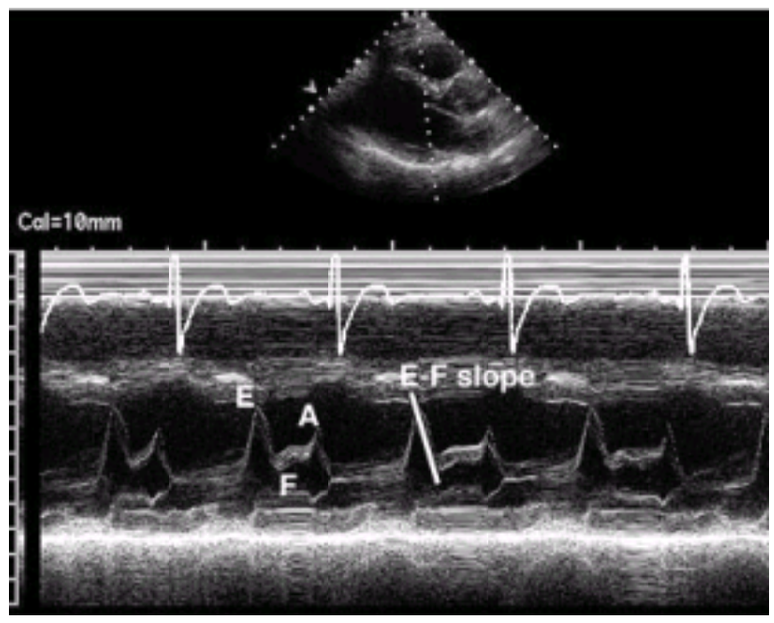
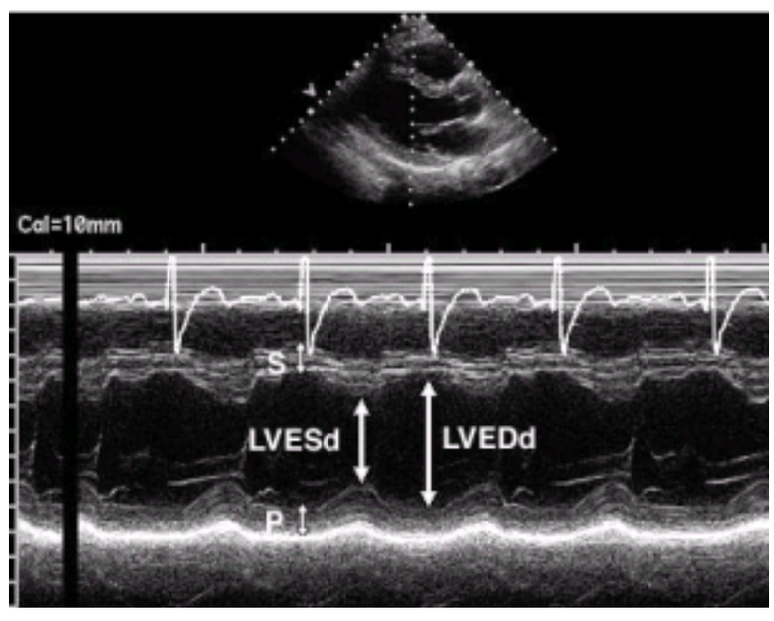
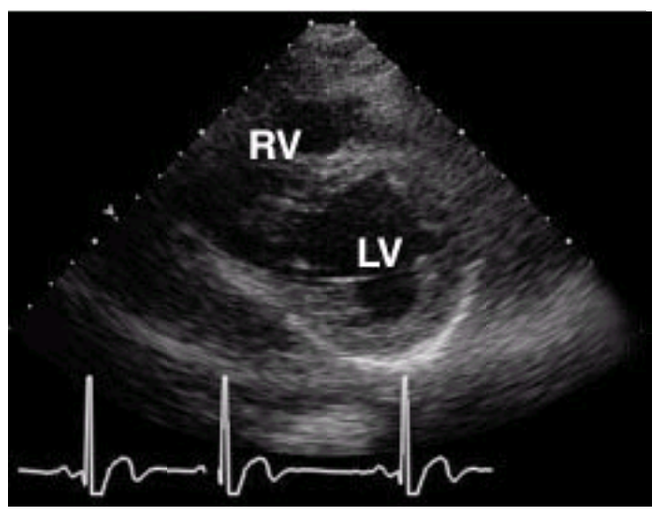


M-mode trace through the level of the mitral valve from the parasternal long-axis view. Note the E point, F point, A point, and the E-to-F slope.



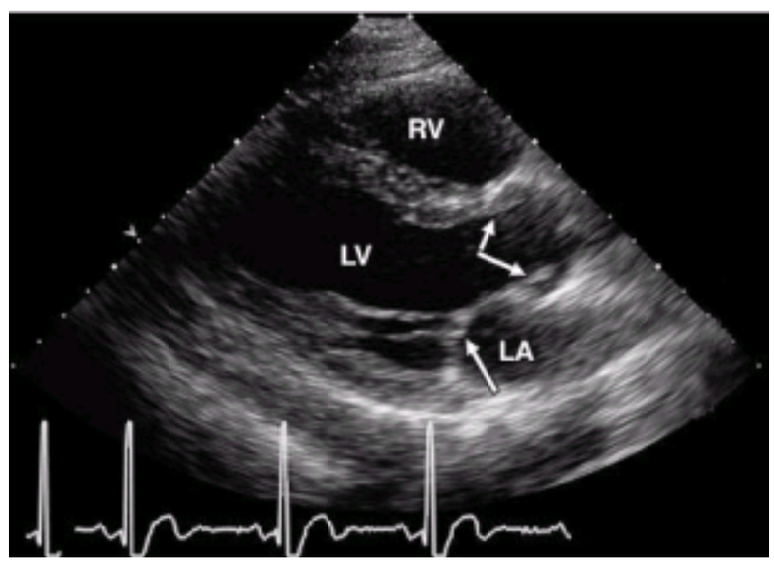
M-mode at the left ventricular (LV) level from the parasternal long-axis view. Note the location of the various measurements. LVEDd, LV end-diastolic dimension; LVESd, LV end-systolic dimension; P, posterior wall thickness; S, interventricular septal wall thickness.

A further M-mode guide to overall LV function is aortic root motion, largely reflecting the atrial filling curve (17,18). With normal cardiac output, change in atrial volume moves the aorta anteriorly approximately 14 mm, but with low stroke volume, the aorta barely moves (19). This also yields information about diastolic function. In youth, most atrial emptying occurs early in diastole, with atrial contraction accounting for less than 30% of the total. Hypertrophy and aging slow early passive relaxation, and therefore the majority (up to 70%) of emptying occurs late in diastole at the time of atrial contraction. Finally, aortic valve (AV) opening yields useful information about LV function, opening fully when stroke volume is normal but incompletely when stroke volume falls.

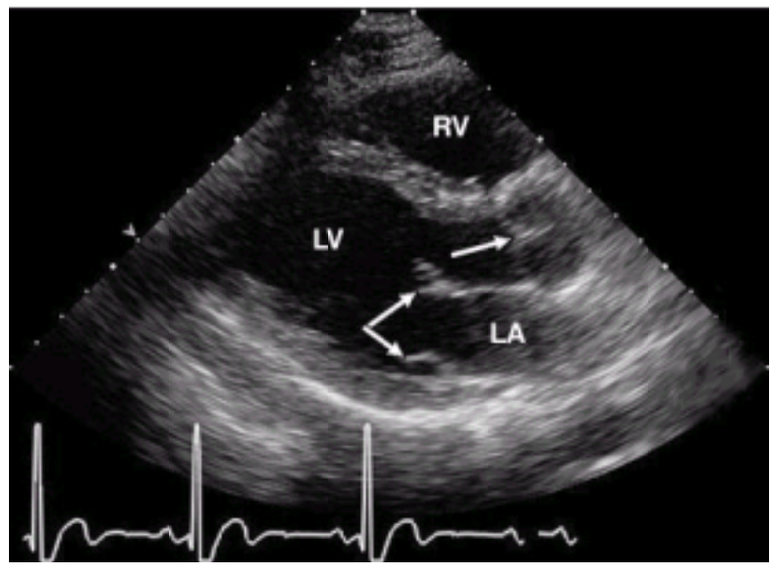


Short-axis view of the left ventricle (LV) from the parasternal window of a transesophageal echo. RV, right ventricle.

Magnified view of the short-axis of an aortic valve from the parasternal window as seen in diastole. Note the position of the LCC (left coronary cusp), RCC (right coronary cusp) and NCC (noncoronary cusp).



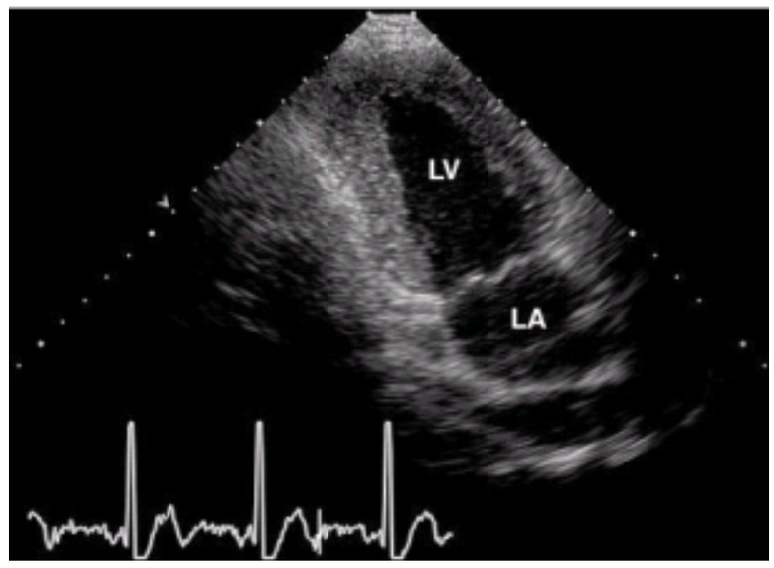
Normal parasternal long-axis view by transthoracic echo (in systole). Note the closed mitral valve (*single arrow*) and opened aortic valve (*double arrow*).



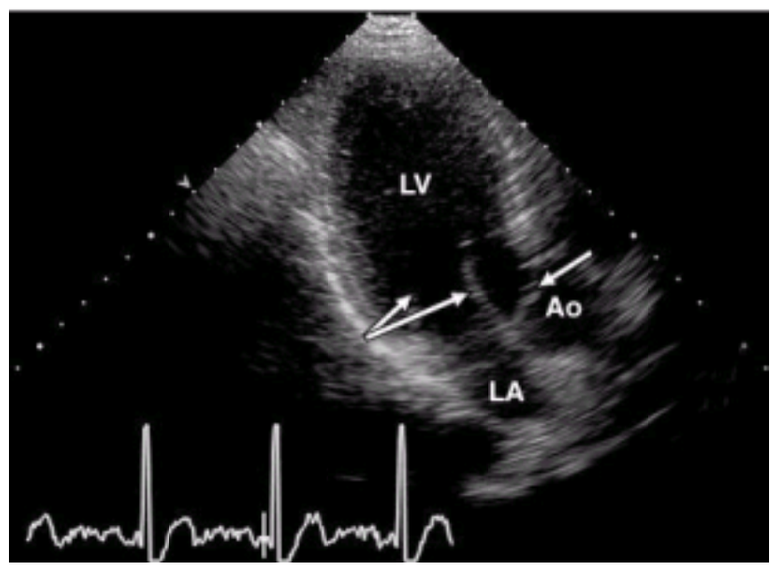
Parasternal long-axis view of a transthoracic echo in diastole. Note the left atrium, left ventricle, and right ventricle. The mitral valve (*double arrow*) is open, and aortic valve (*single arrow*) is closed.

Apical Window Imaging

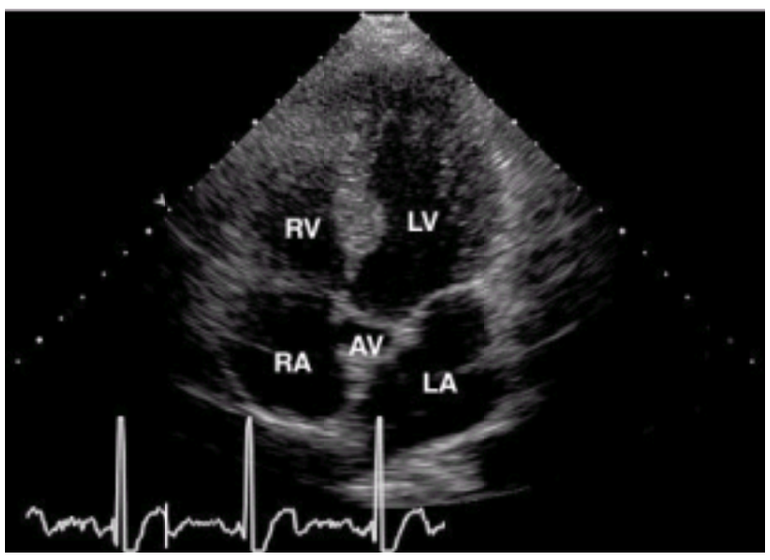
After the parasternal images, the left ventricle is displayed along its long axis from the apical impulse location, with axial rotation of the transducer producing any number of long-axis views. However, the standard examination typically includes the apical four- and two-chamber views (orthogonal to each other, Fig. 49.2) and the apical long-axis view (20,21).



Normal apical two-chamber view by transthoracic echo. Note the location of the anterior wall of the left ventricle (to the right) and the inferior wall (to the left).



Normal apical long-axis view by transthoracic echo in diastole. Note the open mitral valve designated by the double arrow and the closed aortic valve designated by the single arrow. The posterior wall of the left ventricle is to the left of the screen and the anteroseptum is to the right.



Normal apical five-chamber view by transthoracic echo. View is obtained by angling the transducer anteriorly from the apical four-chamber view, thus bringing the aortic valve (AV) into view. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

VIDEO

Video 49.1 Normal apical five-chamber view in a transthoracic echo obtained by angling the transducer anteriorly from the four-chamber view to bring the aortic valve into view (see the center of screen). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

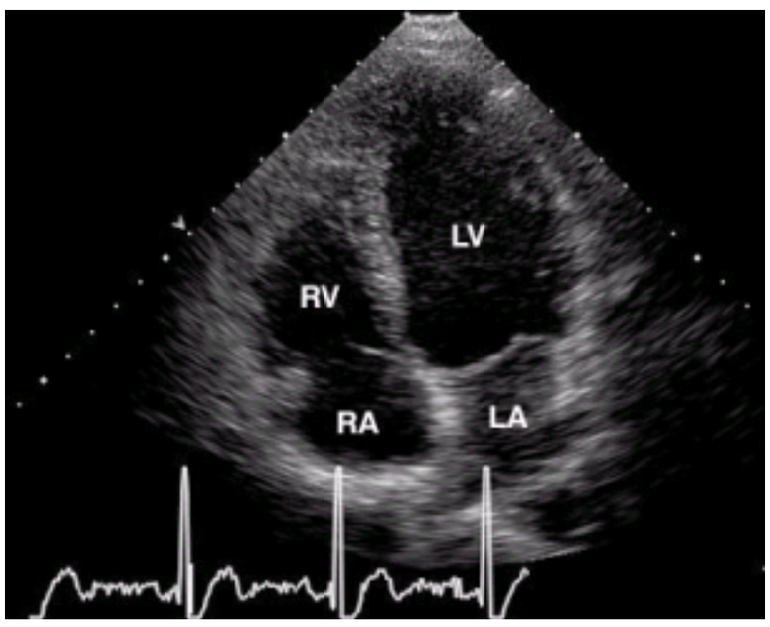
VIDEO

Video 49.2 Normal apical four-chamber view of a transthoracic echo. Note that the left ventricle is on the right of the screen showing the septum and lateral walls, and the right ventricle is to the left. The left atrium is in the lower right of the screen and the right atrium to the lower left. The mitral and tricuspid valves can be seen in this view. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

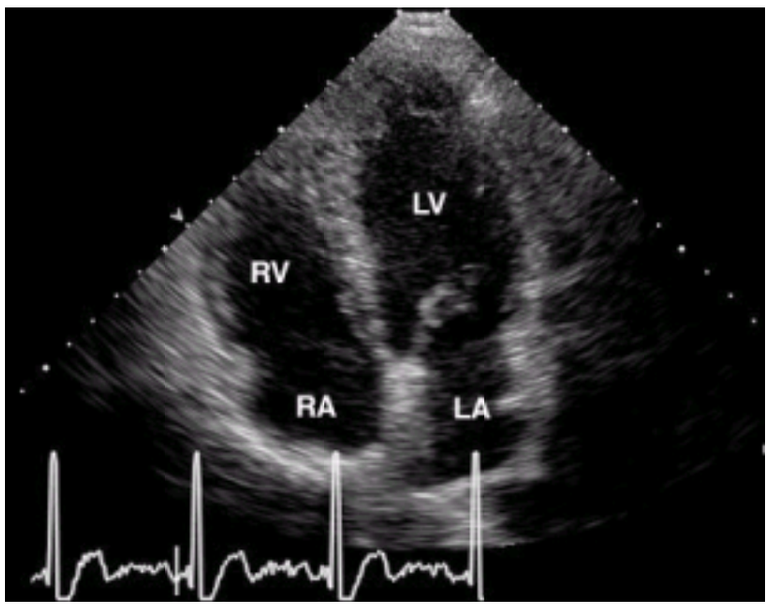
VIDEO

Video 49.3 Normal apical two-chamber view of a transthoracic echocardiogram. The anterior wall of the left ventricle is on the right of the screen and the inferior wall is to the left. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The four-chamber view (20) displays the midseptum and inferolateral LV wall and shows the right ventricle (RV) at its widest point, including the moderator band. At the cardiac base, the mitral and tricuspid valves (TVs) are shown, with the TV being displaced approximately 1 cm more apically than the MV by the membranous septum. The atria are shown partitioned by the interatrial septum. Posterior transducer angulation reveals the coronary sinus and papillary muscles. Anterior angulation shows the LV outflow tract. To enhance endocardial definition, ultrasonic contrast agents that cross the lungs intact (unlike agitated saline contrast) can be used. Because ultrasound energy can destroy these bubbles, intermittent insonification (e.g., once per cardiac cycle) permits the development of greater contrast effects in the myocardium and the cavity. Further contrast augmentation is gained by displaying the second harmonic of the transmitted ultrasound carrier frequency.

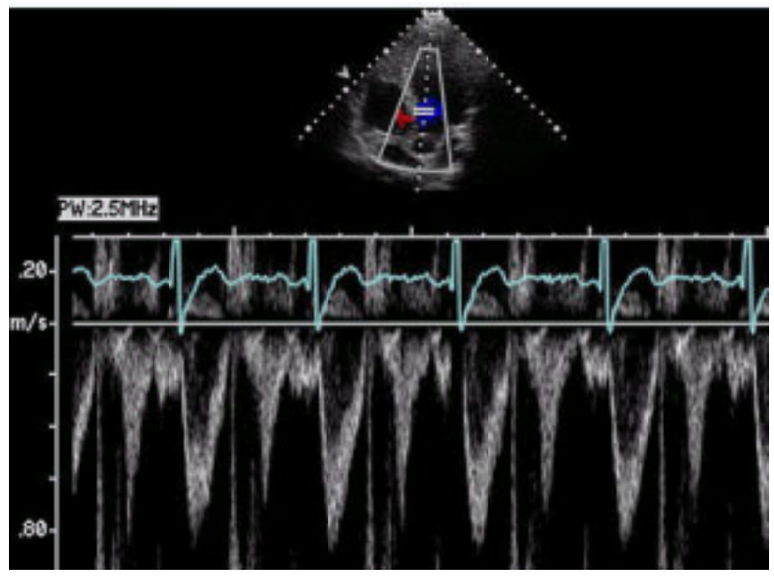


Normal apical four-chamber view by transthoracic echo (in systole). Closed mitral (*right*) and tricuspid (*left*) valves.



Normal apical four-chamber view (in diastole) by transthoracic echocardiography. Note location of left ventricle (LV), right ventricle (RV), open mitral valve

(right), and open tricuspid valve (*left*) and corresponding atria. LA, left atrium. RA, right atrium.

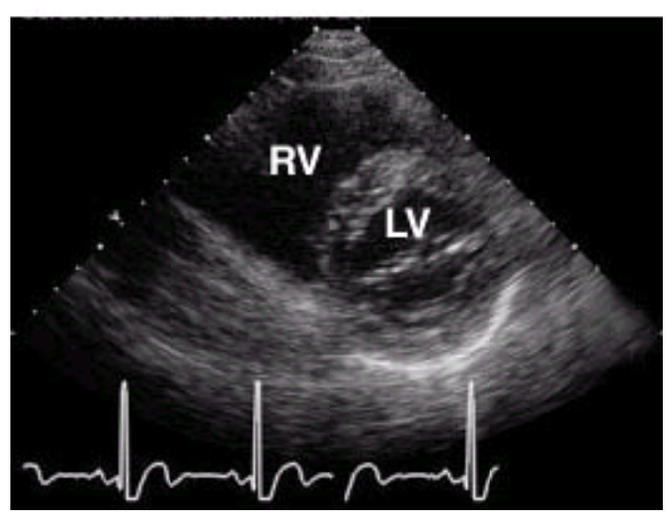


Normal pulsed wave Doppler signal from the left ventricular outflow tract. Note the maximal velocity is only 80 cm/second.

The shape of a healthy left ventricle is a truncated ellipsoid with the long axis roughly twice the length of the short axis. As the heart decompensates, it assumes a more globular shape (22) (eFig. 49.4.1). Diastolic wall thickness is viewed in absolute terms (approximately 1 cm is normal, >1.2 cm is considered hypertrophied) and relative to LV cavity size, with a radius-thickness ratio that is typically about 2:1. The distribution of hypertrophy is important. In secondary hypertrophy (e.g., from hypertension or outflow obstruction), the increase in wall thickness is uniform or concentric, whereas it is typically confined to the septum in asymmetric hypertrophy. Regional LV function is assessed by looking for inward motion of the endocardium and, more importantly, segmental thickening. Myocardial texture is also informative. Scar formation results in a thin bright segment, and infiltrative disease yields increased reflectance in approximately half of such cases. Geometric uniformity is another useful feature and becomes important after infarction. LV remodeling in its extreme form involves an entire region in an aneurysm (eFig. 49.4.2), which is distinguished from simple dysfunction by deformity throughout the cardiac cycle. Generally, all endocardial segments should move inward synchronously, with incoordinate contraction suggesting at least moderate LV dysfunction. However, it can also be seen with left bundle branch block (23) or RV pacing. Finally, the longitudinal motion of the heart can be observed by the descent of the cardiac base (annular plane) toward the nearly fixed cardiac apex (24). A decrease in this parameter is often the first sign of nascent cardiomyopathy.

***e*FIGURE 49.4.1** Dilated cardiomyopathy. Parasternal long-axis view demonstrating an enlarged left ventricle with incomplete closure of the mitral valve and left atrial enlargement.

***e*FIGURE 49.4.2** Lateral left ventricular aneurysm. Apical four-chamber view of a patient with a recent lateral wall infarct. Note that the neck of the aneurysm is quite broad, indicating that this is a true aneurysm and not a pseudoaneurysm.



Parasternal short-axis view of the mitral valve and left ventricle (LV). RV, right ventricle.

Video 49.4 Normal parasternal short-axis view of the left ventricle by transthoracic echo. The anterior wall is located at the top and the inferior and posterior walls are located towards the bottom of the screen. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.5 Normal parasternal long-axis view in a transthoracic echocardiogram. The mitral and aortic valves are well seen, as are the anteroseptal and posterior walls of the left ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Left bundle branch block. Wide QRS complex, negative in lead V_1, is associated with secondary T-wave inversions.

Quantitation of Left Ventricular Function

Although automated methods of measurement have been developed for assessing LV function (25), the standard method remains manual border tracing (26,27 and 28). Although ejection fraction (EF) is commonly estimated by visual inspection, this is prone to error and interobserver variability.

M-mode measurements of LV function (29,30,31 and 32) are limited because they use a single LV short-axis dimension, generally assuming a long-axis–short-axis ratio of 2:1 to extrapolate information to three dimensions. Unfortunately, many pathologic states introduce regional asymmetry or alter the ratio toward unity. Because volume is a cube function of dimension, errors are compounded (26,33,34). In contrast, two-dimensional volumes and mass compare favorably to those that are obtained from angiography and autopsy, but only if care is taken to optimize data acquisition and analysis (12).

The best apical images are usually obtained with the patient lying in the left recumbent position. Image enhancement can be accomplished by using a mattress with a removable panel and positioning the sonographer to the patient's left. A foreshortened ventricle can be avoided by maximizing the visualized long axis. Because the heart moves with respiration, images should be obtained during unforced suspended expiration. Digital acquisition enhances accuracy and ease of review, with systolic frames stored from four views in a quad screen format. Routine digital storage also allows easy comparison with prior studies. Finally, on-line sonographer measurement is preferred to off-line measurement for accuracy and for improved workflow.

Electronic calipers are used to measure distances and areas. To quantify LV volume, the endocardium is traced in systole and in diastole, using the highest frequency transducer to enhance endocardial definition. *End systole* is defined as the last frame before mitral opening with end diastole just before valve closure.

The biplane method of disks (referred to less precisely as *modified Simpson's rule*) most closely predicts angiographic volumes (21,26,27 and 28). The single-plane area length is also suitable, provided that the ventricle is symmetric (35) (Fig. 49.5). These algorithms are applied to orthogonal apical two- and four-chamber views. The apical four-chamber view (21) should display the true LV apex, showing neither the aorta nor the coronary sinus while maximizing RV size. The two-chamber view should not include any portion of the RV, aorta, or right atrium (RA) (Fig. 49.2).

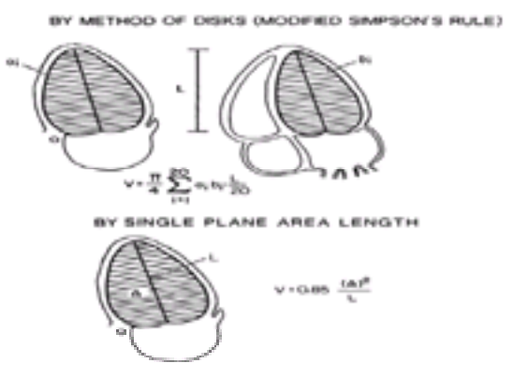


FIGURE 49.5 Left ventricular (LV) volume determination. The biplane method of disks (*upper panels*) requires orthogonal two- and four-chamber apical views and is more accurate in asymmetric hearts than the single-plane method shown below. In symmetric ventricles, the single-plane method is almost as accurate as the biplane one. [Reproduced with permission from the American Society of Echocardiography (26).

LV mass computed from two-dimensional images is more reproducible and anatomically rational than M-mode values but is still limited by relatively wide standard deviations (±35 g for 95% confidence intervals) (36,37). The truncated ellipsoid and area-length methods are both recommended by the American Society of Echocardiology for mass determination (12,38).

Clinical Use

End systolic volume is a powerful measurement. Sagawa et al. (35) have noted that the end systolic pressure-volume ratio is relatively insensitive to loading conditions and is a good marker for contractility. Fortunately, it is one of the easiest and most reproducible echo volume measurements to make (39). Borow et al. (40) have shown that complications following aortic and mitral surgery were confined to patients with end systolic volume indexes greater than 66 mL per m^2. Hammermeister et al. (41) showed that an end systolic volume index of 45 mL per m^2 led to a threefold increase in mortality in patients with coronary artery disease (50 vs. 150 deaths per 1,000 patient-years). White et al. (42) confirmed these data with ventriculography in 600 patients following myocardial infarction. After accounting for end systolic volume, the other variables showed no additional predictive value. The Study of Survival and Ventricular Enlargement (43) showed that the end systolic size (area) was the most powerful predictor of survival. In summary, if an echocardiography laboratory were to choose one simple measurement to report, end systolic volume index would be a strong candidate parameter.

End diastolic volume is important, although less predictive of cardiac events. Endocardial definition is often problematic, especially of the lateral wall (95% confidence intervals of ±25 mL) (37). EF is probably the most commonly cited clinical index of LV function, which should be measured (stroke volume/end diastolic volume, 95% confidence interval of ±6%) rather than visually estimated. Although not as predictive as end systolic volume, EF provides highly useful prognostic data, as shown by a large-scale thrombolytic trial (44) and White et al.'s study (42).

Video 49.6 Apical long-axis view of a patient with severe left ventricular dysfunction and annular dilatation causing 4+, centrally directed mitral regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Wall Thickness and Left Ventricular Mass

Hypertrophy is defined anatomically as an increase in the mass of the ventricular myocardium, but wall thickness often serves as its surrogate. Initially obtained from M mode (45), wall thickness is usually determined from two-dimensional images with normal values from 0.6 to 1.1 cm. Wall thickness should be measured at the onset of the QRS (rather than in diastasis), because atrial contraction may thin the wall considerably. Analogously, if filling volume is greatly reduced (e.g., in cardiac tamponade), the wall becomes thickened despite normal mass and a dilated ventricle may have increased mass with normal thickness. To overcome the shortcomings of simple wall thickness, actual mass can be estimated. However, M-mode formulas (29,46,47 and 48) suffer the same theoretical limitation as the cube method of estimating LV volume, especially in hearts with asymmetric thickening (49). Despite this, the Framingham Study has used M-mode methods to yield valuable insight into the electrocardiographic (ECG) criteria for hypertrophy (47,50,51) and the adverse prognosis of ventricular hypertrophy (52).

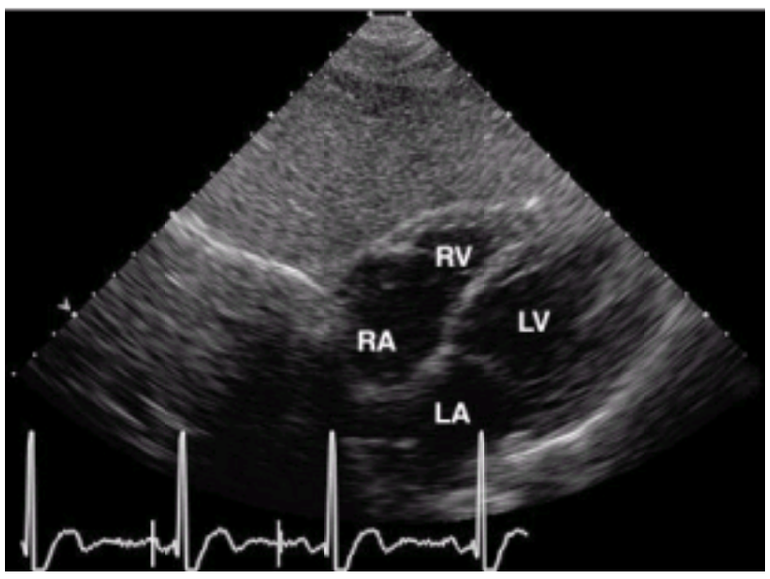
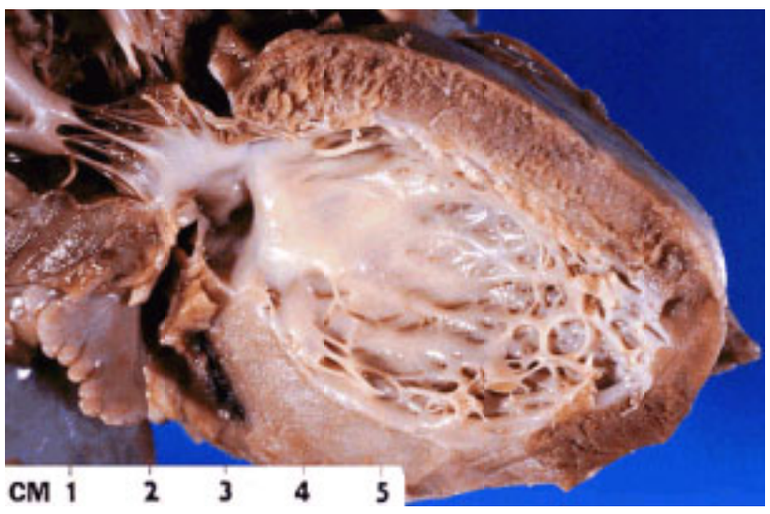
Video 49.7 Transthoracic apical four-chamber view of a patient with amyloidosis. Note the thickened “sparkling” walls of the right and left ventricles. Both the mitral and tricuspid valves are mildly thickened and there is biatrial enlargement and a trivial pericardial effusion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.8 Transthoracic subcostal view of a patient with amyloidosis showing markedly thickened right and left ventricular walls, showing the characteristic “sparkle.” The right ventricle is towards the top of the screen and the right ventricle free wall is 1.5 cm thick. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Most two-dimensional methods for determining LV mass (12,36,37 and 38) are similar because they combine a short-axis estimation of wall thickness with an estimation of ventricular length. The difference between the endocardial and epicardial volumes multiplied by the specific gravity of myocardium (1.05 g per mL) yields myocardial mass. Even two-dimensional methods have relatively wide 95% confidence bounds (±25 g) (34,36,37).



Long-axis view from the subcostal window of a transesophageal echo showing the left and right ventricles (LV and RV) and the left and right atria (LA and RA).



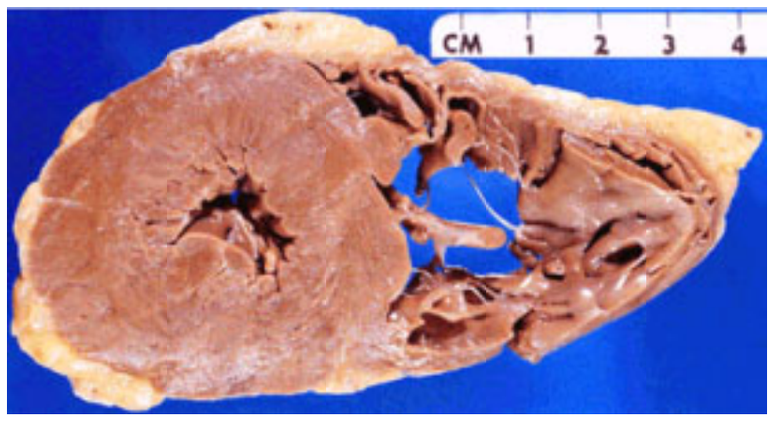
Fibroelastosis and hypertrophy of the left ventricle. This specimen was obtained from a 3-month-old child with incomplete closure of the foramen ovale.

Three-dimensional imaging techniques may improve the reproducibility of volume and mass measurements, with preliminary studies demonstrating accuracy comparable to that of magnetic resonance imaging and computed tomographic echocardiography (53,54,55,56,57,58,59,60 and 61). If these techniques could be obtained with standard instruments, and the requirement for hand tracing eliminated by automation, echocardiographic mass could be routinely determined.

eTable 49.0.1 lists normal values for LV volume and mass. Left atrial volumes are derived from several studies (12,21,62,63,64,65,66,67,68,69 and 70) and may serve as a reference for clinically measured studies.

***e*TABLE 49.0.1** NORMAL VALUES FOR LEFT AND RIGHT VENTRICULAR VOLUME, LEFT VENTRICULAR MASS, AND LEFT AND RIGHT ATRIAL VOLUME DERIVED FROM SEVERAL STUDIES

End diastolic volume left ventricle (two-and four-chamber apical views/biplane method of disks)
Male: 111 mL index 58 mL/m^2 (80)
Female: 80 mL index 50 mL/m^2 (66)
End systolic volume left ventricle (two- and four-chamber apical views/biplane method of disks)
Male: 34 index 18 mL/m^2 (30)
Female: 29 index 18 mL/m^2 (32)
Ejection fraction
61 ± 10%
End diastolic volume right ventricle (based on normal ratio of left ventricle–right ventricle of 0.6)
Male: 67 mL
Female: 48 mL
Left ventricular mass (truncated ellipsoid)
Male: 135 g index 71 g/m^2 (96)
Female: 99 g index 62 g/m^2 (89)
Volume-mass ratio: 83
Left atrial volume (two- and four-chamber apical views/biplane method of disks)
Male: 38 mL index 21 mL/m^2
Female: 32 mL index 21 mL/m^2
Left atrial volume four-chamber view (single-plane area-length)
Male: 38 mL
Female: 34 mL
Left atrial volume two-chamber view (single-plane area-length)
Male: 46 mL
Female: 36 mL
Right atrial volume four-chamber view (single-plane area-length)
Male: 39 mL
Female: 27 mL



Left ventricular hypertrophy secondary to chronic hypertension with secondary ectasia of the right ventricle.

Two-Dimensional Echocardiography in Ischemic Heart Disease

Myocardial infarction produces regional akinesis within seconds of coronary occlusion. The presence of scarring (thinning and increased brightness) indicates an old infarction. The interface between contracting and akinetic tissue forms a visually distinctive “hinge point.” The diffuse hypokinesis of ischemic cardiomyopathy can be difficult to distinguish from primary myocardial disease.

To localize segmental wall motion abnormalities in a standardized format, the American Society of Echocardiography has recommended dividing the ventricle into 16 segments (12). Grading of these segments generates a wall motion score index that has been shown to have prognostic value (71). A diastolic deformity, sharply demarcated, indicates aneurysm formation. Hypokinesis without wall thinning suggests ischemia rather than completed infarction, but the specificity of this is not high. Echocardiography is valuable in the assessment of chest pain (72,73,74,75 and 76), because a normal echocardiogram makes cardiac ischemia unlikely. The reliability and speed in detecting ischemic hypokinesis have led to the use of echocardiography in conjunction with exercise and pharmacologic stress testing (see Chapter 50).

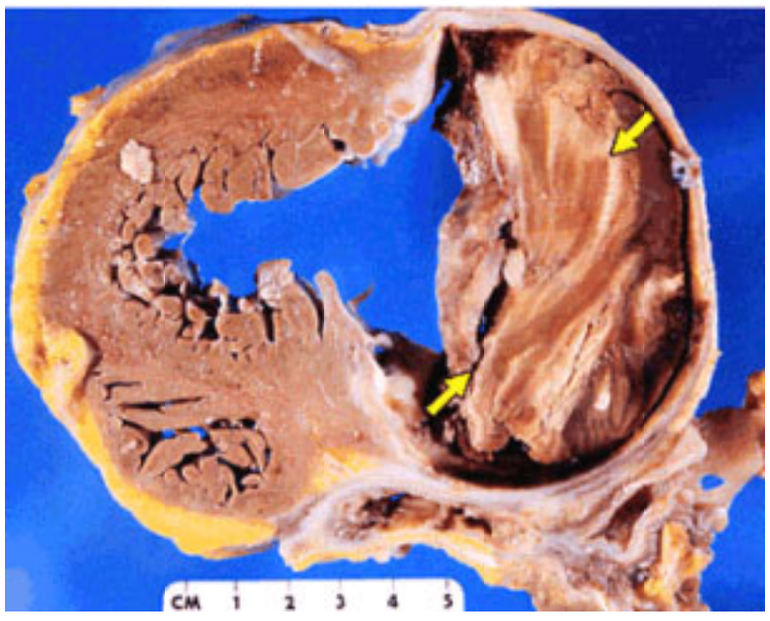
Histology showing the early stages of healing following myocardial infarction. These changes are typical in the second week after the acute event. This is a hematoxylin-eosin stain showing removal of the necrotic myocytes and early ingrowth of vascular tissue and fibroblasts, particularly evident at the edges of the lesion (*yellow arrows*).

Complications of Myocardial Infarction: Recognition by Echocardiography

Many of the complications of myocardial infarction can be diagnosed by a bedside echocardiogram. LV thrombi occur frequently in the setting of extensive anteroapical infarction and rarely in inferior infarction. They can appear within days of the infarction and typically are highly mobile. Older thrombi tend to have smooth surfaces and a texture like liver and may have a layered appearance (eFig. 49.5.1). The more mobile and irregular the surface of the thrombus, the higher the risk of embolization (77,78,79 and 80). Thrombi can be difficult to differentiate from apical trabeculations, which may be pronounced in cardiomyopathy (81).

***e*FIGURE 49.5.1** Apical thrombus in the apical two-chamber view. This patient had recently experienced a large anteroapical myocardial infarction, and this apical thrombus, approximately 2.5 cm in greatest dimension, subsequently developed. LV, left ventricle.



Healed, atrophic posterolateral infarct and ventricular aneurysm containing a mural thrombosis (*yellow arrows*).

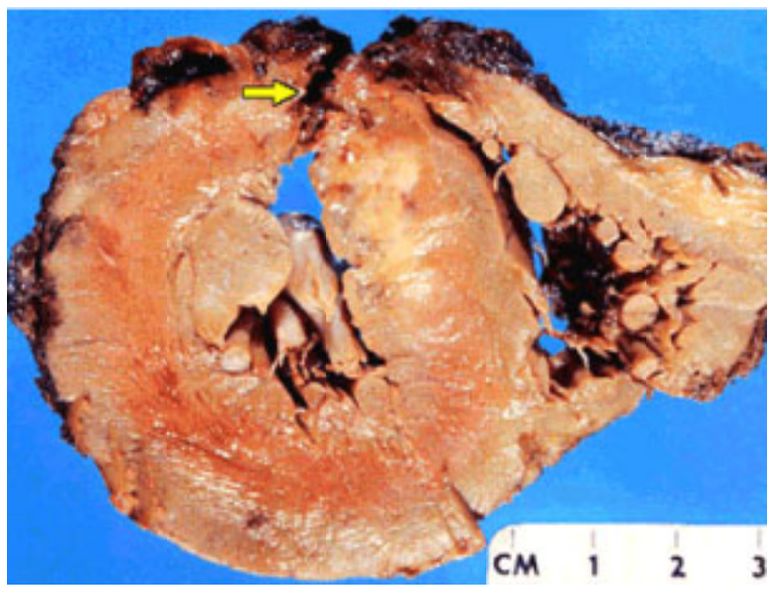
Embolus. Dislodged thrombus that embolized to the toes and caused gangrene (*arrows*).

Postinfarction aneurysms are characterized by a wall motion abnormality with a diastolic deformity. The ability of echocardiography to delineate aneurysm is emphasized (82,83 and 84) (*e*Fig. 49.4.2).

Video 49.13 Post–myocardial infarction true aneurysm (long-axis). Dyskinesia and thinning of the left ventricular apex due to an occlusion of left anterior descending artery. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Pseudoaneurysms, which result from frank wall rupture or cardiorrhexis, are actually composed of pericardium, which confines the rupture. Because only small ruptures in the wall are compatible with survival, pseudoaneurysms tend to have narrow necks, in contrast to the more open neck of true aneurysms (see Chapter 19). Pseudoaneurysms typically form at the inferoposterior base of the heart, are usually accompanied by pericardial effusion (85), and carry a poor prognosis if unrepaired.



Cardiac rupture after acute transmural anteroseptal myocardial infarction. The yellow arrow indicates the site of rupture.

Video 49.14 Aortography showing an aneurysm of the ascending aorta with 3+ aortic regurgitation. The aortogram in this patient with cystic medial necrosis shows a maximum dimension of 5.4 cm. Video 49.16 A 61-year-old male patient with left ventricular pseudoaneurysm after acute anterolateral myocardial infarction. Patient underwent successful surgical repair. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

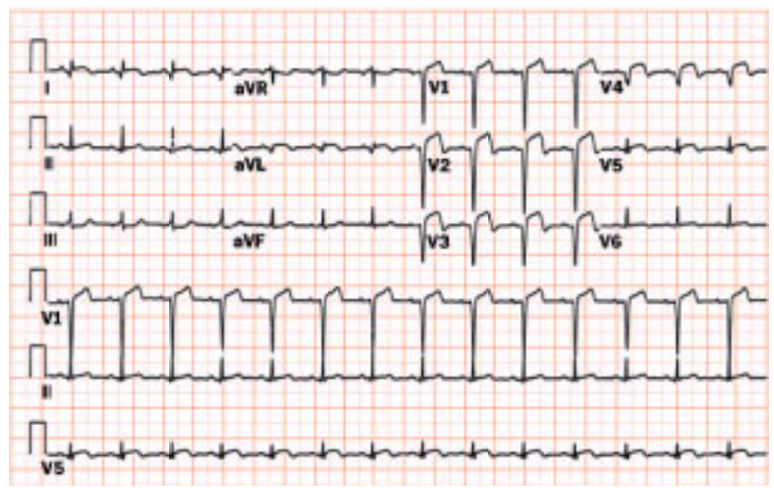
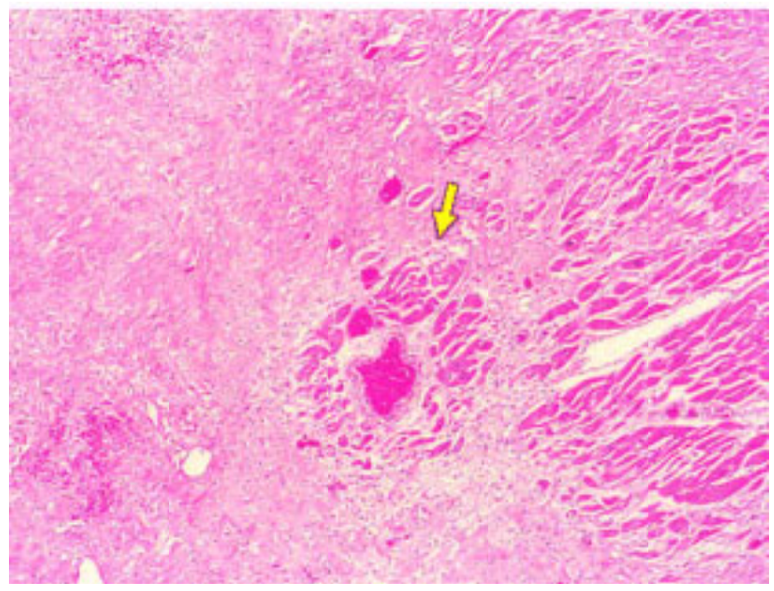
Abrupt myocardial rupture into the pericardial sac is rapidly fatal, although slower accumulations can allow time for surgery. Most postinfarction pericardial effusions are either due to local inflammation (early) or Dressler's syndrome (late). The incidence of pericardial effusions has ranged from 6% (86) to 37% (87) after infarction, and there is poor correlation with physical signs of pericarditis. Ventricular septal defect is a contained cardiorrhexis (88,89,90,91 and 92), typically at the anteroapex for left coronary infarction and the inferior base for right coronary infarction.



Evolution of acute anterolateral myocardial infarction at 72 hours. Q-wave pattern in the anterolateral leads is well established. Persistent ST-segment elevation suggests complication by aneurysm or pericarditis.



Healed patchy myocardial infarction. The arrow demonstrates an island of "trapped" myocytes.

If you do not have QuickTime you may download it here.*

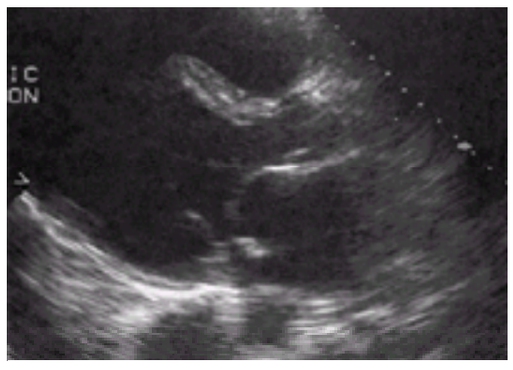
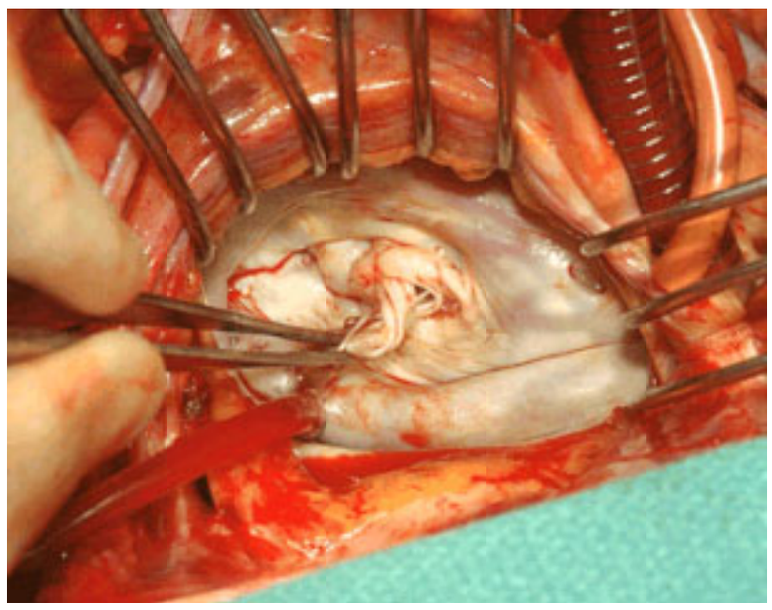
Mitral regurgitation (MR) is regularly encountered as a periinfarction complication (22,88). Papillary muscle rupture is always disabling and may be rapidly fatal (93,94) (*e*Fig. 49.5.2). Because of cross support of the chordae, free motion of the liberated papillary muscle can sometimes be inapparent. Therefore, any patient with severe heart failure and unexpectedly good ventricular function after infarction should have papillary muscle rupture considered. Less severe MR is also commonly seen after myocardial infarction, typically due to the abnormal wall motion displacing or undermining the papillary muscle (see Chapter 51).



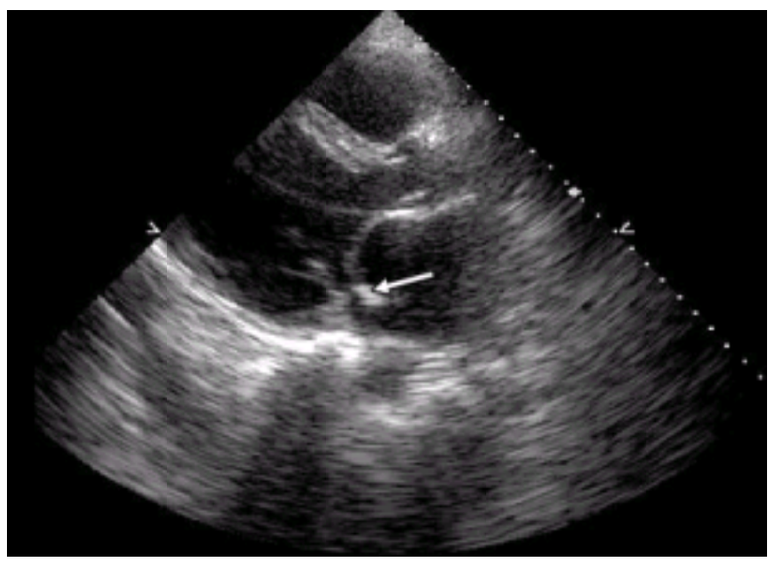
***e*FIGURE 49.5.2** Ruptured papillary muscle. In this parasternal long-axis view, a ruptured posteromedial papillary muscle is seen flailing into the left atrium. This rupture resulted from a recent inferior myocardial infarction.



Intraoperative field demonstrating a mitral valve with a torn papillary muscle prolapsing across the mitral valve into the left atrium. The surgeon has the papillary muscle in forceps demonstrating the chordae attached to the posteromedial commissure, predominantly attached to the anterior mitral leaflet. (The patient's head is to the left of the screen and feet to the right.)

Surgical pathology specimen demonstrating a torn papillary muscle seen to the lower right of the screen, attached via chordae to a portion of the anterior mitral leaflet. Note the torn "ragged edges" at the bottom of the papillary muscle head.

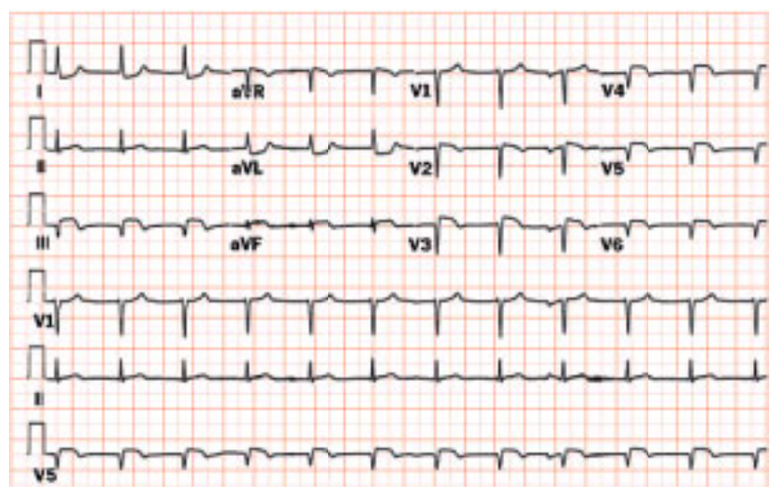
Video 49.19 Parasternal long-axis view of a ruptured papillary muscle after myocardial infarction. Note the bright mass (papillary muscle) attached to the tip of the anterior mitral leaflet as it flails into the left atrium. This resulted in severe mitral regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Parasternal long-axis view of a papillary muscle rupture after myocardial infarction. Note the piece of papillary muscle attached to the tip of the anterior mitral leaflet as it flails into the left atrium (demonstrated by the arrow).

RV infarction can be seen in approximately 40% of inferior infarctions (95,96), with injury ranging from subclinical depression to severe RV dysfunction causing a low-output state with high mortality. RV infarction is characterized by ventricular enlargement, decreased descent of the base, and inferior vena cava (IVC) plethora (95,96). Elevation of right-sided filling pressures can cause right-to-left shunting through a patent foramen ovale and can be easily documented by the passage of saline microbubbles across the interatrial septum.

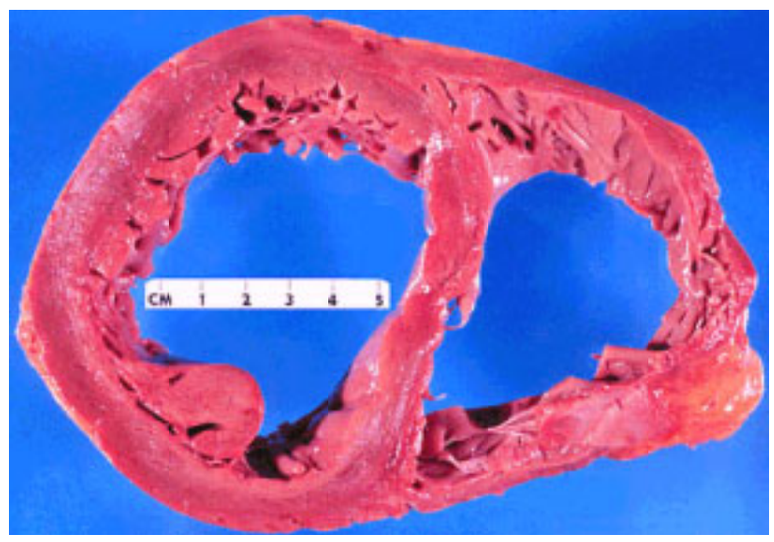
Right ventricular infarct. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)



Right ventricular infarction. ST-segment elevation in leads V_4R and V_5R reveals right ventricular involvement complicating the inferior infarct.

Cardiomyopathies: Their Recognition by Echocardiography

Dilated, hypertrophic, and restrictive cardiomyopathies can be characterized by two-dimensional echocardiography. Congestive cardiomyopathy shows spherical cavitary dilatation (LV volume often >250 mL), normal wall thickness, and poor wall thickening and endocardial motion (eFig. 49.4.1).M-mode echocardiography displays mitral-septal E-point separation, poor mitral and AV opening, and decreased systolic aortic root motion. Involvement of the right heart is important because it implies pulmonary hypertension and RV cardiomyopathy, which independently worsen prognosis (97,98). In spite of an EF of less than 30%, cardiac output (stroke volume × heart rate) may be normal due to tachycardia and the large end diastolic volume.



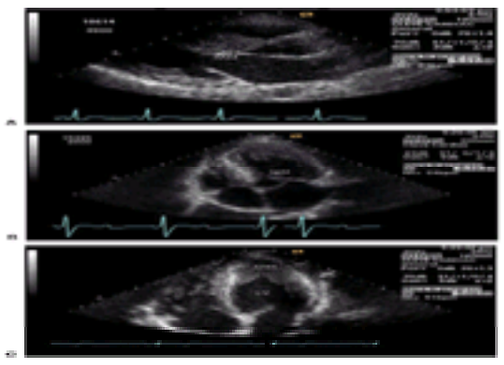
Dilated congestive cardiomyopathy. Both the left and right ventricles are significantly enlarged. In this example, the left ventricular wall thickness falls within normal limits.

Early signs of cardiomyopathy are a decrease in the descent of the cardiac base (24), an increase in sphericity (24), and a rise in end systolic volume index (40,42). This latter value is highly useful in detecting early cardiomyopathy because the end systolic volume tends to be more sensitive to contractility than the preload volume (35). An end systolic volume index that exceeds 30 mL per m^2 indicates significant global dysfunction. In valve disease, patients whose end systolic volume index exceeded 60 mL per m^2 (40) had a much poorer outcome than did other patients. Similarly, in ischemic cardiomyopathy the value of 45 mL per m^2 segregates patients with poor outcome.

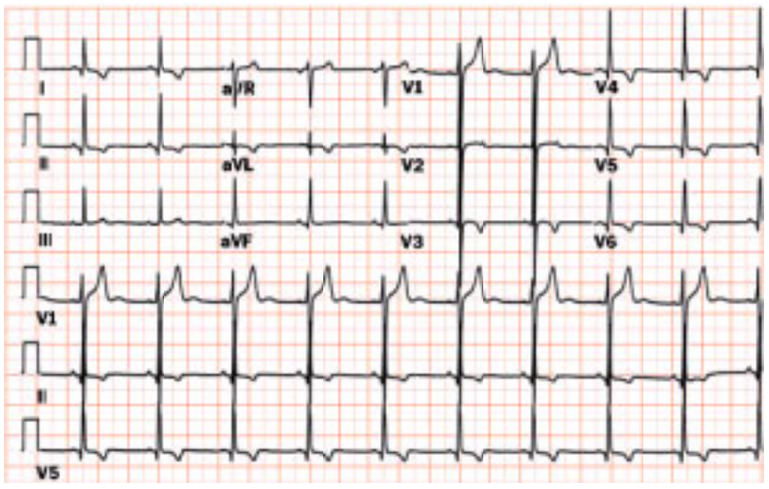
In South America, a congestive or a segmental cardiomyopathy raises the possibility of Chagas' disease (99), in which insect-borne *Trypanosoma cruzi* eventually leads to damage of the myocardium. It may appear as global dysfunction or as an apical aneurysm that, unlike coronary disease, spares the interventricular septum. Less commonly, the inferior base can be the site of segmentally isolated thinning and scar formation.

Hypertrophic Cardiomyopathies

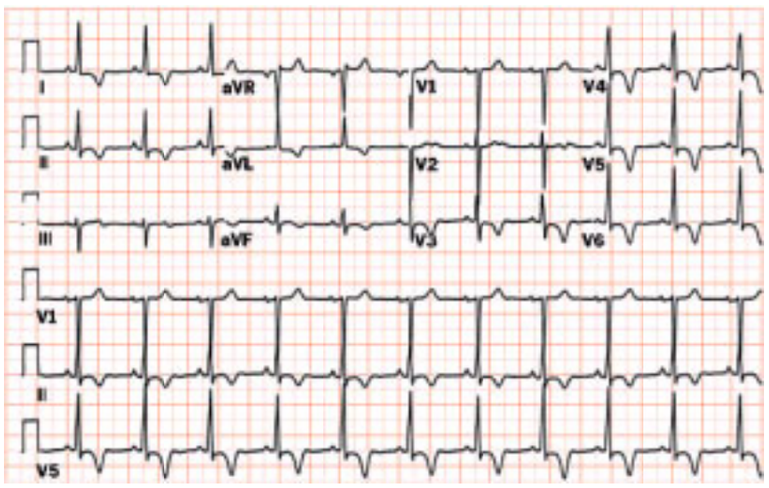
Primary hypertrophic cardiomyopathies are characterized by increased LV mass without apparent etiology, such as hypertension or aortic stenosis, and can be asymmetric or symmetric (100,101,102 and 103). In asymmetric septal hypertrophy (ASH), the increased wall thickness is typically localized in the basal septum (101) (eFig. 49.5.3A and eFig. 49.5.3B), and, although it is clearly heritable, there is variable expressivity among affected family members. An unusual variation of ASH is apical hypertrophy (so-called Yamaguchi's disease) (104,105) (eFig. 49.5.3C). When dynamic outflow tract obstruction accompanies ASH, hypertrophic obstructive cardiomyopathy is present (106,107 and 108). Findings that are consistent with obstruction may be noted echocardiographically at rest or with provocation by amyl nitrite, exercise, or inotropic stimulation (100). Fully developed hypertrophic obstructive cardiomyopathy consists of ASH, systolic anterior motion of the MV, crowding of the LV outflow tract by the mitral apparatus and septum, partial mid-systolic closure or notching of the AV, and mitral annular calcification.



***e*FIGURE 49.5.3** Hypertrophic cardiomyopathy. Parasternal long-axis view **(A)** and apical four-chamber view **(B)** of two patients with hypertrophic cardiomyopathy, demonstrating asymmetric septal thickening with systolic anterior motion (SAM) of the mitral valve. **C:** Apical four-chamber view of a patient with apical hypertrophy or Yamaguchi's disease. LV, left ventricle.



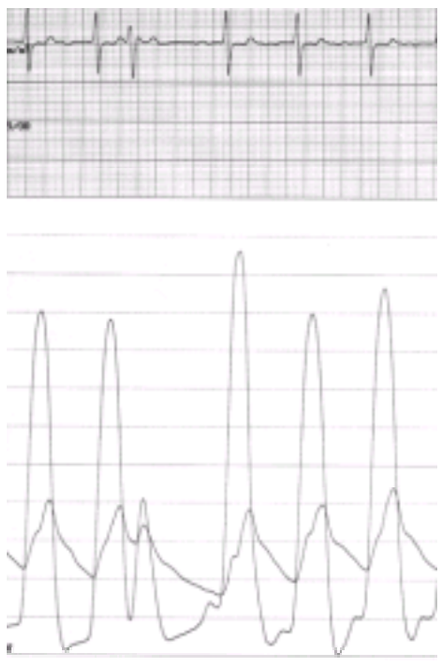
Hypertrophic cardiomyopathy. Inverted precordial T waves associated with hypertrophic cardiomyopathy.



Yamaguchi's disease. Note anterior precordial T wave inversion in this Asian patient with apical hypertrophy.

VIDEO

Video 49.20 Ventriculography in a patient with Yamaguchi's apical hypertrophy. In this syndrome there is just proportionate hypertrophy near the apex, which produces a characteristic prolongation of the left ventricular silhouette during ventriculography (right anterior oblique view). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



A 57-year-old female patient with hypertrophic cardiomyopathy. This figure shows the Brockenbrough response after a ventricular premature beat. The Brockenbrough response includes an increase in left ventricular systolic pressure, a decrease in aortic systolic pressure, an increase in left ventricular–to-aortic gradient, and diminished aortic pulse pressure.

VIDEO

Video 49.21 A four-chamber transesophageal echo (TEE) of a patient with hypertrophic obstructive cardiomyopathy before myectomy **(A)**. Note the mitral regurgitation due to systolic anterior motion of the mitral valve leaflets. Intraoperative TEE after myectomy **(B)** for hypertrophic cardiomyopathy. Note that there is no longer mitral regurgitation from systolic anterior motion of the mitral valve leaflets, and the left ventricular outflow tract is opened up compared with the preoperative TEE. Secondary LV hypertrophy (LVH) is most commonly due to hypertension and conveys a poor prognosis (52). The sensitivity of M-mode echocardiography for detecting LVH is clearly superior to ECG (50), but two-dimensional echocardiography has superior reproducibility.

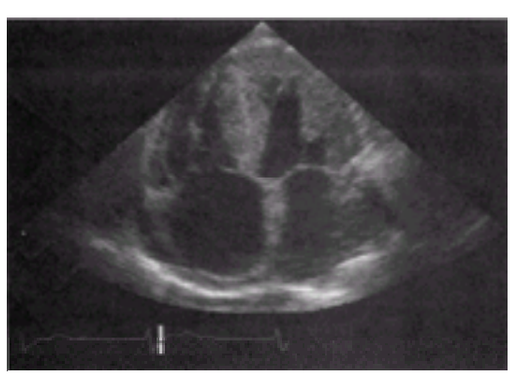
M-mode tracing of hypertrophic cardiomyopathy with severe septal hypertrophy seen at the top of the trace and systolic anterior motion (SAM) of the mitral valve in systole seen in the middle of the trace (designated by the arrow).

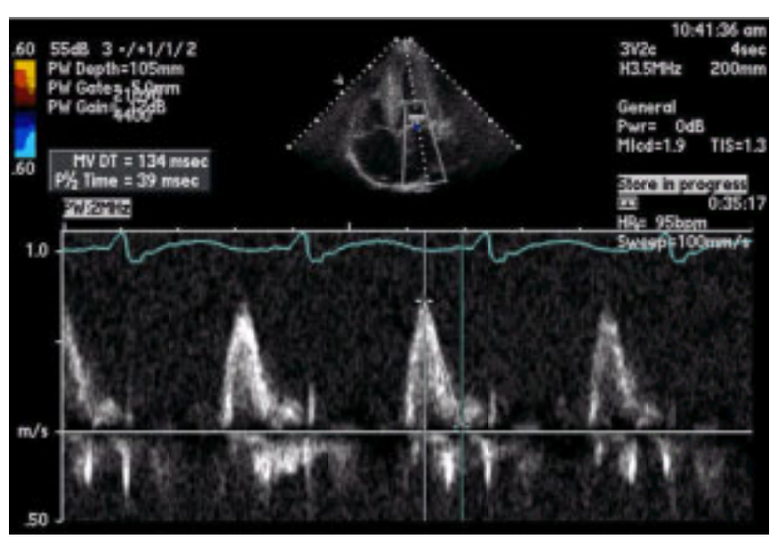
Restrictive Cardiomyopathy

Restrictive cardiomyopathies are more difficult to diagnose than hypertrophic or congestive states, but echocardiography remains the most effective diagnostic test. The most common restrictive state is the small stiff heart of diabetes (109). It is clinically inapparent in the majority of diabetics but may lead to pulmonary congestion in association with regional ischemia.

Amyloid heart disease is rare (110,111 and 112) and carries a poor prognosis (113). Amyloid infiltration is characterized echocardiographically by increased LV wall thickness and a peculiar glittering or scintillating appearance of the myocardium (eFig. 49.5.4). Superficially, amyloid heart disease can resemble typical LVH (110). Contractile function is nearly normal or mildly depressed, and the left atrium (LA) is usually enlarged. The presence of these findings along with typical clinical signs or symptoms (e.g., low ECG voltage, neuropathy) should prompt a gingival or rectal biopsy.



***e*FIGURE 49.5.4** Amyloidosis. Apical four-chamber view showing typical appearance of amyloidosis, including wall thickening with highly reflective myocardium (speckling). The interatrial septum is also thickened, helping to distinguish this from left ventricular hypertrophy.



Pulsed wave Doppler of the mitral valve inflow in a patient with amyloidosis demonstrating a short deceleration time (134 ms) consistent with restrictive physiology.

Unclassified Cardiomyopathy

Ventricular noncompaction is a rare form of ventricular dysplasia that results from intrauterine arrest in endomyocardial morphogenesis (114,115). It involves the LV or the LV and RV, most commonly in association with other congenital malformations, but occasionally in isolation (116). The myocardium is characterized by numerous prominent, excessive trabeculations with deep intertrabecular recesses. Noncompaction most commonly affects the apical, mid-inferior, and mid-lateral segments (117).

Video 49.23 Ventricular noncompaction. Apical four-chamber view without **(A)** and with **(B)** intravenous contrast of a patient with ventricular noncompaction. Note the characteristic trabeculations and recesses that result from arrest on intrauterine development. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.24 Ventricular noncompaction. Apical four-chamber view without **(A)** and with **(B)** intravenous contrast of a patient with ventricular noncompaction. Note the characteristic trabeculations and recesses that result from arrest on intrauterine development. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

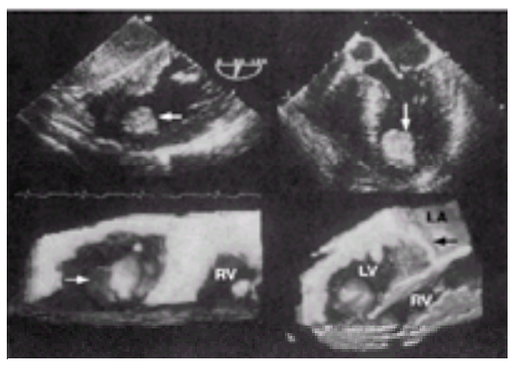
Video 49.25 Apical two-chamber view of a patient with noncompaction with the inferior wall to the left of the screen and the anterior wall to the right. Again, note the thickened, heavily trabeculated myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.26 Apical four-chamber view of a patient with noncompaction with the right ventricle to the left of the field and the left ventricle to the right. Note the thickened, heavily trabeculated myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.27 Apical long-axis view of a patient with noncompaction. Isolated ventricular noncompaction is a rare idiopathic cardiomyopathy characterized by abnormal structure of the myocardium caused by intrauterine arrest of compaction of the myocardial fibers without any coexisting congenital lesions. The typical echocardiographic appearance includes segmental thickening of the myocardium consisting of two layers: a thin compacted epicardial and an extremely thickened endocardial layer with prominent trabeculations and deep recesses. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Left Ventricular Masses

Nonthrombotic masses of the left ventricle are quite rare, but approximately 25% are malignant (33% angiosarcomas, 20% rhabdomyosarcomas, 10% mesotheliomas, and 11% fibrosarcomas with melanomas reported) (118). In the pediatric population, the most common tumors are rhabdomyomas associated with tuberous sclerosis. *e*Figure 49.5.5 shows a three-dimensional image of an apical mass, found to be a benign lipoma at surgery. Nonmalignant lesions include myxomas and fibroelastomas, and both have considerable embolic potential. Myxomas can occur anywhere in the left ventricular cavity, whereas fibroelastomas usually occur on the MV or valvular apparatus.



***e*FIGURE 49.5.5** Left ventricular lipoma. Transgastric (*upper left*) and transesophageal (*upper right*) two-dimensional echocardiograms demonstrating a highly reflective mass in the left ventricular apex. The lower panel shows three-dimensional reconstruction of this mass, demonstrating its relationship to the surrounding myocardial wall. LA, left atrium; LV, left ventricle; RV, right ventricle. (Images courtesy of Dr. Raymond Stainback.)

Video 49.28 Transgastric 90-degree long-axis transesophageal echo view of a patient with a sarcoma metastatic to his left ventricular anterior wall. Note the invasion of the myocardium by this large mass. Additionally, there is severe hypokinesis of the anterior wall. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Endomyocardial fibrosis is a disease of the impoverished living in North Africa and South America. It is associated with restriction of LV and RV filling by obliteration of one or both cardiac apices by a thrombotic fibrocalcific process (119). The disease can also occur in relation to eosinophilia (Loeffler's or Davies' disease) and eosinophilic leukemia. In addition to the unique appearance of the apices, the atria are strikingly enlarged, with mitral and tricuspid regurgitation (TR) complicating the picture. Its recognition depends on a high degree of clinical suspicion and a characteristic echocardiographic appearance. In South America, a surgical approach has been developed that debulks fibrotic material from the apex and restores LV compliance.

Right Ventricle

Imaging the RV is an essential portion of a comprehensive echocardiographic evaluation, as occult right heart disease may occur as a result of left-sided pathology.

Right Ventricular Wall Thickness, Contractile Function, and Size

RV wall thickness, assessed from the parasternal or subcostal windows, should be only 3 to 4 mm thick, with 5 mm considered hypertrophied (13,45,120). In contrast to the elliptical LV, the shape of the RV frustrates volumetric measurement. It has been described as a pyramid with a triangular base or as a teapot. The tomographic nature of echocardiography makes imaging this irregular-shaped organ in a single plane impractical (56,120,121,122,123 and 124). One simple analog is the parasternal M-mode diameter of the RV, although a more accurate dimension can be obtained from a two-dimensional image. The size of the normal RV is considerably less than the left ventricle, whether imaged from the parasternal long axis, the parasternal short axis, or the apical four-chamber view (Fig. 49.2). In the latter view, the LV should form the cardiac apex. If the RV even shares the apex, RV dilatation should be suspected.

A 42-year-old female patient with right ventricular hypertrophy.

Muscular hypertrophy of the arterial wall in a case of arrhythmogenic right ventricular dysplasia. (Courtesy of Norman Ratliff, M.D., and Marc Smith, M.D., Cardiac Pathologists at The Cleveland Clinic Foundation.)

To assess RV contractility visually, careful adjustments of instrument settings may be needed to detect RV inward systolic motion or wall thickening accurately. Most M-mode images are of the RV outflow tract region, which may not be representative of the whole chamber.

RV volume and EF can be estimated by the area-length algorithm applied from the apical four-chamber or subcostal views (122,123 and 124). This correlates reasonably well (r = 0.83) with radionuclide scanning for EF (121), although absolute volumes are significantly underestimated. The four-chamber area-length RV-LV volume ratio should be approximately 0.6, but it increases to greater than 1.1 in cor pulmonale (125).

Descent of the RV base toward the fixed apex is easily seen in the subcostal and four-chamber views and, if depressed, is a sensitive indicator of RV systolic dysfunction (124). Descent of the RV base was 0.7 ± 0.2 cm in patients with hemodynamically significant RV infarction, 1.3 ± 0.4 cm in those with ECG evidence but without hemodynamic compromise, and 2.0 ± 0.2 cm in a group of 20 normal control patients (p <.001). Doppler tissue imaging has yielded similar results in normal subjects (126).

Segmental Abnormalities of the Right Ventricle

The most common segmental RV abnormality results from RV infarction, usually in the setting of inferior wall myocardial infarction (95), and may lead to a lethal low-output syndrome even when LV damage is not extensive. In RV infarction, there is cavity enlargement (96) with mid-anterior and inferior wall akinesis or even aneurysm by two-dimensional imaging. A hinge point may differentiate infarcted from normal segments, and the descent of the RV base is impaired (95). The degree of RV dilatation and IVC plethora provides clues to the hemodynamic severity of RV infarction (95).

Endocardial fibrosis (with or without eosinophilia) can also segmentally affect the RV. The apex fills with fibrothrombotic matter, resulting in RV restriction, TR, and atrial enlargement (99,119).

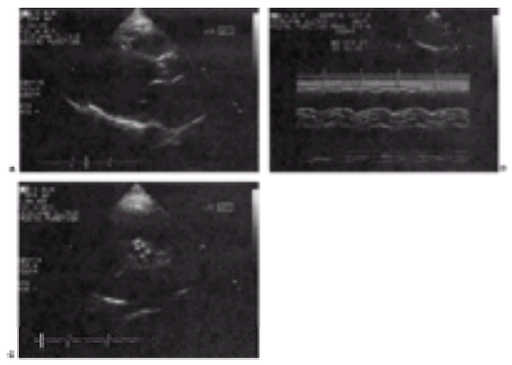
Right Ventricular Tumors and Masses

RV masses can be primary, metastatic, or embolic in nature (127,128). Generally, the same masses that affect the LV can also involve the RV. Myxomas are the most common benign RV tumors and tend to be larger because they are detected later. Primary malignant tumors are very rare and are usually angiosarcomas. Metastatic melanoma can occur, but usually very late in the course of the disease. More commonly, tumors reach the right heart by propagating through the venae cavae. Hepatic, renal, and adrenal tumors can present in this manner, and a malignant thymoma that obstructs RV inflow has been observed. Such masses can be surgically palliated.

The most important propagating masses are embolic thrombi from the lower extremities (129). These thrombi, which may present as a localized mobile RV mass, are generally less reflective than malignant masses. RV enlargement and pulmonary hypertension suggest multiple pulmonary emboli. These masses may remain in the right heart, embolize to the lungs, or rarely cross a patent foramen ovale (130). These thrombi generally have an ominous prognosis and require aggressive medical or surgical intervention.

Conditions Associated with Right Ventricular Dilatation

RV volume overload without pulmonary hypertension is seen in atrial septal defect (ASD), tricuspid insufficiency, and pulmonary insufficiency, in which cases the RV enlarges to form the cardiac apex. RV contractile function is usually preserved, and wall thickness remains normal. In ASD, the pulmonary artery is also enlarged. *e*Figure 49.5.6 shows a suprasternal view of the aortic arch and pulmonary artery bifurcation. If the right pulmonary artery is of normal caliber, pulmonary hypertension and left-to-right shunts of any magnitude are unlikely. Similarly, the short-axis basal precordial view is the best window for evaluating the size of the main pulmonary artery.



***e*FIGURE 49.5.6** Pulmonary artery bifurcation. Parasternal image demonstrating the right ventricular outflow tract (RVOT), pulmonary valve (PV), and bifurcation of the pulmonary artery (PA) into the right (RPA) and left (LPA) pulmonary arteries. AO, aorta.

An ASD can be further confirmed by saline contrast injection, showing a negative contrast jet in the RA or right-to-left shunt flow in the LA. Sometimes the defect itself can be seen, especially with color Doppler, which may also show discrepant flow through the RV and LV outflow tracts (121). Congenital absence of the pericardium may cause RV enlargement (131) due to rotation of the heart, but with a small pulmonary artery, low pulmonary pressure, and a normal contrast study. RV enlargement may also be caused by severe TR, most commonly due to LV dysfunction, rheumatic disease, endocarditis, and primary pulmonary hypertension. Two-dimensional signs of TR include leaflet flail or malcoaptation, although color Doppler is the most reliable modality.

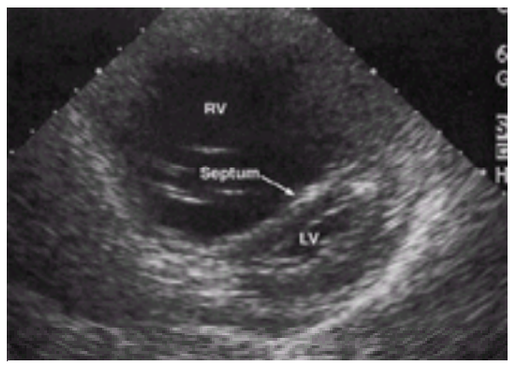
Chronically elevated pulmonary vascular resistance leads to cor pulmonale with a dilated apex-forming RV (125), mild to moderate RV hypertrophy, and a dilated IVC that is unresponsive to respiration. A patent foramen ovale (20–30% of patients) may show right-to-left shunting with contrast injection. The etiology usually is chronic obstructive lung disease but may be chronic pulmonary embolism, cystic fibrosis, bronchiectasis, connective tissue disease, adult respiratory distress syndrome, asthma, sarcoid, obesity with sleep apnea, or chronic pulmonary infection.

Severe right ventricular hypertrophy resulting from pulmonary hypertension. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Video 49.29 Apical four-chamber transthoracic view demonstrating a patient with severe pulmonary hypertension with a markedly dilated right ventricle with right ventricular dysfunction and a dilated tricuspid annulus. This annular dilatation causes severe tricuspid regurgitation. Because of the severe tricuspid regurgitation, there is significant right atrial dilatation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.30 Apical four-chamber view with color Doppler demonstrating severe tricuspid regurgitation due to annular dilatation. There is right ventricular dilatation and significant right ventricular dysfunction. Note the large zone of proximal flow convergence on the right ventricular side of the tricuspid valve. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Echocardiographic features of primary pulmonary hypertension are similar to those of cor pulmonale but with greater RV hypertrophy and septal flattening (eFig. 49.5.7), often preceding IVC plethora. Pulmonary hypertension from congenital heart disease (atrial or ventricular septal defect) may cause severe RVH, but right heart failure may be minimal early on. In the end stage, it may be difficult to distinguish ASD/Eisenmenger complex from primary pulmonary hypertension with a patent foramen ovale.

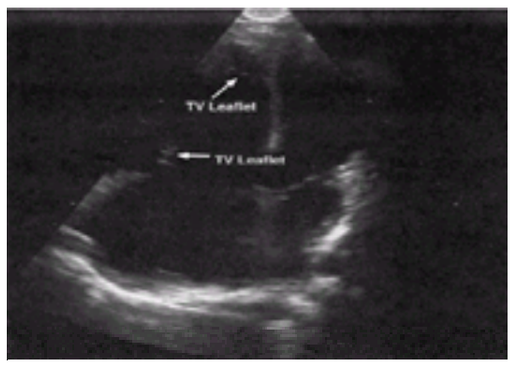


***e*FIGURE 49.5.7** Pulmonary hypertension. Parasternal short-axis view showing a massively enlarged right ventricle (RV) causing marked septal flattening and a small left ventricular (LV) cavity.

Isolated RV dilatation may be seen in arrhythmogenic RV dysplasia (parchment ventricle or Uhl's disease) (132). Features of RV dysplasia include a thin RV wall, increased epicardial fat, aneurysms of the RV free wall, and a prominent moderator band with complex attachment to the septum and RV free wall. Spontaneous fatal ventricular arrhythmias may be seen with this condition.

In Ebstein's anomaly, the septal leaflet of the TV is displaced toward the RV apex, leaving an "atrialized ventricle" behind the valve (eFig. 49.5.8). Contraction during

systole may cause right-to-left shunting across a patent foramen and cyanosis (133,134).

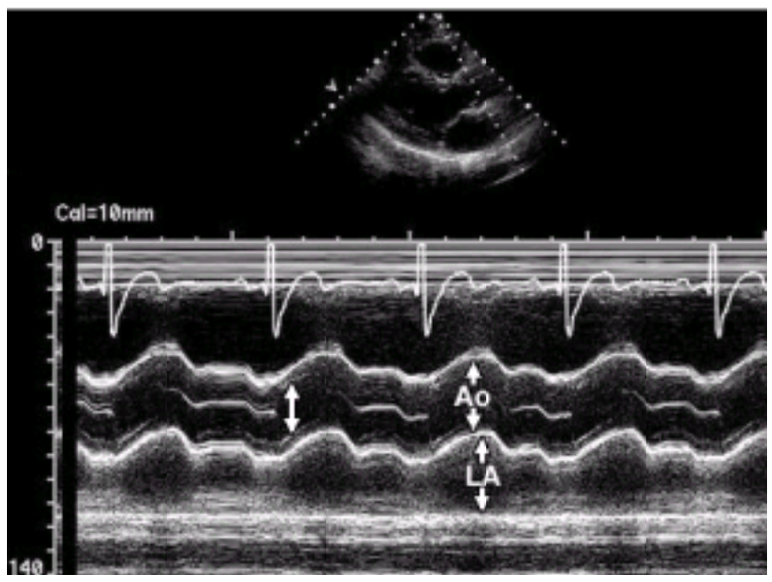


***e*FIGURE 49.5.8** Ebstein's anomaly. Apical four-chamber view of a patient with Ebstein's anomaly. The septal leaflet of the tricuspid valve (TV) is misplaced apically, leaving an atrialized portion of the right ventricle.

ECHOCARDIOGRAPHY OF THE ATRIA

Left Atrium

The LA serves reservoir, conduit, and booster pump functions for blood that enters the LV. It is commonly involved in pathologic processes, including dilation, thromboembolic and neoplastic disease, extrinsic compression, and fibrillation, each of which is well assessed by echocardiography.



Normal M-mode through the aortic valve and left atrium (LA) in the parasternal long-axis view by transthoracic echo. (The unlabeled arrow represents the opening of the aortic valve.) Ao, aorta.

Surgical specimen of the large left atrial mass explanted at the time of surgery. Note its somewhat pale, glistening surface, suggesting that the thrombus is not fresh and possibly endothelialized.

Echocardiographic Assessment of Left Atrial Volume and Function

The standard parasternal M-mode image yields the anterior-to-posterior dimension of the LA (Fig. 49.4), typically the smallest, perhaps because of confinement between the sternum and the spine (135). This dimension is the least sensitive to enlargement but, when increased, is highly specific.

Because this single anterior-to-posterior dimension may underestimate overall LA size, volume estimates are preferred, requiring two sector scans, preferably orthogonal apical planes. The area-length formula has shown good correlation (r = 0.82–0.98) with angiography and contrast computed tomographic scanning (66,135), with some underestimation (up to 23%) but good reproducibility (95% confidence interval = 10 mL). Normal values throughout the cardiac cycle are shown in *e*Table 49.0.1 (65,68). Maximal volume occurs at end systole and averages 40 mL, falling to 25 mL after passive and active emptying. For a normal LV stroke volume of 65 mL, approximately 25 mL is reservoir emptying and 40 mL is conduit flow from the pulmonary veins. In the healthy young heart, only 10 mL atrial transport occurs with atrial contraction, the rest entering by passive flow early in diastole. With aging, the amount of active atrial transport more than doubles.

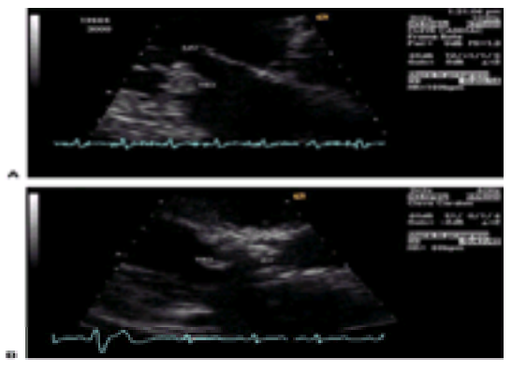
Atrial fibrillation causes progressive LA enlargement (136), which may be prevented by cardioversion (137). In rheumatic disease, LA diameter is predictive of atrial fibrillation (138) and the restoration of atrial function after cardioversion (139). However, the recurrence of lone atrial fibrillation appears to be independent of atrial diameter (140). Atrial volume has not been used in these studies.

Left Atrial Thrombi, Masses, and Tumors

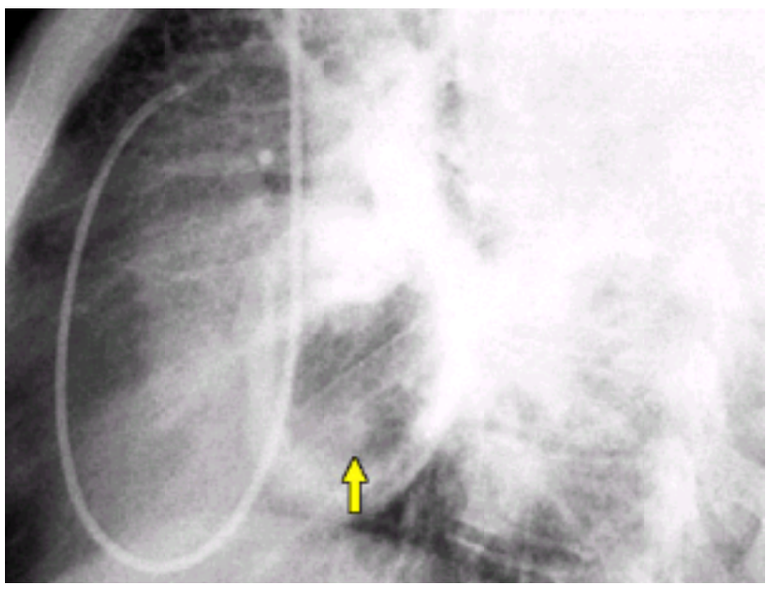
Left atrial thrombi are common but must be large to be identified by transthoracic echocardiography (TTE). This is especially true of the left atrial appendage, which usually requires transesophageal interrogation (141).

The most common LA tumor is myxoma (*e*Fig. 49.5.9), a benign mass that most commonly arises from the inferior limb of the fossa ovalis. It can present with

embolism or obstruction to mitral inflow. Myxomas may be encapsulated or highly mobile and amorphous, with the latter at highest risk for peripheral emboli. Encapsulated myxomas may have clear spaces (cysts) and highly reflective patches (bone). Attachment is typically by a stalk to the interatrial septum and may be biatrial. The attachment of amorphous myxomas is broader based, with a highly mobile, less reflective tip. Malignant LA tumors include fibrosarcoma, liposarcoma, and osteogenic sarcoma that may metastasize through the pulmonary vein.



***e*FIGURE 49.5.9** Left atrial (LA) myxoma (Myx). Apical four-chamber view showing a left atrial myxoma attached to the lower portion of the interatrial septum. RA, right atrium; RV, right ventricle.



Left atrial myxoma. This left anterior oblique projection depicts the left atrial filling phase of a pulmonary angiogram performed via a pulmonary artery catheter inserted into the right jugular vein. A large contrast free space (*yellow arrow*) depicts a space occupying mass within the left atrial cavity, which surgical pathology confirmed to be a myxoma.

Atrial myxoma. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Video 49.31 Atrial myxoma (long-axis). A myxoma attached to the interatrial septum is seen. During diastole, the myxoma moves through the mitral orifice into the left ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Right Atrium

M-mode techniques for measuring the RA have not been developed. However, area and volume can be assessed by two-dimensional imaging from the four-chamber and subcostal views. Viewed qualitatively, the two atria normally appear similar in size and smaller than the respective ventricle. Using true RA size as a standard, the best ECG criteria for RA enlargement (142) are a P-wave height of greater than 1.5 mm in lead V_2, a QRS axis of greater than 90 degrees, and an R/S ratio of greater than 1 in lead V_1 (without right bundle branch block; combined sensitivity 49% with 100% specificity). P-pulmonale detected only 6% of patients with right atrial enlargement. Tumors and thrombi (143,144) are discussed in the section Right Ventricular Tumors and Masses. Rarely, biatrial myxomas are observed (*e*Fig. 49.5.10).

***e*FIGURE 49.5.10** Biatrial myxoma. Apical four-chamber view demonstrating myxomas in the right and the left atria.

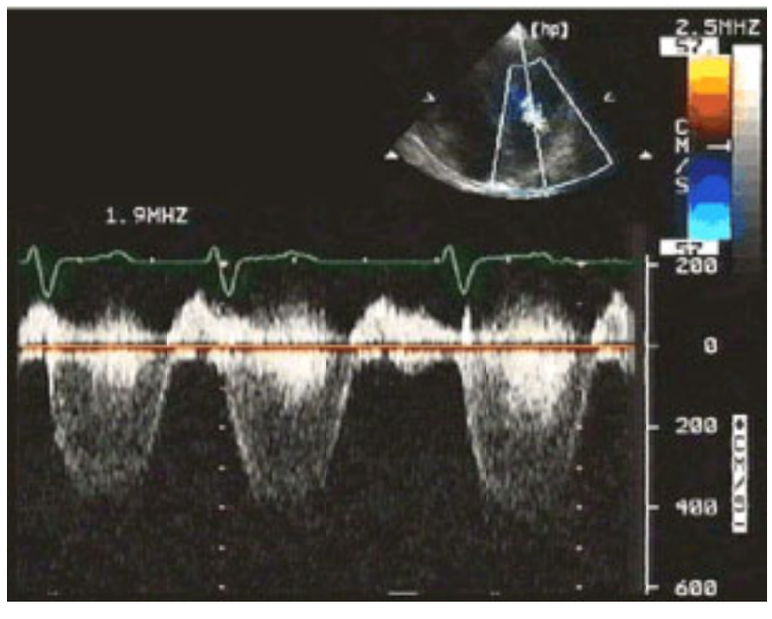
Video 49.32 Apical four-chamber view with the dilated right ventricle and right atrium to the left of the screen. Note the doming appearance of the rheumatic tricuspid valve. (The small left ventricle and left atrium are to the right of the screen.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

ECHOCARDIOGRAPHY OF THE CARDIAC VALVES

Echocardiography images the cardiac valves as does no other modality, providing high temporal and spatial resolution while relating valve structure to surrounding structures. Doppler is also critical to valve interrogation. It is discussed in detail in Chapter 51.

Evaluation of the Mitral Valve

Historically, the mitral valve was the first structure to be identified by echocardiography (3,4 and 5,145). An integrated investigation of the MV includes an M-mode tracing, several two-dimensional views, a Doppler evaluation, and, if needed, transesophageal imaging (141).



Apical continuous wave spectral Doppler recording of mitral regurgitation (systolic parabolic downward velocities). Note beat-to-beat variation due to atrial fibrillation.

The anterior mitral leaflet is highly mobile and quite echogenic, whereas the posterior leaflet is somewhat less apparent (Fig. 49.2). Images are acquired from the parasternal, apical, and subcostal regions. By M mode, an M-shaped pattern of MV motion is seen, reflecting first passive rapid filling and second atrial contraction, with near closure during diastasis, although blood may still pass from pulmonary veins to LV using the atrium as a conduit (65). Final closure results from atrial inflow deceleration and isovolumic LV contraction (Fig. 49.4).

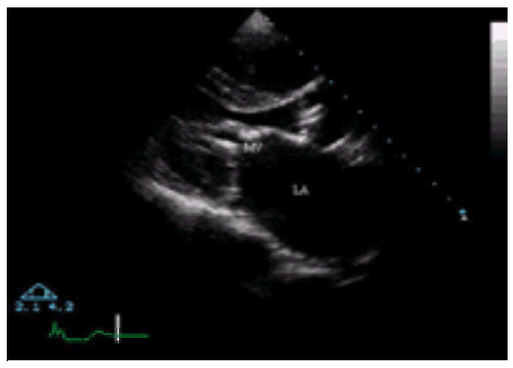
By two-dimensional imaging in the short-axis plane (Fig. 49.2), the MV is an ovoid orifice. In the long-axis plane, it resembles clapping hands moving freely in diastole, but forming a stable coaptation plane in systole. The MV and annulus descend with the cardiac base to assist left atrial filling.

Normal mitral leaflets are thin (<2 mm), although somewhat thicker at points of chordal attachment to the free margin (primary chordae) and leaflet body (secondary chordae). Transducer frequencies of greater than 2.5 MHz are required for adequate resolution. The papillary muscles can be seen in the short-axis view at four and eight o'clock with highly variable anatomy. From the apical four-chamber view, posterior angulation (typically showing the coronary sinus) is necessary to show the papillary muscles and chordae. Normal chordae appear fragmented unless they are thickened and fused by fibrosis or calcification. The mitral annulus has been shown to be nonplanar (saddle-shaped) and highly dynamic by three-dimensional imaging. On two-dimensional imaging annular diameter and calcification can be noted.

Mitral Pathology

Mitral Stenosis

From the earliest days of echocardiography (4), MS has been recognized by altered motion of the valve due to commissural fusion and chordal shortening. MS severity can be assessed on M mode by measuring the delay in diastolic closure (E-F slope). A normal value is greater than 60 mm per second; a slope of less than 10 mm per second indicates severe MS (146). By two-dimensional echocardiography, the leaflets dome into the ventricle throughout diastole (eFig. 49.5.11). In short axis, the mitral orifice can be reliably measured by direct planimetry (146,147), with an area of less than 1 cm^2 defining severe MS. Doppler quantitation methods are discussed in Chapter 51.



***e*FIGURE 49.5.11** Mitral stenosis. Parasternal long-axis view showing doming of the mitral valve (MV) in diastole with restricted opening and an enlarged left atrium (LA).

Video 49.33 Apical four-chamber view of a patient with severe rheumatic mitral stenosis with marked thickening and doming of the mitral leaflets, with severe ALE and spontaneous echo contrast within the left atrium. Note the left ventricle remains small. Because of long-standing severe mitral stenosis, the patient has severe pulmonary hypertension with right ventricular hypertrophy and right ventricular failure and severe right atrial enlargement. *This video must be viewed with QuickTime. If*

you do not have QuickTime you may download it here.

HEART SOUNDS

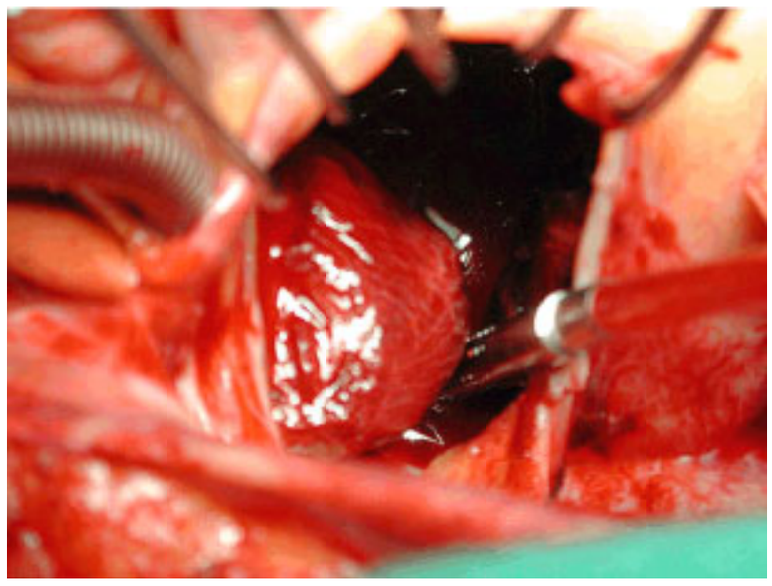
Audio 49.34 Severe mitral stenosis. Auscultation performed in a 42-year-old female patient with rheumatic mitral valve disease, leading to severe stenosis and mild regurgitation. The peak and mean diastolic gradients across the mitral valve were 14 and 9 mm Hg, respectively. The mitral valve area by pressure half-time was 0.8 cm^2. Note the loud S_1, opening snap, mid-diastolic rumble, and presystolic accentuation. Left upper sternal border **(A)** and apex **(B)**. (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

HEART SOUNDS

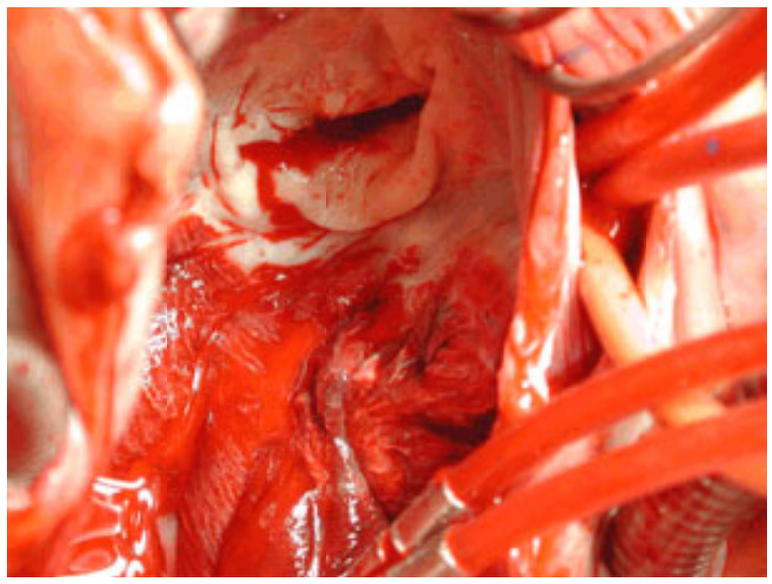
Audio 49.35 Severe mitral stenosis. Auscultation performed in a 42-year-old female patient with rheumatic mitral valve disease, leading to severe stenosis and mild regurgitation. The peak and mean diastolic gradients across the mitral valve were 14 and 9 mm Hg, respectively. The mitral valve area by pressure half-time was 0.8 cm^2. Note the loud S_1, opening snap, mid-diastolic rumble, and presystolic accentuation. Left upper sternal border **(A)** and apex **(B)**. (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Indirect signs of MS severity include chordal shortening, leaflet calcification, LA enlargement, LV underloading, and right heart involvement (pulmonary hypertension). Progression cannot be accurately predicted, although those with mild MS and aortic insufficiency progress slightly faster (148).

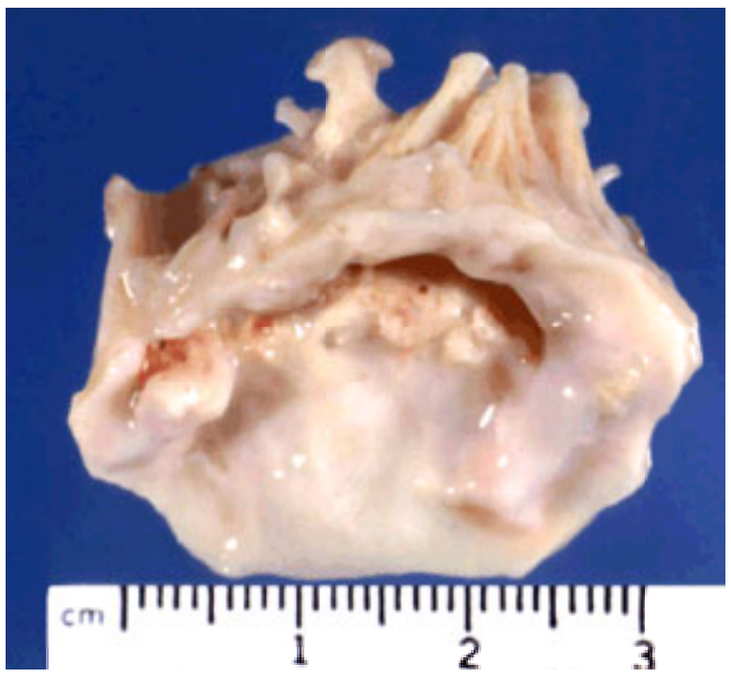
A 62-year-old female patient with mitral stenosis.



Intraoperative field looking into the left atrium of a patient with severe mitral stenosis who developed extensive clot within the left atrium. Notice the large mass in the center of the field, to the left of the opening within the left atrium. This is the largest portion of the left atrial thrombosis.



Intraoperative field looking into the left atrium after the large left atrial thrombus was resected demonstrating the rheumatic mitral valve at the top of the screen. Note the scarred, thickened, restricted mitral leaflets. This patient had severe mitral stenosis with a mean pressure gradient of 20 mm Hg across the valve and a mitral valve area of 0.7 cm^2.



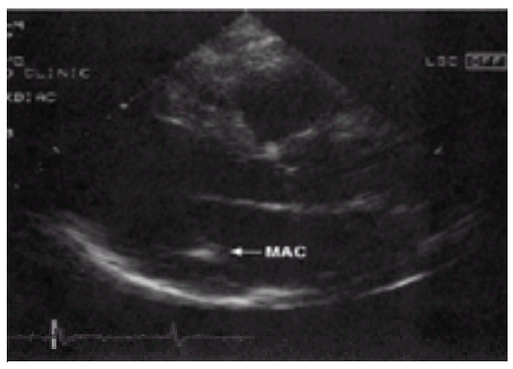
Rheumatic mitral valve. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Echocardiography in Balloon Valvuloplasty

Echocardiography is useful in guiding the transseptal puncture in balloon valvuloplasty and identifying appropriate candidates for this procedure. A “splitability score” grades four morphologic features of the MV—mobility, thickness, calcification of the anterior leaflet, and severity of subvalvular disease—each on a four-point scale (149,150). A total score of less than 7 indicates a high probability of success. An alternate score is based on the distribution of calcium around the stenotic orifice (151). More than mild insufficiency usually disqualifies patients from this procedure. This topic is covered in Chapter 86.

Other Causes of Inflow Obstruction

Mitral annular calcification is easily recognized in the long-axis view as a bright reflector in the atrioventricular groove, shadowing objects behind it (152,153 and 154). It may grow into the surrounding myocardium and inflow tract and should be distinguished from posterior leaflet calcification. In the short-axis view, it is C-shaped, lying between the papillary muscles, and is rarely associated with hemodynamically important mitral insufficiency, stenosis, or endocarditis (155,156) (eFig. 49.5.12). Annular calcification is mostly associated with age but is seen with hypertrophic cardiomyopathy (103), embolic stroke (156), secondary hyperparathyroidism (157), and atrioventricular conduction defects. Rarely, inflow obstruction becomes severe enough to warrant surgery (158).



***e*FIGURE 49.5.12** Mitral annular calcification (MAC). Parasternal long-axis view demonstrating hyperreflective material in the posterior mitral annulus.

Mitral stenosis. Left atrial enlargement and right ventricular hypertrophy have developed secondary to mitral stenosis, causing fixed pulmonary hypertension.

Congenital causes of MS include parachute MV (single papillary muscle), supravalvular mitral ring (between the left atrial appendage and MV), and cor triatriatum (a linear LA structure above the appendage). When detected in adults, they usually are not severely obstructive. Left atrial myxomas may rarely cause inflow obstruction by their bulk. Carcinoid syndrome (usually confined to right-sided valves) and ergot use may rarely cause MS (159). When bronchial carcinoid occurs alone, it can result in isolated MS.

Mitral Regurgitation

Regurgitant lesions may be structurally more subtle than stenotic ones, with Doppler (see Chapter 51) playing an even more dominant role. Nevertheless, careful structural interrogation is critical to evaluating MR.

HEART SOUNDS

Audio 49.36 Mitral regurgitation. Auscultation performed in a 52-year-old male patient with severe bileaflet mitral prolapse and regurgitation. Note the muffled S_1 and the holosystolic blowing murmur that radiates to the axilla at the apical position. A musical, squeaky quality is heard over the left sternal border. Left upper sternal border (*first clip*), left lower sternal border (*second clip*), and apex (*third clip*). VIDEO

Video 49.47 Parasternal long-axis view of a rheumatic mitral valve with color Doppler. Mitral regurgitation is the primary problem seen by color Doppler, with only mild mitral stenosis due to the thickened and doming leaflets. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 49.48 Left ventriculography with severe mitral regurgitation. After contrast injection in the left ventricle, the left atrium achieves the equal opacity to the left ventricular cavity indicative of severe (4+) mitral regurgitation. Before contrast injection, calcification in the mitral annulus and descending aorta is evident. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Rheumatic Mitral Regurgitation

In rheumatic disease, the posterior leaflet is fixed and shortened, allowing the anterior leaflet to override it on closure and resulting in posteriorly directed MR. The degree of malcoaptation is predictive of MR severity (160).

VIDEO

Video 49.49 Parasternal long-axis view of a rheumatic mitral valve with thickened, restricted, doming leaflets. Severe mitral regurgitation is the primary functional problem with this valve with only mild mitral stenosis. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

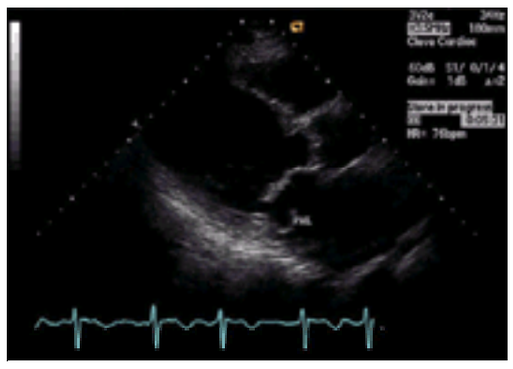
Mitral Valve Prolapse

The original clinical, auscultatory, and angiographic descriptions of mitral valve prolapse (MVP) (161,162) were rapidly supplemented by echocardiographic studies (163,164 and 165), which contributed to an “epidemic” of MVP by overly liberal diagnostic criteria.

VIDEO

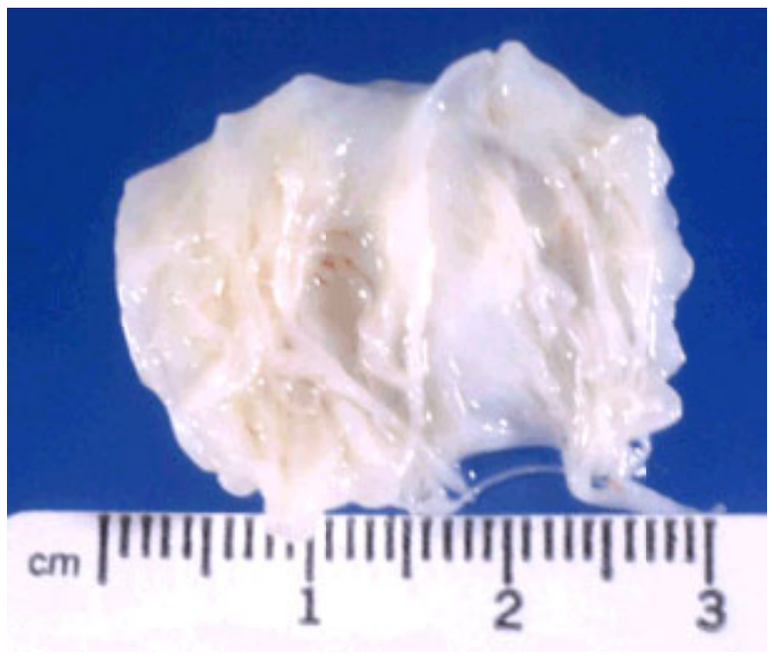
Video 49.50 Severe angiographic mitral valve prolapse with mitral regurgitation. In the angiogram there is a prolapse of the posterior leaflet accompanied by severe mitral regurgitation (4+). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Although MVP has a classic appearance by M mode (mid- or pansystolic posterior motion), up to 23% of healthy asymptomatic women may be diagnosed by these criteria (165). Two-dimensional echocardiography yielded a similar diagnostic prevalence until Levine et al. (166) demonstrated that the mitral annulus was saddle-shaped (nonplanar). Thus, leaflets may appear to close above the annulus in the apical four-chamber view (cutting through the low points of the annulus), while being normally oriented in a long-axis view (through the high points of the annulus). Current diagnosis of MVP rests on this long-axis displacement, although anatomic variability dictates that the full anterior leaflet and each of the three posterior scallops be thoroughly interrogated (eFig. 49.5.13).



***e*FIGURE 49.5.13** Mitral valve prolapse. Parasternal long-axis view of myxomatous mitral valve disease with prolapse and flail of the posterior mitral leaflet (PML).

MVP is also associated with myxomatous leaflet thickening and redundancy, with the tips sometimes being club-like, with a ground-glass appearance extending onto the chordae. The degree of MV deformity has been related to chest pain, arrhythmias, endocarditis, systemic emboli, and chordal rupture (167). Extreme prolapse may be difficult to differentiate from frank chordal rupture or endocarditis.



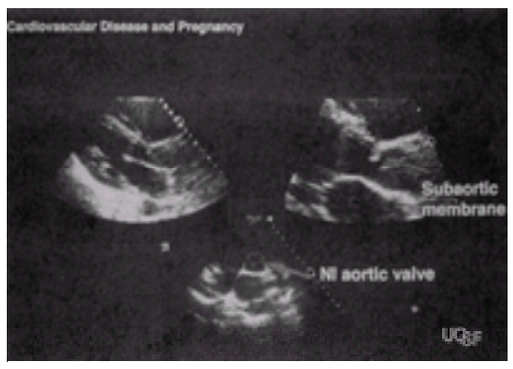
Myxoid mitral valve. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

ECHOCARDIOGRAPHY OF THE AORTIC VALVE

Aortic Valve

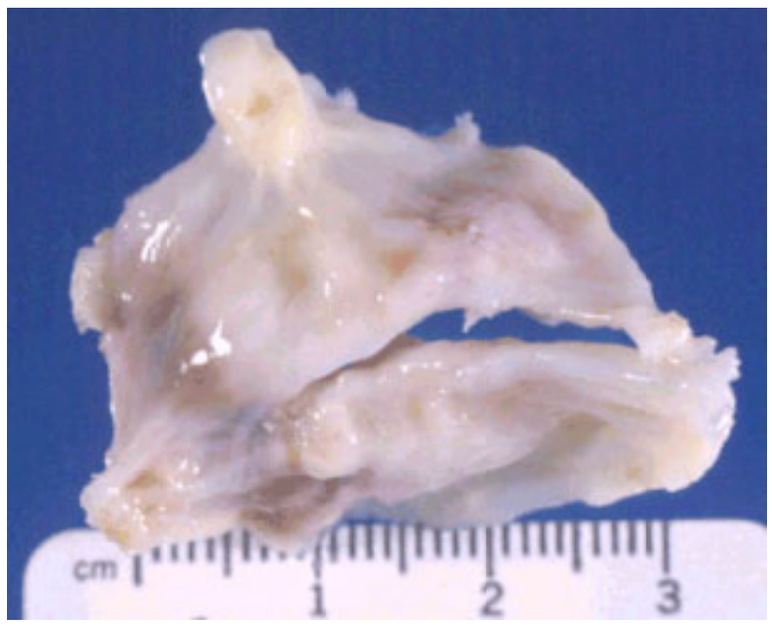
Normal Aortic Valve

M-mode echocardiography of the AV and root demonstrates leaflet closure at the midpoint of the aortic root and opening throughout systole to the walls of the aortic root, producing a “box-like” M-mode waveform. Fine systolic vibrations can be seen and correspond to a normal flow murmur. Failure to achieve or sustain full opening implies decreased stroke volume. Abrupt early closure may be caused by fixed subvalvular stenosis (*e*Fig. 49.5.14), and subsequent reopening in later systole may imply dynamic subvalvular obstruction. The coapted leaflets move parallel to the aortic root in diastole, with vibrations suggesting valve disruption or endocarditis. Eccentricity on closure typically indicates a congenital bicuspid valve (*e*Fig. 49.5.15).



***e*FIGURE 49.5.14** Subvalvular membrane. Parasternal long-axis view (*upper left with zoomed image in upper right*) of a discrete subvalvular membrane within the left ventricular outflow tract. The short-axis view of the aortic valve (*lower panel*) shows it to be a normal trileaflet valve. NI, normal. (Courtesy of Dr. Elyse Foster.)

***e*FIGURE 49.5.15** Bicuspid aortic valve. Transesophageal echocardiogram showing a functionally bicuspid aortic valve with fusion between the right (*bottommost*) and left (*right-sided*) coronary cusps. The valve opens with an oval orifice but may appear nearly normal when closed in diastole.



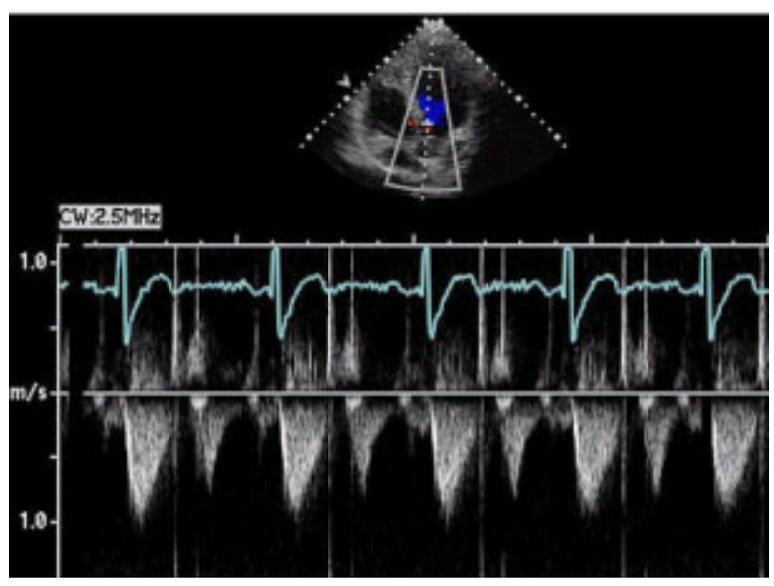
Bicuspid aortic valve with calcification. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Unicuspid aortic valve (A,B). (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Video 49.51 Congenital bicuspid aortic valve with mild aortic regurgitation (left anterior oblique view). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

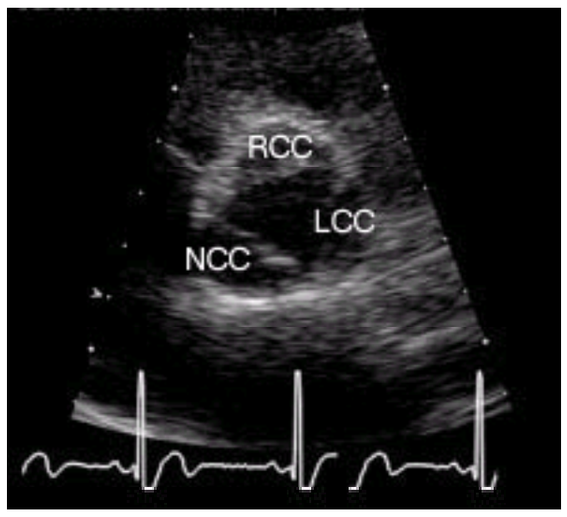
Video 49.52 A 76-year-old female patient with bicuspid aortic valve, aortic stenosis, and coarctation of aorta. Left anterior oblique aortogram revealed coarctation of the aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Normally, the aortic root moves more than 7 mm anteriorly in systole, with fair concordance to stroke volume independent of LV EF (e.g., an underfilled LV with normal EF causes decreased root motion). Augmented motion of the root despite reduced aortic leaflet separation is typical of mitral insufficiency. Slowed posterior motion of the root in early diastole with augmented presystolic movement is analogous to the delayed relaxation pattern of mitral inflow. In restrictive states, root motion is flat, reflecting reduced stroke volume.

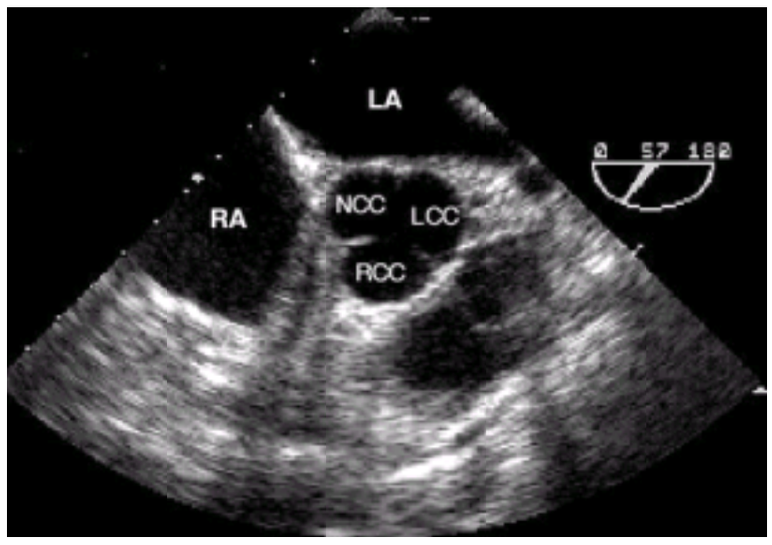


Normal continuous wave Doppler through the aortic valve by transthoracic echo. Note that the maximal velocity is approximately 1 m/sec (capillary wedge pressure gradient = 4 mm Hg).

Two-dimensional imaging of the normal AV demonstrates three thin leaflets, opening as a circular orifice and closing as a three-pointed star with slight central thickening. The left coronary cusp is adjacent to the left atrial appendage, the left main coronary artery, and the pulmonary valve and artery. The right lies just posterior to the RV outflow tract, close to the septal attachment of the TV. The noncoronary cusp sits above the RA and the interatrial septum. Aortic diameter is largest at the sinuses of Valsalva and should not exceed 3.5 cm.



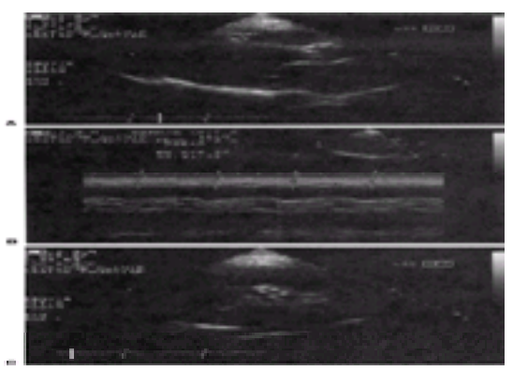
Magnified view of the aortic valve in short axis as seen from the parasternal window in systole. All three leaflets are opened. LCC, left coronary cusp; NCC, noncoronary cusp; RCC, right coronary cusp.



Short-axis transesophageal echo view of the aortic valve seen in diastole. Note the closed leaflets of the aortic valve.

Aortic Stenosis

In severe AS, the M mode shows dense persistent echoes with little systolic separation (168) (eFig. 49.5.16). Aortic sclerosis without stenosis shows dense echoes, but at least one leaflet will move rapidly or will vibrate, indicating a peak systolic gradient below 50 mm Hg. M mode also shows secondary features of AS such as LVH and LA enlargement.



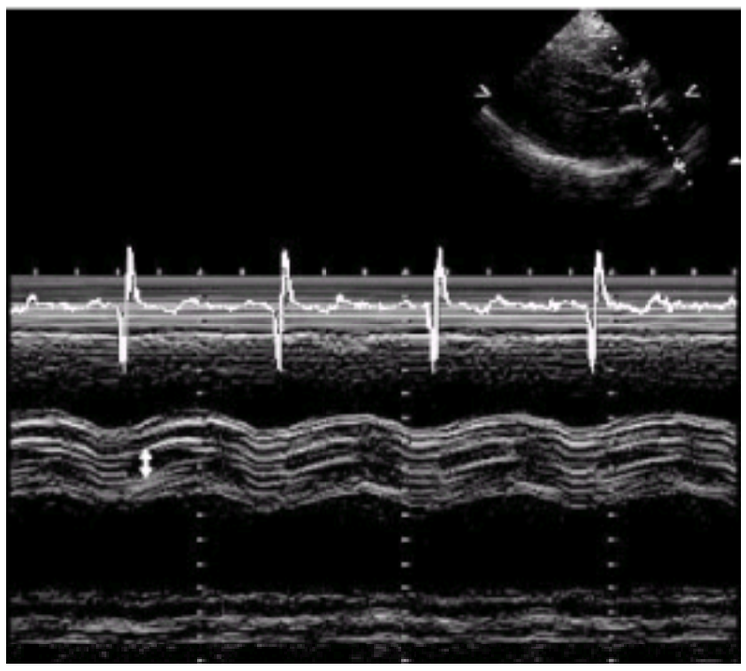
***e*FIGURE 49.5.16** Calcific aortic stenosis. **A:** Parasternal long-axis view showing thickened hyperreflective mitral leaflets with restricted opening. **B:** M mode through aortic valve showing multiple echogenic structures with limited leaflet separation in systole. **C:** Parasternal short-axis view showing calcific deposits within the cusps of the aortic valve.

HEART SOUNDS

Audio 49.53 Severe valvular aortic stenosis. Auscultation at the right upper sternal border performed in a 70-year-old male patient with a calcified and degenerated aortic valve. The peak and mean systolic gradients across the aortic valve were 100 and 55 mm Hg, respectively. The valve area calculated by the continuity equation was 0.5 cm^2. Note the soft A_2 and the high-pitched mid-systolic crescendo-decrescendo murmur. Right upper sternal border (*first clip*) and left upper sternal border (*second clip*). (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

HEART SOUNDS

Audio 49.54 Severe valvular aortic stenosis. Auscultation at the right upper sternal border performed in a 70-year-old male patient with a calcified and degenerated aortic valve. The peak and mean systolic gradients across the aortic valve were 100 and 55 mm Hg, respectively. The valve area calculated by the continuity equation was 0.5 cm^2. Note the soft A_2 and the high-pitched mid-systolic crescendo-decrescendo murmur. Right upper sternal border (*first clip*) and left upper sternal border (*second clip*). (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



M-mode through a stenotic aortic valve. Note the thickened aortic leaflets with decreased excursion. (The small arrow designates the limited excursion of the aortic leaflets.)

HEART SOUNDS

Audio 49.55 Moderately severe valvular aortic stenosis. Auscultation at the right upper sternal border (sitting) in a 72-year-old male patient with moderately severe aortic valve stenosis (peak gradient of 58 mm Hg and mean gradient of 32 mm Hg with calculated aortic valve area by continuity equation of 0.8 cm^2). Note the systolic ejection murmur and the soft second heart sound. Right upper sternal border, sitting (*first clip*); right upper sternal border, supine (*second clip*); left upper sternal border (*third clip*); left lower sternal border (*fourth clip*); and apex (*fifth clip*). (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

HEART SOUNDS

Audio 49.56 Moderately severe valvular aortic stenosis. Auscultation at the right upper sternal border (sitting) in a 72-year-old male patient with moderately severe aortic valve stenosis (peak gradient of 58 mm Hg and mean gradient of 32 mm Hg with calculated aortic valve area by continuity equation of 0.8 cm^2). Note the systolic ejection murmur and the soft second heart sound. Right upper sternal border, sitting (*first clip*); right upper sternal border, supine (*second clip*); left upper sternal border (*third clip*); left lower sternal border (*fourth clip*); and apex (*fifth clip*). Cusp separation by two-dimensional imaging is helpful if it is less than 8 mm or more than 12 mm but poorly predictive between 8 and 12 mm (169). Leaflet doming, poststenotic aortic dilatation, and LVH are predictive of significant AS, although none approaches the utility of Doppler-derived pressure gradient and valve area (169,170,171 and 172).

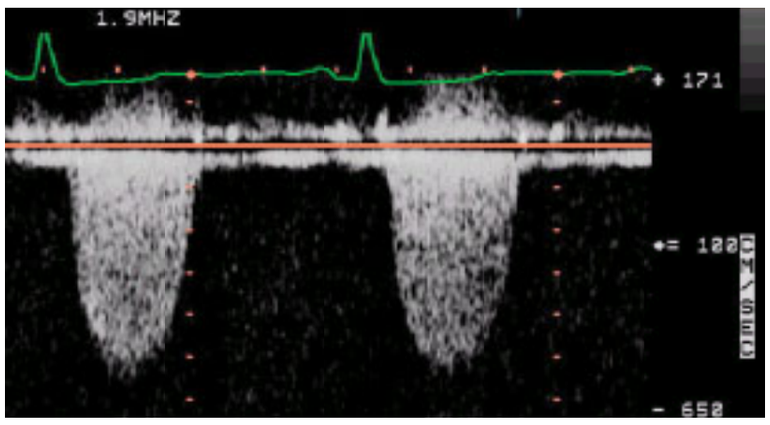
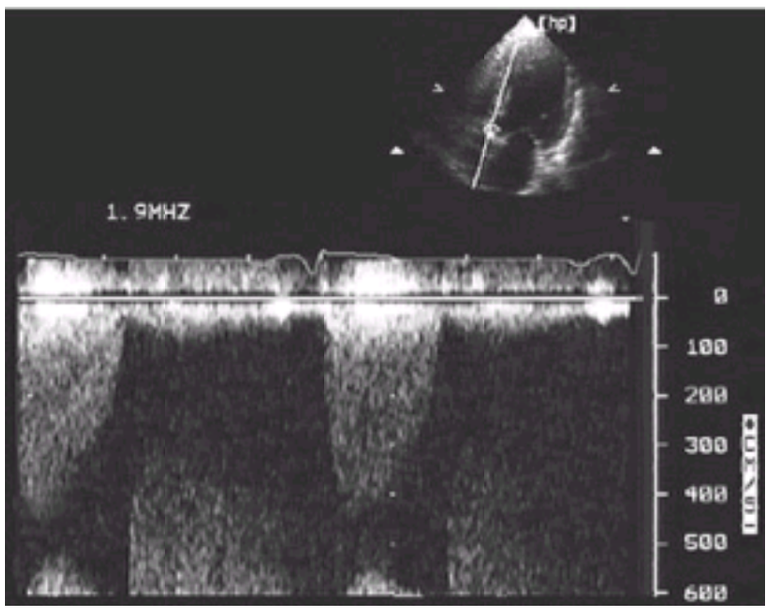
Short axis transesophageal view of a unicuspid aortic valve with aortic stenosis. The arrow designates the single commissure present in this aortic valve. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)



Continuous wave Doppler through a stenotic aortic valve. The maximal velocity is 5.5 m/sec, consistent with a peak pressure gradient of 121 mm Hg.

The severe calcification of senile AS is nonspecific as to underlying pathology. In younger patients, bicuspid valves show eccentric opening and only two moving leaflets. On closure of the valve, three commissures may be seen due to raphe formation between two leaflets, usually the left and right. Rheumatic AS shows commissural fusion and leaflet retraction and is generally associated with rheumatic mitral disease. Senile calcification typically begins in the aortic annulus, spreading centrally into the leaflets.



Apical continuous-wave Doppler spectrum of aortic valve disease. Note high forward velocities in systole (V_{max} 4.5 m/sec) and early peak of aortic stenosis. At the bottom, wrapped-around diastolic flow velocities from aortic regurgitation are seen.

Subvalvular and Supravalvular Stenosis

Fixed subvalvular stenosis is occasionally encountered in the adult population (173,174 and 175), often with prior ventricular septal defect. The subvalvular membrane is a narrow ridge in the distal septum (eFig. 49.5.14). Because the narrowing may be difficult to appreciate by inspection, Doppler remains the definitive quantitative modality. Dynamic subvalvular stenosis is discussed above under Normal Aortic Valve. Supravalvular AS is rarely seen in adults. Features include narrowing above and affixed to the valve leaflets, aortic insufficiency, enlarged coronary arteries (sometimes obstructed), and severe hypertrophy (176).

VIDEO

Video 49.66 Subaortic stenosis. A radiolucent membrane is visualized just below the aortic valve cusps (left anterior oblique view). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 49.67 Transesophageal echo in a patient with a subvalvular membrane in the left ventricular outflow tract. Note the normal mobility of the aortic valve. This patient had a significant pressure gradient across the left ventricular outflow tract/AV. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Aortic Regurgitation

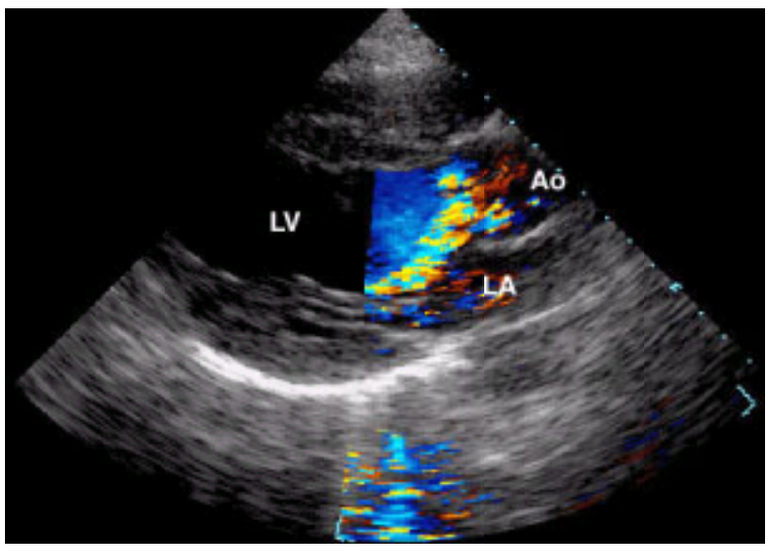
Aortic regurgitation (AR) can be seen with diastolic fluttering of the anterior mitral leaflet by M mode (177), a sign largely supplanted by Doppler. With severe acute AR, M mode may show early closure of the MV (178), indicating precarious hemodynamics and a need for urgent pharmacologic or surgical intervention (178). Henry et al. (179) have suggested that an LV end systolic dimension of greater than 55 mm predicts poor operative results—a concept challenged by Fioretti et al. (180), perhaps due to improvements in myocardial preservation at surgery. Assessment of AR severity by two-dimensional echocardiography has not been adequately studied (181). Posteriorly directed AR may reverse the diastolic curvature of the anterior mitral leaflet (182), but no two-dimensional sign replaces a quantitative Doppler examination (177,183) (see Chapter 51).

VIDEO

Video 49.68 Parasternal long-axis view (transthoracic echo) of a bicuspid aortic valve with prolapse of the anterior leaflet causing posteriorly directed aortic insufficiency. The aortic insufficiency hits the anterior mitral leaflet, causing deformation of this leaflet. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 49.69 Parasternal long-axis view (transthoracic echo) of a bicuspid aortic valve with prolapse of the anterior cusp (right and left coronary cusps fused) causing posteriorly directed aortic insufficiency. Note the posterior displacement of the anterior mitral leaflet (AML) caused by the aortic insufficiency jet hitting this leaflet. The left ventricular cavity is dilated. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Parasternal long-axis view (transthoracic echo) with color Doppler demonstrating the posteriorly directed aortic insufficiency caused by prolapse of the anterior leaflet of a bicuspid aortic valve. Note that the jet hits the anterior mitral leaflet.

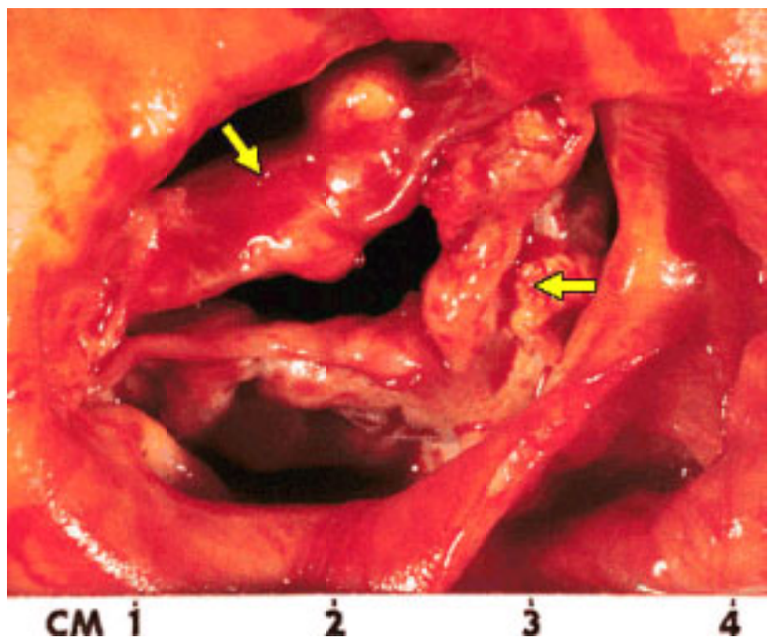
Video 49.70 A 49-year-old male patient with bicuspid aortic valve and severe aortic regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.71 Multiple gated acquisition scan of a patient with aortic insufficiency, ascending aortic aneurysm, and congestive heart failure. The ascending aorta is dilated, and there is moderate to severe left ventricular dilatation (ejection fraction approximately 30%). There is a prominent septal separation suggesting left ventricular hypertrophy. Analysis of regional wall motion reveals mild septal and posterolateral hypokinesis, moderate anterolateral and anterior hypokinesis, and inferoapical and apical dyskinesis in the anterior (*first video*) and left anterior oblique (*second video*) projections. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.72 Multiple gated acquisition scan of a patient with aortic insufficiency, ascending aortic aneurysm, and congestive heart failure. The ascending aorta is dilated, and there is moderate to severe left ventricular dilatation (ejection fraction approximately 30%). There is a prominent septal separation suggesting left ventricular hypertrophy. Analysis of regional wall motion reveals mild septal and posterolateral hypokinesis, moderate anterolateral and anterior hypokinesis, and inferoapical and apical dyskinesis in the anterior (*first video*) and left anterior oblique (*second video*) projections. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Senile calcification typically results in mild AR. Rheumatic disease causes leaflet retraction and a central AR jet. Bicuspid aortic valves may have significant AR due to leaflet prolapse, usually of a conjoined anterior leaflet. Endocarditis may cause acute severe AR, recognized as mobile echoes prolapsing into the LV outflow tract. Transesophageal echocardiography (TEE) has greatly improved detection of aortic vegetations (184). AR can arise from subaortic membrane jets that undermine valve integrity. Myxomatous disease can cause AV prolapse. In Marfan disease (eFig. 49.5.17), isolated dilation of the sinuses of Valsalva causes traction on the aortic commissures and a central jet of AR (185). Other aortic diseases that are associated with AR include dissection, sinus of Valsalva aneurysms, aortoannular ectasia, and aneurysms due to atherosclerosis, syphilis, and ankylosing spondylitis. As discussed in Chapter 52, TEE is preferred for emergent diagnosis (186). Small perimembranous ventricular septal defects may close in childhood but leave behind AR. Doubly committed subarterial ventricular septal defect is also associated with aortic regurgitation.

***e*FIGURE 49.5.17** Aortic aneurysm. Parasternal long-axis view of a patient with Marfan syndrome showing dilatation of the aortic root and ascending aorta (AO), with effacement of the sinotubular junction.



Bicuspid aortic valve with calcific stenosis. The yellow arrows identify each of the valve leaflets.

Aortic valve calcification. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

VIDEO

Video 49.73 Parasternal short-axis view of a patient with senile calcific aortic stenosis. Note the heavily calcified, distorted leaflets with restricted motion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 49.74 Transgastric view (transesophageal echo) of the mitral valve in a patient with severe aortic insufficiency. Note the fluttering of the anterior mitral leaflet (*left*) due to the jet of aortic insufficiency hitting it (color flow seen on the left). Tricuspid Valve

The TV has anterior, septal, and posterior leaflets; the latter two are somewhat variable in size and position. M mode from the parasternal window with rightward and

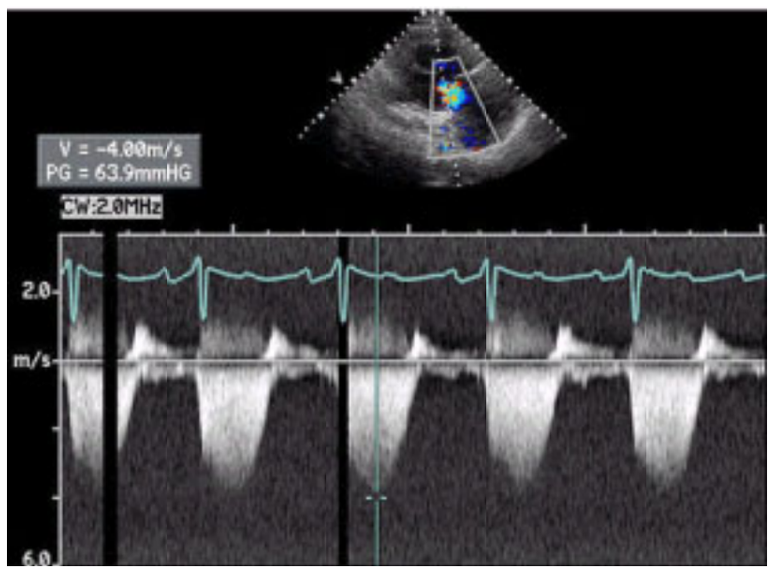
inferior angulation is useful for timing. Two-dimensional imaging can be recorded from the parasternal long- and short-axis and apical four-chamber views for anatomic and Doppler evaluation. The TV is apically displaced by the membranous septum, which is useful in identifying the TV in congenital heart disease. Transesophageal imaging offers relatively little advantage, especially for measuring TR velocity (187).

Tricuspid Insufficiency

Contemporary echocardiography confirms Sir James Mackenzie's claim, made in 1908, that TR is ubiquitous. Present in 80% of normal subjects and nearly all cardiac patients, this "abnormality" usually is just a convenient means to estimate pulmonary artery pressure (188). Pathologic TR causes RV and RA enlargement, paradoxical septal motion, and systolic IVC pulsation from retrograde flow. M mode shows paradoxical septal motion, with anterior systolic motion of the septum related to the exaggerated RV stroke volume. M mode can also record systolic IVC expansion, which should not be confused with respiratory fluctuations. By two-dimensional imaging, RV dilatation can be seen, although quantitation is imprecise (125) and hyperdynamic function can be seen due to the augmented stroke volume (24,236). RA enlargement is common and is related to TR duration and severity and the presence of atrial fibrillation. With severe TR, the normal leftward bulging of the interatrial septum is reversed (189).

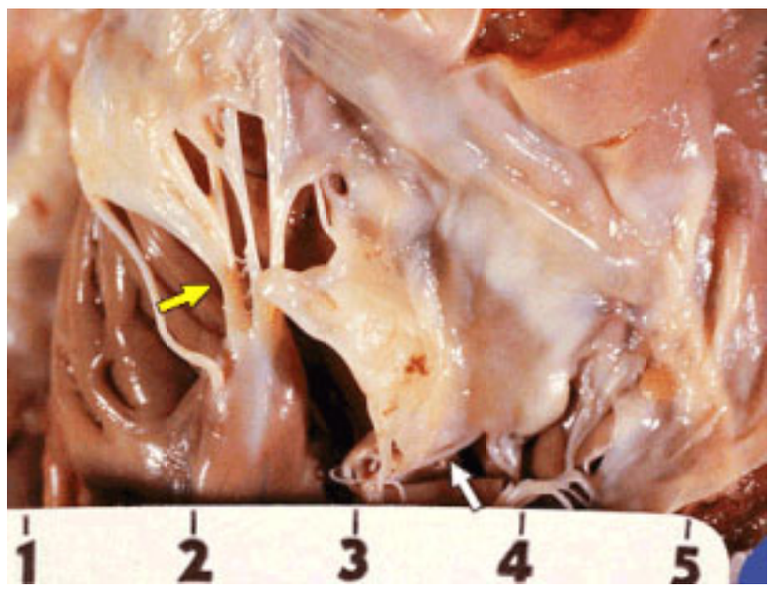
The most common cause of significant TR is RV failure from high LV filling pressures, with annular dilatation and failure of leaflet coaptation (190). Rheumatic TR rarely exists without MV involvement. It is characterized by leaflet thickening, commissural fusion and calcification, and chordal shortening. Myxomatous MV disease may be accompanied by tricuspid prolapse (191), but severe TR is uncommon unless there is chordal rupture (192). RV biopsy may rarely cause iatrogenic chordal rupture (193). Endocarditis (usually due to intravenous drug use) causes bulky prolapsing vegetations and flail leaflets (194) (*e*Fig. 49.5.18). Metastatic liver carcinoid causes TV leaflet shortening with more regurgitation than stenosis (159). Ebstein's anomaly commonly causes severe TR (133) (*e*Fig. 49.5.8).

***e*FIGURE 49.5.18** Tricuspid valve endocarditis. Apical four-chamber view showing multiple bulky vegetations on the tricuspid valve with an enlarged right atrium and the interatrial septum bowing to the left, consistent with elevated right atrial pressure. (Images courtesy of Advanced Technology Laboratories, Bothel, WA.)



Continuous wave Doppler trace through the tricuspid valve of a patient with pulmonary hypertension. The maximal jet velocity of 4 m/sec corresponds to a pressure gradient of 64 mm Hg or a PA pressure of approximately 80 mm Hg.

Video 49.76 Transesophageal four-chamber view focusing on the tricuspid valve showing myxomatous tricuspid valve disease with severe prolapse causing severe tricuspid regurgitation (pre-operative). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Rheumatic disease of the tricuspid valve. Note the shortened cordae (*yellow arrow*) and thickened valve leaflet (*white arrow*).

Video 49.77 Transthoracic right ventricular inflow view demonstrating rheumatic tricuspid valve disease. Note the doming of the tricuspid valve leaflets as well as their restricted closure causing both tricuspid stenosis and regurgitation. *This video must be viewed with QuickTime. Verrucal endocarditis of the aortic valve. Multiple vegetations are seen on the aortic valve cusps in this patient with subacute bacterial endocarditis.

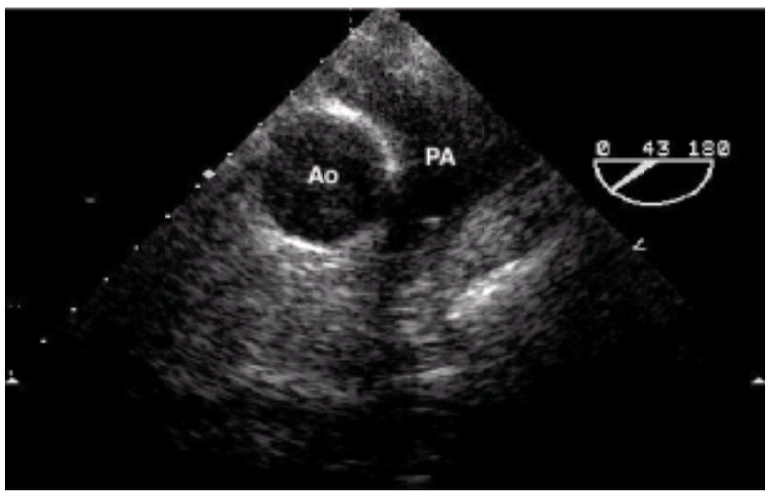
Surgical field of a patient with infectious endocarditis and a large vegetation with perforation of the anterior mitral leaflet. The entire surgical view is filled with the large vegetation.

Tricuspid Stenosis

Tricuspid stenosis may be due to rheumatic disease, carcinoid syndrome, or prolapsing RA tumors. Two-dimensional planimetry is not reliable, making Doppler the mainstay of quantitation.

Pulmonary Valve and Artery

Pulmonary valve pathology is common in congenital disease but is rarely acquired. M-mode and two-dimensional imaging are limited to leaflet inspection (often difficult) and pulmonary artery dilatation. The M mode in pulmonary stenosis (PS) shows an exaggerated diastolic "'a' wave" caused by powerful RA contraction opening or doming the pulmonary valve. By two-dimensional imaging, PS shows systolic leaflet doming, variable leaflet thickening, poststenotic dilation of the main PA with decreased pulsations, and variable RV hypertrophy. PS must be distinguished from subpulmonic stenosis and double-chamber RV that results from prior ventricular septal defect.



Transesophageal echo view demonstrating the pulmonary artery bifurcation at the center of the screen and the aorta in short axis to the left. This view is useful to look for a large, saddle embolus to the pulmonary artery bifurcation, although smaller, more distal emboli will be missed.

HEART SOUNDS

Leopard's syndrome. Figure shows a patient with Leopard's syndrome characterized by multiple basal cell nevi and broad facies. There is an association with pulmonic stenosis.

VIDEO

Video 49.81 Transesophageal echo of a patient with congenital pulmonary stenosis. Note the severe hypertrophy of the right ventricular outflow tract, causing infundibular pulmonary stenosis as well as valvular pulmonary stenosis. The pulmonic leaflets are thin and pliable; however, there is marked doming caused by tethering of the leaflet tips. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Trivial pulmonary regurgitation (PR) is present in most healthy persons. Severe PR rarely occurs from prior tetralogy of Fallot repair, endocarditis (195), or carcinoid (159). Moderate PR can result from pulmonary hypertension (Graham Steell's murmur).

Infective Endocarditis

Echocardiography is essential to the diagnosis and management of patients with infective endocarditis (IE). Early studies of echocardiography and IE used the criteria of Von Reyn et al. (196) for diagnosis. New echocardiographic criteria for diagnosing IE have been prospectively tested by the Duke Endocarditis Service (197,198). In these studies, echocardiography increased the sensitivity for detecting IE from 51% to 80%, although TEE was required to visualize the vegetations in 41% of cases.

If you do not have QuickTime you may download it here.*

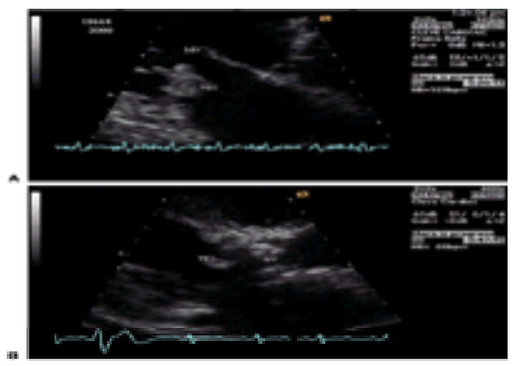
Vegetations

The hallmark of IE is the vegetation. Identification depends on a variety of patient and technical factors (eFig. 49.5.19). Images should be obtained with the highest transducer frequency (>2.5 MHz) that is capable of penetrating the chest for optimal resolution. Dynamic range should be optimized and the highest frame rate used. Color encoding ("B color") may enhance the appearance of vegetations. Echocardiographic visualization of vegetations is hampered by obesity, chronic lung disease, valvular calcification, and prostheses and may require TEE. A high degree of pretest suspicion promotes sensitivity for small vegetations, but it should be recognized that all valves normally have small nodules and that overvigilance may lead to false-positive findings.



***e*FIGURE 49.5.19** Mitral and aortic endocarditis. Parasternal long-axis views of **(A)** mitral (MV) and **(B)** aortic (AV) valve vegetations (VEG).

M-Mode Echocardiography

M mode may detect vegetations as small as 5 mm (199). Its key advantage (at least historically) is the very high sampling rates (>1,000 Hz) that can detect vegetative vibrations from the AV (diastole) and MV (systole) (200). These signs are less helpful currently, as M-mode rates are only approximately 200 Hz with contemporary equipment.

Two-Dimensional Imaging

In a metaanalysis of 16 early studies (641 patients), O'Brien and Geiser (201) reported a mean sensitivity of 79% for two-dimensional detection of vegetations and 52% for M mode, with vegetations as small as 3 mm reported by two-dimensional imaging (200). More recently, however, the reported sensitivity of TTE has dropped to 62% despite equipment improvement (184,202,203,204,205,206 and 207), reflecting less biased case selection and the fact that these studies used TEE (sensitivity of 92%).

Sanfilippo et al. (208) retrospectively studied 204 patients with IE, showing that larger (>10 mm) mobile noncalcified vegetations were predictive of antibiotic failure, congestive heart failure, embolization, surgery, and death. Size was highly predictive of complications: 10% for 6-mm vegetations, 50% at 11 mm, and almost 100% at 16 mm.

Explanted Carpentier-Edwards mitral valve regurgitation in a patient with severe infective prosthetic valve endocarditis. The patient had severe mitral stenosis due to the large vegetations on the prosthesis.

Transesophageal Echocardiography

Just as two dimensional supplanted M mode as the imaging mode of choice (209), TEE (210) brings even better sensitivity in IE (184), although at the cost of a semiinvasive procedure (190,206,207,208 and 209,211). Diagnostic features of vegetations (208) include texture (like myocardium), location (upstream side of valves), motion (chaotic, prolapsing), shape (lobulated, amorphous), and accompanying abnormalities (abscesses, fistulae). A negative TEE renders endocarditis very unlikely but not impossible. False positives may occur as a result of minor valve irregularities (184), such as Lambl's excrescences, suture material, redundant chordae, false tendons, and Chiari networks. Prosthetic valve endocarditis, in particular, requires TEE because of shadowing from the chest wall, with sensitivities reported from 82% to 100% versus 25% to 43% for transthoracic imaging (212,213 and 214).

VIDEO

Video 49.85 Intraoperative transesophageal echo of a mitral valve with multiple, large, highly mobile vegetations from endocarditis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

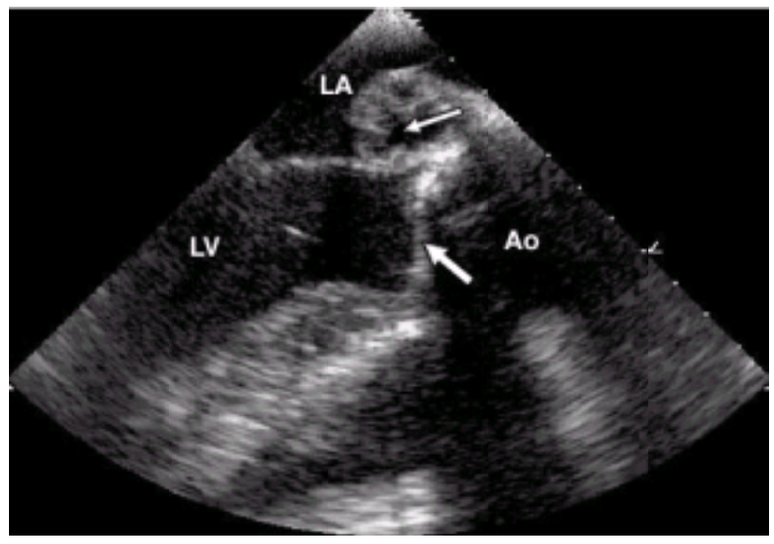
Prognosis in Infective Endocarditis

Echocardiography has proved useful in predicting complications of IE, although the data are somewhat discrepant (202,208,215,216 and 217). Heinle et al. (217) found high interobserver agreement on location, but not size, of vegetations and little prognostic value for complications. Mugge et al. (202) found that vegetations of greater than 10 mm had an embolic rate of 46% versus 20% for smaller ones (p <.001). Rohmann et al. (215) observed an adverse prognosis if vegetations failed to regress with therapy: valve replacement (45% vs. 2%), emboli (45% vs. 17%), abscess (13% vs. 2%), and mortality (10% vs. 0%; all p <.05).

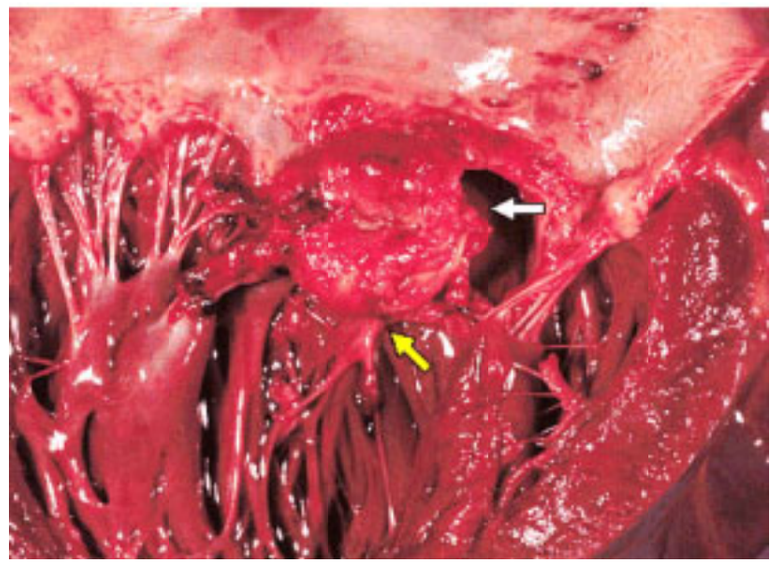
A negative TEE has 98% negative predictive value for IE (184), although vegetations may be missed with monoplane examination (206), especially on an aortic prosthesis.

Complications of Infective Endocarditis

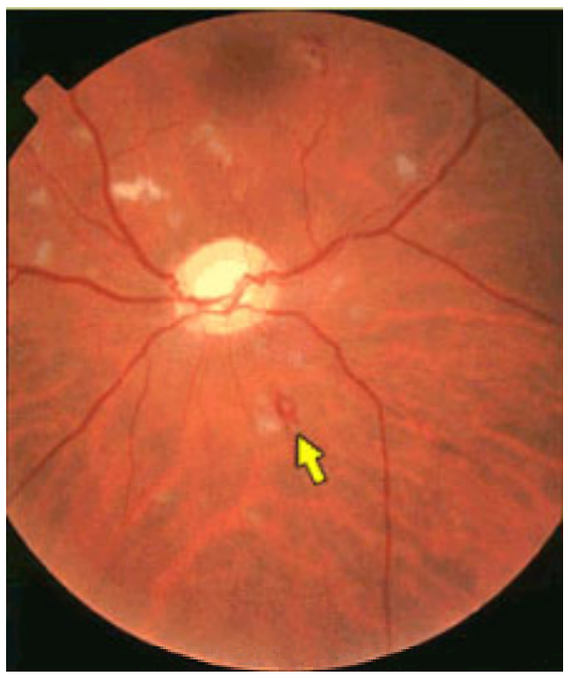
Infection may invade the surrounding myocardium and fibrous tissue, causing cellulitis and, ultimately, an abscess that can rupture into another cavity as a fistula (218). A septal abscess can cause arteriovenous block (219). Daniel et al. (205) found an abscess in 37% of 118 cases, with a sensitivity of 87% by TEE versus 26% by TTE, which was subsequently confirmed by others (219,220).



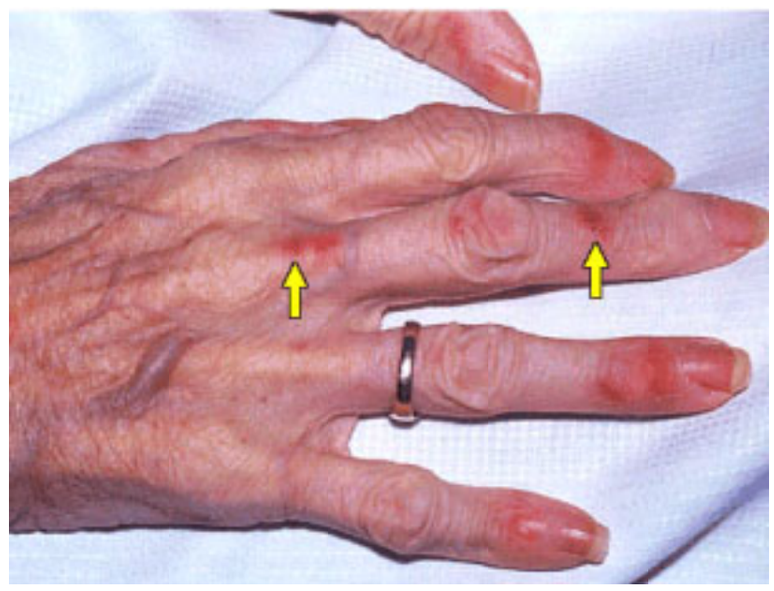
A 120-degree transesophageal echo of an aortic valve abscess seen in the inner annular fibrosa. The thin arrow designates the abscess cavity, while the thicker arrow demonstrates the aortic valve.



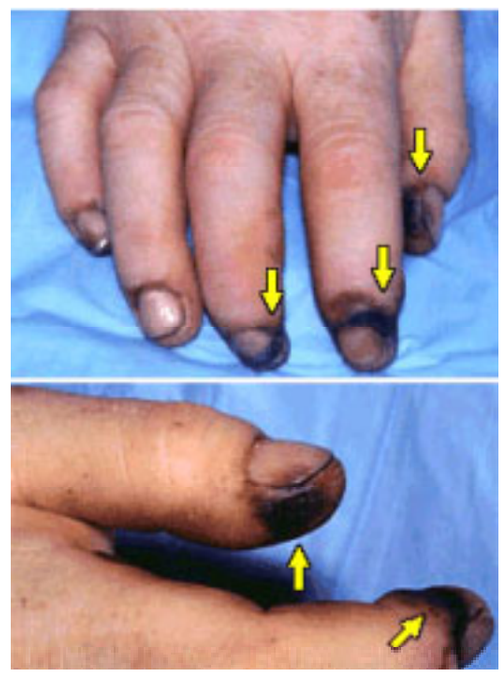
Infectious endocarditis of the mitral valve with cordal rupture. The infected leaflet is indicated by the yellow arrow. The usual cordal attachment to the leaflet is absent (*white arrow*).



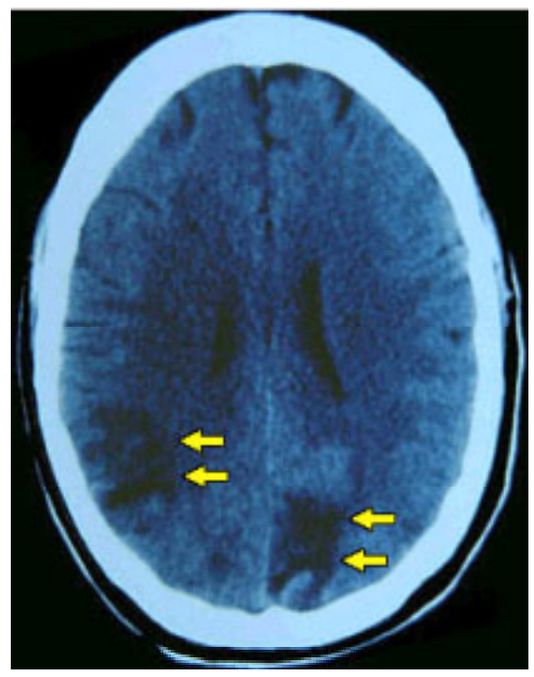
Roth's spot. The yellow arrow indicates a hemorrhage with a white central spot typical of subacute bacterial endocarditis.



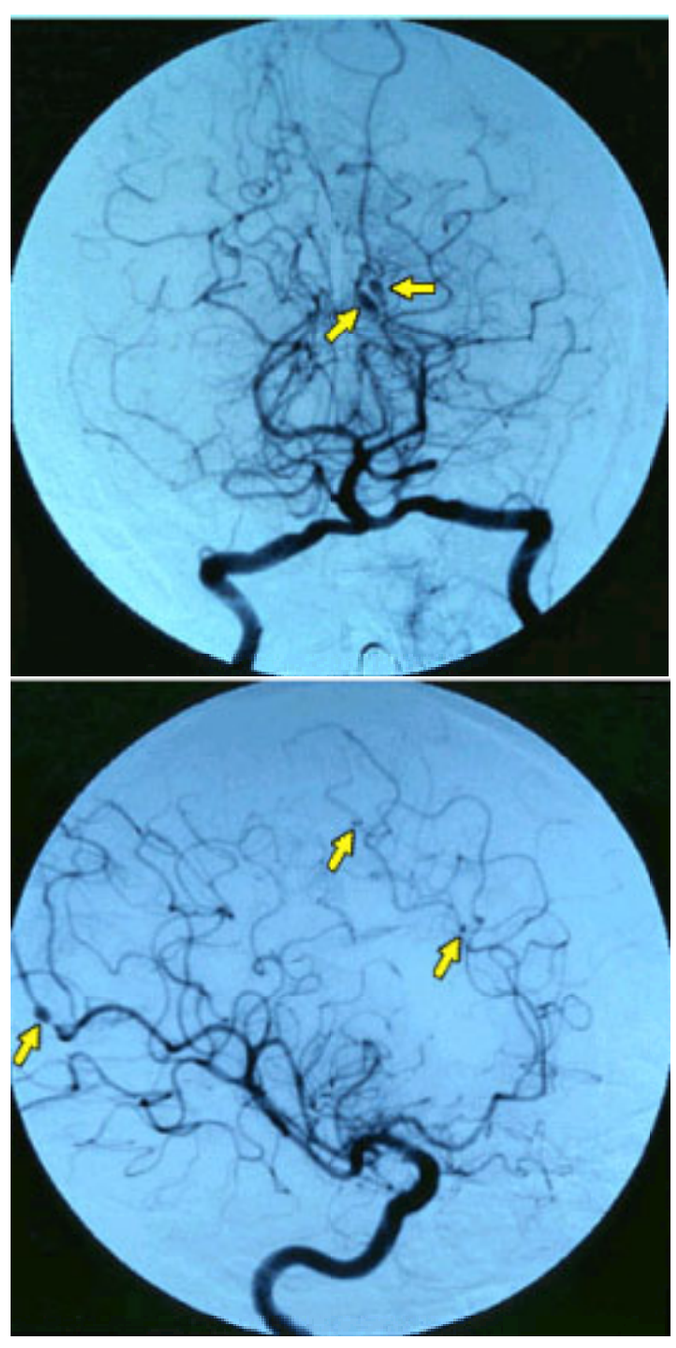
Septic emboli from infective endocarditis (*arrows*).



Janeway lesions of endocarditis. There are hemorrhages with nodular character at the fingertips (*arrows*).



Ruptures mycotic aneurysms. Several areas of hypodensity representing ruptured mycotic aneurysms as a result of endocarditis (*arrows*).



Mycotic aneurysms from infective endocarditis. Localized aneurysmal dilatation of cerebral vessels as a result of endocarditis (*arrows*, A,B).

Osler nodes. There are tender nodules on the toe pads (*arrows*) secondary to infective endocarditis.

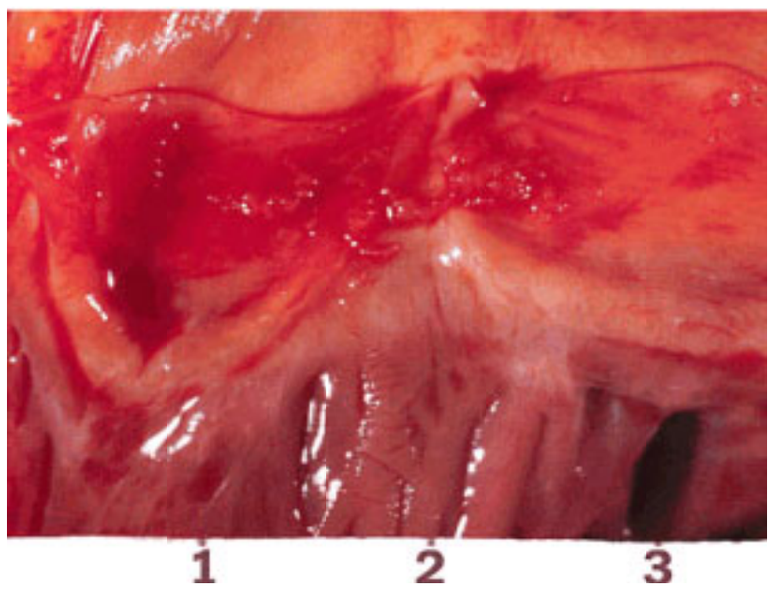
Septic emboli. Raised nodules from septic embolization from infective endocarditis.

Splinter hemorrhages. Linear hemorrhages on the fingertips of a patient with infective endocarditis.

Note the systolic expansion of the cavity located between the aortic and mitral valved in the inner annular fibrosa. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Right-Sided Infective Endocarditis

Tricuspid IE (usually *Staphylococcus aureus*) typically occurs in intravenous drug users (221) and causes large vegetations that are equally well detected by TTE and TEE (187). Multiplane TEE may be of value for the very rare pulmonic vegetations (195).



Marantic (nonbacterial) endocarditis of the pulmonic valve. Multiple vegetations are seen on the pulmonic valve in this patient with no bacterial growth from multiple blood cultures.

Video 49.87 Transesophageal echo of a large tricuspid valve vegetation in a patient with infectious endocarditis. This patient was an intravenous drug user, which is common in patients with right-sided endocarditis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

PERICARDIAL DISORDERS

Echocardiography detects virtually all pericardial effusions (222,223) and is the diagnostic test of choice (224), providing important hemodynamic data as well. Normally, there is less than 20 mL pericardial fluid (225), barely detected during systole by M mode. The high temporal resolution of M mode is valuable in assessing pericardial motion and RA and RV dynamics. The parietal pericardium is highly echogenic.

Two-Dimensional Echocardiography

Two-dimensional echocardiography and Doppler are key in assessing pericardial disease, with small effusions first seen above the RA. The normal systolic torsion of the heart is lost when inflammation causes adhesions between the pericardial layers. Pericardial fat may mimic effusion (226), typically seen anterior to the heart. D'Cruz and Hoffman (227) have described an ellipsoidal formula for estimating effusion size, although effusions typically are graded as small (separation seen throughout the cardiac cycle), medium, and large (typically >2 cm circumferentially). Although transudates, exudates, and blood appear similar, septations suggest chronicity.

Tamponade

Tamponade is a continuum of hemodynamic embarrassment, often associated with large effusions (228,229,230,231,232,233,234 and 235), although small rapid accumulation can be life threatening. Characteristic echocardiographic features are listed in Table 49.1. The heart is usually small, unless previously enlarged (229), and respirophasic ventricular interdependence is seen. The RV enlarges with inspiration and the LV with expiration, the echocardiographic equivalent of pulsus paradoxus (229,236). RV diastolic collapse and RA invagination (>one-third of cardiac cycle) are seen (229,230,232,233) (eFig. 49.5.20). Central venous pressure (CVP) can be estimated from IVC dynamics (231). If CVP is normal, the IVC is greater than 17 mm and decreases by more than 5 mm during inspiration. With elevated CVP, typical of tamponade, the IVC exceeds 20 mm and respiratory change is blunted (231,237) (eFig. 49.5.21), a sign that is less useful with mechanical ventilation (238).

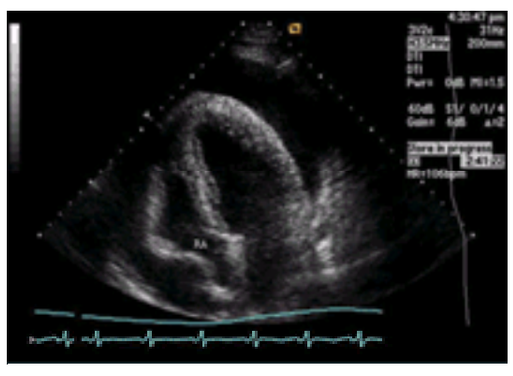
Large effusion
Right atrial (RA) expiratory collapse
Right ventricular (RV) expiratory compression or collapse
IVC plethora with diminished respiratory response
Left atrial compression
Small chamber volumes
Reciprocal size changes between RV and LV and excursion between MV and TV

Sensitivity, specificity, and positive and negative predictive values

	Sen	Spec	PPV	NPV
Size (large vs. moderate)	—	97	45	96
RV compression	48	95	38	96
RA compression	55	88	10	99
IVC plethora	97	66	7	96

IVC, inferior vena cava; LV, left ventricular; MV, mitral valve; NPV, negative predictive value; PPV, positive predictive value; TV, tricuspid valve.

TABLE 49.1 TWO-DIMENSIONAL ECHOCARDIOGRAPHIC FINDINGS IN TAMPONADE



***e*FIGURE 49.5.20** Pericardial tamponade. Apical four-chamber view showing large circumferential pericardial effusion with invagination of the right atrial (RA) free wall, consistent with tamponade.

it here.

Loculated Effusion

Following pericardiotomy, effusions may be loculated, making the diagnosis of tamponade and differentiation from pleural effusions difficult. Many two-dimensional signs of tamponade (such as RA invagination) may be absent if the hematoma is not localized to that area. Postcardiotomy (Dressler's) syndrome may develop days to weeks after surgery and requires a high degree of clinical suspicion to diagnose.

Pleural versus Pericardial Effusion

Left pleural effusions can be distinguished by their posterior location, passing behind the descending aorta. Large bilateral pleural effusions may occasionally cause tamponade that is responsive to drainage (239).

Video 49.89 Subcostal short-axis view of a large pericardial effusion causing tamponade. Note that the right side is small and under filled. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.90 Apical four-chamber view (transthoracic) in a patient with metastatic lung cancer demonstrating a moderate to large pericardial effusion and a very large, highly organized pleural effusion encasing the heart. (Pleural effusion is towards the right of the screen.) Note the extensive fibrinous network in the pleural effusion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 49.91 Subcostal short-axis view demonstrating the left ventricle surrounded by an organized pericardial effusion, which is adjacent to highly organized pleural effusion in a patient with metastatic lung cancer. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Pericardial Thickening and Constriction

Pericardial thickening is common, although constriction is rare. Thickening and adhesion are distinguished from simple effusion by the parallel (rather than damped) motion of the epicardium and visceral pericardium with the parietal pericardium. Pericardial constriction is a continuum of hemodynamic impairment, which may overlap with tamponade and (when the visceral layer is primarily involved) may have a component of restriction. By M mode, a septal notch may be seen in early diastole around the time of the pericardial knock (between S_2 and S_3) (240,241). Two-dimensional echocardiography may show extensive adhesion and a diastolic septal bounce (237), which may resemble left bundle branch block or RV pacing. IVC plethora is usually seen (231,237) unless the patient is severely dehydrated. In the four-chamber view, the ventricles appear elongated, and the atria are globally enlarged. Brief constrictive phases may be seen with resolution of simple effusions. Table 49.2 lists two-dimensional signs of constriction, distinct from restrictive cardiomyopathy. Malignancy often causes pericardial effusions and pericardial studding, and frank-mass effect may be seen.

Pericardial thickening and adhesion: lack of "sliding"; heart motion transmitted to other organs ("tugging")
Septal bounce: abrupt transient rightward movement
Inferior vena cava plethoric and unresponsive; hepatic veins dilated
Left and right ventricle size decreased; heart tubular in shape
Mild biatrial enlargement

TABLE 49.2 PERICARDIAL CONSTRICTION FINDINGS ON TWO-DIMENSIONAL ECHOCARDIOGRAPHY

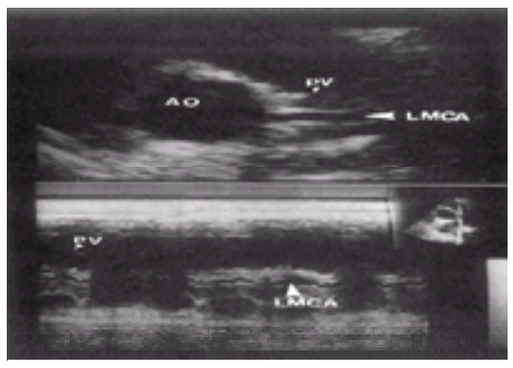
Video 49.92 Transesophageal echo (four-chamber view) demonstrating constrictive pericarditis. Note the abnormal septal bounce and the tethering of the right atrium and right ventricle by the thickened pericardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Congenital Abnormalities

Complete absence of the pericardium causes RV enlargement and paradoxical septal motion (144). Partial absence may cause LV herniation through the defect with coronary compression and myocardial infarction. Pericardial cysts are difficult to localize by echocardiography due to their lateral position (242).

Aorta and Great Vessels

Despite the primacy of TEE, TTE is useful in assessing the great vessels. The aortic root and ascending aorta are well seen in the parasternal long- and short-axis views. Coronary artery ostia can be visualized (eFig. 49.5.22), sometimes allowing for diagnosis of coronary anomalies and Kawasaki's disease.



***e*FIGURE 49.5.22** Coronary artery visualization. Parasternal short-axis view showing the left main coronary artery (LMCA) arising from the aorta (AO). PV, pulmonary valve.

Aortic Aneurysm

Symmetric sinus of Valsalva aneurysms (243,244) may be seen in Marfan syndrome. Echocardiographic enlargement of the root beyond 55 mm should generally prompt surgery. Ascending aortic dilatation may be poststenotic or atherosclerotic in origin, requiring high parasternal and right parasternal imaging to observe. The descending thoracic aorta can be seen in the long- and short-axis parasternal views posterior to the AV groove. The left and right pulmonary arteries may be seen in the short-axis view. The suprasternal notch allows visualization of the transverse and descending aorta as well as the origins of the innominate, left common carotid, and left subclavian vessels. In the apical views, posterior angulation often produces long- (two-chamber) and short- (four-chamber) axis views of the thoracic aorta. Atheroma and aneurysms of the abdominal aorta may be seen subcostally to the left of and deep to the IVC (245). Thoracic aortic dissection with effusion can also be imaged from the left paraspinal window, although TEE is the preferred method to assess the aorta (246).

Ascending aortic dissection extending into the left main. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Video 49.94 Intraoperative 120-degree transesophageal echo of an ascending aortic dissection. Note the large, complex flap in the ascending aorta seen originating near the origin of the right coronary artery. There is a small amount of aortic insufficiency. Flow is seen in the true lumen (*left*) whereas no flow is seen in the false lumen (*right*). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Great Veins

The IVC is seen subcostally, crossing the diaphragm just after receiving the confluence of the hepatic veins. Its size and response to respiration predict RA pressure (247,248). If the vessel loses 50% of its initial expiratory diameter during deep inspiration (while lying supine with the knees bent), RA pressure is considered normal. The superior vena cava can be seen from a suprasternal notch plane orthogonal to the aortic arch view, allowing Doppler interrogation of its flow.

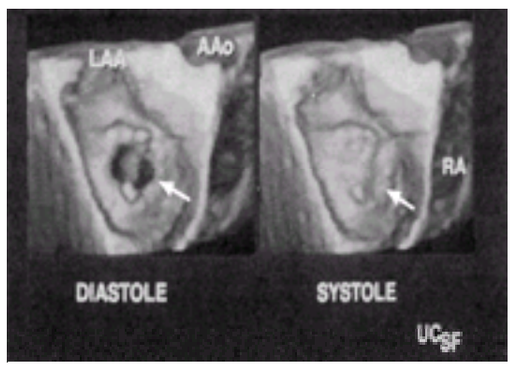
ADVANCES IN INSTRUMENTATION

Advances in instrumentation are occurring in many areas. Included in these are automatic border detection, Doppler tissue imaging, ultrasonic tissue characterization, video densitometry, and three-dimensional echocardiography.

Automatic border detection can track the LV endocardium (249,250,251 and 252), although it requires technically excellent images and has wide standard deviation among measurements. Another promising approach to endocardial border detection is Doppler display of low-velocity myocardial movement (so-called Doppler tissue imaging) (253,254). Enhancement of the LV blood pool and myocardium using ultrasonic contrast may allow these methods to become the standards.

Ultrasonic tissue characterization has shown slow progress, with cyclic variation in backscatter used as a marker for segmental ventricular function (255,256). Although many studies have sought to identify histologic changes (257,258,259,260 and 261), none has as yet entered common practice. Video densitometry can plot instantaneous changes in backscatter intensity as a bolus of contrast passes through the vasculature of the myocardium. Because it provides an analog of local flow, it should become useful when improved intravenous agents that can cross the pulmonary circulation intact and behave as surrogate red cells (262) become available.

Three-dimensional echocardiography can be accomplished by spatially registering each tomographic slice relative to the other (263,264,265 and 266). Quantitation of a three-dimensional data set can be done by selecting two-dimensional slices and tracing an outline of each slice (57,58,59,60 and 61,267). The slices are then added together to yield a volume or mass, a process that is independent of geometry yielding measurements that are accurate and reproducible. Unfortunately, this approach is time consuming and tedious; however, it may be improved by automated edge tracing and contrast enhancement of the myocardium and blood pool. Once it has been collected, a three-dimensional data set can place a virtual imaging window in any position (eFig. 49.5.23). Three-dimensional imaging remains in its formative stages. Two commercially available systems acquire spatially registered data sets over many cardiac cycles by using ECG and respiratory gating (264,268). These are limited by prolonged acquisition time between slice artifacts and long reconstruction times.



***e*FIGURE 49.5.23** Three-dimensional echocardiography. Three-dimensional reconstruction of a St. Jude valve (*arrow*) in the mitral position. The images are in diastole (*left*) and systole (*right*). LAA, left atrial appendage; AAo, ascending aorta; RA, right atrium.

CONTROVERSIES AND PERSONAL PERSPECTIVES

TTE is the single most useful imaging test in cardiology. Its use has grown tremendously over the last 10 years. However, this examination is not performed and interpreted uniformly—a fact that has attracted unfavorable attention to the potential overuse of echocardiography in the United States. Particularly appalling is the lack of quantitation in many echocardiographic reports. Echocardiography is quantitative in nature—calibration marks are included on every screen, and the Digital Imaging and Communications in Medicine (DICOM) standard allows them to be stored digitally; yet, echocardiograms too often are interpreted in general categoric terms.

Of the emerging echocardiographic (distinct from Doppler) technologies, three are most noteworthy: three-dimensional imaging, contrast echocardiography, and harmonic imaging. Three-dimensional reconstruction has been available commercially for several years and is a valuable tool in quantifying chamber size and visualizing cardiac structures. Nevertheless, it has failed to penetrate the clinical arena completely, primarily because of the prolonged acquisition and display times. With the development of real-time three-dimensional acquisition, however, examination time could become shorter, as all structural data could be captured in a data set

from a single cardiac cycle. True three-dimensional display remains problematic, but even scanning the data with properly oriented two-dimensional planes would be of great value.

Recent advances in echocardiography have resulted in improvements in image quality, especially for patients whose echocardiographic examination was previously suboptimal. Intravenous contrast agents are now available for LV opacification and endocardial border detection. Guidelines for the use of ultrasonic contrast in echocardiography have been published (269). Intravenous contrast agents should be used to provide additional diagnostic information for the detection of cardiac disease in difficult-to-image patients. They have been shown to be especially beneficial in obese patients, those with lung disease, and individuals who are receiving mechanical ventilation.

Use of harmonic frequencies to image tissue and contrast agents can further enhance image quality. In contrast harmonics, the harmonic frequency energy is generated on reflection of the ultrasound wave from the microbubble contrast agent. In tissue harmonics, the energy is gradually generated as the ultrasound wave propagates through the tissue. Essential to the utility of tissue-generated harmonic frequencies is their origin beyond the chest wall and their nonlinear relation to the fundamental frequency energy strength. These characteristics ensure that the echocardiograms that are most likely to produce artifact are least likely to produce harmonic waves (270). It is anticipated that harmonic imaging will become the standard for assessment of regional and global LV function in difficult-to-image patients.

Contrast agents that cross the lungs to opacify the LV cavity and myocardium combined with novel imaging techniques (e.g., transmitting at 2 MHz but receiving at 4 MHz) allow myocardial perfusion to at least be assessed in a binary sense (presence of coronary occlusion, occurrence of reperfusion). This may greatly assist in the detection and management of acute coronary syndromes. Even more exciting is the possibility of quantifying regional perfusion and flow reserve, an achievement that would bring echocardiography close to the holy grail of “one-stop shopping” that is claimed by other modalities.

THE FUTURE

Over the next 10 years, the field of echocardiography will be under intense pressure as cost containment leads to decreased reimbursement. This is ironic, because the value of the test should grow enormously as contrast, three-dimensional, and digital technologies mature. Although videotape will still be used, digital storage would allow retrieval throughout the hospital and transmission anywhere in the world, eliminating repetition of tests. Adherence to international formatting standards is critical. Attesting to the value of echocardiography are plans for a permanent ultrasound machine aboard the International Space Station for scientific research and for medical diagnosis.

OVERVIEW

Stress echocardiography provides a means of identifying myocardial ischemia by detection of stress-induced wall motion abnormalities on comparison of pre-stress and post-stress images. The technological revolution of ultrasound and digital technology has driven the development of this modality from a research to a clinical tool. However, interpretation of these studies remains subjective, and the learning curve of skills required to use this modality must be considered.

Echocardiography may be combined with various stressors and used in a variety of environments. The test is patient friendly because it is rapidly performed and inexpensive. The accuracy of stress echocardiography in detecting significant coronary stenoses ranges from 80% to 90%, depending on the population studied, and the specificity is high. The accuracy exceeds that of exercise electrocardiography (ECG), especially in subgroups among whom the latter is unreliable (e.g., women and patients with left ventricular hypertrophy), and the accuracy is comparable with that of stress myocardial perfusion scintigraphy. The need to induce ischemia limits the accuracy of stress echocardiography in detecting coronary artery disease (CAD) in patients who exercise submaximally or who are on antianginal therapy. However, the detection of ischemia may prove to be of value in using this test for prognostic evaluation or for monitoring the efficacy of therapy. Use of dobutamine echocardiography for identification of viable myocardium following myocardial infarction is another application that has moved this modality into the arena of assisting decision making in the management of CAD. Similarly, this test may provide useful data for the management of valvular and primary myocardial disease.

Stress echocardiography has been refined significantly over the last 3 years, and progress is likely to continue at a rapid pace. Endocardial border detection has been facilitated by harmonic imaging and contrast echocardiography. Tissue Doppler imaging and acoustic quantification techniques have been used to develop a quantitative approach to interpretation that is likely to become more sophisticated. The next major step is likely to be routine or selective use of echo-contrast agents to permit acquisition of both left ventricular (LV) function and perfusion data at rest and after stress.

GLOSSARY

Coronary steal: A situation in which a vasodilator increases runoff to a normal branch, thus reducing the driving pressure in an artery proximal to a stenosis and causing ischemia because of reduced blood flow across the stenosis.

Echocardiographic contrast agents: Injectable compounds comprising gas-filled microbubbles approximately the size of or smaller than erythrocytes that increase the reflected signal of the cardiac structures in which they are located.

Myocardial tissue Doppler imaging: Use of Doppler principle to examine myocardial rather than blood flow velocity.

Sensitivity: Proportion of patients with CAD correctly identified as abnormal.

Single-photon emission computed tomography (SPECT): A means of acquiring and portraying scintigraphic data in a tomographic fashion.

Specificity: Proportion of patients without CAD correctly identified as normal.

Viable myocardium: Myocardial segments characterized by reduced function at rest but potentially recoverable either spontaneously (*stunned*) or with revascularization [usually associated with reduced myocardial perfusion (i.e., *hibernating myocardium*)].

INTRODUCTION

The use of exercise testing to provoke ischemic symptoms, ECG changes, and assess exercise capacity for the purpose of evaluating CAD dates back to the 1950s (1). However, while the exercise ECG is the most commonly accepted functional test for the diagnosis of CAD, there are situations in which it is inappropriate. First, patients who either cannot exercise or exercise submaximally account for 30% to 40% of patients presenting for functional testing (2). These patients are best studied using the combination of pharmacologic stress with various imaging techniques for the diagnosis of coronary disease. Second, even if the patient is able to exercise, the ECG may be uninterpretable because of repolarization abnormalities. In these circumstances, the ability of the patient to exercise is exploited by the combination of exercise testing with an imaging modality.

The use of stress imaging tests is not restricted to the diagnosis of coronary disease. As the ability to perform revascularization has improved, there has been a need to evaluate coronary disease on a functional basis, both to understand the site of ischemic tissue (and hence the likely culprit lesion) and to distinguish between ischemic,

infarcted, and viable myocardium. Exercise ECG testing is unable to provide these data, which mandate the use of imaging. Similarly, the management of non–coronary heart disease, including valvular heart disease, primary myocardial disease, and some obstructive lesions may be facilitated by an appreciation of functional responses to stress.

Imaging modalities that may be used to examine regional and global LV function include contrast ventriculography, nuclear ventriculography, echocardiography, magnetic resonance imaging (MRI), and fast computed tomographic scanning. Contrast ventriculography is invasive, and although serial measurements may be performed in the course of pressure volume loop analysis, this is of little clinical value. The use of the MRI in combination with exercise has been constrained by the need to use nonmagnetic materials in this environment, so that most studies have been performed with pharmacologic stress (3,4 and 5). The cost and availability of both MRI and fast computed tomography are also important limitations. Thus, nuclear ventriculography and echocardiography are the most commonly used techniques for the assessment regional and global LV function in combination with stress. These techniques are compared in the section Comparison with Other Techniques.

DEVELOPMENT OF STRESS ECHOCARDIOGRAPHY

In the 1970s, the clinical role of echocardiography became established in the diagnosis and management of predominantly valvular and congenital heart disease. The use of M-mode echocardiography for the analysis of ventricular function was constrained by the need to assume that the ventricle had a geometric shape (6)—an assumption that is often inappropriate in a setting of ischemic heart disease. Nonetheless, M-mode echocardiography was combined with exercise stress for the detection of ischemia-induced wall motion abnormalities in the late 1970s (7).

The development of two-dimensional echocardiography in the 1980s permitted echocardiography to become a truly tomographic technique for the analysis of ventricular function. The calculation of global ventricular function became less limited by geometric assumptions (6). Not surprisingly, cross-sectional echocardiography was combined with stress (8), although the narrow (30-degree) sector angle of the early scanners, combined with poor imaging quality and the need to compare segmental function in different segments of videotape, posed important technical limitations on the new approach. As the technology became more sophisticated and image quality improved, successful image acquisition became possible in over 90% of patients using a wide angle (90-degree) sector (9,10). It was soon recognized that the most feasible approach was the comparison of pretreadmill and immediate posttreadmill images (10) as peak exercise imaging on the treadmill was difficult (11), although peak bicycle stress imaging using the subcostal approach was used in the same era (12). Even with the technical limitations of exercise echocardiography at that time, it was found to be comparable in accuracy with nuclear ventriculography (13,14 and 15) and planar thallium imaging (16).

The major impetus to the development of stress echocardiography as a routine clinical tool came with the development of digital image processing in the late mid-1980s (17). The use of digital frame grabbers enabled the rapid acquisition of postexercise cine loops, gated in systole, and independent of respiratory artifact. Moreover, the digital approach allowed the side-by-side analysis of images that facilitated the recognition of regional wall motion abnormalities. Future advances in stress echocardiography are likely to be in the realm of quantitation and obtaining data regarding myocardial perfusion.

PATHOPHYSIOLOGY

Effects of Ischemia on Left Ventricular Function

Ischemia develops after a mismatch occurs between nutrient supply and the demands of the cardiac myocyte. Most commonly, this mismatch occurs because of fixed stenoses in epicardial coronary vessels, and less commonly due to vasoconstriction or small vessel disease. The vasodilator reserve of the coronary vasculature is such that ischemia occurs at rest only in the setting of critical (greater than 90% coronary diameter) narrowings (18). During stress, limitation of the ability to generate a hyperemic response may reduce maximal hyperemic coronary flow in the presence of stenoses of greater than 50% diameter, although the anatomic severity of stenosis and the physiologic consequences are poorly related (19). Clearly, the ability to provoke ischemia in the setting of relatively mild coronary stenoses is dependent on the performance of maximal stress.

Detection of schemia by Echocardiography

The normal response of the left ventricle to increasing workload is a uniform increase of regional wall motion, thickening, and a reduction of end-systolic LV cavity size, with minimal changes of diastolic size during exercise or vasodilation (20). These changes return to baseline usually within minutes of the conclusion of the stress (21).

The distinction between resting and stress-induced wall motion abnormalities (Table 50.1) fundamentally differentiates prior myocardial infarction, identified by resting akinesis or dyskinesis, from induced ischemia, characterized by either new or worsening wall motion abnormalities. This effect of ischemia on regional ventricular function has been well defined with microcrystals (22), as well as with echocardiography (23,24). A more subtle index of myocardial ischemia is delayed contraction (25). The presence of LV enlargement following stress identifies severe ischemia or other serious heart muscle diseases. The time course of offset of regional myocardial dysfunction is variable and probably reflects the severity and duration of ischemia. Wall motion abnormalities may rapidly recover following the cessation of stress (26,27) but may also persist for 30 minutes or longer (9), especially if stunning is induced.

Characterization of tissue	Resting function	Low-dose	Peak/poststress function
Normal	Normal	Normal	Hyperkinetic
Ischemic	Normal	Normal (ischemic with severe coronary artery disease)	Reduction vs. rest Reduction vs. adjacent segments Delayed contraction
Viable, nonischemic	Rest WMA	Improvement	Sustained improvement
Viable, ischemic	Rest WMA	Improvement	Reduction (compared with low-dose)
Infarction	Rest WMA	No change	No change

WMA, wall motion abnormalities (severe hypokinesis, akinesis, dyskinesis).

TABLE 50.1 INTERPRETATION OF EXERCISE AND PHARMACOLOGIC STRESS ECHOCARDIOGRAPHY

VIDEO

Video 50.1 Appearance of myocardial scar at exercise echocardiography. The resting images (*left*) show thinning and akinesis of the anteroseptal wall. Even though this wall is not resolved after exercise, the diagnosis of left anterior descending territory scar is clear. The posterior wall is initially normal and deteriorates after exercise, consistent with left circumflex territory ischemia. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

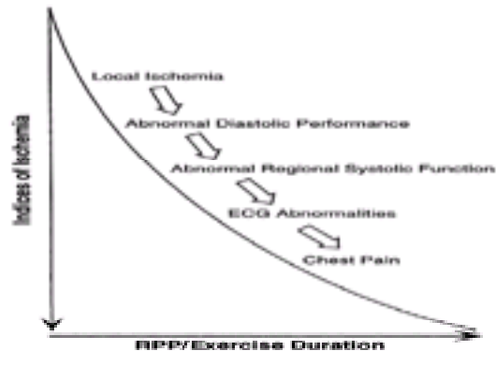
Video 50.2 Diagnostic information from changes in left ventricular shape and size at exercise echocardiography in a patient with left anterior descending coronary artery and left circumflex coronary artery disease. The apical four-chamber view shows development of akinesis in the mid and apical septum after stress; this causes the left ventricular cavity to assume an “hourglass” shape in systole due to an apical bulge. The development of left ventricular cavity enlargement draws attention to a lateral wall motion abnormality after stress. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The presence of regional systolic dysfunction is usually caused by CAD, although cardiomyopathic processes may be regional rather than global. Resting wall motion abnormalities may not necessarily indicate the presence of transmural infarction; hypokinetic segments may be partially infarcted (especially the subendocardium) or

viable (28). Viable segments may recover spontaneously (if the tissue is stunned) or following revascularization (if the myocardium is hibernating) (29,30). The presence of residual viable tissue is more common in hypokinetic than akinetic segments and least common in dyskinetic segments (31). Viable myocardium augments function in response to inotropic stimulation, and this response may be detected using echocardiography, as discussed in the section Identification of Myocardial Viability. Probably, both stunned and hibernating tissue contribute to chronic LV dysfunction due to CAD, and the conventional stress echo interpretation algorithm has been modified by the application of these findings to the clinical arena (Table 50.1).

Ischemic Cascade

The ischemic cascade describes a temporal sequence of physiologic disturbances that occur sequentially in the context of ischemia (*e*Fig. 50.0.1). These were initially described in the setting of supply-based ischemia (32). Following the initial development of regional malperfusion, the development of regional systolic dysfunction was preceded by abnormalities of diastolic function (33) with global changes of systolic function occurring later, and finally the development of ST-segment changes and chest pain. The sequence of these changes might be expected to lead to a superiority of myocardial perfusion imaging (which identifies regional flow heterogeneity) over stress echocardiography (which identifies regional systolic dysfunction). However, this supposition ignores the characteristics of these diagnostic modalities, and the description of such a sequence does not necessarily indicate a substantial delay between these phenomena. In particular, the development of ventricular dysfunction occurs rapidly following coronary occlusion (34). Moreover, there is a relationship between the severity of reduction of flow and the presence and extent of wall motion abnormalities; for detectable regional wall motion abnormalities to occur, flow needs to be reduced by at least 50% in at least 5% of the myocardium (35). Finally, it should be made clear that the classical description of the ischemic cascade, based on “supply side” ischemia, may not necessarily be applicable to stress-induced ischemia, which is due to increased myocardial oxygen demand.



***e*FIGURE 50.0.1** Ischemic cascade. The development of chest pain and electrocardiographic (ECG) changes of ischemia occur at a greater level of cardiovascular stress than wall motion or perfusion abnormalities. RPP, rate-pressure product.

VIDEO

Video 50.3 Dobutamine echo. Parasternal long-axis view of a patient with left anterior descending artery scar and peri-infarct ischemia. No obvious ischemia is seen in this view (see apical two- and four-chamber views). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 50.4 Parasternal short-axis view of a dobutamine stress echo of a patient with peri-infarct ischemia in the left anterior descending coronary artery territory. No ischemia seen in this view (see ischemia in apical two- and four-chamber views). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 50.5 Apical four-chamber view of a dobutamine stress echo of a patient with peri-infarct ischemia in the left anterior descending coronary artery territory. Note the distal septal resting wall motion abnormality that fails to augment with peak dobutamine infusion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 50.6 Dobutamine stress echocardiogram showing a biphasic response. The quad-screen display shows resting images in the upper left, low-dose (5 and 10 µg/kg/min) in upper right and lower left, and peak stress images in the lower right in the apical two-chamber view. A resting wall motion abnormality of the basal and mid inferior segments improves to normal at 10 µg/kg/min but deteriorates at peak stress. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

METHODOLOGY OF STRESS ECHOCARDIOGRAPHY

Stress Testing Modalities

Exercise Stress

The use of stress echocardiography in patients with known or suspected CAD *who are able to exercise* usually incorporates exercise stress. The choice of modalities in this respect is between the treadmill and cycle ergometry, which may be upright or supine. During exercise, heart rate, blood pressure, and inotropic state all increase, in proportion to the increase of cardiac work. During upright exercise, venous return is relatively reduced, and LV end diastolic volume and pressure are similarly less than they would be during supine exercise (36).

Exercise echocardiography with a treadmill requires selection of an appropriate protocol tailored to the patient to exercise the patient for 7 to 10 minutes. Such a protocol obviously varies according to the patient’s age, gender, state of health, and physical fitness, so most laboratories traditionally use several protocols, including Bruce, modified Bruce, and Naughton. For diagnostic studies, we usually request that the patients withhold antianginal therapy at least on the day of testing. However, when testing is performed to assess the adequacy of therapy, medicines are continued up to the time of testing. Patients are advised to either fast or take only a light meal before undergoing stress. Electrodes are applied in the usual way for exercise testing, but electrodes in the V_2 and V_4/V_5 locations may be moved if they interfere with the echocardiographic windows. Before exercise, imaging is performed in the supine position, with digital capture of parasternal long and short and apical two- and four-chamber views into a quad-screen cine-loop display. After exercise is concluded for symptom-limited end points, post-stress images are obtained, preferably within 1 minute, and certainly within 2 minutes of exercise. The digital images are then remixed to display rest and stress images side by side to facilitate interpretation.

Bicycle exercise may be performed using an upright or supine ergometer. Stress protocols are tailored to the patient in the same way as treadmill protocols, but most frequently involve 2- to 3-minute increments of 20 to 25 W, following a startup workload of 0 to 25 W or more, depending on the patient's functional status. With respect to imaging, the same pre-stress and post-stress images are obtained, but in addition, a set of images is acquired in the upright (or semisupine if this is used) position before exercise and repeated during stress. If upright bicycle exercise is used, images may be obtained during exercise by leaning the patient forward to obtain the parasternal images and sometimes by elevation of the left arm to obtain apical images (37). These maneuvers facilitate the acquisition of all views during bicycle stress and ensure that the heart is imaged in the same orientation before, during, and at peak stress.

The merits and limitations of treadmill and bicycle stress are summarized in Table 50.2. In general, treadmill exercise is more widely accepted among patients and physicians in the United States. On the basis of peak and poststress imaging on the bicycle, it has been identified that a small reduction of sensitivity is possible if postexercise imaging is used. Lower workloads are attainable with bicycle than treadmill exercise, which needs to be traded off against the benefits of peak exercise imaging on the bicycle. It is currently not possible to identify an optimal approach for exercise echocardiography, and the decision between bicycle and treadmill exercise is dependent on local expertise and, to some extent, on the nature of the clinical question in each individual patient. The acquisition of multiple images at peak stress is attractive for making assessments of the functional severity of coronary stenoses, and peak exercise imaging is attractive for assessment of valvular lesions. Moreover, the performance of imaging during stress may facilitate definition of the ischemic threshold.

	Treadmill	Bicycle
Acceptance	Familiar to patient and physicians	Unfamiliarity
Adequacy of stress	Patients stress maximally	Premature termination due to leg fatigue Dependent on patient compliance
Imaging	Postexercise	Peak and postexercise

TABLE 50.2 ADVANTAGES AND DISADVANTAGES OF TREADMILL VERSUS BICYCLE STRESS FOR EXERCISE ECHOCARDIOGRAPHY

Sympathomimetic Stressors

Mechanism of Action

Although a number of sympathomimetic agents, including dobutamine, arbutamine, isoproterenol, dopamine, and even epinephrine, have been combined at echocardiography (38,39), dobutamine is the most widely used. The inotropic activity of these agents reflects a combination of alpha- and beta-stimulation (40,41). The effect of this stimulation is to enhance the inotropic state, heart rate, and blood pressure, all of which are determinants of myocardial oxygen consumption. Dobutamine was initially designed as an agent for use in the intensive care unit, and its chronotropic effect only emerges at high doses. The use of dobutamine for stress testing constitutes the "off-label" use of an approved drug.

Hemodynamic Response

The response to dobutamine is summarized in Figure 50.1. Generally, peak heart rates of 120 to 140 beats/min are attainable (42), this corresponding to at least 85% of age-predicted heart rate in most patients. The systolic blood pressure usually increases by 30 to 40 mm Hg, with peak pressures of 170 to 180 mm Hg, and peak rate-pressure products of approximately 20,000. However, considerable variability occurs between different patients with respect to both the extent and speed of these hemodynamic responses.

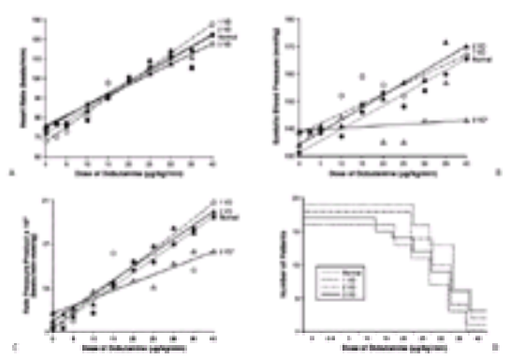


FIGURE 50.1 Hemodynamic responses to dobutamine, including heart rate **(A)**, systolic blood pressure **(B)**, and rate-pressure product **(C)**, according to the extent of coronary artery disease. **D:** The number of patients undergoing testing at each dose level of dobutamine, according to disease extent. 1 VD, one-vessel disease; 2 VD, two-vessel disease; 3 VD, three-vessel disease. (From Cohen JL, Greene TO, Ottenweller J, et al. Dobutamine digital echocardiography for detecting coronary artery disease. *Am J Cardiol* 1991;67:1311–1318, with permission.)

Side Effects

Many patients requiring dobutamine stress are elderly and have serious noncardiac diseases or even severe CAD and LV dysfunction. Despite the use of high doses of these agents, serious complications occur in approximately 3 in 1,000 (43).

Administration Protocol

The protocol for dobutamine administration is empiric. Initially, a peak dose of 20 µg per kg per minute was used with myocardial perfusion imaging (44) and later echocardiography (45). The currently employed high-dose protocols (to 40 µg per kg per minute) were initially described by Sawada and Cohen (42,46) and seem to be more sensitive than lower dose protocols (47), although low-dose protocols provide adequate stress if the duration of each stage is longer (e.g., 5 rather than 3 minutes) (48). Atropine has been combined with dobutamine at peak dose if the heart-rate target is not attained (49) and more recently has been administered earlier in an attempt to shorten test duration (50). When evidence of myocardial viability is being sought, it is important to recognize that augmentation of function may occur at lower doses of dobutamine, and some authors have suggested specific low-dose protocols (e.g., to 12.5 µg per kg per minute in 2.5-µg increments) for this purpose. However, the practice of our laboratory has been to use a single standard protocol (including high dose), which offers the versatility of identifying both viability and ischemia, while at the same time providing a study of acceptable length (Fig. 50.2). A rare exception is the situation in which peak dose is considered unsafe (e.g., history of hemodynamic instability); while caution should be exercised, the test appears safe for studying patients with severe LV dysfunction (51,52 and 53). Moreover, as discussed later in the chapter (see Extent and Severity of Disease), the biphasic response is the most reliable marker of recovery of LV function, and the detection of this usually requires a high-dose protocol. At present, none of the dobutamine protocols is clearly superior to the others, and the main consideration should be to ensure the adequacy of stress.

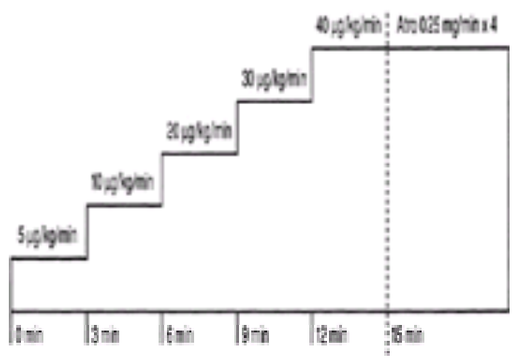

FIGURE 50.2 Dobutamine-atropine infusion protocol. Atro, atropine. (From Otto K. *Practice of clinical echocardiography*. Philadelphia: WB Saunders, 1996, with permission.)

The patient is usually requested to fast for a few hours before the test. It is desirable for antianginal medication (especially beta-blockers) to be withheld for diagnostic studies. The patient is attached to an ECG machine for the purpose of monitoring, although the accuracy of the ST-segment response for the identification of coronary disease is poor. Resting imaging is performed before stress, as with exercise echocardiography. Although we use the same dobutamine infusion protocol for all patients, our approach to imaging varies according to the clinical situation. When a dobutamine study is performed for the diagnosis of coronary disease, a single set of low-dose images (10 µg per kg per minute) is captured in digital format, and the remaining two quadrants of the quad-screen display are used to record prepeak (usually 30 µg per kg per minute) and peak (40 µg per kg per minute, or 40 µg per kg plus atropine). A complete set of images is recorded on videotape at each stage of the dobutamine protocol and in recovery. In patients with resting wall motion abnormalities, in which myocardial viability may be of interest, two sets of low-dose images (5 and 10 µg per kg per minute) are recorded in the second and third quadrants, followed by peak images. This facilitates the recognition of viable myocardium.

Vasodilator Stress

Mechanism of Action

The mechanism of effect of vasodilator agents in inducing ischemia is more complex than with other methodologies. In conjunction with myocardial perfusion imaging, vasodilator agents are used to achieve maximal coronary vasodilation in all vascular territories, and the diagnosis of ischemia is made if the regional hyperemia is compromised by a coronary stenosis. The identification of a stress echocardiogram result as positive is dependent on the induction of ischemia, for which the main mechanism with these agents is coronary steal (54), due to decreased proximal driving pressure caused by increased runoff to the normally vasodilated, patent vessel. This process may be either vertical (subepicardial from subendocardial) or horizontal (from stenosed territory to nonstenosed). Other potential contributors include collapse of the stenosis in the face of systemic hypotension, a minor increment of myocardial oxygen demand, or rarely coronary spasm. Generally, these phenomena occur in the setting of severe or extensive coronary disease. The dipyridamole test has also been used for the identification of myocardial viability, this process presumably reflecting a vasodilator effect in hibernating tissue, and perhaps increasing turgor in tissue with an intact hyperemic response.

Adenosine and dipyridamole differ in respect to the rate of onset and duration of their effects. Adenosine is a powerful endogenously occurring vasodilator, which acts directly on the vasculature, having a vasodilator efficacy equivalent to papaverine and dipyridamole (55,56). The action of dipyridamole is indirect, as this agent increases endogenous adenosine levels by reducing adenosine reuptake and metabolism (57). Thus, peak vasodilation occurs almost instantaneously with adenosine, but this process is delayed with dipyridamole. Similarly, the offset of the effect of adenosine is rapid (the half-life of this agent is less than 1 minute) while the half-life of the dipyridamole vasodilator effect is approximately 6 hours.

Hemodynamic Response

The hemodynamic effects of these stressors are minor. Blood pressure is little influenced by vasodilator stressors, although hypotension may occur. There may be a small increment of heart rate, which may occur in response to various side effects.

Side Effects

Serious side effects occur in approximately 1 in 1,000 patients. The most common side effects of dipyridamole and adenosine are headache and dyspnea, respectively (58,59). The speed of onset and potency of adenosine render its side effects less well tolerated, but these effects resolve rapidly with cessation of the drug. Both techniques are contraindicated in patients with untreated atrioventricular block and bronchospastic disorders, and abstinence from xanthene-containing foods and drugs is required before either stress.

Administration Protocol

The standard dipyridamole dose for myocardial perfusion imaging is 0.56 mg per kg administered over 4 minutes. For stress echocardiography, this dose induces ischemia only in patients with severe coronary disease. Thus, 0.56 mg per kg is administered first, but if ischemia is not induced, an additional 0.28 mg per kg is administered over 2 minutes. Atropine may be added if the response to dipyridamole is negative (60), and imaging is continued over 16 minutes. In some laboratories, dipyridamole is reversed with aminophylline. Although this is not usually necessary, aminophylline is useful for reversing the effect of dipyridamole in the presence of significant side effects. However, if aminophylline is needed for the treatment of severe ischemia, the supervising physician should be aware that the effect of dipyridamole may last longer than that of aminophylline, leading patients to become ischemic after they have left the stress laboratory.

The standard dose of adenosine for myocardial perfusion imaging is 0.14 mg per kg per minute intravenously over 4 minutes. This is also the most widely used dose for stress echocardiography, although both higher and lower doses have been studied. Although analogous to the dose of dipyridamole, higher dose protocols are constrained by dose-limiting side effects.

Combined Stressors

The simplest combined stressors are the combinations of dobutamine or dipyridamole with atropine, which have become part of the standard protocols using these agents. The combination of dipyridamole with dobutamine has been suggested as a means of producing a gradation of stress, with each stage of the test offering an increment of sensitivity for the detection of CAD (61). This protocol involves the initial administration of the two-phase dipyridamole stress described previously, followed by a standard dobutamine stress if the first test result is negative. Although this approach has increased the sensitivity of either of the pharmacologic techniques without a significant increment of side effects, it has the disadvantage of excessive length with commensurate high cost. Probably because of these practical considerations, this combined stress modality has not gained wide acceptance.

Pacing Stress

Of the nonpharmacologic approaches to nonexercise stress, pacing is the most widely used, although technical limitations and patient tolerance have limited the application of this modality. The mechanism of effect of this stress is to increase cardiac workload, although most of the increment is due to increased heart rate. To optimize the degree of stress, pacing may be combined with a pharmacologic stressor such as dobutamine; certainly this may be of use for the assessment of viable myocardium. Atropine is often administered to overcome atrioventricular block. The most widely used approach is transesophageal atrial pacing (62,63,64,65 and 66), although invasive pacing has also been studied (67). Despite the problem of lesser patient tolerance than the pharmacologic stressors (68,69), the attractions of this technique are that it is rapid, reliably produces tachycardia, and may be suddenly terminated, which renders this a relatively safe technique. Moreover, the rapid resolution of tachycardia in the presence of ischemia allows the evaluation of diastolic function, which is difficult at rapid heart rates (70).

A variety of pacing protocols have been studied. We use this technique in situations in which pharmacologic stressors are contraindicated, especially in patients on dialysis, in whom hypertension may be a limitation to standard dobutamine stress. Loss of capture is best avoided by using a short protocol; whereas previously we used an incremental protocol tailored to the patient (37), we now capture baseline images just above resting heart rate (to ensure ECG triggering works during pacing), increase to 85% predicted heart rate, and then 100% of predicted heart rate, each for 3 minutes. The most common side effect is esophageal discomfort if a large

current is required for atrial capture.

Other Techniques

Other stressors (e.g., isoproterenol) have been used in small numbers of patients and appear to be effective. A significant literature has developed regarding the use of ergonovine stress echocardiography for the diagnosis of coronary spasm. This agent is usually used in the angiography laboratory (where spasm is visualized directly), but it appears safe to apply noninvasively in patients without significant stenoses (71,72 and 73), as well as in some patient groups without preceding angiography (74,75). The standard protocol involves repeated bolus doses of ergonovine maleate at 5-minute intervals up to a total cumulative dosage of 0.35 mg, unless echocardiographic evidence of abnormal LV wall motion is detected.

Selection of the Optimal Stress Agent

Pharmacologic stressors enhance the feasibility of imaging, but they have a number of important disadvantages (Table 50.3). Generally, comparable levels of sensitivity are obtainable, although the performance of submaximal stress due to side effects is an important limitation. If a patient can exercise, we believe that he or she should undergo exercise echocardiography, unless the test has been performed for other reasons than the detection of myocardial ischemia (e.g., in specialized situations in which viability or coronary spasm are being evaluated). The development of new technologies such as tissue Doppler imaging, automated border detection, and contrast echocardiography have made pharmacologic stressors more attractive than exercise, but whether the incremental data offered by the addition of these features justifies the disadvantages of using a pharmacologic stressor in all patients remains to be established.

Evaluates exercise capacity
Correlates symptoms with physical workload
ST-segment evaluation
Cardiac workload is greater with exercise
Prognostic information
Probably greater sensitivity for ischemia

TABLE 50.3 BENEFITS OF EXERCISE OVER PHARMACOLOGIC STRESS

The type of pharmacologic stress may also be the source of debate. The frequency of side effects with dipyridamole and dobutamine stress is comparable, but the contraindications of each test are different. Thus, patients with asthma or untreated conduction system disease might be better tested using dobutamine echocardiography, whereas dipyridamole stress would be preferable in those with serious arrhythmias or severe hypertension. Most patients do not fall into these categories, so that either stressor might be used. In this situation, the choice might be based on physician preference, cost (dobutamine costs considerably less than dipyridamole in the United States, but the situation is reversed in Europe), and the clinical question to be addressed. If this relates to the diagnosis of coronary disease, the sensitivity of dobutamine echocardiography is somewhat greater than that of dipyridamole echocardiography, especially in patients with single-vessel disease. On the other hand, if the main interest is in prognostic evaluation, the agents are both attractive, and certainly a wealth of information is available regarding dipyridamole echocardiography as a prognostic test (see Prognostic Considerations in Coronary Artery Disease).

Imaging Techniques

Stress echocardiography is almost universally performed using transthoracic echocardiography, although transesophageal imaging is sometimes used in the setting of poor image quality. The procedure brings together facilities for stress testing, echocardiography, and at least two and sometimes three personnel including physician, sonographer, and nurse. To use all of these resources efficiently, there is a need to limit the duration of activities that precede and follow the stress, during which time all resources are required. Consequently, it is not possible to perform an exhaustive echocardiographic examination in the context of stress echocardiography. Nonetheless, a screening M-mode and color Doppler examination should be performed at the beginning of every study. If more complex (e.g., valvular) problems are identified, these issues should be analyzed by echocardiography at another time. Using this approach, it should be possible to perform a treadmill echocardiogram in approximately 35 minutes, a bicycle stress echocardiogram in 45 minutes, and a dobutamine stress echocardiogram in approximately 1 hour.

Analysis of digital loops is beneficial for the interpretation of all forms of stress echo. Side-by-side comparison of cine loops in a split-screen display permits easy comparison of regional wall motion at rest and stress, and frame-by-frame review facilitates definition of the endocardium as well as evaluation of the temporal sequence of contraction. The disadvantage of this approach, however, is the finite number of views that can be compared using the quad-screen display and the presentation of single cardiac cycles. Consequently, review of the videotape is an important part of stress echocardiographic interpretation (76).

The most common sources of poor image quality are obesity and the presence of superimposed lung in one of the transthoracic windows. Transesophageal stress echocardiography offers excellent endocardial visualization (77,78) and has been useful in situations in which definition of the endocardium is considered particularly important, e.g., in the identification of viable myocardium. Pharmacologic and pacing stresses have been combined with the transesophageal approach, but because of its invasiveness, and issues of patient acceptance, this technique has a limited role in routine practice. Moreover, harmonic imaging has dramatically improved the visualization of myocardial segments and the accuracy of stress echocardiography (79,80). In the current context, transthoracic images are interpretable in greater than 95% of patients, and the indications for transesophageal stress echo are fewer than previously.

Interpretation of Stress Echocardiography

Qualitative Approaches

A qualitative approach is currently used for the interpretation of stress echocardiography. Using a segmental model of the left ventricle, each segment is compared before, during, and after stress. It is important in this evaluation that myocardial thickening is examined wherever possible, in preference to myocardial motion, which may occur due to translational movement, or tethering. Table 50.1 illustrates the criteria used to identify ischemia, myocardial viability, and myocardial scar. In general, ischemia is identified by the development of a new or worsening wall motion abnormality. Subtle indices of ischemia include delayed contraction; a temporal evaluation of myocardial contraction can be appreciated by stepping through individual freeze-frame images in the digital cine loop. Stress-induced LV enlargement is often a marker of multivessel coronary disease, and changes of ventricular shape as well as size are useful diagnostic clues to ischemia. As summarized by Table 50.1, myocardial viability is characterized by improvement of a dyssynergic zone in response to *low-dose* dobutamine. It is especially important that myocardial thickening is sought in patients with extensive infarction, as tethering can induce wall motion in nonviable segments. The most specific indicator of myocardial viability in the setting of hibernation is deterioration of this zone showing initial augmentation in response to increasing dobutamine dose, the “biphasic” response (81). In contrast, stunned myocardium augments functioning in response to low-dose dobutamine, but does not subsequently deteriorate. The presence of augmentation at *peak doses* of dobutamine is a nonspecific response, which is poorly predictive of myocardial viability.

The subjectivity of current approaches to the interpretation of stress echocardiography is the greatest shortcoming of this technique. This has two major manifestations: first, the need for training, and, second, the problems posed for reproducibility of the test. The importance of training in stress echocardiography was studied by a comparison of experts in stress echocardiography and skilled echocardiographers without stress echocardiography experience (82). The experts demonstrated a significantly greater accuracy than the other echocardiographers, but after a training period, during which the trainees were instructed using 100 studies, this difference in accuracy became insignificant (Fig. 50.3). This training period may not need to be as long as 6 months, and we and others (83) have documented enhancement in reviewer accuracy over a 3-day course, during which fewer than 70 studies were reviewed. However, once this level of skill is attained, we believe that a regular workload is required to prevent it from attenuating. Finally, even among expert readers, while the concordance of interpretations within the same center is high (84), concordance between different centers may be less than or equal to 80% (85). Uniform interpretive criteria have reduced but still not avoided this problem of discordance (86). As this is particularly a problem in studies of poor technical quality, and in patients with milder forms of coronary disease, it is not surprising that technical advances including harmonic imaging and digital display have further improved observer agreement (87), although this remains imperfect.

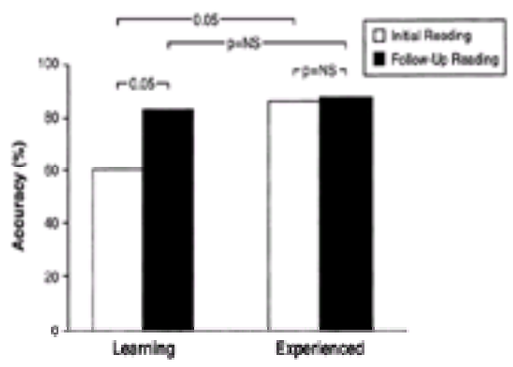

FIGURE 50.3 The learning curve of stress echocardiography. Over 6 months and 100 supervised echos, the trainees increased their accuracy from approximately 60% to 80%. NS, not significant.

To control issues related to subjectivity and concordance between observers, we review stress echocardiograms systematically. Quad-screen displays are first examined to assess their quality and the presence of technical limitations (e.g., gating problems); in technically limited studies, more reliance will need to be based on analysis of the videotape. Resting images are then examined in each view, using the American Society of Echocardiography 16-segment model to score regional wall motion (Fig. 50.4). Global function may be assessed subjectively by calculation of a wall motion scoring index or by measurement of the ejection fraction. The rest and stress images are then compared. The first step is to check for the presence of LV enlargement and shape changes, which are global indicators of ischemia, and in the case of the former, of multivessel disease. Each segment is then scored and compared with the equivalent segment at rest to identify the site, extent, and severity of abnormal function. If a bicycle or dobutamine stress study is used, the ischemic threshold is an important clue to the severity of ischemia. The report should therefore describe the site, extent, and severity of scar and ischemia, the global LV function before and after stress, and the presence of other abnormalities.

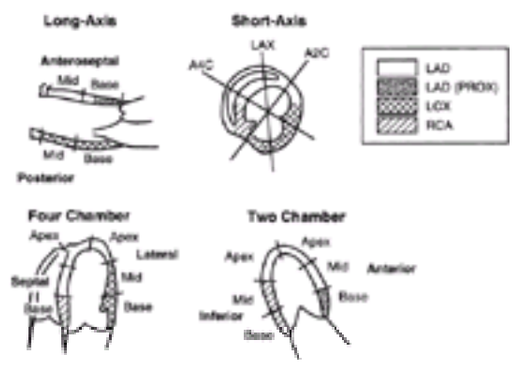

FIGURE 50.4 Systematic evaluation of the left ventricle using the 16-segment model of the American Society of Echocardiography. Each segment must be scored individually at rest and during, after, or both during and after stress. LAD, left anterior descending coronary artery; LAX, long axis; LCX, left circumflex coronary artery; PROX, proximal; RCA, right coronary artery.

Quantitative Approaches

Given the limitations of the qualitative approach, a quantitative approach would seem desirable. Global systolic indices (e.g., ejection fraction or volumes) have limited value, as they are usually abnormal only in the setting of severe ischemia. Wall motion scoring is semiquantitative, but is similar to the standard qualitative approach. Quantitative techniques may be used for the measurement of radial or longitudinal function (Table 50.4).

	Radial	Longitudinal
Displacement	Centerline Acoustic quantification	M-mode
Thickening	Anatomic M-mode	Backscatter
Velocity (including velocity gradient)	Tissue Doppler	Tissue Doppler, strain
Timing	Tissue Doppler	Tissue Doppler

TABLE 50.4 QUANTITATIVE TECHNIQUES FOR THE EVALUATION OF STRESS ECHOCARDIOGRAPHY

Myocardial displacement may be measured in the short- or long-axis dimension. Although long-axis shortening is easily measured using M-mode echocardiography and the timing of long-axis contraction may be altered by ischemia (88), this is not specific for the location of ischemia. The centerline approach is well established as a means of measuring regional function (Fig. 50.5) and has been applied to the interpretation of stress echocardiograms (89). Using this technique, radial excursion is measured by tracing of the endocardial surface (thickening is sometimes possible to measure by tracing of endocardial and epicardial surfaces) at peak diastole and peak systole, and compared with a normal range. There are three major limitations with this technique. First, many stress echocardiograms are not of satisfactory quality to provide excellent border definition, although this has improved in the era of harmonic imaging. Second, the approach requires compensation for translational or rotational cardiac movement, and methodologies for compensating for these technical issues are not well defined. Third, the process of tracing the wall is time consuming and not applicable in a busy clinical laboratory.

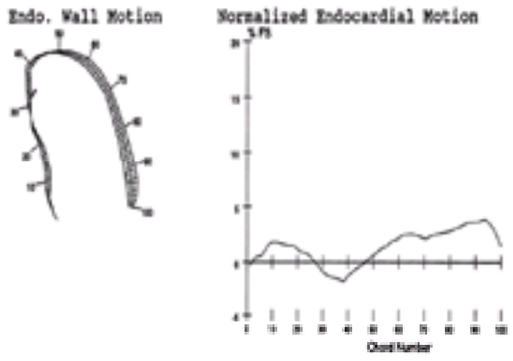

FIGURE 50.5 Quantitative stress echocardiography. A centerline is drawn between diastolic and systolic images and the excursion compared with a normal population. Endo., endocardial; FS, fractional shortening. (From Marwick T, ed. *Stress echocardiography*. New York: Kluwer, 1994, with permission.)

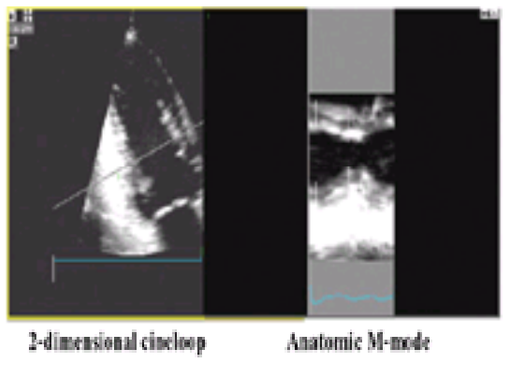
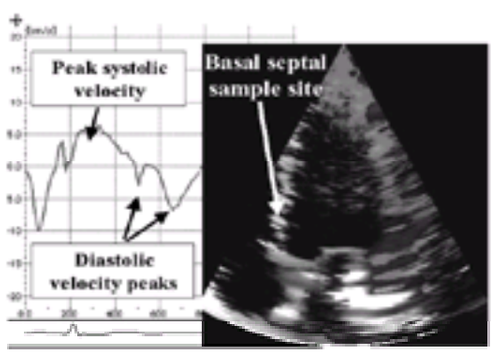
The latter limitation has been partly addressed by automated border recognition, although this remains dependent on good image quality. These methods involve using the difference between the backscatter of the myocardium and blood and pattern-recognition methods (including splines, snakes, and active appearance models) that are applicable to the two-dimensional images. Acoustic quantification techniques identify the blood-tissue interface based on the changes of backscatter within pixels as the wall moves across the pixel. It may be expressed by coloring successive frames to express the excursion in each frame over time throughout systole or diastole (90). The excursion within each segment may be compared with a normal range in histogram format. Unfortunately, this does not distinguish myocardial thickening from translational motion, and the technique is gain and angle dependent. The technique has been applied in the clinical setting, with favorable levels of accuracy reported in both exercise and dobutamine studies (90,91).

Myocardial thickening should be a more sensitive marker of ischemia than abnormal wall motion, and radial thickening may be measured using the same centerline approach. However, the measurement of thickening necessitates tracing of both epicardial and endocardial contours, and in many patients, the epicardium remains difficult to discriminate. M-mode echocardiography has traditionally been applied to the measurement of thickening but is constrained by the need to image structures in the orthogonal plane. An alternative approach (anatomic M-mode) is to reconstruct the M-mode image from high frame rate two-dimensional data (eFig. 50.5.1). However, although changes in thickening correspond to the pathology of the underlying segment, the degree of variation precludes the definition of a “cutoff” for identification of disease (92). This most likely relates to difficulties posed by discrimination of the epicardium. Finally, another approach to this could be the analysis of myocardial backscatter, which reflects myocardial fiber cross-over due to thickening, although it is unaltered by inotropic state (93). Changes in cyclic variation of this parameter correlate with ischemia (94), but at present, the analysis remains dependent on image quality and is too time-consuming for application.



***e*FIGURE 50.5.1** Anatomic M-mode (*right*) of the anterior and inferior walls showing myocardial thickness in diastole and systole, derived from a high frame-rate two-dimensional image (*left*) in the apical two-chamber view. (From Chan J. *Int J Cardiol Imaging* 2001;16:247–255, with permission.)

The velocity of myocardial contraction is reduced by ischemia (95), and this may now be reliably measured using myocardial tissue Doppler. Myocardial velocity may be assessed using either color or pulsed wave techniques, although the time taken to move the pulsed wave sample volume to each myocardial segment is unacceptable for combination with stress echocardiography. Postprocessing of the color data may be performed to generate a velocity profile (eFig. 50.5.2), but adequate resolution of the peak velocity and timing necessitate high color frame rates. Tissue velocity during exercise and dobutamine echocardiography has been shown to correlate with expert assessment of wall motion (96,97) and SPECT (98). More recently, the derivation of normal velocity ranges has permitted the test to be applied to the diagnosis of CAD; this modality has comparable accuracy with expert assessment (99). A number of problems with this technique remain: It is still somewhat dependent on image quality, does not visualize the apex, has unacceptable sensitivity for single-vessel disease, is no better than standard analysis for assessment of multivessel disease, and distinction of ischemia from scar tissue remains problematic. Nonetheless, tissue Doppler parameters appear to be feasible methods for quantifying stress echo and will be improved by further developments, including examination of myocardial velocity gradient and strain.



***e*FIGURE 50.5.2** Myocardial velocity profile obtained from tissue Doppler. The systolic velocity can be recognized as the first sustained wave after isovolumic contraction; peak velocity and time to peak are readily measured.

DIAGNOSIS OF CORONARY ARTERY DISEASE

Influences on Accuracy of Stress Echocardiography

Angiographic Considerations

The accuracy of tests for the detection of CAD is usually expressed as the sensitivity and specificity of the technique for the detection of angiographically demonstrated coronary stenoses. However, while the angiogram has been considered the gold standard for historical reasons, this test has important limitations as the arbiter of the presence or absence of CAD (100).

Stenoses limit the hyperemic response of the coronary vasculature when they exceed approximately 50% of the luminal diameter (18). However, a number of variables influence the physiologic effect of coronary stenoses, which include the site of the stenosis in the vessel, the length of the stenosis, and the size of the vessel. Indeed, there is a poor correlation between the anatomic severity of coronary stenosis and its physiologic consequences, particularly for stenoses of between 50% and 75%. Moreover, the coronary angiogram is a lumenogram, while coronary disease itself induces enlargement of the arterial wall in addition to reduction of the lumen. Consequently, reference segments of the coronary angiogram can be either larger or smaller than the size of the vessel without pathologic involvement. The result of this is respective overestimation and underestimation of coronary lesion severity. Taking these considerations into account, the comparison of any diagnostic test against an anatomic measure of coronary disease such as stenosis severity intrinsically precludes tests from attaining a perfect accuracy, merely because the reference standard is itself not a good marker of the severity of the disease.

Nature of the Study Population

A number of other variables influence the accuracy of diagnostic testing. Populations with a high prevalence of multivessel coronary disease and previous myocardial infarction are more likely to develop ischemia in response to stress. Indeed, the presence of a resting wall motion abnormality usually indicates the presence of coronary disease, although these may be seen with cardiomyopathies or conduction disturbances (which may consequently lead to false-positive identification of coronary disease). The strong association of resting wall motion abnormalities with coronary disease implies that the diagnosis may be made from resting echocardiography, without the need for stress. Studies examining the sensitivity and specificity of stress echocardiography for the diagnosis of coronary disease should therefore either exclude patients with prior myocardial infarction or at least analyze these separately.

Although sensitivity and specificity are less dependent on the population under study than are the predictive values of negative and positive test results, these results nonetheless may be influenced by population selection. It is important that the accuracy of the studies is assessed in a population that parallels that seen in clinical practice; examining the performance of the test in the sickest of the sick and the most well of the well will inevitably inflate both the sensitivity and specificity. When the test is used to decide which patients should undergo coronary angiography, distortion of the results obtained for sensitivity and specificity may occur. As patients with positive test results predominate in those proceeding to the reference standard test, this tends to inflate the sensitivity (as most tests have true-positive results) and reduce the specificity (as the majority of patients undergoing negative angiography have positive test results). Similarly, when the test is used for clinical purposes, a disproportionate number of “difficult” patients may be involved, with coronary stenoses of borderline severity, in whom, as discussed previously, the angiogram is not a good arbiter of the functional significance of disease.

Adequacy of Stress

The use of stress testing is inherent to all functional tests for the diagnosis of coronary disease. Failure to stress the heart maximally will not engender either maximal coronary hyperemia (used for myocardial perfusion imaging) or ischemia (used for stress echocardiography and ECG analysis). Thus, failure to stress the patient maximally will be associated with reduced sensitivity, especially for milder coronary disease. Indeed, in our experience of exercise echocardiography, apart from the number and severity of coronary stenoses, the only predictor of false-negative results was failure to obtain 85% of age-predicted maximum heart rate (101). As discussed previously, patients who are unable to exercise, or likely to exercise submaximally, should undergo pharmacologic stress testing.

The use of pharmacologic stress testing may be particularly useful in patients with previous myocardial infarction and resting wall motion abnormalities. In these situations, the identification of ischemia may be facilitated by the availability of low-dose augmentation in viable tissue (102), which may not be appreciated during exercise testing. This topic is discussed further in a later section (see Identification of Myocardial Viability).

Echocardiographic Considerations

Image quality is probably more important during stress echocardiography than during alternative stress imaging techniques. Poor image quality reduces concordance between expert observers (85), and likely reduces the accuracy of the test, if not for the identification of coronary disease (101) then at least the ability to recognize multivessel disease. Not all segments of the myocardium are equally well visualized; the lateral wall is usually parallel with the ultrasound beam in the apical four-chamber view, and the endocardium may be poorly defined, with consequent effects on the sensitivity for left circumflex disease. Fortunately, this problem has been improved by the development of lateral gain correction techniques as well as harmonic imaging. The basal inferoposterior walls are particularly difficult to interpret due to tethering to the plane of the mitral valve and poor endocardial definition. Wall motion abnormalities involving the latter segments should be identified only if adjacent segments are abnormal (103).

VIDEO

As discussed in a previous section, stress echocardiography is interpreted qualitatively and subjectively, and several interpretive factors may influence the accuracy of the data. First, a low threshold for identifying wall motion abnormalities (e.g., identification of minor stress-induced wall motion abnormalities as ischemic, or identification of failure to enhance function as being indicative of ischemia) is attended by a high sensitivity, but a correspondingly low specificity. Interpreter bias may also be an important source of inaccuracy. It is important that the echocardiographic data are interpreted independent of the clinical and stress testing data; failure to do so may compromise accuracy (particularly the specificity). The experience of the reader is obviously an important determinant of accuracy during stress echocardiography. Factors responsible for false-negative and false-positive results are summarized in Table 50.5.

False-negative results	False-positive results
Inadequate stress	Overinterpretation, interpreter bias
Antianginal therapy	Localized basal inferior wall abnormalities
Mild coronary artery disease	Abnormal septal motion (left bundle branch block, post-coronary artery bypass grafting)
Left circumflex disease	Cardiomyopathies
Poor image quality	Hypertensive responses to stress
Delayed images post-stress	

TABLE 50.5 CAUSES OF FALSE-NEGATIVE AND FALSE-POSITIVE STRESS ECHOCARDIOGRAM RESULTS

Exercise Echocardiography

The feasibility of exercise echocardiography in the more recent studies has been approximately 100%. In significant studies of exercise echocardiography (greater than 100 patients), the sensitivity and specificity range from 74% to 97% and 64% to 86%, respectively (eTable 50.5.1) (27,101,104,105,106,107,108 and 109). Some variability is apparent, for the reasons discussed previously. The effect of differing criteria of stenosis significance is well illustrated in the study by Robertson (9), which showed a sensitivity of 100% but a specificity of 75%, using a cutoff including more severe lesions (e.g., greater than 75% diameter) in the sensitivity group. This cutoff makes it highly likely that any patient with anatomically defined disease would have ischemia, whereas patients with less than 75% stenoses may indeed have ischemia, particularly if the stenosis is in the 50% to 75% range.

S/Bike, supine bike; Tml, treadmill; U/Bike, upright bike.

Using a 50% stenosis diameter cutoff at quantitative angiography, Shiekh reported a sensitivity of 81% and a specificity of 92% (110), and patients with single-vessel coronary disease and inducible wall motion abnormalities had a stenosis diameter of 1.0 mm, compared with patients without inducible ischemia in spite of detectable stenoses, among whom the diameter was 1.7 mm. A similar study by Agati et al. (111) used quantitative wall motion analysis to define abnormal function and identified an absolute lumen diameter of 0.7 mm, corresponding to an 85% diameter stenosis, as best predictive of inducible wall motion abnormalities, although the sensitivity of exercise echocardiography in that study may have been compromised by the quantitative criteria used for defining a positive test result.

The type of exercise probably also has an important effect on the accuracy of exercise echocardiography. Posttreadmill exercise echocardiography may be compromised by resolution of ischemia during the delay between peak exercise and echocardiographic imaging. Generally, this occurs in patients with mild, usually single-vessel, coronary disease. However, imaging at peak stress during either supine or upright bicycle exercise is attended by a greater sensitivity than postexercise imaging (26), although this occurs at the cost of specificity, presumably because of motion-induced artifactual wall motion abnormalities. Finally, although peak exercise imaging has been shown to be more sensitive than postexercise imaging using the bicycle, these data may be influenced by the lower level of exercise attainable with this form of stress. A single study of 74 patients (112) who underwent treadmill testing and supine bicycle stress showed maximum heart rate to be higher during treadmill echo, but systolic blood pressure was higher during supine bicycle exercise, so that the double product was comparable. The wall motion score index at maximal exercise and extent of myocardial ischemia were greater during supine bicycle stress, which had a greater sensitivity (82% vs. 75%) but lower specificity (80% vs. 90%). Because of the greater familiarity of treadmill exercise, this remains the most widely used technique.

Pharmacologic Stress Echocardiography

Dobutamine Stress Echocardiography

Significant studies (greater than 100 patients) of dobutamine stress echocardiography show a range of sensitivity of between 61% and 95%, whereas that for specificity ranged from 51% to 95% (eTable 50.5.2) (3,46,61,106,113,114,115,116,117,118,119,120,121,122 and 123). Again, some variability in the reported accuracy of the test is apparent. The addition of atropine increases sensitivity (49), as does the use of transesophageal echocardiography (77), although the feasibility of the latter is limited, as discussed previously.

atro, atropine.

At quantitative coronary angiography (124,125 and 126), the optimal correlates of a positive dobutamine test result are a lumen diameter of 1.07 mm, percent diameter

stenosis of 52%, and percent area stenosis of 75%, and minimal lumen diameter has the best predictive value for a positive dobutamine stress test result (sensitivity 94%, specificity 75%, odds ratio 51) (124). Stenoses less than 1 mm in diameter can be identified with a sensitivity of 86% (125,126). However, although quantitative angiography deals with the problem of reproducibility of angiographic interpretation, it still has the limitation of being an anatomic measure of disease severity, which may not necessarily correlate with functional indices. One such parameter that takes into account collateral flow is myocardial fractional flow reserve, which is calculated as the ratio of mean hyperemic distal coronary to aortic pressure. The magnitude of wall motion abnormalities correlated more closely with functional than anatomic markers of lesion severity, and dobutamine echocardiography was found to be a more sensitive marker of ischemia in lesions involving larger (greater than 2.6 mm in diameter) vessels than smaller vessels (125).

Some of the earlier studies of dobutamine echocardiography (46,117) show a sensitivity above the usual level (*e*Table 50.5.2), suggesting a decrement in the accuracy of dobutamine stress since its inception, reflecting clinical application of the test. As the technique is applied for clinical decision making, referral bias to angiography may inflate sensitivity but produce more adverse findings for specificity (127). Moreover, dobutamine is not a very robust stress, and sensitivity is likely to be compromised if the cardiac workload is reduced by medical therapy or dose-limiting side effects. Comparison of the quoted ranges (*e*Table 50.5.1 and *e*Table 50.5.2) suggests that the sensitivity of dobutamine echocardiography is somewhat less than exercise echocardiography, but its specificity is slightly greater. In studies in which exercise and pharmacologic stress echocardiography were performed in the same patients, the accuracy of stress echocardiography has been comparable with either stressor (106,128,129,130,131 and 132). In situations in which stress is submaximal because of side effects with pharmacologic agents, exercise is superior. Clearly, the converse is true when patients are unable to exercise maximally and a pharmacologic agent is more desirable. Nonetheless, the hemodynamic effects of the agents are different, so that the markers of severe (including left main) disease including LV cavity dilation and marked ST-segment depression occur more often with exercise than with dobutamine echocardiography (133). Because exercise is a more potent stress on the heart, a greater extent of abnormal wall motion may be induced, and this may compensate for the more difficult imaging with exercise (130,132). As discussed previously, a number of features favor the use of exercise testing over pharmacologic techniques, provided that the patient can exercise maximally.

Vasodilator Stress Echocardiography

The ranges for the sensitivity and specificity of dipyridamole and adenosine stress echocardiography for the detection of CAD are 61% to 81% and 90% to 94%, respectively (*e*Table 50.5.3) (60,61,106,119,120 and 121,123,134,135). The low-dose dipyridamole protocol (0.56 mg per kg) is associated with low sensitivity. For the high-dose and adenosine protocols, more variability is present than for any of the other stressors, reflecting variations in the populations studied. The inclusion in some studies of patients with prior myocardial infarction has inflated the sensitivity of adenosine echocardiography, but the sensitivity of patients without prior infarction is only approximately 60% (136,137). Likewise, populations with a high prevalence of extensive coronary disease are associated with a high sensitivity, but single-vessel disease is more difficult to detect using this technique (137).

atr, atropine; CAD, coronary artery disease; Dipy, dipyridamole.

[a]Low-dose positivity permits conclusion of study before stated "peak" dose.

The type of pharmacologic agent to select in a patient who is unable to exercise maximally remains a source of debate. Studies comparing dobutamine and vasodilator agents in the same patients have shown that the sensitivity of dobutamine is somewhat higher than that of dipyridamole echocardiography, this difference being mainly attributable to patients with single-vessel disease (*e*Table 50.5.4) (61,106,119,121,138). In an environment in which most of the studies are being performed for diagnostic purposes, dobutamine is probably more attractive as some patients may have single-vessel disease. In situations in which the main interest is prognostic evaluation, the agents are both attractive, and certainly a wealth of information is available regarding dipyridamole echocardiography as a prognostic test (see Prognostic Considerations in Coronary Artery Disease). Other factors influencing this decision, such as side effects and cost, have been discussed earlier (see Selection of the Optimal Stress Agent).

Stress Echocardiography Using Other Stress Techniques

The most commonly used nonexercise stress is performed with atrial pacing. The accuracy of this technique for the detection of coronary disease has ranged from 83% to 93%, with a specificity of 76% to 100% (62,63,65,66,69,139,140,141 and 142). Although the application of this approach has been limited by concerns regarding patient acceptance and feasibility, more recent work suggests that this test has a feasibility of 96% (143), a high level of acceptance, and good correlation with the results of dobutamine stress.

Important Limitations in the Diagnostic Use of Stress Echocardiography

Extent and Severity of Disease

Stress echocardiography is effective for the detection of severe coronary stenoses, as these are usually associated with more extensive wall motion abnormalities (125). Extensive coronary disease is also marked by an early onset of ischemia, at a low heart rate and rate-pressure product, or at a low dose of pharmacologic stressor. However, the sensitivity of stress echocardiography for single-vessel CAD has been quite limited in several studies and is probably less than that of myocardial perfusion scintigraphy. This reflects the need for ischemia to involve a significant extent of myocardium for the stress echocardiogram to be positive, which may not be fulfilled if the involved vessel is small or distal or if the stenosis is only mildly flow limiting.

The presence of extensive areas of ischemia, the development of global ventricular dysfunction (reduction of ejection fraction or LV enlargement), or both indicate the presence of multivessel disease (144). However, while the predictive value of these findings is high, the predictive value of their absence is dependent on the resting LV function. In patients with a history of previous myocardial infarction, the sensitivity of stress echocardiography for recognition of multivessel disease (effectively, "ischemia at a distance") is approximately 80% to 85%. In contrast, the sensitivity for multivessel disease in patients without previous infarction is approximately 50% (145). These data contrast with a sensitivity greater than 70% in this situation using myocardial perfusion scintigraphy (146). However, when the extent of ischemia defined by dobutamine echocardiography and perfusion scintigraphy was compared with the angiographic extent of disease (a modified Gensini score), the extent was comparable, and both underestimated the disease extent (137).

VIDEO

Video 50.18 Recognition of multivessel coronary artery disease. Apical four- and two-chamber views before (*left*) and after exercise show inducible wall motion abnormalities in the septum, apex, and anterior walls (left anterior descending), lateral wall (circumflex), and inferior walls (right coronary) associated with left ventricular cavity enlargement. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The identification of ischemia within areas of resting wall motion abnormalities is difficult, because of the problems posed by identification of minor gradations of wall motion in the setting of abnormal function. Comparison of the regional findings of exercise echocardiography and SPECT have shown this to be an important cause of discordant diagnoses (109). The problem is probably less during dobutamine stress because ischemic segments with abnormal resting function often show a biphasic response (102).

VIDEO

Video 50.19 Diagnosis of ischemia within an area of resting wall motion abnormality. Apical four-and two-chamber views at rest (*left*) show akinesis in the basal septum, with inferior wall hypokinesis. Post exercise (*right*), there is worsening of wall motion in the inferior segment, indicating scar with residual ischemia. Assessment of gradations of hypokinesis may be difficult and cause discordances between observers as well as between echocardiography and other imaging modalities. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

These aspects represent a fundamental limitation of an ischemia-based technique. Their solution will require either a more sensitive tool for assessment of wall motion or combination with a perfusion marker such as contrast echocardiography.

Site of Disease

Although the extent of coronary disease has an important influence on the accuracy of functional testing in general, the location of coronary disease may have important implications for the sensitivity of stress echocardiography in particular. The allocation of segments to particular vascular territories is ambiguous, especially in the apex (usually assumed to be within the territory of the left anterior descending coronary artery) and the posterior wall (usually assumed to be supplied by the left circumflex). Using exercise echocardiography, Marwick (145) reported regional sensitivities of 77% for the anterior descending, 67% for the left circumflex, and 70% for the right coronary, and Hecht (147) reported respective sensitivities of 95%, 78%, and 81%. However, Armstrong (148) reported a 22% sensitivity for the recognition of left circumflex disease, and Pozzoli (149) reported a sensitivity of 45% at this site. The sensitivity for circumflex disease may be limited by difficulties in the evaluation of the lateral wall due to unfavorable imaging characteristics.

COMPARISON WITH OTHER TECHNIQUES

Comparison with Stress Electrocardiography

The presence of ST-segment depression in response to exercise remains the simplest and most widely used test for the documentation of myocardial ischemia. However, the proportion of patients in whom adequate exercise is achieved and the ST segment is interpretable is less than 50% in many tertiary referral centers. In patients with left bundle branch block, ECG changes with stress are nondiagnostic (150). In patients with LV hypertrophy or resting ST- and T-wave changes, additional ST-segment changes are not specific markers for coronary disease, although the sensitivity of ECG (and hence the predictive value of a negative test result) is debated (151,152).

In patients who are unable to exercise maximally, the use of exercise testing is attended by inadequate sensitivity (153). Even if pharmacologic stress testing is performed, the combination of these stresses with ECG alone has limitations with respect to sensitivity (154,155 and 156).

In those who can exercise and have an interpretable ECG, exercise echocardiography has benefits in both sensitivity and specificity (17,101,109,157). This greater sensitivity of exercise echocardiography over the exercise ECG is not surprising in view of the earlier occurrence of wall motion abnormalities than ST-segment changes during stress; these data are analogous to those reported for thallium imaging. However, as it would be financially and logistically impossible to replace diagnostic exercise testing with imaging, we have sought subgroups in whom the standard stress test is unreliable, despite an interpretable ECG. These groups might include women and patients with LV hypertrophy.

The accuracy of exercise ECG in women has been extensively debated. Depending on the population studied, either the sensitivity or the specificity may be compromised (158,159,160 and 161). Although some of the differences from stress testing in men may be caused by lower disease prevalence, these results are influenced by non-Bayesian factors, including the presence of milder coronary disease in women than men, the likelihood of submaximal stress, and intrinsic gender-based differences in the ST-segment response. A number of large studies have now shown that the accuracy of stress echocardiography is not compromised in women (114,135,162,163), and these results are superior to those of the exercise ECG, even after correction for referral bias. A cost analysis suggested that the use of exercise echo as an initial test caused more initial expense but was cheaper in the long run because of the avoidance of unnecessary angiograms in patients with false-positive ECG responses (162).

Comparison with Nuclear Imaging

Nuclear ventriculography and perfusion scintigraphy have an established record for the detection of coronary disease. Although nuclear ventriculography and echocardiography appear to hold superficial similarities with respect to analysis of LV function during stress, the two are actually quite dissimilar. Stress nuclear ventriculography is the older technique, which is used for analysis of global functional response to stress, calculated as ejection fraction change, and measured using a count-based approach (164). The development of ischemia does not necessarily provoke a change of ejection fraction, because of compensatory hyperfunction of the nonischemic walls. This protective mechanism is less likely to occur in patients with multivessel coronary disease, in which a number of segments may become ischemic, and indeed stress nuclear ventriculography is most sensitive under these circumstances (164). Conversely, the development of global functional changes with stress is not necessarily an indicator of ischemia and may occur in the setting of hypertensive or valvular heart disease. Thus, the global parameters measured using nuclear ventriculography have proved to be of disappointing accuracy.

Regional LV function may also be analyzed using nuclear ventriculography, but various technical limitations have become apparent. First, the technique is not truly tomographic, usually involving only one or two views, so that only a limited amount of the myocardium can be visualized. Second, using the gated approach, numerous cycles are summated, causing some blurring of the endocardial border with respiratory movement. This has the effect of combining the function of normal and ischemic segments and blunting the extent of wall motion abnormalities due to ischemia. Third, the silhouette produced by the nuclear ventriculogram limits the analysis of regional ischemia and precludes analysis of thickening.

Nuclear ventriculography and stress echocardiography have been compared in three studies, involving a total of only 100 patients (13,14 and 15). These data suggest that stress echocardiography is more sensitive for the detection of regional LV dysfunction than nuclear ventriculography, a result consistent with the better definition of regional wall motion at echocardiography. Of the stress imaging tests used to examine regional function, stress echocardiography is currently favored.

Despite competition from echocardiography, perfusion scintigraphy remains the most widely performed stress imaging test in the United States, and its use continues to increase.

Theoretical Considerations

The presence of CAD is inferred at myocardial perfusion scintigraphy by the detection of perfusion heterogeneity during maximal coronary hyperemia. The latter is induced either directly (e.g., dipyridamole or adenosine stress) or indirectly, whereby endogenous adenosine is released secondary to increases in cardiac workload. Although only severe coronary stenoses compromise myocardial perfusion at rest, narrowings greater than 50% limit flow in the presence of maximal coronary vasodilation (165). Keeping in mind the ischemic cascade (see Ischemic Cascade, earlier in this chapter), it might be expected that these variations in myocardial perfusion would be more sensitive indicators of coronary disease than regional ischemia. However, both tests are imperfect measures of regional perfusion and ischemia, respectively. Thus, the comparison between these modalities does not reflect the underlying pathophysiology alone, but is also influenced by the limitations of the imaging techniques. Thus, despite their physiologic differences, the results of myocardial perfusion imaging and stress echocardiography are remarkably similar.

Comparison of Stress Perfusion Imaging and Stress Echocardiography

Studies of the accuracy of SPECT myocardial perfusion scintigraphy have shown that this technique has a sensitivity greater than 90% for the detection of CAD (166). However, they also show that the specificity is approximately 70%, partly reflecting the phenomenon of posttest referral bias (127) as well as the problems of false-positive results related to image artifacts. In a metaanalysis, the superior sensitivity of SPECT was balanced by a greater specificity with echocardiography, so that the accuracy of the techniques was comparable (167). However, although the analytic technique permitted correction of a number of population-based factors that influence the accuracy of diagnostic testing, including the prevalence of prior infarction and multivessel coronary disease, comparisons between separate studies of myocardial perfusion imaging and stress echocardiography are difficult, not the least because of the different level of maturity of the investigations, which affects the posttest referral bias effect. An alternate design involves head-to-head comparison in the same patients, in the presence of an additional test (e.g., coronary angiography) to act as the arbiter of which result is correct, even though this design has the disadvantage of studying a selected population who are undergoing angiography (168).

A number of large studies have compared the results of stress echocardiography and perfusion scintigraphy in the same patients using various stressors (109,115,118,137,149,169,170 and 171) (*e*Table 50.5.5). Comparisons of vasodilator stress echocardiography and perfusion scintigraphy have confirmed the insensitivity of adenosine stress, particularly for single-vessel disease. When exercise and dobutamine stress are used, however, the sensitivities of the two techniques have also been shown to be comparable, with most studies showing a minor benefit for perfusion scintigraphy. The slightly lower sensitivity of stress echocardiography than perfusion scintigraphy may reflect superiority of perfusion imaging (which does not require the development of ischemia in a metabolic or functional sense) for the identification of patients with single-vessel disease. For similar reasons, patients on therapy with antianginal agents may be better studied using perfusion scintigraphy (as ischemia does not need to be induced for the test result to be positive) than stress echocardiography. As discussed in the section on limitations, perfusion scintigraphy appears to be significantly more sensitive for the recognition of multivessel disease as such (146) and may be superior in the detection of ischemia in the setting of resting wall motion abnormalities, in which circumstance the recognition of worsening wall motion may be difficult (109). These issues cannot be measured by consideration of sensitivity and specificity. Finally, scintigraphy can be expected to be superior in patients with poor echocardiographic windows (e.g., due to pulmonary disease).

On the other hand, there appears to be a particular benefit of echocardiography over perfusion scintigraphy with respect to specificity. This difference is most marked in patients with LV hypertrophy and left bundle branch block. Breast attenuation artifacts and other issues have led to lower reported levels of accuracy of perfusion imaging in women, and the results of a metaanalysis suggest this may be a group better studied with stress echocardiography (172). Finally, stress echocardiography is versatile, rapidly performed, and less expensive than perfusion imaging. In situations in which other cardiac problems are present as well as ischemia (e.g., valvular, pericardial diseases), the selection of stress echocardiography avoids duplicate testing.

Practical Considerations

The selection between SPECT and stress echocardiography is influenced by numerous factors, some of which are summarized in Table 50.6. Of these, the most important is local expertise. Thus, at a center with an excellent nuclear laboratory and an echocardiographer inexperienced in stress echocardiography, the selection of the latter test would likely engender unfavorable results. The converse is true of facilities without the requisite nuclear experience.

TABLE 50.6 ADVANTAGES AND DISADVANTAGES OF STRESS ECHOCARDIOGRAPHY AND MYOCARDIAL PERFUSION SCINTIGRAPHY

Comparison with Magnetic Resonance Imaging

Modern MRI protocols promise to deliver information of gross cardiac anatomy, details of structure, function, and perfusion, all of which are of value in the diagnosis and evaluation of ischemic heart disease and are discussed in another chapter (see Chapter 54). There is no question that MRI can provide information of similar accuracy to echocardiography during stress, both for identification of ischemia (3) and assessment of viable myocardium (173). The problems with the widespread application of this technology relate to issues of feasibility, access, and cost. It seems most likely that in the future, technically difficult studies will be performed using MRI, and that this modality will be especially useful for evaluation of complex problems such as detection of viable myocardium in severe LV dysfunction.

USE OF STRESS ECHOCARDIOGRAPHY IN MANAGEMENT DECISIONS

Evaluation of Patients undergoing Myocardial Revascularization

Patients undergoing myocardial revascularization procedures should have some documentation of the presence and site of ischemia (174). Although stress echocardiography can accurately localize disease, the assumptions inherent in allocating territories of the heart to individual coronary vessels may compromise its ability to designate a “culprit” lesion. This is particularly problematic if multivessel disease is present, in which case the most ischemic territory is most commonly detected.

Following both surgical (175,176) and percutaneous revascularization (177), stress echocardiography appears to have similar accuracy to its use in patients with native disease. However, its use in asymptomatic patients may be limited by Bayesian considerations.

Identification of Myocardial Viability

Background

In a number of acute animal models of myocardial stunning, the use of sympathomimetic amines such as isoproterenol and dobutamine have been shown to reverse regional LV dysfunction in stunned myocardium (178). The same response appears to be applicable to chronic ischemic LV dysfunction, which is often considered to be truly hibernating tissue. In the presence of dysfunctional but viable myocardium, regional function is enhanced by the inotropic effect of low-dose dobutamine (usually 5 to 10 µg per kg per minute), which enhances calcium cycling before dobutamine-induced tachycardia increases oxygen consumption and leads to ischemia. Dipyridamole also exerts similar effects at low dose, the mechanism of which is ill defined; increasing myocardial turgor has been suggested to produce a mini-Starling effect, and augmentation of coronary flow has also been suggested. Viable myocardium supplied by a patent infarct-related vessel (generally corresponding to stunned myocardium) demonstrates a sustained improvement during the infusion. Viable tissue supplied by a stenosed infarct-related artery (which may involve stunned or hibernating tissue) is characterized by an initial improvement followed by deterioration of regional function as the chronotropic effect becomes more prominent and myocardial work increases (Table 50.1).

Accuracy for Detection of Improvement after Revascularization

In regions predicted to be viable by low-dose dobutamine echocardiography early (less than 2 weeks) after "incomplete" infarction (non–Q-wave infarcts, and infarction treated with lytic therapy), improvement may be observed spontaneously (179,180). Several studies have addressed the accuracy of dobutamine echocardiography to predict regional functional recovery at follow-up (179,180,181,182,183,184 and 185), although most studies involve small patient numbers (eTable 50.6.1). Later after myocardial infarction, myocardial hibernation might be expected to constitute an important source of reversible dysfunction in preference to myocardial stunning. Comparisons with positron emission tomography (PET) have suggested that a dobutamine response is more likely in the presence of preserved myocardial perfusion (stunning) than in the situation of a perfusion metabolism mismatch (hibernation) (181). Dobutamine echocardiography has been effective for the prediction of myocardial viability in this group of patients (186,187 and 188), possibly because recurrent episodes of myocardial stunning are an important source of viable tissue late following infarction (189). The evidence base for the accuracy of dobutamine echocardiography for the prediction of regional functional recovery after revascularization is larger (eTable 50.6.1). In these studies, the sensitivity of dobutamine stress to identify an improvement of systolic function in response to revascularization ranged from 69% to 86%, with a range of specificity from 57% to 100%.

Comparison of Stress Echocardiography with Other Techniques for Identification of Viable Myocardium

The ability of dobutamine echocardiography and other techniques to predict recovery of regional function (Fig. 50.6) has been compared in metaanalyses (190,191) and direct comparison in individual patients. Both analyses suggest that the accuracy of dobutamine echocardiography for identification of viable myocardium is equivalent to that of thallium-201 reinjection imaging (188,192,193,194,195,196,197,198,199,200,201 and 202). In comparison with thallium imaging, dobutamine echocardiography was similarly somewhat less sensitive but substantially more specific. Pierard demonstrated that the prediction of myocardial viability using low-dose dobutamine echocardiography correlated with PET in 79% of segments (181). Similar levels of correlation have been reported from other centers (203); in our experience, although dobutamine echocardiography is less sensitive than PET, it is more specific (204). Finally, as mentioned previously, the accuracy of dobutamine echo and MRI are similar, especially if good echo images are obtained (173).

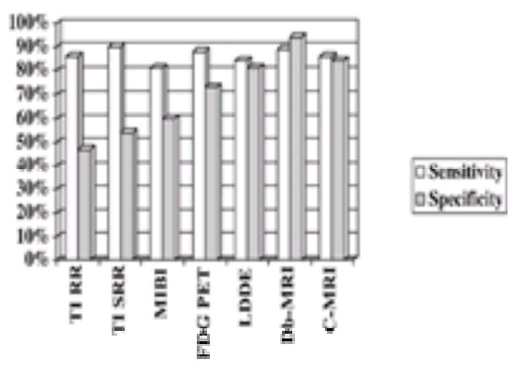

FIGURE 50.6 Prediction of viability (defined as recovery of regional function after revascularization) using thallium rest redistribution (Tl RR), thallium stress rest reinjection (Tl SRR), Tc-99m sestamibi (MIBI), positron emission tomography (FDG PET), low-dose dobutamine echocardiography (LDDE), dobutamine magnetic resonance imaging (Db-MRI), and contrast-enhanced MRI (C-MRI) for the detection of viable myocardium. Dobutamine magnetic resonance imaging predicts contractile recovery of chronically dysfunctional myocardium after successful revascularization. *J Am Coll Cardiol* 1998;31:1040–1048.)

Prediction of Recovery of Functional Capacity

The evidence base regarding the accuracy of tests for prediction of myocardial viability is based on comparison with recovery of regional LV function. However, decision making regarding revascularization in patients with LV dysfunction is more influenced by the likelihood of improving ejection fraction, functional capacity, and quality of life.

Although ejection fraction is the most widely used index of global LV function and an important predictor of outcome, it is not a good marker for recovery of viable tissue, as it is load dependent and influenced by changes elsewhere in the heart. Hypercontractility in uninvolved regions of the myocardium may compensate for regional dysfunction; when these dysfunctional segments improve after revascularization, the compensating segments may resume normal function and the ejection fraction may remain unchanged. Nonetheless, improvement of ejection fraction can be expected if sufficient viable tissue is identified before revascularization; if greater than 25% of segments are viable (205) or if there is an improvement of ejection fraction with low-dose dobutamine (206), a significant (5%) improvement in ejection fraction can be predicted with an accuracy greater than 80%. Clearly, the response to revascularization is also dependent on a number of other variables, including the adequacy of revascularization target vessels, the overall status of the ventricle (very large ventricles are unlikely to recover dramatically), and the extent of scar tissue (thinned tissue is unlikely to recover). The extent of data regarding the ability to predict global functional recovery with dobutamine echocardiography is still limited. In patients with severe LV dysfunction, improvement in exercise capacity was predicted by the extent of viable myocardium, but PET appeared superior to dobutamine echocardiography (207). Extensive (greater than 25%) viability has also been associated with increased functional class after revascularization (208).

Prediction of Prognosis after Revascularization

Several observational studies have shown viable myocardium to be prognostically important. Medical treatment of patients with viable myocardium is associated with adverse outcome, whereas myocardial revascularization has been shown to improve survival in patients with viable tissue (209). Relatively recent data suggest that this effect is related to the extent of viable tissue (210).

PROGNOSTIC CONSIDERATIONS IN CORONARY ARTERY DISEASE

The previous sections have documented the large body of published data that support the diagnostic accuracy of stress echocardiography, in combination with various stressors. However, prognostic considerations are at least as important as diagnostic information in decision making. The prognostic implications of stress echocardiography are less extensively defined than other modalities because of its relative youth as a clinical tool. However, in more recent years the evidence base involving both exercise and nonexercise stress has increased, with significant contributions regarding patients with known stable chronic coronary disease, the evaluation of patients following myocardial infarction, and in risk stratification before major noncardiac surgery. Analysis of these data involve a comparison between the results of echocardiography and various end points, including “hard” events (death and myocardial infarction), hard and “soft” (progressive or unstable angina), and total events (all spontaneous cardiac events as well as myocardial revascularization).

Stable Chronic Coronary Artery Disease

In addition to information regarding the presence of ischemia and scar, exercise and pharmacologic stress testing offer adjunctive information that may be of prognostic significance. With exercise, these include exercise capacity, hemodynamic responses to exercise, and the ST-segment response. However, although ECG evidence of ischemia carries incremental prognostic value, most prognostic information derives from echocardiographic evidence of ischemia. Similarly, although prognostic analysis of stress testing data has shown reduced exercise capacity to be a strong predictor of adverse outcome, the presence of ischemia at stress echocardiography adds significant prognostic information. With dobutamine, the rate pressure product at the onset of ischemia is important, and the equivalent measure using dipyridamole stress testing (dipyridamole time) is also of prognostic value. However, as discussed previously, the ECG component of both dipyridamole and dobutamine stress testing is rather insensitive (154,155), and the development of hypotension during these tests is not meaningful prognostically.

Many patients who present for exercise testing are either unable to exercise or exercise submaximally, and these individuals have a high cardiac event rate (221). From the prognostic standpoint, the detection of ischemia during either dobutamine or dipyridamole stress is analogous to its development during exercise stress. Likewise, the detection of ischemia during dobutamine stress (relative risk 5.6) was a stronger predictor of outcome than most clinical variables and superior to the prognostic significance of significant coronary stenoses (215). Although ejection fraction is recognized as an important predictor of cardiac events, the change of ejection fraction in response to dobutamine does not appear to be predictive of outcome (222). Similar findings have been reported using dipyridamole echocardiography; in the largest reported study, death and hard events were predicted by the presence of a positive dipyridamole echo test result, together with ECG positivity and angina (135,220). In particular, the degree of stress required to induce ischemia (evidenced by the dipyridamole time) was most predictive of hard events, whereas total events were predicted by the wall motion score at peak stress, reflecting the extent of both ischemia and infarction. Moreover, a number of studies have reported that the stress data are not only independent of other variables, but also incremental to the information obtained clinically (135,211,212).

Stress echocardiography offers important prognostic material in patients with chronic stable coronary disease (*e*Table 50.6.2). The presence and time of onset of ischemia is clearly associated with increased events, and these data are adjunctive to exercise capacity and ST-segment changes. Unfortunately, only limited comparisons are available between stress echocardiography and perfusion scintigraphy in terms of their ability to predict events; these data suggest that the techniques are comparable (223).

Postinfarct Risk Stratification

The factors predicting outcome following myocardial infarction include ejection fraction and the presence and extent of ischemic and viable myocardium. All of these may be identified using stress echocardiography, and a number of large studies have gathered prognostic data using stress echocardiography in postinfarction patients (224,225,226,227,228,229 and 230) (*e*Table 50.6.3). Most of these data have been obtained with pharmacologic stress, with only two small studies with exercise echocardiography (231,232). This may reflect reluctance to perform exercise stress in the early postinfarct period. In contrast to patients with chronic stable coronary disease, cardiac events more commonly occur than in patients without evidence of ischemia (reflecting the risk associated with LV dysfunction), but hard events occur in greater than 50% of those with positive stress echocardiographic results.

The timing of postinfarct risk stratification is a critical consideration as recurrent cardiac events may occur early after infarction. Because dipyridamole leads to a negligible increment of cardiac workload, this stress is attractive for early stress testing. In a report of a group of 250 patients who were studied with dipyridamole echocardiography 3 days following myocardial infarction (226), ischemia at dipyridamole stress testing was predictive of both total and hard events. In a multivariate model, the combination of both echocardiographic evidence of ischemia and angina was the strongest predictor of subsequent events, followed by ischemia alone, and anterior infarction.

As discussed in the previous section, hibernating myocardium may be identified by dobutamine echocardiography, with an accuracy of approximately 80% for the prediction of functional recovery (*e*Table 50.6.1). However, while the presence of this tissue is a positive feature if it is revascularized, it is associated with cardiac events if left unrevascularized; this finding appears to be the case whether this finding is identified by either PET (233,234 and 235) or dobutamine echocardiography (52).

In the evaluation of patients following myocardial infarction, the influence of resting wall motion abnormalities on the identification of ischemia is an important limitation of the interpretation of stress echocardiography. As discussed previously, this reflects the difficulty of judging minor deteriorations in the severity of wall motion abnormalities, which may denote the presence of myocardial ischemia. However, it should be emphasized that this problem concerns homozonal ischemia, and the presence of previous infarction does not compromise the ability to recognize ischemia in another zone. The ability of stress echocardiography to recognize heterozonal ischemia may explain the ability of stress echocardiography to predict events in postinfarction patients. In a small study from the Thoraxcenter (265), the presence of

ischemia at thallium scintigraphy was not predictive of total cardiac events over 2 years of follow-up, whereas ischemia at stress echocardiography was associated with a significantly worse prognosis than the absence of ischemia. Although this study involved few hard events, these findings imply that the interpretive challenge of resting wall motion abnormalities may not constitute a major limitation. Additional comparative data are needed between stress echocardiography and scintigraphy in this group.

Peripheral Vascular Disease

Anatomic evidence of CAD is present in over 80% of patients with aortic, lower limb, and cerebral vascular disease (236). However, the challenge of preoperative risk stratification is that although *anatomic* coronary disease is highly prevalent, serious perioperative cardiac complications are infrequent. For example, cardiac death and myocardial infarction occurs in 5% of unselected patients who have not undergone myocardial revascularization before undergoing vascular surgery (237). The identification of this small subgroup is a major challenge on Bayesian grounds, as the low pretest probability of an event influences the posttest probability, irrespective of the results of testing. This problem may at least in part be addressed by clinical evaluation (e.g., using Eagle's criteria for assigning the risk of a cardiac event). Patients with none of these factors (diabetes, age greater than 70 years, angina, myocardial infarction, or heart failure) have a negligible risk of cardiac complications, irrespective of the results of stress testing (238).

The inability of most of these patients to exercise maximally necessitates the use of pharmacologic stress testing. Just as perfusion scintigraphy has shown to be effective in predicting outcome in patients with vascular disease (239,240,241,242 and 243), a number of studies have shown dipyridamole and dobutamine echocardiography to be predictive of perioperative cardiac events (*e*Table 50.6.4) (244,245,246,247,248,249,250 and 251), and echocardiographic test results appear to be at least as predictive as those performed with nuclear imaging (252). The largest experience of the use of stress echocardiography for risk stratification of patients undergoing vascular surgery has been reported from the Thoraxcenter in Rotterdam. In the initial report of 136 patients, physicians looking after these vascular patients were blinded to the results of dobutamine echocardiography. During perioperative follow-up, five patients died, and ten suffered cardiac events; dobutamine echocardiography was positive in all patients with cardiac events and was the strongest predictor of events. In a multivariate model, only dobutamine echocardiography (odds ratio, 95; 95% confidence interval, 11 to 822) and age were predictive of cardiac complications.

In many studies of risk stratification, although a negative test result renders a cardiac complication unlikely, a positive result generally confers 20% to 30% risk of a cardiac complication. Risk stratification may be enhanced by considering the ischemic threshold (i.e., the cardiac workload necessary to induce myocardial ischemia). Using dobutamine stress (250), a low ischemic threshold rather than extensive ischemia was seen in patients suffering events, including death and infarction. The extent and time of onset of ischemia during dipyridamole echocardiography are also associated with cardiac events (245). The combination of clinical evaluation and the presence and threshold of ischemia may be integrated into a patient care algorithm as illustrated in Figure 50.7. First, the patient is stratified on clinical grounds. If the patient has clinical risk variables, he or she should undergo a dobutamine stress echocardiogram, and if this result is negative for ischemia, even if scar is present, the patient should proceed to surgery. If ischemia develops, a decision should be made as to its severity, based more on the ischemic threshold than the extent of ischemia. Patients with limited areas of ischemia, only appearing at peak dose, can probably safely proceed to surgery. Those with more extensive ischemia or that occurring at a low dose should either have an alteration of surgical planning or be considered for cardiac catheterization.

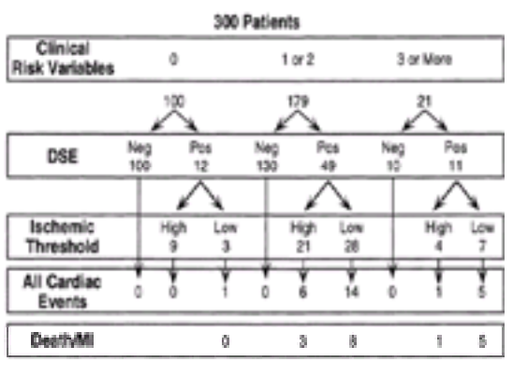

FIGURE 50.7 Integration of clinical data with ischemic threshold to dobutamine to predict events in patients undergoing vascular surgery. DSE, dobutamine stress echocardiography; MI, myocardial infarction; Neg, negative; Pos, positive. (From Poldermans D, Arnese M, Fioretti PM, et al. Improved cardiac risk stratification in major vascular surgery with dobutamine-atropine stress echocardiography. *J Am Coll Cardiol* 1995;26:648–653, with permission.)

In summary, stress echocardiography offers useful prognostic data. More material needs to be obtained for the comparison between stress echocardiography and perfusion scintigraphy for prognostic purposes, both with respect to accuracy and cost effectiveness.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The use of stress echocardiography as a diagnostic tool is supported by a large evidence base. Although studies of the learning curve have been presented, there are limited data reflecting the accuracy of this technique outside of the hands of experts. However, the future of this technique is likely to be influenced by the balance between the training requirements of this methodology and technical developments. The growth of this methodology has been so dramatic that many studies are likely being performed by individuals with limited training in this discipline. The need for training and quality control in this, as in other diagnostic techniques, warrants attention. However, the development of new quantitative approaches may improve the reproducibility and robustness of this technique. Of the new technologies, myocardial Doppler and contrast echocardiography are most likely to offer lasting contributions.

Apart from the impetus of technological development, the driving forces behind the growth of stress echocardiography have been practical. In comparison with nuclear imaging, stress echocardiography is relatively inexpensive to perform; there are no disposables, equipment is cheaper, and less processing is required. A less costly test was attractive to the patient and insurer in the conventional fee-for-service model of care, but is even more so for the physician and hospital in the current era of managed care and capitation. Finally, although the new dual-isotope techniques are shorter to perform than the older thallium techniques, stress echocardiography is versatile and patient friendly. The results are available immediately after testing, and the equipment is relatively inexpensive and portable, enabling the service to be offered in the physician's office or at a satellite clinic.

As in other fields of medicine, the challenge of the future will be to balance the technological and financial forces supporting the growth of stress echocardiography with the need to maintain quality.

THE FUTURE

Quantitative Techniques for Interpretation of Stress Echocardiography

The development of harmonic imaging and contrast echocardiography has improved border detection to the extent that this is no longer the greatest limitation of the technique. Instead, the issue of training and expertise has become the most pressing problem, and a feasible quantitative approach to interpretation is needed. There is no doubt that, although Doppler myocardial imaging of longitudinal motion and integrated backscatter-based approaches are currently feasible, further developments will be needed before quantitation becomes a routine component of the interpretation of stress echocardiography.

Ancillary Techniques for Detecting Ischemia

The detection of myocardial ischemia is currently dependent on the detection of stress-induced wall motion abnormalities. As discussed in the limitations section, this may cause problems with the recognition of multivessel disease as such, the detection of single-vessel coronary disease, and the distinction of ischemia and scar. Techniques that detect more subtle evidence of ischemia, such as myocardial contrast echocardiography and analysis of cyclic backscatter variation, may supplement these findings and may indeed exceed the sensitivity of two-dimensional echocardiography alone for the detection of coronary disease.

Non–air-filled echocardiographic contrast agents traverse the lungs to reach high concentration in the left-sided heart chambers and thereby may enhance the reflectivity of the myocardium. Although these agents do not currently conform to the characteristics of diffusible tracers, analysis of the degree of myocardial opacification corresponds to the concentration of tracer and therefore gives a semiquantitative measure of regional myocardial perfusion. This field has developed a large evidence base, but for the purposes of this topic, it is important to recognize that myocardial contrast echocardiography has already been successfully applied during stress by several authors (253). Importantly, it has been shown to improve the sensitivity of the technique for recognizing all involved vascular territories in patients with multivessel disease. Although the application of the technique is currently constrained by technical complexity, it seems likely that the use of myocardial contrast will facilitate detection of coronary disease by examination of both wall motion and perfusion at stress echocardiography.

When myocardium becomes ischemic, its reflectivity changes. Using video densitometry, Picano et al. have shown that the backscatter profile of ischemic myocardium during angioplasty is altered before the development of wall motion abnormalities (254). Other authors have demonstrated that cyclic variation of backscatter is preserved in akinetic but viable myocardium (94,255). These findings remain to be applied to the routine clinical arena and at present are limited by considerations pertaining to image quality.

Use in Noncoronary Heart Diseases

The stress echocardiography literature mostly pertains to the detection of myocardial ischemia. However, the functional response to stress is important in the evaluation of myocardial and valvular heart diseases, and the importance of stress echocardiography for this purpose is likely to grow. Patients at risk for anthracycline toxicity may be detected using stress echocardiography (256,257). Similarly, loss of contractile reserve in response to stress also appears to be a marker of impending contractile dysfunction in patients with LV volume loading related to mitral regurgitation (Fig. 50.8) (258).

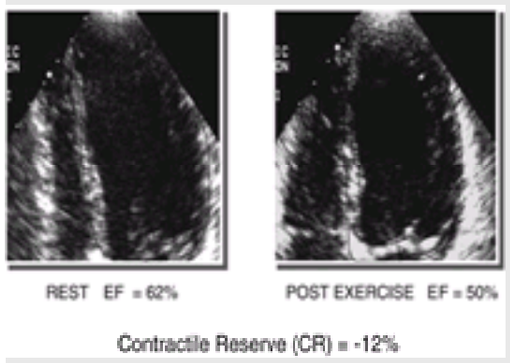

FIGURE 50.8 Determination of left ventricular contractile reserve in a patient with severe mitral regurgitation and preserved resting function (*left*). After exercise (*right*), the left ventricular cavity increases and ejection fraction (EF) falls. Despite normal left ventricular size and function at rest, this response implies that the ventricle is becoming compromised.

In patients with valvular stenosis, the response to stress may differentiate the interrelated influences of ventricular function and valvular disease on the production of gradients. The finding of a low gradient in a patient with aortic stenosis may reflect the influence of reduced ventricular function. Dobutamine echocardiography is able to distinguish a low-output state due to myocardial disease from tight aortic stenosis (Fig. 50.9) (259). Similarly, patients with latent LV outflow tract obstruction may demonstrate exercise-induced outflow tract obstruction in response to exercise or amyl nitrite (260).

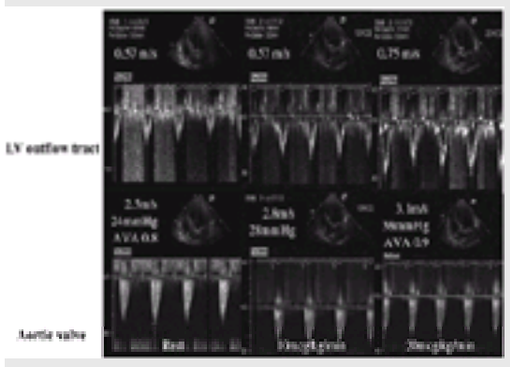

FIGURE 50.9 Application of dobutamine echocardiography to low output aortic stenosis. Resting Doppler measurements show a low gradient in the setting of left ventricular (LV) dysfunction. The increment of the valvular gradient (which exceeds that of the LV outflow tract velocity) signifies a primary valvular problem. AVA, aortic valve area.

Finally, measurement of tricuspid regurgitant velocity may be used to calculate pulmonary artery pressure after exercise. Exercise-induced pulmonary hypertension is a common pathway of cardiac decompensation following stress and may be a particularly useful measurement in patients with apparently moderate mitral stenosis at rest but marked decompensation with stress. The development of this response may correlate with a marked increment of diastolic gradient with exercise.

OVERVIEW

Doppler echocardiography measures blood flow velocities. From flow velocities, pressure gradients can be calculated by the simplified Bernoulli equation in valvular and other stenoses. Doppler echocardiography has the highest sensitivity in the detection of valvular regurgitation of all diagnostic techniques, and regurgitant lesions can be graded at least semiquantitatively by several Doppler techniques. Using additional echocardiographic data, it is possible to obtain reliable estimates of cardiac output, systolic pulmonary artery pressure, and the magnitude of cardiac shunts. Doppler data can identify pathologic changes in diastolic left ventricular function, and the restrictive mitral flow pattern is associated with a reduced prognosis in various cardiac diseases. Doppler has an important role in diagnosing structural complications of myocardial infarction, aortic dissection, pulmonary embolism, cardiac tamponade, and other life-threatening cardiac diseases. Finally, tissue Doppler allows analysis of regional myocardial velocities and contraction and elongation (strain).

GLOSSARY

Aliasing: The maximal velocity unambiguously identifiable by pulsed (and color) Doppler is the aliasing velocity, which depends on the pulse repetition frequency, the frame rate, the sampling depth, and the carrier frequency (see Chapter 46 for more details).

Color Doppler flow mapping: A Doppler display that codes blood flow velocities by colors (red toward the transducer and blue away from the transducer) and superimposes this color map on the two-dimensional image. Thus, a cross-sectional display of blood flow velocities is created. Color Doppler is a way of simultaneously displaying Doppler data from multiple sites in an easily interpretable way. This modality serves for quick orientation about pathologic blood flow (turbulence, regurgitation, shunt flows) and for analysis of valvular regurgitation.

Continuous wave Doppler: A Doppler modality that measures velocities along one scan line. Any velocities are measured unequivocally, but along the scan line there is no spatial resolution. This modality serves to measure the high velocities encountered in valvular stenosis or regurgitation.

Flow profile: The plot of flow velocities measured by pulsed or continuous wave Doppler over time (e.g., diastole for the mitral valve). Essentially synonymous with spectral Doppler display.

Gradient: Pressure drop (or difference) across a restrictive orifice (e.g., a valve).

Jet: A flow stream created by discharge from a narrow orifice (e.g., valvular regurgitation occurs as a jet).

Orifice: See Restrictive orifice.

Pressure half-time: The time that it takes for a pressure gradient to decay to half of its peak value. The pressure half-time is used to evaluate mitral stenosis and aortic regurgitation.

Pulsed wave Doppler: A Doppler modality that measures blood flow velocity in a specific region, the *sample volume*. Thus, unlike continuous wave Doppler, pulsed wave Doppler allows the choice of the site of measurement. The tradeoff is that the maximal unequivocally identifiable velocity is limited (see Aliasing).

Restrictive orifice: Narrowing in the path of flow stream. Stenotic and regurgitant lesions are restrictions to forward and backward flow, respectively. Restrictive orifices have a geometric or anatomic orifice area, which is the smallest cross-sectional area between the solid boundaries of the lesion, and an effective area, which is the smallest cross section of the jet created by such a lesion.

Sample volume: The volume of blood or tissue from which an average velocity is measured by pulsed Doppler. Technically, the length of the sample volume depends on the pulse length (the number of ultrasound wavelengths in one pulse), and the axial position of the sample volume along the cursor depends on the range gate, which defines which time interval is allowed to elapse between transmit and receive. Spatial position and sample volume length can be chosen by the operator, and angle correction is also possible.

Spectral Doppler: Display of continuous or pulsed wave Doppler plotting blood flow velocity against time.

Strain: The deformation (lengthening or shortening) of myocardium during the cardiac cycle. It is dimensionless (e.g., a strain of 0.2 means a 20% elongation). Strain rate (strain divided by corresponding time, in 1/s units) is measurable by tissue Doppler between two chosen points in the myocardium by subtracting the tissue velocities at these points and dividing by the distance between the points. From strain rate, strain is obtained by temporal integration.

Stroke length, stroke distance: Synonymous with velocity-time integral.

Tissue Doppler: Pulsed or color Doppler modality measuring the velocity of solid cardiac structures (e.g., the movement of the myocardium with respect to the transducer over the heart cycle). Typically, these are low-velocity (rarely exceeding 20 cm per second), relatively high-amplitude signals, in contrast to transvalvular blood velocity measured by classic pulsed and color Doppler, which even in healthy subjects reaches 1 m per second and more and has relatively low amplitudes.

Turbulence: Characteristic of flow under certain conditions (especially at high velocities) in which fluid particle velocity and direction change rapidly and chaotically.

Velocity-time integral: The area enclosed by the envelope (the boundary) of the spectral pulsed or continuous wave Doppler display (unit, centimeters). This term is synonymous with stroke length.

HISTORICAL PERSPECTIVE

Christian Doppler, the Austrian physicist (1803 to 1853), first precisely analyzed the effect that motion of the observer relative to the source of a wave has on the perceived wave frequency, a phenomenon that has become known as the *Doppler effect* (1). With ultrasound waves, this effect has first been used in medicine to measure intravascular blood flow (2,3). Although the first instruments used a continuous emission of ultrasound, pulsed Doppler devices were introduced at the end of the 1960s (4,5). The breakthrough for Doppler ultrasound came with its success in quantifying pressure drops across valvular stenoses by means of the simplified Bernoulli equation (6,7) in the late 1970s. Since then, the Doppler technique has become progressively integrated into ultrasound equipment, and *duplex* instruments emerged, combining two-dimensional (2-D) imaging and Doppler blood velocimetry. With the use of multigated pulsed Doppler, a color-encoded display or *map* of velocities could be superimposed on M-mode and later 2-D echocardiographic images (8,9,10 and 11). Transesophageal Doppler recordings of aortic blood flow velocity were obtained as early as 1973 (12), and in the 1980s Doppler capabilities were added to transesophageal imaging probes. The first intravascular, catheter-mounted Doppler devices were introduced in the late 1960s (13,14 and 15). In 1971, the first Doppler-based velocimetry in the human coronaries was reported. Tissue Doppler was introduced in the early 1990s, both in color-coded and spectral form (16).

FROM DOPPLER SIGNALS TO HEMODYNAMICS: BASIC CONCEPTS

The Doppler Signal

The Doppler signal contains the following data: the Doppler frequency shift, the intensity of the signal, and the audio signal.

The Doppler frequency shift (between emitted and received ultrasound) quantifies the instantaneous velocity component of the moving reflectors (usually blood cells) toward or away from the transducer (in centimeters per second) at a site determined by the sample volume of the pulsed Doppler or along the scan line in continuous wave Doppler. The display of this instantaneous velocity over time is called the *spectral Doppler display* (Fig. 51.1). Usually, an electrocardiographic (ECG) signal is also displayed for the purpose of timing. The occurrence of flow faster than normal (in stenotic lesions), of flow in the opposite direction than normal (in regurgitant lesions), or of flow where usually no flow exists (in shunt lesions) can be detected. If velocities are integrated over time, the time velocity integral is obtained (in centimeters). With color Doppler, multiple measurements at different sites in the heart cavities are made simultaneously and represented qualitatively in colors (Fig. 51.1). Velocities toward the transducer are represented in shades of red and away from the transducer in shades of blue. Rapid variations in velocity, as in turbulent flow, are characterized by an admixture of green, which changes red hues to yellow and blue hues to cyan (17).

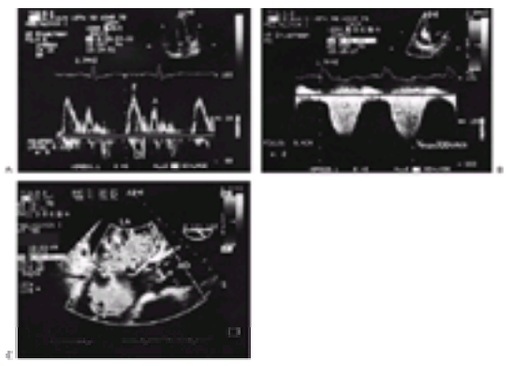

FIGURE 51.1 Pulsed, continuous, and color flow Doppler. **A:** Normal transmitral flow pattern. The sample volume is positioned at the tip of the mitral leaflets. Diastolic transmitral flow in sinus rhythm consists of an early, usually larger and higher E wave (E), and a late, usually smaller, A wave (A). Deceleration time (DT, *arrows*) of the E wave is the time between peak E-wave velocity and cessation of E wave. **B:** Continuous wave Doppler of tricuspid regurgitation in pulmonary hypertension. The maximal regurgitant velocity (v_{max}) of 330 cm per second implies a maximal systolic pressure gradient between the right ventricle and right atrium of 44 mm Hg, and, hence, a systolic pulmonary pressure of 44 mm Hg plus central venous pressure. **C:** Transesophageal color Doppler flow mapping of severe mitral regurgitation due to a posterior flail leaflet. The left atrium (LA) is on top. A proximal convergence zone (*black arrow*) is seen, as well as the eccentric, anteriorly directed turbulent jet in the left atrium (*white arrows*). AO, ascending aorta; LV, left ventricle.

The intensity (amplitude) of the signal is represented in shades of gray in the spectral display. It is related to the number of scatterers (red blood cells) found within the sample volume moving with the measured velocity. Characteristically, if a pulsed Doppler sample volume is positioned in a region where all scatterers move with approximately the same velocity, the result is a bright, narrow bandwidth display of this velocity over time. The width of the signal reflects the variation in velocity within the sample volume. The brightest line is the *modal* velocity, which is the velocity most frequently measured by the Doppler device in the sample volume (Fig. 51.1). This is important when calculating flow rates from cross-sectional areas and pulsed Doppler data. In contrast, continuous wave spectral displays are filled with white signals up to the maximal velocity, the envelope. The reason for this is that the continuous wave Doppler device measures velocities along a whole scan line, so that all

flow velocities that the scan line encounters are represented.

Experienced echocardiographers use the audible signal to optimize the angulation of the transducer. The magnitude of the Doppler shift for usual carrier frequencies lies within the audible range (under 20 kHz). Therefore, high pitch corresponds to high blood flow velocity, and purity of tone to a narrow range of flow velocities.

Use of Doppler Signals to Evaluate Obstruction to Flow

Valvular stenoses and other obstructions to blood flow (e.g., left ventricular outflow tract obstruction) can be quantified by Doppler. The mainstay of this evaluation is the calculation of maximal and mean pressure gradients across an obstruction from transstenotic blood flow velocities by the *simplified Bernoulli equation*:

$$\Delta p = 4v^2$$

(D*p*, pressure drop in millimeters of mercury; *v*, velocity in meters per second)

Another way to quantify stenoses is the calculation of effective stenotic orifice area, which is usually accomplished by the continuity equation (Fig. 51.2): $A_{EFF} = A_1 \times TVI_1/TVI_{MAX}$, where A_{EFF} is the effective stenotic orifice area, A_1 is the area of the flow cross section, usually calculated as p × $d^2/4$, where *d* is the left ventricular outflow tract diameter, TVI_1 is time velocity integral at another flow cross section (by pulsed wave Doppler), usually the left ventricular outflow tract, and $TVI_{MAX}$is the transstenotic time velocity integral (by continuous wave Doppler). Instead of time velocity integrals, the maximal transstenotic velocity and the maximal velocity in the outflow tract can be used.

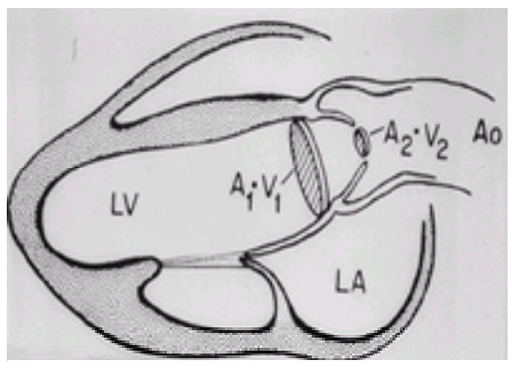

FIGURE 51.2 Schematic drawing of the continuity principle. By virtue of the conservation of mass between the left ventricular outflow tract and the aortic valve, the flow rate in the outflow tract ($A_1 \times v_1$, where A_1 is outflow tract area and v_1 is average blood flow velocity in the outflow tract) and the flow rate across the aortic valve ($A_2 \times v_2$, where A_2 is aortic valve area and v_2 is average velocity across the aortic valve) are equal. Hence, $A_2 = A_1 \times v_1/v_2$. For this calculation, the outflow tract is taken to be circular and calculated from outflow tract diameter *D* as A_1= p × $D^2/4$. AO, ascending aorta; LA, left atrium; LV, left ventricle. (From Weyman AE. *Principles and practice of echocardiography*, 2nd ed. Philadelphia: Lea & Febiger, 1994, with permission.)

Quantification of Regurgitant Lesions

Regurgitation is easily identified by spectral or color Doppler, but difficult to quantify. The *area of the regurgitant jet* by color Doppler is the easiest way to grade severity but does not reliably differentiate moderate and severe regurgitation. Useful other approaches are measurement of the proximal jet diameter immediately at the origin of the jet and the proximal flow convergence zone concept.

Quantification of Cardiac Output

Stroke volume across any flow cross section and thus across any valve can in theory be calculated by multiplying the time velocity integral across that valve by valve orifice area. Unfortunately, neither is easily and reliably measured. Usually, stroke volume (and, hence, by multiplication with heart rate, cardiac output) is measured by multiplying the time velocity integral of the pulsed Doppler signal of systolic transaortic flow by the aortic orifice area (calculated by p × $d^2/4$, where *d* is aortic annulus diameter).

Basic Hydrodynamic Principles

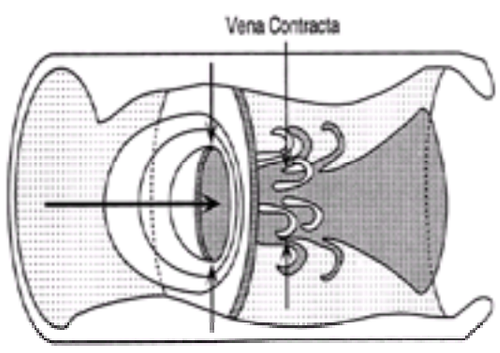
To derive information on hemodynamics from Doppler signals, some hydrodynamic principles governing flow must be understood (18,19).

Continuity Principle

The continuity principle is an application of the fundamental law of the conservation of mass in a closed system (Fig. 51.2). In steady flow of an incompressible fluid through a tube, the volume flow rate (milliliters per second) is equal at any cross section of the tube. Since flow rate is equal to the product of (mean) velocity *v* and cross-sectional area *A*, it follows that

$$v_1 \times A_1 = v_2 \times A_2$$

at any cross sections 1 and 2 of the flow stream. Thus, effective orifice area A_{EFF} of a narrowed flow cross section (e.g., a stenosis) can be calculated from the maximal flow velocity across the orifice v_{MAX}, cross-sectional area A_1, and mean flow velocity v_1 of any other cross section by $A_{EFF} = A_1 \times v_1/v_{MAX}$. The *effective* orifice area of flow is always smaller than the geometric orifice area and occurs slightly downstream from the restrictive orifice (eFig. 51.2.1). The ratio between effective and geometric area is called the *coefficient of contraction* and is always smaller than 1. Hence, effective orifice area by the continuity equation is smaller by a variable factor than orifice area by planimetry or by Gorlin's equation. Note also that the continuity principle is valid at each point in time, and thus effective area can be calculated both from the time-velocity integrals or the maximal velocities at two cross sections. Both are equal if the cross sections are constant over time.



***e*FIGURE 51.2.1** Schematic drawing of flow through a restrictive orifice. Upstream (*left*) from the restrictive orifice, a flow convergence zone develops, consisting of concentric isovelocity shells of approximately hemispheric shape. Downstream (*right*) a jet develops, which entrains stagnant fluid along its way. Immediately after

discharge from the orifice, the cross section diminishes to a minimal value (the vena contracta) and then reexpands further downstream.

Stenotic, Regurgitant, and Shunt Lesions

Stenotic, regurgitant, and shunt lesions involve a restriction to flow. Because of the continuity principle, any narrowing of the cross-sectional area of flow implies an increase in flow velocity. The *convective* flow acceleration necessary for this increase in flow velocity is the main cause of the pressure drop across cardiac restrictive lesions, whereas factors such as viscosity, pulsatile acceleration of stagnant blood, and others only play a minor role. In contrast, normal cardiac valves pose little restriction to flow, such that the energy consumed to propel blood across native valves is largely due to pulsatile acceleration of blood. The general relationship between pressure difference and velocity difference between two points along a stream line is expressed in Bernoulli equation, which is derivable from the more general Euler and Navier-Stokes equations of flow. It can be viewed as an application of the principle of energy conservation:

$$p_1 - p_2 = \frac{1}{2}\rho(v_2^2 - v_1^2) + \rho\int_1^2 \frac{dv(s,t)}{dt}\, ds + R(v)$$

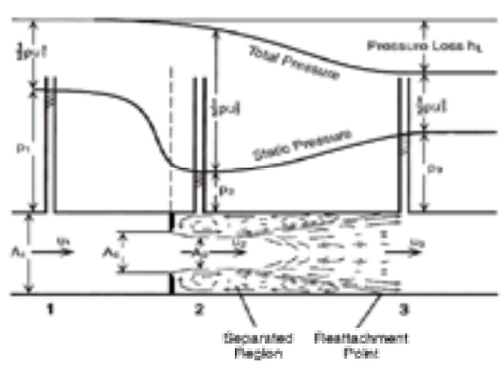
where p_1, v_1 and p_2, v_2 are pressure and velocity at points 1 and 2 on a stream line, respectively, $v(s,t)$ is blood velocity as a function of distance s along the stream line between points 1 and 2 and of time t, r is blood density (1.05 g per cm^3), and $R(v)$ is viscous friction loss between points 1 and 2 as a function of velocity. The first term on the right side describes convective acceleration, the second term flow describes acceleration over time (e.g., acceleration of stagnant blood at valve opening and closure), and the third term describes viscous loss. For clinical purposes in valvular stenoses, the proximal velocity v_1 and the second and third terms on the right are neglected, and Bernoulli equation is simplified to $Dp = 4v_{MAX}^2$, where Dp is the pressure drop in millimeters of mercury and v_{MAX} is the maximal velocity in meters per second. Under the following conditions, however, the simplified version does not apply:

1. High proximal velocities, as in subaortic obstruction or significant regurgitation coexisting with valvular obstruction. Here, the proximal velocity v_{PROX} has to be taken into account: $Dp = 4(v_{MAX}^2 - v_{PROX}^2)$.
2. Tunnel-like lesions, where the length of the obstruction is not negligible in relation to its width. For example, *in vitro* data indicate that at tunnel cross sections of 0.5 cm^2 or lower and lengths of 2 cm or higher the true pressure drop is higher than predicted from the simplified Bernoulli equation, because viscous friction loss becomes relevant (20). Here, Poiseuille's law, where pressure drop is directly and linearly proportional to flow rate, and inversely proportional to the fourth power of tube radius, becomes more appropriate to describe the relation between pressure drop and flow. Poiseuille's law can be expressed as:

$$\Delta p = Q \times 8 \times \eta \times L/(\pi \times r^4) = v \times 8 \times \eta \times L/r^2$$

$$\text{or } R = 8 \times \eta \times L/(\pi \times r^4)$$

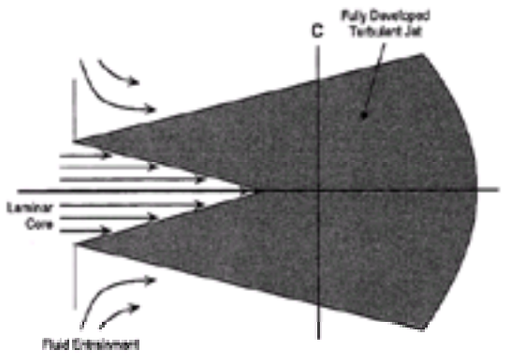
3. or $R = 8 \times h \times L/(p \times r^4)$
4. where Dp is pressure drop, Q is volume flow, R is vascular resistance, v is mean velocity, h is viscosity, L is tube length, and r is tube radius. However, such ratios of cross section and length are almost never encountered in echocardiography; nevertheless, they do exist in coronary stenoses.
5. In normal native valves. In this case, proximal velocity is not negligible in relation to maximal transvalvular velocity, and time-dependent flow acceleration is not negligible compared with convective acceleration.
6. If pressure recovery occurs. The kinetic energy present at the effective orifice area of restrictive cardiac lesions is partly dissipated in turbulent eddies and, ultimately, heat. This energy is lost irretrievably. However, restriction geometries that allow the jet to expand gradually until reaching the boundaries of the receiving chamber minimize eddy formation and allow some of the kinetic energy to be reconverted into static pressure energy downstream (eFig. 51.2.2). The most prominent example of this is seen in bileaflet prostheses in the aortic position (see Prosthetic Heart Valves, later in this chapter). The amount of pressure recovery depends on the morphology of the obstruction and the receiving chamber, being large in gradually tapering and flaring obstructions and low in abrupt narrowings.



***e*FIGURE 51.2.2** Schematic drawing of pressure recovery. Flow through a restrictive orifice of diameter A_0 is shown. Attached to the tube are pressure manometers showing the static pressure at different measurement sites (p_1, p_2, and p_3). Also shown is total pressure (the sum of static pressure and kinetic pressure $1/2ru^2$ at each site, with u flow velocity). At cross section A_1, flow velocity u_1 and kinetic pressure are low, and static pressure is high. Immediately distal to the restrictive orifice, at the vena contracta (A_2), flow velocity u_2 and kinetic pressure are maximal, and static pressure is minimal. Their sum is almost unchanged compared with A_1. Flow stream line separation from the solid boundaries occurs, and energy is irretrievably lost by dissipation in eddies. Some of the kinetic pressure present at the vena contracta A_2, however, is recovered and transformed back into static pressure where the stream lines reattach to the solid boundaries. Thus, p_3 is higher than p_2. The irretrievably lost energy is depicted as pressure loss h_L. Flow velocity u_3 is lower than u_2 and (by the continuity principle) equals u_1. The amount of pressure recovery is determined by the geometry and smoothness of the transition between restrictive orifice and downstream flow boundaries. (From Sugawara M, Kajiya F, Kitabatake A, et al., eds. *Blood flow in the heart and large vessels.* Tokyo: Springer, 1989, with permission.)

Laminar and Turbulent Flow

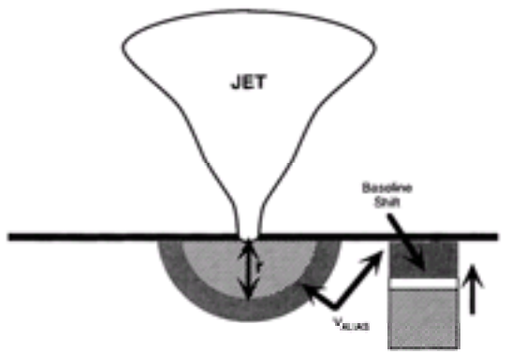
Steady flow of a viscous fluid in a tube occurs in concentric layers of increasing velocity without mixing between the layers, giving rise to a parabolic flow profile, in which the maximal velocity occurs at the central axis and is approximately twice the mean velocity. Poiseuille's law applies (see Stenotic, Regurgitant, and Shunt Lesions). In contrast, under certain circumstances turbulent flow behavior appears, which is characterized by random fluctuations of velocity and pressure at any location. These circumstances may be viewed as the relation of inertial to viscous forces in a flow field and are described by the dimensionless Reynolds number ($2r \times v \times r/h$), where r is radius of the flow cross section, v is mean velocity, r is density, and h is viscosity. Flow becomes turbulent if this number exceeds a cutoff of approximately 2,300; however, *in vivo*, the transition between laminar and turbulent flow may happen at somewhat lower or higher Reynolds numbers. Fluid velocity layers break down, and mixing occurs in eddies. The velocity profile is flattened and no longer parabolic. Poiseuille's law that pressure drop is linearly proportional to flow rate no longer applies; turbulent pressure drop is proportional to flow rate squared. Hence, flow resistance increases if flow becomes turbulent (19). Note that the continuity principle and Bernoulli equation are valid independently of the occurrence of turbulence. Turbulent jets at their orifice contain a small, tapering laminar flow core, which extends for approximately six orifice diameters or less (21) into the receiving chamber, after which the jet is fully turbulent (*e*Fig. 51.2.3). The jet maintains the maximal velocity in the laminar core; after becoming fully turbulent, flow velocity decays inversely proportional to the distance from the orifice. While flow through normal heart valves is laminar, stenotic and regurgitant cardiac lesions create turbulent jets.



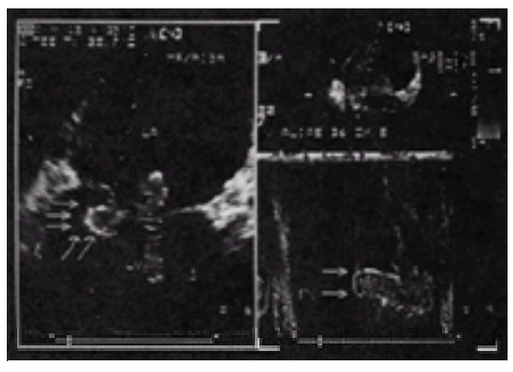
***e*FIGURE 51.2.3** Schematic drawing of the cross section of a turbulent jet. Jet velocity is highest across the orifice. Immediately downstream from the orifice, flow is still laminar, and the high velocity is preserved. This *laminar core* is progressively eroded downstream by turbulence occurring where high-velocity fluid and stagnant fluid mix. After a length of approximately five orifice diameters, the jet is fully turbulent. Mean velocities are now highest along the centerline and decrease laterally. By entrainment of stagnant fluid, the jet's volume and cross section increases, while flow velocities decrease. Jet momentum (jet fluid mass × velocity) is equal at each cross section C. (Adapted from Yoganathan AP, Cape EG, Sung HW, et al. Review of hydrodynamic principles for the cardiologist: applications to the study of blood flow and jets by imaging techniques. *J Am Coll Cardiol* 1988;12:1344–1353, with permission.)

Proximal Convergence Zone or Proximal Isovelocity Surface Area Concept

The proximal convergence zone or proximal isovelocity surface area concept is a continuity-based approach to measure flow rate through a regurgitant orifice by analysis of the flow velocity field proximal to the orifice (22,23 and 24) (eFig. 51.2.1, Fig 51.2.4, and Fig 51.2.5). For this purpose, it is assumed that the issuing chamber is large compared with the orifice, and that concentric hemispheric surfaces of fluid particles of the same velocity centered at the orifice are formed at each moment in time. The smaller the radius of the hemisphere, the higher the flow velocity toward the orifice. Because of the continuity principle, flow rate through the orifice is equal to flow rate across each hemisphere and is given as the product of hemisphere surface area and corresponding flow velocity. If the radius of such a hemisphere r and the corresponding velocity v are known, the instantaneous flow rate Q can be calculated as $Q = 2p\times r^2 \times v$. The assumption of a hemisphere is a simplification of the shape of the isovelocity surfaces, because solid boundaries, simultaneous intracardiac flows, flattening of the isovelocity surface close to the orifice, and other factors influence its shape.



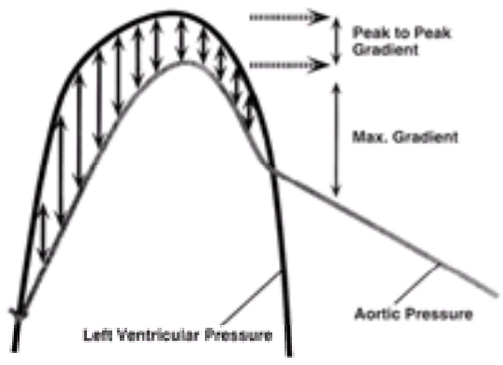
***e*FIGURE 51.2.4** Schematic drawing of the proximal flow convergence concept. Flow through a restrictive orifice is shown as imaged by color Doppler. Proximal to the orifice (lower third of drawing), concentric isovelocity shells of hemispheric shape develop. Two representative shells are shown: the outer, blue one depicts low velocity toward the orifice. At the distance r to the orifice, the aliasing velocity v_{ALIAS} occurs; the inner shell is red, depicting higher velocities. Flow rate is calculated by multiplying the surface of the shell with radius r by v_{ALIAS}. To increase r (and decrease the measurement error of r), the aliasing velocity can be lowered by moving the baseline of the color bar *in the direction of the jet* (i.e., upward in this example).



***e*FIGURE 51.2.5** Example of proximal convergence zone analysis by color Doppler with baseline shift. Mitral regurgitation viewed by transesophageal color Doppler. The circular proximal convergence zone (*arrows*) is seen on the ventricular side of the mitral valve. To increase the aliasing radius, the color bar baseline was shifted upward. The radius can also be measured from color M-mode (*lower right*). In this case, maximal instantaneous regurgitant flow rate was $2p \times (1.1\ cm)^2 \times 36$ cm per second = 274 cm^3 per second, corresponding to severe mitral regurgitation.

Evaluation of Restrictive Orifices: Pressure Gradients and Orifice Areas

A stenosis is a restriction to flow and thus is characterized by a pressure drop, a reduction in the geometrical cross section of flow, and an increase in local flow velocity, regardless of whether this occurs on a valvular or other level. The instantaneous pressure drop across the stenosis is calculated from the instantaneous flow velocity by the simplified Bernoulli equation (eFig. 51.2.6). Maximal and mean pressure drops, or gradients,* can be calculated and are in principle identical to hemodynamic maximal instantaneous and mean gradients (but not to "peak-to-peak" gradients). Maximal gradients are particularly prone to measurement error; thus, in general, mean gradients are preferable to characterize an obstruction. The mean gradient is the mean of $4v_1^2$, $4v_2^2$,..., where v_1, v_2,... are the maximal instantaneous velocities; thus, it is not identical to $4v_{MEAN}^2$ (this is correctly implemented in the analysis packages of available echo machines). However, the pressure drop depends not only on the stenotic orifice area, but also on a number of other factors, most prominently stroke volume. Thus, orifice area is considered to be a more characteristic and stable parameter of a stenotic lesion. It has long been assumed to be flow independent in aortic and mitral stenosis. Although there is evidence that this is not the case in a subset of stenotic lesions (25,26), current usage treats these lesions as fixed. Orifice area can be measured directly by planimetry from 2-D images in mitral and, transesophageally, in aortic stenosis. Alternatively, the continuity principle can be used, and stroke volume from another valve is divided by the time-velocity integral of the stenotic valve to yield the effective orifice area (if both valves are competent). It must be kept in mind, however, that the orifice area calculated by continuity is smaller than the planimetric or (hemodynamic) Gorlin orifice area. Native mitral stenosis can also be estimated using the pressure half-time concept. This concept, derived from hemodynamics, uses the time in which the pressure drop falls to one-half of its initial value as an estimate of the severity of obstruction, which is less flow dependent than the pressure drop itself. Additionally, resistance of a stenosis can also be calculated by dividing the mean pressure gradient (from the simplified Bernoulli equation) by the stroke volume. However, *in vitro* and *in vivo* experiments have clearly shown that resistance is also flow rate dependent, and there is no clear advantage over the more familiar parameters of obstruction pressure drop and orifice area (25,26).



***e*FIGURE 51.2.6** Schematic drawing of pressure gradients in aortic stenosis. Mean gradient is the average of the red arrows. Note that *peak-to-peak* gradient (difference between maximal left ventricular and maximal aortic pressure) never actually exists, because peak aortic pressure occurs after peak ventricular pressure. Peak-to-peak gradient is neither identical with maximal nor mean pressure gradient.

Evaluation of Regurgitation

Regurgitation is flow through a valve occurring in the wrong direction. Regurgitant flow velocities in the receiving chamber (e.g., the left atrium in mitral regurgitation) can be recorded by any Doppler modality. To search for and identify regurgitation, color Doppler is most convenient. In more than “trace” regurgitant lesions, regurgitant jets by color Doppler usually do not have a single color, but instead have a core region with a mosaic appearance containing all colors in a rapidly changing pattern, surrounded by larger regions of pure red or blue (Fig. 51.1). Most color Doppler algorithms also add a green hue to the basic colors red and blue to denote rapid velocity changes. The two main reasons for the mosaic appearance are that (a) jet core velocities in mitral and aortic regurgitation, and often in tricuspid regurgitation, are much higher than the aliasing velocity of the color map and thus, multiple aliasing occurs; and (b) regurgitant jets almost always are truly turbulent, so that flow velocities in all directions occur in random fashion. It should be kept in mind that the color Doppler mosaic appearance is not necessarily identical with the presence of a turbulent jet in the strict hydrodynamic sense; on the other hand, in severe regurgitation, when there is nearly pressure equalization between the issuing and receiving chambers, the driving pressure difference between the chambers may become so small that the classic color Doppler appearance of a turbulent regurgitant jet is absent. This observation has been made in severe prosthetic dehiscence (27). If the presence of regurgitation by color Doppler is unclear, pulsed Doppler confirmation of regurgitant flow velocities should be sought.

The easiest but most treacherous way to grade regurgitation severity is by eyeballing or measuring the maximal color jet area of the regurgitant jet in the frame and the cross section where it appears largest. Although a rough estimate of severity, it is stronger related to the square of regurgitant flow velocity than to flow rate and therefore is highly load dependent. Specifically, color jet area is proportional to momentum flux (the transfer of momentum over time) in the regurgitant jet (28). Momentum in physics is a parameter defined as the product of mass (in grams) times velocity (in centimeters per second). Importantly, the momentum of each cross section of a free jet ideally is the same (with little mass at high velocity at the orifice, and more entrained fluid mass at lower velocity downstream; *e*Fig. 51.2.3). Because color jet area is proportional to jet momentum flux, it is quadratically related to regurgitant flow velocity, whereas regurgitant volume or regurgitant fraction is linearly related to regurgitant velocity. In other words, a volume of blood regurgitating at a high velocity due to a high pressure difference has a larger color jet area than the same amount of blood regurgitating at a lower velocity due to a lower pressure difference. Another important problem is that jets often are eccentric and may spread out on an adjacent wall (in the left atrium) or hug the anterior mitral leaflet (in aortic regurgitation), thus making size assessment difficult. Eccentric jets in general are substantially underestimated when taken at face value (29). Finally, instrument settings, carrier frequency, and other factors influence the area of a regurgitant jet. Nevertheless, assessment of color jet size is the easiest and fastest way to roughly estimate regurgitation severity. Several other methods are available to assess the severity of regurgitant lesions:

1. The proximal jet diameter or cross-sectional area, measured as the smallest diameter or area immediately downstream of the jet’s anatomic orifice, ideally represents the diameter of the effective orifice area. Since this area is not necessarily circular, it can also be planimetered, or two orthogonal diameters can be measured to calculate an ellipse area. Cutoff values with good discriminating power have been reported, especially for mitral regurgitation. The limiting factors are image quality, influence of gain, and measurement error.
2. The stroke volume of different valves can be compared, if only one of them is insufficient. In mitral regurgitation, regurgitant volume is calculated by subtracting aortic stroke volume from total stroke volume, which is obtained either as mitral stroke volume or as the difference of diastolic and systolic left ventricular volumes. Aortic regurgitant volume can be calculated analogously. Although validated in dedicated hands, its accuracy depends obviously on the reliability of all the stroke volume calculations and is therefore subject to several potential errors (e.g., accuracy of orifice area, skewed velocity profiles, and others).
3. The proximal convergence zone method has been outlined (see Proximal Convergence Zone or Proximal Isovelocity Surface Area Concept, earlier in this chapter). This approach, which has been clinically validated for the atrioventricular valves, yields quantitative values for maximal regurgitant flow rates. Two derived parameters can be calculated from the maximal regurgitant flow rate Q_{max}:
   a. Effective regurgitant orifice area (ROA), for which maximal regurgitant flow velocity (v_{max}) must be additionally measured (by continuous wave Doppler): ROA = Q_{max}/v_{max}. Effective regurgitant orifice area is a useful parameter clearly less load dependent than maximal regurgitant flow rate, but apparently less fixed than effective orifice area of stenotic valvular lesions (30,31).
   b. Regurgitant volume (RV), which is the product of the regurgitant time velocity integral from continuous wave Doppler (TVI) and effective regurgitant orifice area: RV = TVI × ROA.
   c. Application of the proximal convergence zone method requires good image quality and works best for moderate or severe regurgitation, since then the proximal convergence zone is clearly and reproducibly visible. To maximize the radius of the convergence zone and improve definition of the convergence zone, the zero line of the color bar should be shifted in the direction of the regurgitant jet; thus, the aliasing velocity is lowered and the convergence zone radius is maximized (see *e*Fig. 51.2.5). Although applicable to any flow through a restrictive orifice, the method has been clinically validated for regurgitation of the atrioventricular valves and for mitral stenosis (32). Its application to aortic regurgitation is theoretically and clinically not well validated.

Evaluation of Flow Rates

Flow rate is calculated by multiplying the cross section of a flow stream with its average velocity. In pulsatile flow, the product of the cross-sectional area of flow and the time-velocity integral of the modal velocity measured by pulsed Doppler at the site of the cross section is used to calculate stroke volume. Cardiac output is calculated by multiplying the stroke volume with the heart rate. Usually, this principle is applied to the left ventricular outflow tract at the aortic annulus level. The diameter of the aortic annulus or left ventricular outflow tract immediately below the aortic valve is measured in a parasternal long-axis view, and a circular cross section of the outflow tract is assumed, which is calculated as p× r^2, with r one-half of the diameter. An apical long-axis view is used to acquire the pulsed Doppler recording, with the sample volume positioned at the annulus or, in the presence of aortic stenosis, in the outflow tract directly below the aortic valve. Cardiac output can also be measured analogously at the level of the mitral annulus or the pulmonary valve annulus. For mitral stroke volume, several methods have been proposed. The simplest uses diameter of the annulus in the four-chamber view, assumes a circular orifice, and multiplies the area with the time-velocity integral from pulsed Doppler at the annulus level. Alternatively, an elliptical annulus shape may be assumed with two diameters measured in the four-chamber and in the two-chamber views, with area p × D_1 × D_2/4. Since the mitral orifice area is neither circular nor constant over time, a more accurate, but more cumbersome, method measures maximal orifice area in a short-axis view, multiplies it with the ratio of mean to maximal mitral leaflet separation from a mitral M-mode to obtain a *mean orifice area*, and multiplies this value with the pulsed wave Doppler time-velocity integral at the leaflet tips (33). For pulmonary stroke volume, the maximal pulmonary annulus diameter is multiplied with the time-velocity integral at the pulmonary valve leaflet tips. From such calculations, regurgitant volumes or shunt ratios (Q_P/Q_S) are derived (as the ratio of pulmonary stroke volume and left ventricular outflow tract stroke volume, if no pulmonary or aortic regurgitation is present) (34). However, accuracy of stroke volume measurements depends on how accurately the cross section is measured and how well the modal velocity by pulsed Doppler reflects the average flow velocity at this site. Automated integration of color Doppler velocities is commercially available. The algorithm calculates flow rate by spatial and temporal integration of flow velocities across a flow cross section. This cross section is defined by a diameter and assumed to be circular. The diameter is represented by an electronic bar that can be positioned freely in the image sector. This is the equivalent of using multiple minute sample volumes instead of just one, as conventionally done, for example, in the left ventricular outflow tract. Within the limits of spatial and temporal color Doppler resolution, flow profiles are taken into account by this method (35).

CLINICAL DOPPLER EXAMINATION

General Considerations

Modern echo machines have imaging transducers with incorporated Doppler capabilities and show the Doppler cursor or sample volume in the current 2-D image. Additionally, guidance is provided by the audio output. However, in difficult continuous wave Doppler examinations (e.g., in aortic stenosis), a dedicated, stand-alone

transducer without imaging frequently is superior to the combined 2-D and Doppler transducer for technical reasons and because of the smaller transducer face size (e.g., for use with the suprasternal window). Furthermore, although carrier frequency for imaging ideally should be as high as possible to optimize spatial resolution, for pulsed Doppler there is a trade-off between spatial resolution and the maximal unambiguously identifiable flow velocity at a given range. Therefore, transducers often operate at a lower carrier frequency in Doppler mode than in imaging mode.

The following practical points should be observed:

1. The interrogating beam should be aligned with the direction of flow. This is difficult even using 2-D–guided Doppler, because the third dimension is missing. It is better to change the transducer position to enable optimal alignment than to use the angle correction option. Although angle correction is possible in available Doppler devices, it is likely to introduce more error than it corrects, unless the true direction of flow is evident, as in a vessel imaged in a long axis. Fortuitously, in truly turbulent flow, which is present in severe valvular stenosis and in left-sided regurgitation, high flow velocities occur in all spatial directions; therefore, optimal alignment is less critical in these instances. A few heart cycles should be recorded, especially in the presence of atrial fibrillation.
2. The visual and the audio output should be used to optimize the signal (see Instrument Settings, later in this chapter).
3. Timing of the Doppler signal should be compared with the corresponding ECG. For example, the mitral regurgitation signal, which may be mistaken for an aortic stenosis signal, begins earlier (immediately after mitral valve closure) than the aortic ejection signal. If the origin of the continuous Doppler signal is unclear, the timing of a 2-D–guided pulsed Doppler signal in relation to the ECG should be obtained for orientation.
4. The pitfalls include that clear flow velocity recordings by Doppler cannot be created *ex nihilo* (but they can represent a flow that was not intended to be recorded). An exception is mirror artifacts, which are created by high amplitude signals (or too high gain) and which duplicate an existing signal with inverse sign or reverberations of color Doppler signals, which also duplicate real existing flow at a manifold of the real depth (Fig. 51.3). An important example of the latter is *phantom flow* in transesophageal color Doppler images of the descending aorta, resulting in a *double-barrel* descending aorta. Conversely, there is never proof that the recorded velocities are truly the highest ones that exist, because there is always the possibility of false placement or malalignment of the echo beam. Thus, to minimize the first type of error, ECG timing, 2-D orientation, and characteristics of the flow profile should always be checked. Practically, the most important error is misreading mitral regurgitation for aortic stenosis. The second type of error is minimized by carefully using all echo windows, patience, and clinical judgment. If doubts remain, it is preferable to state that the echo examination is suboptimal than to report possibly false values without this caveat.

FIGURE 51.3 Phantom flow in the descending aorta. On top, the true descending aorta is seen by transesophageal echo with color Doppler imaging. At the twofold distance, a second lumen with phantom flow is seen (*arrows*). This “double-barrel” appearance of the descending aorta is frequently found and represents a mirror artifact, which can be misdiagnosed as dissection.

5. Normal values for forward flow velocities are, of course, dependent on cardiac output and heart rate, and in some instances also on other factors. For instance, the ratio of early to late velocity of transmitral flow decreases with age, as does the ratio of diastolic to systolic peak velocity of pulmonary venous flow. Minimal or trace regurgitation by color and pulsed Doppler is frequently seen in all valves without clinical evidence of heart disease. The incidence increases with age.

Anatomic Windows

All 2-D windows are used for Doppler recordings. However, the best transducer position for Doppler interrogation almost always is not the best position for imaging. Doppler recordings often are sufficient even if 2-D image quality is impaired, because the signal-to-noise ratio in Doppler recordings is higher than for 2-D echo. Right parasternal windows (for aortic stenosis, with the patient in the right lateral decubitus position) and suprasternal windows (mostly for aortic stenosis or aortic coarctation) are often helpful, as are epigastric windows.

Instrument Settings

Gain, scale (which in pulsed and color Doppler is equivalent to pulse repetition frequency), baseline, and filter settings should be individualized to obtain a well-defined signal. As little gain as possible while preserving the integrity of the velocity signal should be used to avoid artifacts, and, with pulsed Doppler, to achieve a narrow width of the envelope. In pulsed Doppler, the length of the sample volume can be varied. Better signal-to-noise ratio by a larger sample volume has to be weighed against the loss in spatial resolution. The wall filter, a high-pass filter, is intended to eliminate noise, but excessive wall filters, by excluding low flow velocities, obscure the onset and end point of flow. This is of importance when measuring isovolumic relaxation time. With color Doppler, gain should be increased until *random color pixels* appear, and then slightly decreased. The appearance of turbulent jets by color Doppler flow maps depends somewhat on the proprietary algorithms of the individual echo machines.

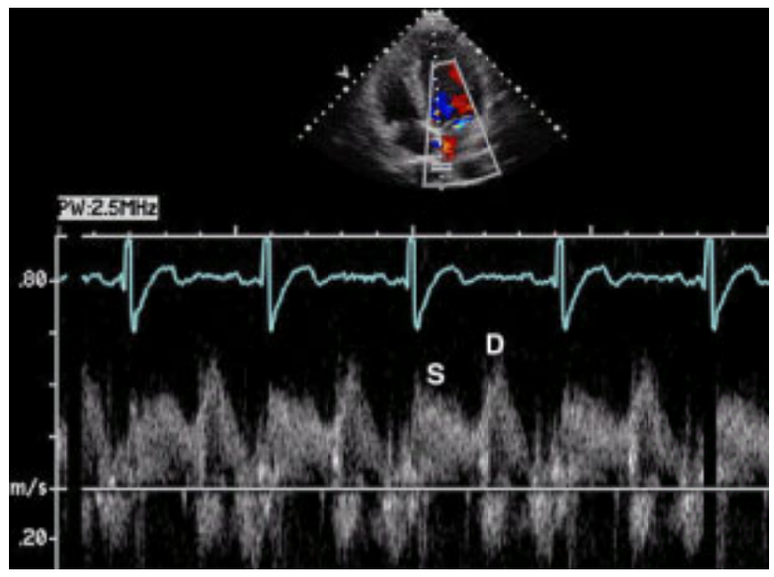
The Routine Examination

The Doppler examination is an integral part of the routine echocardiographic examination. However, specific pathologies (as in aortic stenosis or congenital heart disease) frequently require use of additional echo windows and additional examination time.

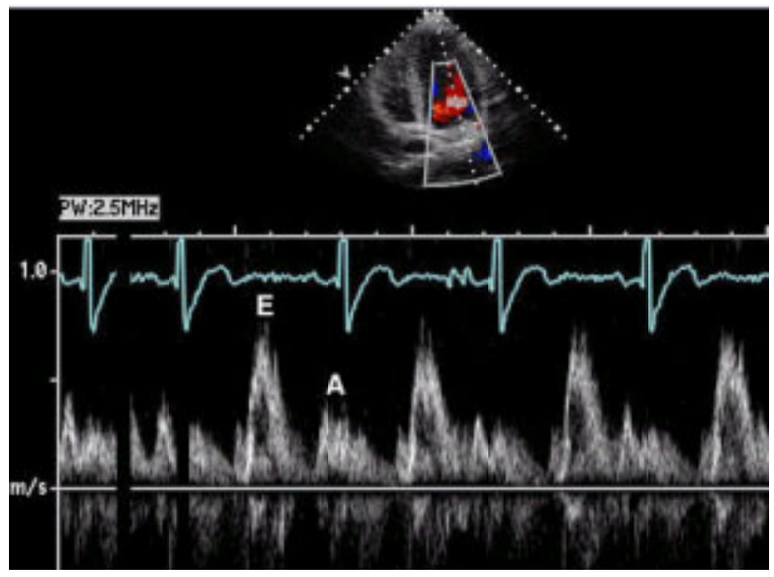
In the parasternal views, because the left heart flows are approximately orthogonal to the echo beam, velocity measurements are not practical. However, color Doppler reveals the occurrence and direction of mitral and aortic regurgitation. The width of these jets is well assessed in parasternal long-axis views, and the minimal cross section in appropriate basal short-axis views. Subaortic obstruction and ventricular septal defects can also be detected by color Doppler. Short-axis views at the aortic root level allow both pulsed or continuous wave Doppler and color Doppler assessment of the right ventricular inflow and outflow tract, including tricuspid and pulmonary forward and, if present, regurgitant flow. Congenital anomalies such as atrial septal defects, membranous ventricular septal defects, or a patent ductus arteriosus may also be detected.

In the routine examination, mitral and aortic valves and the left ventricular outflow tract should be examined by color Doppler in parasternal long-axis views. Also, color Doppler recordings of the tricuspid and pulmonary valves should be obtained in basal short-axis views.

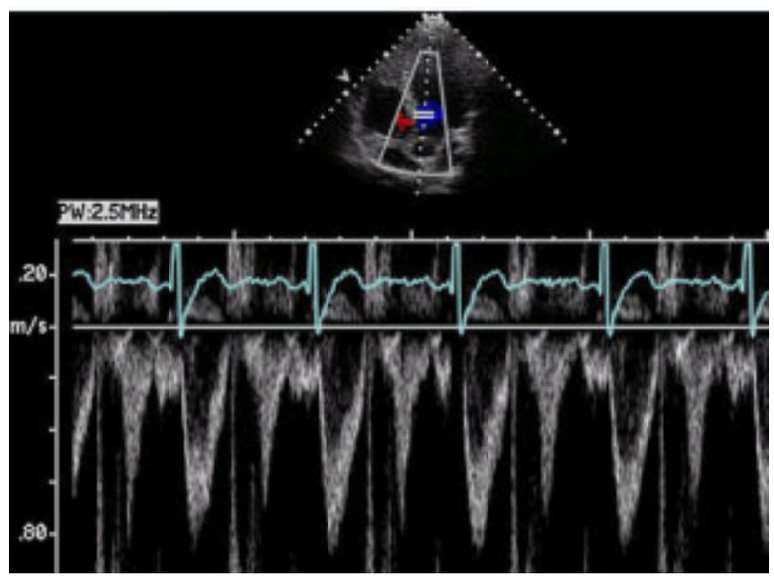
The apical views are ideally suited to record left ventricular inflow and outflow velocities. Transmitral flow is well assessed in four-chamber and two-chamber views. Flow velocities in the left ventricular outflow tract, at the aortic valve level, and in the first centimeters of the ascending aorta are recorded in the apical long-axis view. The four-chamber view also allows measurement of tricuspid flow. Furthermore, atrial and ventricular septal defects (especially of the muscular type) may be detected by color Doppler in the apical four-chamber view. Pulmonary venous flow may be interrogated in a slightly cranially angulated four-chamber view in the right upper pulmonary vein. In the routine examination, a transmitral flow profile should be obtained by pulsed Doppler at the leaflet tips (where transmitral velocities are highest); if cardiac output calculations are to be made, a recording at the mitral annulus level should also be obtained. Mitral regurgitation is sought by color Doppler in all apical views. A transaortic flow profile and an outflow tract profile are recorded by pulsed Doppler. An additional continuous wave Doppler recording of outflow tract and aortic valve is valuable to exclude an obstruction that may have been overlooked by 2-D imaging. Color Doppler of the outflow tract should also be recorded to exclude aortic regurgitation. The tricuspid valve is examined by color Doppler for the presence of regurgitation; if present, the maximal regurgitant velocity is recorded by continuous wave Doppler. By the simplified Bernoulli equation, the maximal systolic pressure difference between right ventricle and right atrium can be calculated from the maximal tricuspid regurgitant velocity. This is an estimate of maximal right ventricular, and, thus, pulmonary, pressure. The pressure difference either can be reported as such, or 10 mm Hg can be added as an estimate of right atrial pressure, or right atrial pressure can be assessed clinically by the collapse level of the neck veins. Further, a color Doppler map of flows in the proximity of the interatrial septum should be obtained to rule out atrial septal defect.



Pulmonary vein pulsed wave Doppler flow. Note the S (systolic) wave and the D (diastolic) wave.

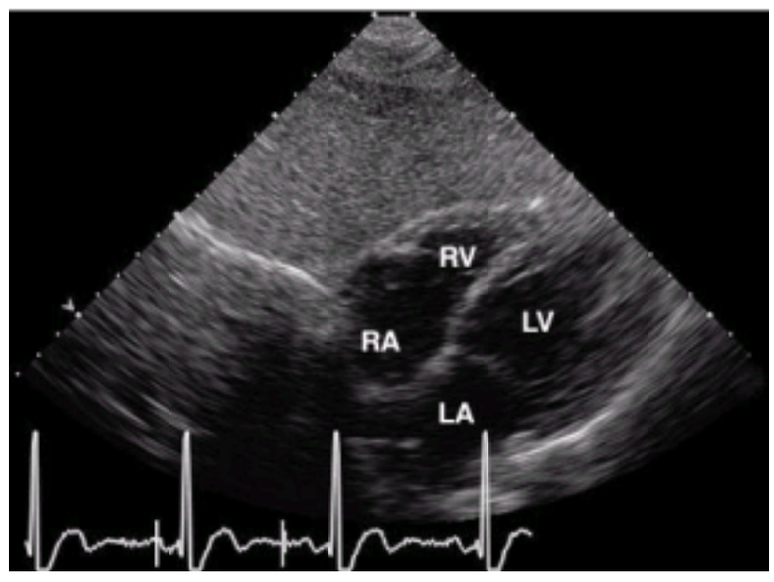


Pulsed wave Doppler signal from the mitral valve inflow. Note the E (early) and A (atrial) waves.



Normal pulsed wave Doppler signal from the left ventricular outflow tract. Note the maximal velocity is only 80 cm/second.

The subcostal views are rarely optimal windows for Doppler examination except for atrial septal defects, in which the echo beam orientation is more appropriate than in the apical four-chamber view. Routinely, the interatrial septum should be examined by color Doppler to rule out atrial septal defect. The subcostal views, however, provide a valuable alternative if more cranial windows are insufficient (e.g., in aortic stenosis). Aortic coarctation and aortic stenosis should be evaluated from the suprasternal position, which in adults often is difficult to use except with a dedicated continuous wave probe.

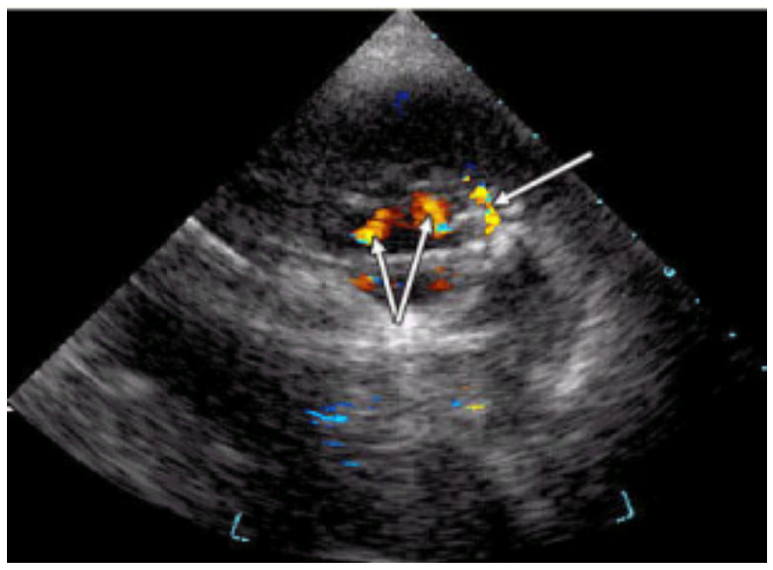


Long-axis view from the subcostal window of a transesophageal echo showing the left and right ventricles (LV and RV) and the left and right atria (LA and RA).

Transesophageal Doppler

Transesophageal echo offers a full set of echo windows for the 2-D and Doppler examination that are almost never obstructed (36). Evidently, transmitral flow can be studied under ideal conditions and even eccentric regurgitant jets are well depicted by color Doppler. Aortic regurgitation is well seen by color Doppler from transesophageal windows, especially long-axis views (at 130 to 160 degrees) of the left ventricular outflow tract. It is difficult, however, to obtain a good alignment of transvalvular aortic flow with the echo beam; this is best done from a transgastric position by rotating from the left ventricular short axis to a long-axis view or using maximal anteflexion of the instrument in the stomach. Tricuspid flow is also sometimes difficult to align with the echo beam. Continuous wave Doppler of the tricuspid valve may be contaminated with a mitral regurgitation signal, since the echo beam always first traverses the left atrium before reaching the tricuspid valve. The pulmonary valve is mostly not well visualized transesophageally. Transesophageal echo offers a unique access to measuring emptying and filling velocities in the left atrial appendage, which are related to thromboembolic risk. Furthermore, pulmonary venous flow is easily interrogated either in the left upper or right upper pulmonary

vein. Being the diagnostic procedure of choice in the setting of aortic dissection, entry and reentry jets and flow in the true and false lumen can be examined by transesophageal echocardiography. Given the excellent visibility of the interatrial septum, a color Doppler examination for an atrial septal defect should be performed. The sensitivity of transesophageal color Doppler for a patent foramen ovale, however, is inferior to that of contrast echo. If cardiac embolism is suspected, especially in atrial fibrillation, a pulsed Doppler recording of left atrial appendage flows should be obtained. Flow velocities in the ascending and descending aorta can be visualized by color Doppler, while absolute velocity values are unreliable because of the large angle between flow direction and echo beam.



Transgastric short-axis view during intraoperative transesophageal echo of a paravalvular leak of a CarboMedics mitral valve replacement. Note the two normal physiologic prosthetic jets of mitral regurgitation (within the sewing ring) as designated by the double arrow and the one abnormal, laterally originating jet outside the sewing ring (to the right of the screen) designated by the single arrow. There was significant mitral annular calcification (MAC), making it difficult to achieve close contact between the annulus and the sewing ring.

Contrast-Enhanced Doppler

Injection of echo contrast agents enhances the amplitude and signal-to-noise ratio of the Doppler flow signal. Thus, echo contrast may be injected to improve the quality of recordings in difficult cases. Intravenous injection of a left-sided heart contrast agent can be helpful, especially in the evaluation of aortic stenosis (37) and of pulmonary venous flow by transthoracic Doppler.

Left-sided heart contrast agents also improve coronary vessel visibility by transesophageal color Doppler; in a study, satisfactory pulsed wave Doppler acquisition from the left anterior descending artery improved from 23% to 66% after injection of a galactose-based agent (38). Left-sided heart contrast agents, because of their small bubble size, have flow characteristics of red blood cells and therefore have potential as myocardial perfusion tracers. Several techniques are currently under evaluation to detect and semiquantitate these agents in the myocardium. Some of them are *power* Doppler techniques. Doppler power (the square of the amplitude of the Doppler signal) is primarily related to the number of scatterers, not to their velocity or direction. Contrast bubbles create power Doppler signals both by their motion and, most importantly, by ultrasound-induced destruction of contrast bubbles, which leads to the creation of a strong Doppler shift. It has been convincingly shown that power Doppler is better suited for measuring the amount of myocardial contrast than gray scale imaging (39).

Normal Transvalvular and Pulmonary Venous Flow Velocity Signals

The normal transmitral flow velocity signal consists of an early (E) wave, which is produced by the rapid decrease in left ventricular pressure caused by relaxation below the level of left atrial pressure (Fig. 51.4). E-wave upslope reflects the rapid growth of the early diastolic atrioventricular pressure gradient. When this pressure gradient ceases to exist, deceleration ensues, which reflects largely the passive compliance of the left ventricle and the left atrium, with a steep deceleration if compliance is low and a slow deceleration if compliance is high. The E wave in sinus rhythm is followed by the late diastolic atrial (A) wave, which is the result of atrial contraction and occurs after the ECG P wave. It reflects atrial contraction force and elastic properties of the left ventricle and atrium at end diastole.

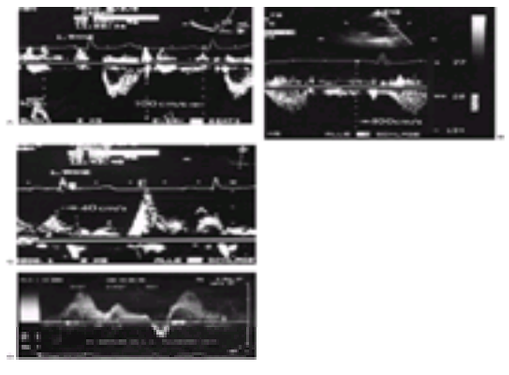

FIGURE 51.4 Normal flow velocity profiles by pulsed Doppler. (See Figure 51.1 for normal transmitral profile.) **A:** Normal transaortic flow pattern. The sample volume is positioned at the aortic valve annulus in an apical long-axis view. **B:** Normal transpulmonary flow. The sample volume is positioned in the pulmonary valve in a basal parasternal short-axis view. **C:** Normal transtricuspid flow pattern. The sample volume is positioned at the tricuspid leaflet tips in an apical four-chamber view. A, late atrial wave; E, early inflow wave. **D:** Normal pulmonary venous inflow pattern from the left upper pulmonary vein by transesophageal Doppler. Systolic (SYST) and

diastolic (DIAST) inflow into the left atrium is seen, as well as a short reverse (REV) wave representing atrial contraction.

Aortic flow velocities have an approximately triangular shape, with a slightly more rapid upslope than downslope (Fig. 51.4). The slopes reflect left ventricular contraction and relaxation and aortic resistance. Aortic flow ends before mitral flow begins, and the time between aortic valve closure and mitral flow onset is the isovolumic relaxation time (normally, approximately 60 ms). Conversely, mitral valve closure occurs before the onset of aortic flow (isovolumic contraction time).

Tricuspid forward velocities form an early diastolic wave and a late wave after atrial contraction, analogous to the transmitral flow pattern (Fig. 51.4). Transtricuspid flow velocities are the lowest of all valves, because the tricuspid valve has the largest orifice area. Pulmonary forward flow is represented by an approximately triangular-shaped systolic velocity signal with a symmetric upslope and deceleration. A steep upslope or a mid-systolic notch are typical of pulmonary hypertension.

Pulmonary venous flow velocities in sinus rhythm have a systolic and a diastolic portion directed toward the left atrium and a short low-velocity retrograde wave after atrial contraction (Fig. 51.4). Systolic and diastolic inflow velocities in young individuals are approximately equal. Diastolic inflow velocities decrease with age and in general behave as the transmitral E wave, because in diastole the atrium acts largely as a passive conduit. Note that peak diastolic pulmonary venous velocity follows peak transmitral E-wave velocity by approximately 50 ms (40), again because early diastolic left ventricular relaxation initiates transmitral left ventricular inflow, which in turn gives rise to pulmonary venous diastolic inflow.

Normal values for the flow velocities obtained during routine examination are given in Table 51.1.

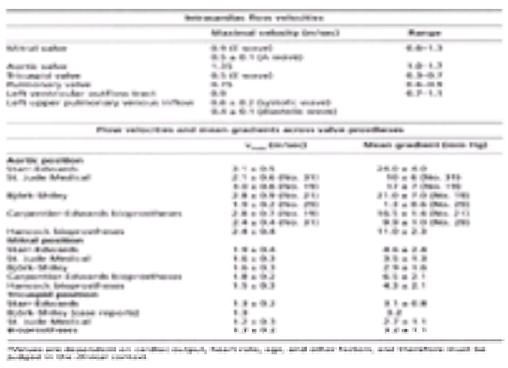

TABLE 51.1 NORMAL VALUES FOR FLOW VELOCITIES IN ADULTS COMPILED FROM SEVERAL REFERENCES (17,18,66,116,117)[a]

ACQUIRED VALVULAR HEART DISEASE

Mitral Valve

Mitral stenosis is best assessed in one of the apical views. Continuous wave Doppler recordings of transmitral flow should be obtained; in atrial fibrillation, at least a short and long diastolic period should be recorded to document the range of occurring gradients. The mean gradient and the pressure half-time should be calculated (Fig. 51.5). The latter is calculated from the downslope of the E wave or the single diastolic wave in atrial fibrillation. It is the time of decay from maximal velocity of flow (immediately after mitral valve opening) to $1/\sqrt{2}$ of the maximal velocity (the $1/\sqrt{2}$ factor is due to the quadratic relation between pressure drop and velocity in Bernoulli equation). The pressure half-time (PHT, in milliseconds) is relatively robust against changes in cardiac output and heart rate; a useful empiric relationship exists with mitral valve area (MVA, in centimeters squared), given by MVA = 220/PHT (41). However, pressure half-time also depends on left atrial and left ventricular compliance and the maximal pressure gradient.

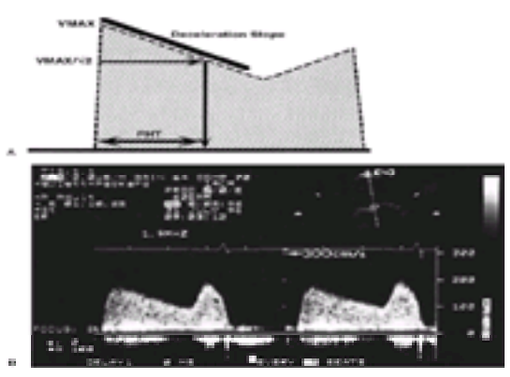

FIGURE 51.5 A: Schematic drawing of measurement of time-velocity integral and pressure half-time (PHT) in mitral stenosis. VMAX, maximal early diastolic velocity. The area surrounded by the dotted line is the time-velocity integral. See text for details. **B:** Transmitral flow by apical continuous wave Doppler in mitral stenosis with preserved sinus rhythm. Peak gradient is 15 mm Hg, mean gradient is 9 mm Hg, and pressure half-time is 228 ms, corresponding to an orifice area of 1 cm^2.

It can be shown analytically (36,37) that in mitral stenosis the following relationship between pressure half-time, MVA, maximal diastolic pressure drop (p_0), and net compliance of left ventricle and left atrium (C_{NET}) holds: PHT = 11.6 × C_{NET} × Öp_0/MVA. Thus, pressure half-time has an inverse relationship with mitral valve area but is also influenced by the other parameters. Furthermore, it is influenced by concomitant aortic regurgitation, which shortens pressure half-time, the presence of an atrial septal defect, or the presence and type of a prosthetic mitral valve (42,43 and 44). Thus, in these instances it is unreliable and should be used mainly for serial measurements, but not to calculate mitral valve area. Consequently, if mitral valve area by planimetry and by pressure half-time are discrepant, possible reasons are the presence of aortic regurgitation, an atrial septal defect, left ventricular diastolic dysfunction with elevated pressures, or, of course, an error in one of the two measurements. Other ways to calculate (effective) mitral valve area from Doppler data are to obtain cardiac output and to divide it by the time velocity integral of the mitral valve, or to use the diameters of the forward jet by color Doppler in the four-chamber view (D_{4CV}) and the two-chamber view (D_{2CV}) to approximate mitral valve area by p × D_{4CV} × D_{2CV}/4 (the ellipse formula). Alternatively, the proximal convergence zone principle may be used to calculate peak flow rate through a stenotic mitral valve and then to divide peak flow rate by peak velocity to yield effective regurgitant orifice (30). Peak flow rate is calculated as

$$Q_{MAX} = 2\pi r^2{}_{ALIAS}{}^2 \times v_{ALIAS}{}^2 \times \alpha/180°$$

where Q_{MAX} is peak flow rate, r_{ALIAS} is radius (distance from orifice) at which velocity aliases, v_{ALIAS} is aliasing velocity, a is the inflow angle subtended by the mitral leaflets (the factor a/180° corrects for the funnel-shaped inflow geometry in mitral stenosis).

Severity of mitral stenosis is graded as from invasively obtained pressure gradients or Gorlin areas. It has been reported that some amount of stretch of the orifice with increasing stroke volume may occur in patients with mild or moderate, not heavily calcified, mitral stenosis (45).

Mitral regurgitation should be evaluated by color Doppler using all available windows, especially the apical views. If doubtful by color Doppler, it should be confirmed by pulsed Doppler, with the sample positioned on the atrial side of the mitral valve. Mitral regurgitant jets often are eccentric, hugging the atrial walls (Fig. 51.1). Mitral valve prolapse creates jets directed toward the back side of the prolapsing leaflet, while flail mitral leaflets direct the jet to the opposite side (Fig. 51.1). Mitral

regurgitation caused by left ventricular dilatation usually results in central jets (46). Planimetry or eyeballing of maximal color Doppler jet size yields a rough estimate of severity. Division by left atrial area in the same view to *normalize* jet size has been proposed and is particularly convenient for eyeballing [with cutoff values of 20% and 40% of left atrial size (47)], but lacks theoretical justification. By transesophageal echo, where the atrium is not visualized fully in single views, the cutoff values for planimetry are 3 and 6 cm^2 (48). Eccentric, wall-hugging jets are underestimated by an average of 40% by the jet area method (27). Whereas very small and very large jets are usually well identified, the intermediate severities are impossible to reliably grade by color jet area. Two color Doppler–based approaches have been well validated and are clinically practical, if image quality is good (in particular, using transesophageal echocardiography):

Video 51.4 Color Doppler of a myxomatous mitral valve with *Streptococcus* endocarditis **(A)** showing a large vegetation and perforation of the anterior mitral leaflet causing severe mitral regurgitation. Video 51.8 Intraoperative transesophageal echo with color Doppler of a mitral valve with severe prolapse of the posterior mitral leaflet with 4+, anteriorly directed mitral regurgitation. A very prominent proximal convergence zone is seen in the left ventricle. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

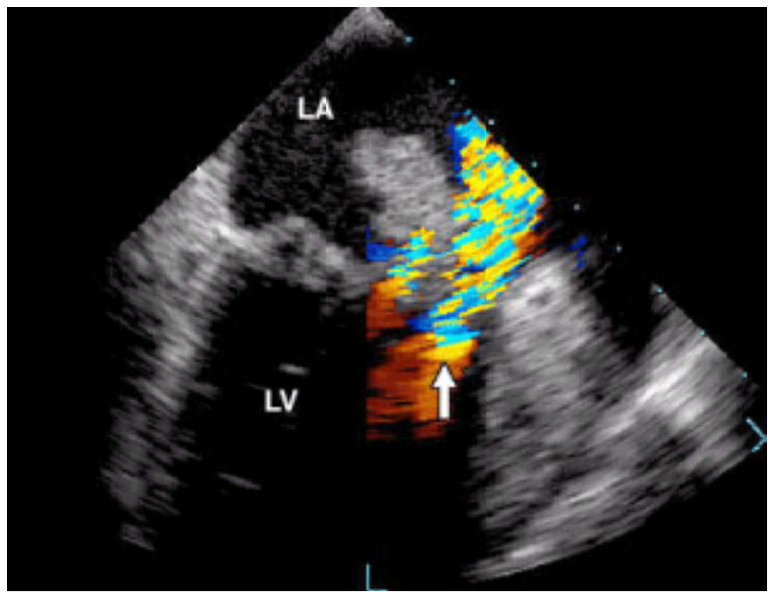
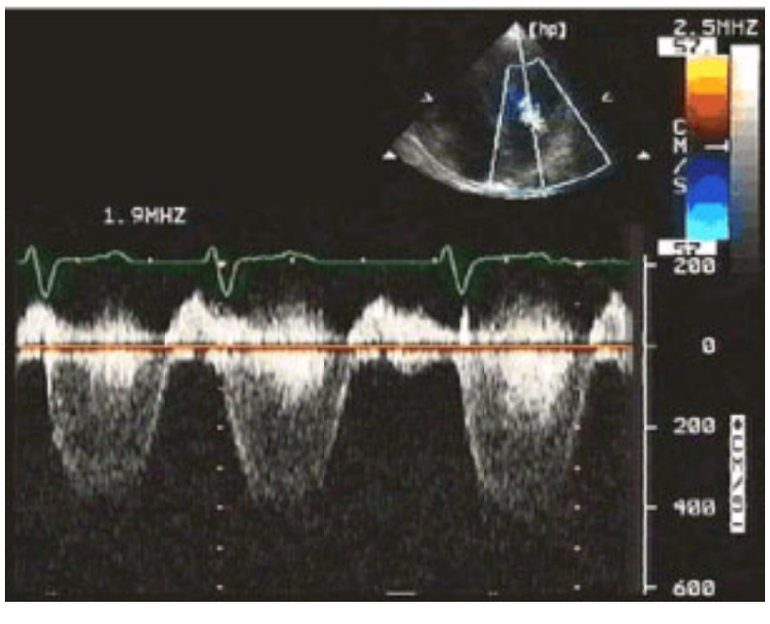
Video 51.9 Color Doppler of 0-degree intraoperative transesophageal echo with prolapse and flail of the posterior mitral leaflet causing very eccentric, anteriorly directed mitral regurgitation. This valve was successfully repaired. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 51.10 Postpump echo (with color Doppler) after repair of the flail posterior mitral leaflet. There is a Cosgrove-Edwards annuloplasty ring in place. There is no residual mitral regurgitation and there is no systolic anterior motion of the mitral leaflets, which can sometimes complicate mitral valve repair. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Color Doppler showing a perforation of the base of the anterior mitral leaflet from *Streptococcus* endocarditis. The patient's underlying pathology was myxomatous mitral valve disease with mitral valve prolapse. The proximal flow convergence of the mitral regurgitation jet is demonstrated by the arrow at

the orifice of the large perforation.



Apical continuous wave spectral Doppler recording of mitral regurgitation (systolic parabolic downward velocities). Note beat-to-beat variation due to atrial fibrillation.

1. Measurement of the proximal jet diameter. The smallest diameter of the jet should be measured, which is within millimeters of its origin (Fig. 51.6). The plane should be sought where the minimal diameter is largest. Jet diameter greater than 7 mm indicates severe regurgitation (49,50).

FIGURE 51.6 Measurement of proximal diameter of a severe mitral regurgitant jet (*horizontal arrows*). The proximal diameter is marked by the oblique arrows. Apical four-chamber view. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

2. The proximal convergence zone method. Although cutoff values have not been extensively validated, maximal regurgitant flow rates greater than 150 mL per second and effective regurgitant orifice areas greater than 0.3 cm^2 indicate grade III or IV mitral regurgitation (21,51). Because of enhanced image quality, this approach works particularly well with transesophageal echocardiography (eFig. 51.2.5).

A number of additional signs are helpful in grading mitral regurgitation. Severe mitral regurgitation creates a continuous wave signal that has a *shoulder* in late systole instead of the symmetric, parabolic appearance of less severe mitral regurgitation. This is due to rapidly increasing end systolic pressure in the left atrium in this circumstance. Pulmonary venous flow recordings show a reduction in the systolic portion of pulmonary venous inflow into the left atrium. In severe mitral regurgitation, the systolic portion of pulmonary venous flow may even be reversed and merge with the end diastolic retrograde flow wave, showing blood being pushed back into the pulmonary vein by the inflow of blood from the left ventricle into the atrium (Fig. 51.7). In eccentric jets, it may be useful to sample both upper pulmonary veins to detect flow reversal (52). Although this sign is quite sensitive, it is not very specific, because impaired systolic pulmonary venous inflow also occurs in atrial fibrillation or impaired systolic function.

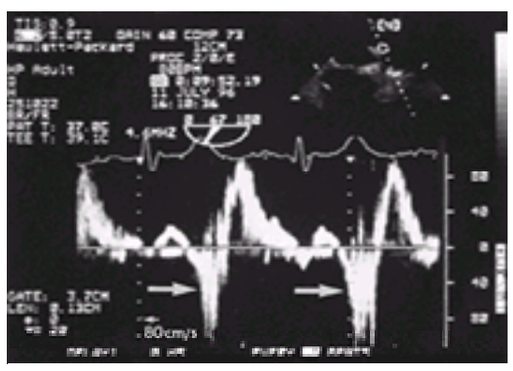


FIGURE 51.7 Pulmonary venous flow in the presence of severe mitral regurgitation. Registration by transesophageal pulsed Doppler from the left upper pulmonary vein. There is only a small positive systolic wave, followed by reversed systolic flow (*arrows*). Diastolic atrial inflow velocities are increased.

Aortic Valve

For the assessment of a stenotic aortic valve, three parameters should be obtained in the best possible quality: the transvalvular continuous wave Doppler, the subaortic pulsed Doppler, and the left ventricular outflow tract diameter (Fig. 51.8). Continuous wave Doppler signals should be recorded at least from two, preferably from three or more, windows (apical, subcostal, suprasternal, right parasternal), to ensure that the maximal velocities have been detected. Mean and maximal pressure gradients are calculated from the continuous wave tracing. In atrial fibrillation, several beats should be analyzed. A slowed early systolic rise in flow velocities across the aortic valve, resulting in an approximately symmetric upslope and downslope, indicates severe stenosis, analogous to the clinical finding of pulsus tardus in this condition (Fig. 51.9). Effective orifice area has traditionally been assumed to be independent of cardiac output and heart rate and thus to be particularly valuable in impaired left ventricular function, when a low-pressure gradient can reflect mild obstruction, low stroke volume, or both. Subaortic pulsed wave tracings and the left ventricular outflow tract diameter (D) are necessary to calculate the effective orifice area (A_{EFF}) by the continuity equation. It is valid to use the maximal velocities from continuous wave Doppler (v_{MAX}) and subaortic pulsed wave Doppler (v_{LVOT}) instead of the time velocity integrals: $A_{EFF} = 1/4p \times D^2 \times v_{LVOT}/v_{MAX}$. However, it has been reported that in some patients with aortic stenosis, orifice area is flow dependent and stretches with increasing cardiac output between 10% and 20% (23,24).

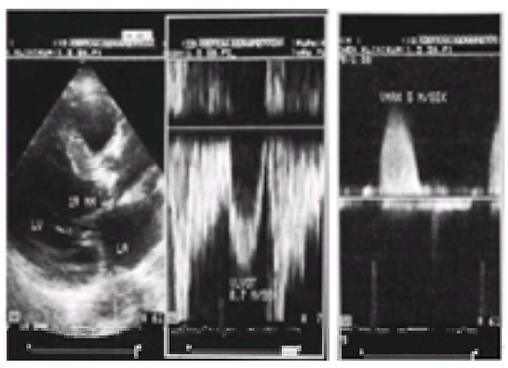

FIGURE 51.8 Aortic valve area calculation by the continuity principle (*top left*). Measurement of left ventricular outflow tract diameter in a parasternal long-axis view (19 mm, corresponding to an area of 2.8 cm^2). **Middle:** Pulsed wave Doppler recording in the left ventricular outflow tract. **Right:** Continuous wave Doppler recording of transstenotic flow velocities. By the continuity equation, an aortic valve area of 0.4 cm^2 was calculated.

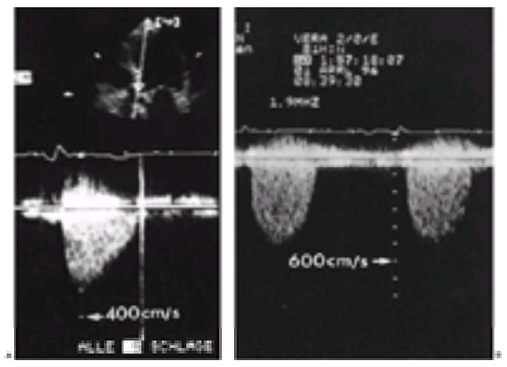

FIGURE 51.9 A: Moderate aortic stenosis with a triangular shape and steep upslope, and **(B)** severe aortic stenosis, with a parabolic shape and a slow upslope.

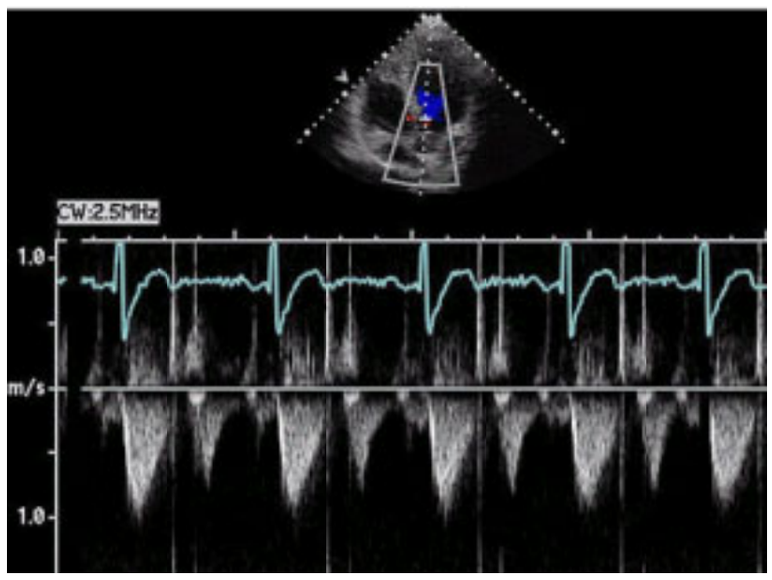
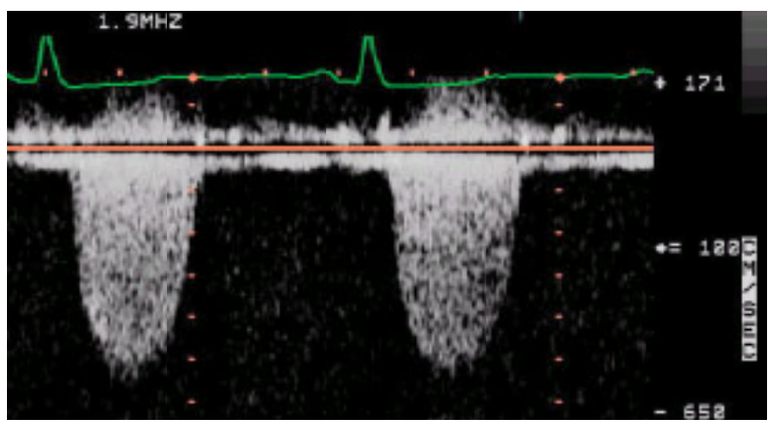
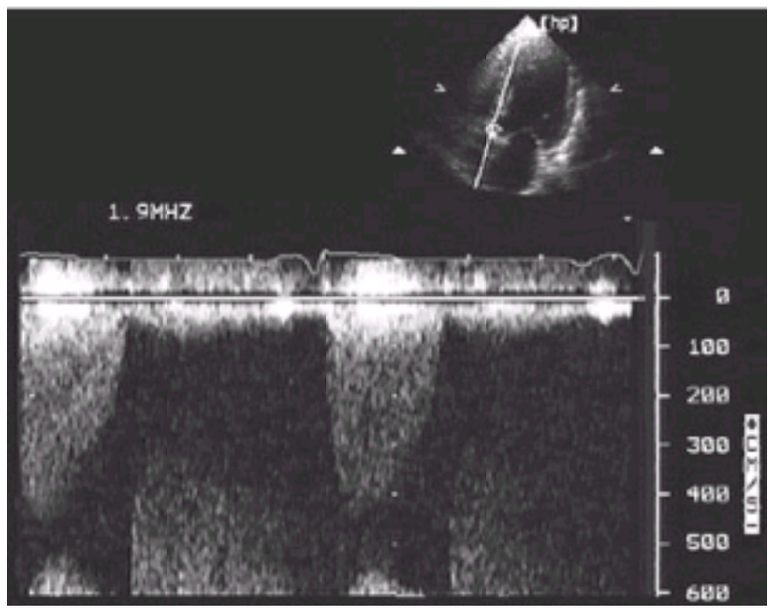


Normal continuous wave Doppler through the aortic valve by transthoracic echo. Note that the maximal velocity is approximately 1 m per second (capillary wedge pressure gradient = 4 mm Hg).



Continuous wave Doppler through a stenotic aortic valve. The maximal velocity is 5.5 m per second, consistent with a peak pressure gradient of 121 mm Hg.



Apical continuous-wave Doppler spectrum of aortic valve disease. Note high forward velocities in systole (V_{max} 4.5 m per second) and early peak of aortic stenosis. At the bottom, wrapped-around diastolic flow velocities from aortic regurgitation are seen.

If Doppler-derived parameters of aortic stenosis are in conflict with other clinical data, the following sources of error should be checked:

a. Doppler gradient too high: misreading the mitral regurgitation signal for aortic stenosis (check timing of velocities); neglect of high proximal velocities, as in aortic regurgitation or high cardiac output; pressure recovery; atrial fibrillation with high beat-to-beat variation in gradient.
b. Pressure recovery may have a clinically meaningful effect in native aortic stenosis if the ascending aorta has a diameter under 3 cm, leading to overestimation of peak and mean gradients by Doppler as compared with invasive hemodynamics. Formulae for estimating the amount of pressure recovery have been published (53,54).
c. Doppler gradient too low: missing the maximal signal (use all available windows).
d. The evaluation of patients with low cardiac output (e.g., due to impaired left ventricular function) and valvular stenosis, especially aortic stenosis, with a low transvalvular gradient is difficult. In these patients, relatively low gradients may be caused by low stroke volume, mild stenosis, or both. Augmentation of cardiac output by 10 to 20 µg per kg per minute of intravenous dobutamine may unmask a *stretch reserve* of the stenotic orifice area in some patients with mitral or aortic stenosis. If the stenosis gives in to dobutamine stress, it can be assumed to be less severe than apparent at baseline (55).

Aortic regurgitation is the most difficult valvular lesion to evaluate. The best parameter to assess severity is the size of the regurgitant jet by color Doppler in the left ventricular outflow tract (Fig. 51.10). Both the height in parasternal long-axis views or the area in short-axis views are used and normalized to the diameter or area of the left ventricular outflow tract, respectively. Twenty percent and 60% of the left ventricular outflow tract area (25% and 65% of the left ventricular outflow tract diameter) are the cutoff values for mild, moderate, and severe regurgitation (56). Another useful parameter is the pressure half-time of the continuous wave Doppler of regurgitant flow (57) (eFig. 51.10.1). This is sometimes difficult to record and may necessitate an orientation of the transducer different from the optimal orientation for recording forward transaortic flow velocity. The shorter the pressure half-time and the more rapidly pressure equalizes between the ascending aorta and the left ventricle, the more severe the aortic regurgitation. Values less than 300 ms indicate severe aortic regurgitation.

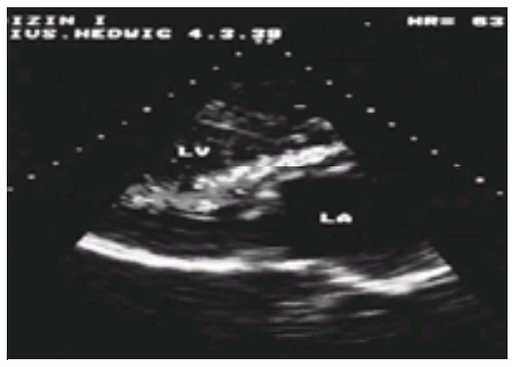


FIGURE 51.10 Aortic regurgitation. Color Doppler flow mapping in a parasternal long-axis view. The regurgitant jet is depicted in the left ventricular outflow tract and left ventricle, hugging the anterior mitral leaflet. LA, left atrium; LV, left ventricle.

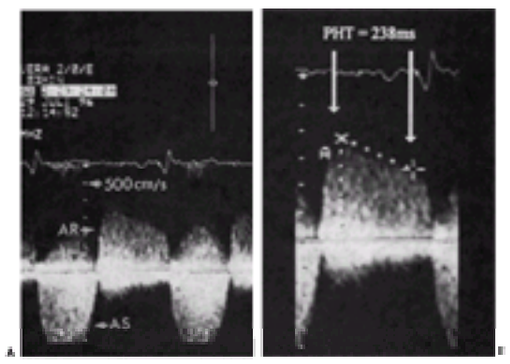
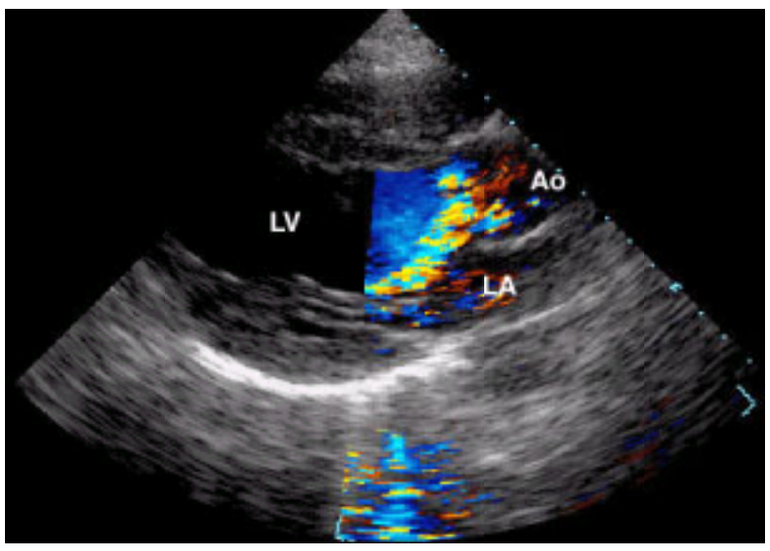


***e*FIGURE 51.10.1 A:** Continuous wave Doppler of combined severe aortic stenosis (AS) and regurgitation (AR). **B:** Calculation of the pressure half-time (PHT) of the aortic regurgitation signal. Pressure half-time shortens with increasing severity of aortic regurgitation. The value of 238 ms indicates severe regurgitation.



Parasternal long-axis view (transthoracic echo) with color Doppler demonstrating the posteriorly directed aortic insufficiency caused by prolapse of the anterior leaflet of a bicuspid aortic valve. Note that the jet hits the anterior mitral leaflet.

Note the remnant thinned, aneurysmal wall of the sinus bowing into the right ventricle (towards the bottom of the screen). Color Doppler interrogation of the aortic valve with sinus of Valsalva in a transesophageal long-axis view **(B)**. Note there is moderate anteriorly directed aortic insufficiency at the top of the screen, and the aortic to right ventricular shunt through the ruptured sinus of Valsalva aneurysm is seen at the bottom of the screen. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

However, pressure half-time does not exclusively reflect severity of regurgitation (the size of the leak, or effective regurgitant orifice), but also depends on left ventricular diastolic compliance and on systemic arterial resistance. For example, if afterload is pharmacologically lowered, pressure half-time can be expected to decrease (due to more forward run-off of blood in diastole), erroneously indicating an increase in regurgitation, when the opposite may be the case (58,59).

Additionally, the presence of a holodiastolic flow signal on pulsed Doppler recordings from the ascending, descending, or (from the subcostal window) abdominal aorta (or a large systemic artery) can be taken as a sign of at least moderate aortic regurgitation (Fig. 51.11).

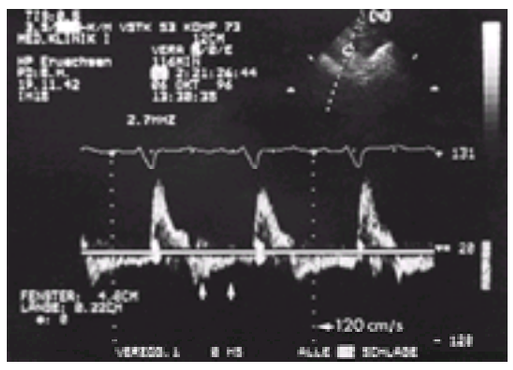

FIGURE 51.11 Holodiastolic flow reversal (*arrows*) in the descending aorta in severe aortic regurgitation. Pulsed Doppler recording from the suprasternal notch.

Tricuspid Valve

The tricuspid valve is examined in the apical four-chamber view, in a basal parasternal short-axis view, or in the (parasternal) right ventricular inflow view. The mean pressure gradient is calculated from continuous wave or pulsed wave Doppler recordings in analogy to transmitral gradients. The pressure half-time may be used for serial measurements, but its use to calculate orifice areas has not been validated in the tricuspid valve. Tricuspid regurgitation is best detected by color Doppler in the apical (or subcostal) four-chamber view (Fig. 51.12). By continuous wave Doppler, it produces a systolic regurgitant velocity spectrum of parabolic shape, similar to mitral regurgitation. As in mitral regurgitation, in severe tricuspid insufficiency there is a rapid late systolic decay of regurgitant velocities because of high end systolic right atrial pressure. The maximal regurgitant velocity is important to diagnose the presence of pulmonary hypertension.

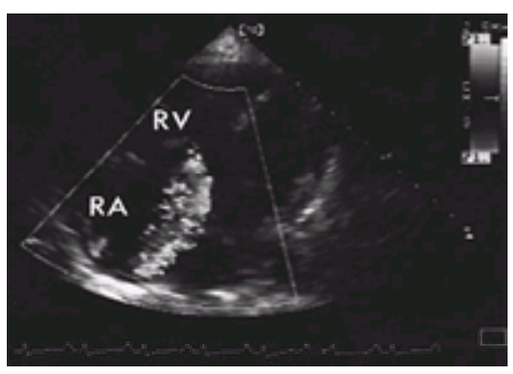

FIGURE 51.12 Moderate tricuspid regurgitation by color Doppler (apical four-chamber view). RA, right atrium; RV, right ventricle.

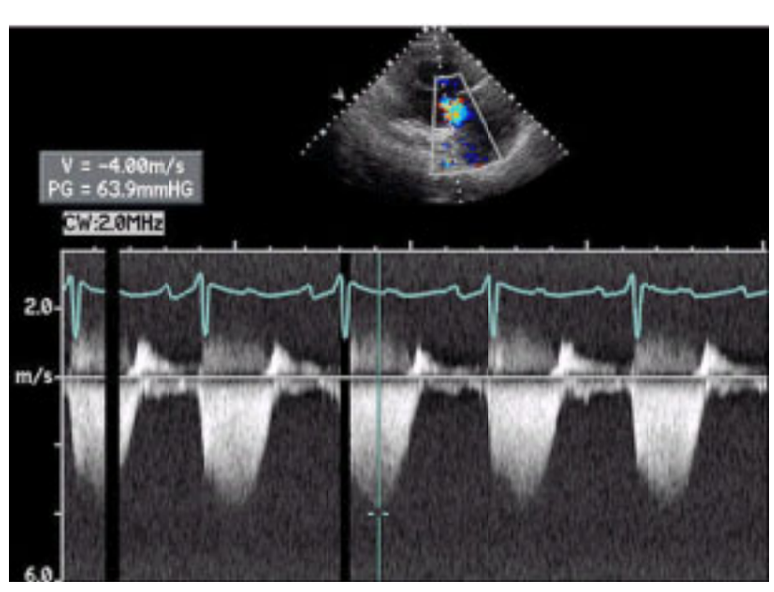


Continuous wave Doppler trace through the tricuspid valve of a patient with pulmonary hypertension. The maximal jet velocity of 4 m per second corresponds to a pressure gradient of 64 mm Hg or a PA pressure of approximately 80 mm Hg.

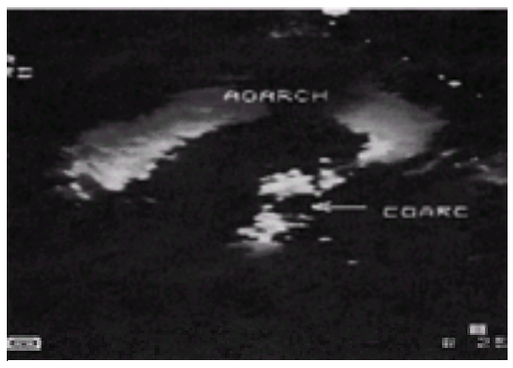
Pulmonary Valve

The pulmonary valve is best examined in the parasternal basal short-axis view or alternatively in a subcostal short-axis view. Minimal pulmonary regurgitation is

frequent in individuals without clinical evidence of cardiac disease. The color Doppler representation of an eccentric pulmonary regurgitant jet may be misread as a membranous ventricular septal defect signal. Pulmonary stenosis is evaluated reliably by the mean transvalvular gradient from continuous wave Doppler.

Aortic Pathology

From the suprasternal window, flow velocity in the ascending and descending aorta can be sampled. Aortic coarctation can be visualized by turbulence, and the gradient measured directly (eFig. 51.12.1). However, although the simplified Bernoulli equation in general is well applicable, it may underestimate the true pressure drop in long, tunnel-like obstructions, or overestimate the pressure drop in the presence of high proximal velocities or downstream pressure recovery. In aortic dissection, transesophageal evaluation is the procedure of choice. Color Doppler flow in the true lumen is usually brighter than in the false lumen, where it may be absent if stasis and thrombosis have ensued. Thus, color flow mapping should be used to confirm the existence of a true and a false lumen. Entry and reentry tears of the intima may also be detected (Fig. 51.13).



***e*FIGURE 51.12.1** Aortic coarctation. Color Doppler flow mapping from the suprasternal notch. On the left side, the ascending aorta is seen in red; on the right side, the descending aorta is in blue. At the stenotic segment (COARC), turbulent flow is present. AOARCH, aortic arch.

PROSTHETIC HEART VALVES

Obstruction

Pulsed and continuous wave measurement of forward flow velocities across valvular prostheses is usually well obtainable even if 2-D image quality is impaired by prosthetic artifacts. Opening and closing clicks are seen on the spectral Doppler display as narrow, bright vertical lines (Fig. 51.14). Mean gradients should be calculated in the same way as described for native stenotic valves (60). Contrary to these, however, there is some degree of obstruction inherent in all prosthetic valves. The limits of normalcy are difficult to define mainly for two reasons: the influence of prosthesis design, and the match or mismatch of the implanted valve and the implantation site. The different prosthesis types and sizes involve different degrees of obstruction (e.g., the caged-ball Starr-Edwards prosthesis is much more obstructive than the St. Jude Medical valve). Normal values for transprosthetic flow velocities or gradients have been published, but because of the additional dependency on cardiac output and heart rate, these values offer only an orientation (61). Furthermore, especially the bileaflet valves by their design create high local gradients and pressure recovery downstream (62,63 and 64).

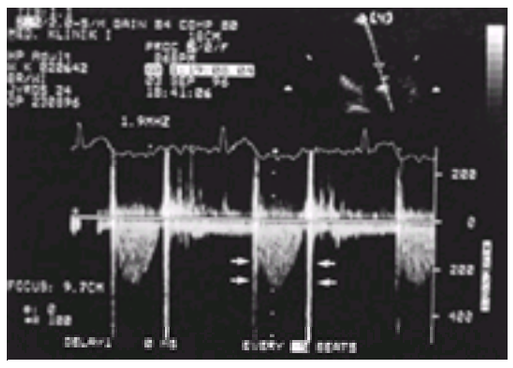

FIGURE 51.14 Aortic prosthetic forward flow in a normal mechanical bileaflet prosthesis (JYROS), with clicks (*arrows*).

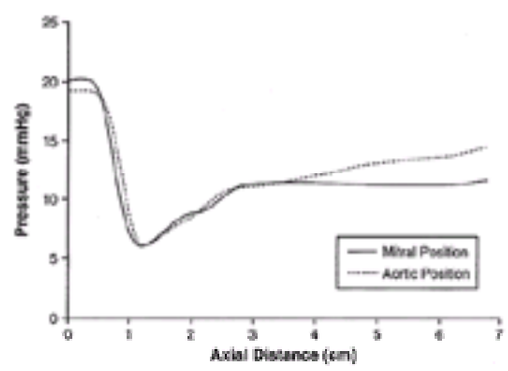
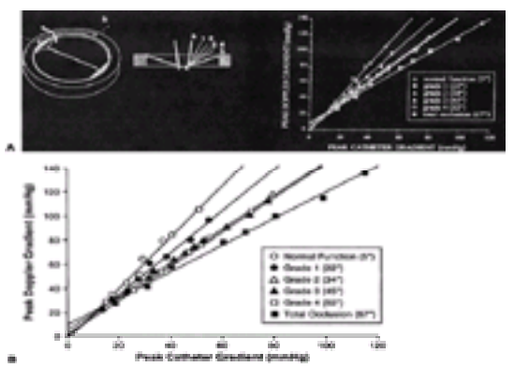
Video 51.16 Beall mitral valve prosthesis with normal antegrade flow seen with color Doppler by transesophageal echo. Note the typical antegrade flow around the disc with marked shadowing beyond the disc. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

In these valves, the maximal velocity and pressure drop across the central orifice is higher than across the side orifices. Approximately one-third of the central pressure drop is recovered regardless of the position of the valve; additionally, a variable amount of further pressure recovery occurs depending on the geometry of the solid boundaries downstream, leading to the recovery of up to 58% of the maximal pressure drop across the central orifice. The maximal velocities by continuous wave Doppler therefore can lead to a calculated pressure drop higher than the net pressure drop between the left ventricle and the ascending aorta a few centimeters downstream from the prostheses (eFig. 51.14.1). Pressure recovery is particularly troublesome in the aortic position, especially if the aorta is small in diameter. Furthermore, it has been shown *in vitro* that in partial obstruction of the prosthesis, pressure recovery diminishes, because energy is lost in turbulent eddies and is not available any more for recovery downstream (65) (eFig. 51.14.2). Therefore, for bileaflet prostheses in the aortic position, a considerable gray zone between clearly normal and clearly pathologic transvalvular gradients exists, which necessitates imaging information on leaflet mobility (from 2-D echo or fluoroscopy) to exclude prosthetic dysfunction.



***e*FIGURE 51.14.1** *In vitro* pressure recordings obtained by catheter pullback through the central orifices of St. Jude Medical bileaflet valve prostheses in an experimental setup mimicking the mitral (*solid line*) and aortic (*dotted line*) position. There is pressure recovery in the proximal vicinity of the central orifice (6 mm Hg between cm 1 and 3); thereafter, there is additional pressure recovery in the *aortic*, but not *mitral*, setup (3 mm Hg between cm 4 and 7). (From Vandervoort PM, Greenberg NL, Powell KA, et al. Pressure recovery in bileaflet heart valve prostheses. Localized high velocities and gradients in central and side orifices with implications for Doppler-catheter gradient relation in aortic and mitral position. *Circulation* 1995;92:3474–3472, with permission.)



***e*FIGURE 51.14.2** *In vitro* effect of partial obstruction in bileaflet (CarboMedics) prosthetic valves. **A:** Left, experimental setup where the left leaflet opens freely and the right leaflet is kept in positions between open (position a) through positions 1 to 4 to complete occlusion (b) by an adjustable stop pin. The plot on the right shows corresponding peak pressure gradient measurements by Doppler and catheter. Catheters were positioned to measure "net" pressure gradients after pressure recovery had occurred, while Doppler measured peak local gradient before pressure recovery. **B:** The plot shows that (a) during normal function, Doppler peak gradients are twice as high as catheter peak gradients in this experimental setting, and (b) with increasing "malfunction" (partial occlusion), Doppler and catheter gradients approximate each other, because pressure recovery diminishes due to altered orifice geometry. (From Baumgartner H, Schima H, Kühn P. Effect of prosthetic valve malfunction on the Doppler-catheter gradient relation for bileaflet aortic valve prostheses. *Circulation* 1993;87:1320–1327, with permission.)

Mismatch obstruction results from the implantation of a prosthesis that is too small for the site and patient. This is mainly a problem in aortic valve replacement. For example, the effective orifice areas of ring size number 21 and smaller prostheses would be considered mild to moderate aortic stenosis in a native valve (see following discussion). This type of obstruction must be differentiated from new prosthetic obstruction due to thrombosis or pannus by comparison with earlier studies, by transesophageal echocardiography, or by fluoroscopy.

Note that pressure recovery and mismatch mainly create problems in the interpretation of velocities across *aortic prostheses*.

Other parameters of prosthetic obstruction have been proposed. The simplest one is *velocity index*, which is based on the continuity concept and is defined as the ratio of maximal outflow and maximal transprosthetic velocity. It is theoretically independent of cardiac output and obviates the need to measure left ventricular outflow tract diameter. Values less than 0.25 are considered pathologic. Continuity areas can also be calculated. Because these are effective areas, they are considerably smaller than areas predicted by sewing ring size. In 46 patients with a variety of small (less than 21 mm) aortic prostheses (mechanical or bioprostheses), effective areas ranged from 0.84 to 1.54 cm^2, mean gradients from 7 to 31 mm Hg, and the velocity index from 0.28 to 0.66 (66). In a survey of 335 stable postoperative patients with mechanical aortic valve replacement and without clinical evidence of prosthetic dysfunction including fluoroscopy, 11 were found with a maximal velocity over 3.5 m per second (67). The average mean gradient of these 11 patients was 48 ± 12 mm Hg. The majority were St. Jude Medical valves, and all valves were of ring size 19 to 23. Seven of these patients were studied invasively, yielding significantly lower gradients and no evidence of dysfunction. The problem of pressure recovery in bileaflet prostheses is not circumvented by calculating the continuity area. If maximal velocity is elevated due to an only locally existing pressure gradient, this results in a particularly small area calculated by the continuity equation that inadequately reflects the *net obstruction* between left ventricle and ascending aorta. For example, for intact St. Jude Medical number 21 aortic prostheses, effective orifice areas of 1.25 ± 0.21 cm^2 have been calculated in clinical studies (68), when the inner sewing ring (1.7 cm) diameter would predict a geometric orifice area of 2.3 cm^2. The advantage of calculating prosthetic resistance over the use of gradients and orifice areas has not convincingly been shown.

In severely stenotic tricuspid prostheses, systolic antegrade blood flow with accentuation in inspiration has been described (69).

For the reasons cited, it is important to document the baseline velocities or gradients of valvular prostheses postoperatively for later comparison. In bioprostheses, because of the well-described degenerative changes, an increase in obstruction with time may be expected.

Regurgitation

All mechanical prostheses, except for the caged-ball Starr-Edwards valve, exhibit some amount of in-built transvalvular leakage, which is intended to prevent the formation of microthrombi at the hinge points and to preclude sticking of the occluder in the closed position. Depending on the prosthesis type, typical spatial orientation patterns of the regurgitant jets are present (70) (Fig. 51.15). Bioprostheses, too, almost invariably present some transvalvular regurgitation. Wear-and-tear lesions in bioprostheses may lead to unpredictable, sudden increases in the severity of regurgitation. In addition to transvalvular regurgitation, paravalvular leakage is frequent in prosthetic valves (Fig. 51.16). Some of these leaks close spontaneously postoperatively; others may arise during follow-up as a result of suture failure or endocarditic tissue destruction. Transesophageal echocardiography is usually better suited than transthoracic imaging to characterize and classify prosthetic regurgitation (71).

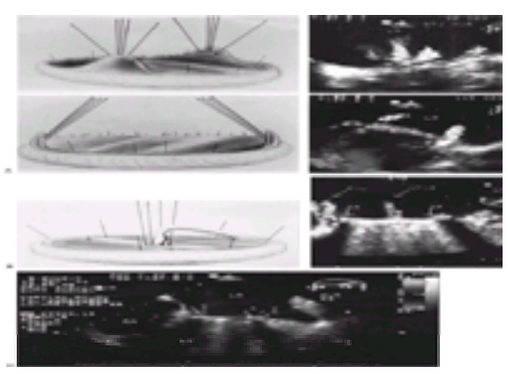


FIGURE 51.15 Normal regurgitant flow patterns of mechanical valves. **A–C:** St. Jude Medical bileaflet prosthesis. Normal regurgitation mainly occurs at the hinge points of the leaflets. Depending on the view of the valve, typical diverging and converging jet patterns occur. **A:** Schematic drawing. **B,C:** Flow imaging by transesophageal color Doppler. **D,E:** Medtronic-Hall tilting-disc prosthesis. Normal regurgitation mainly occurs across the central orifice. **D:** Schematic drawing. **E:** In the closed position, a normal central transvalvular regurgitation (NTVR) and a medial small paravalvular leak (PVL) are seen. SR, sewing ring. **F:** Björk-Shiley tilting-disc prosthesis in the mitral position with small peripheral normal regurgitant jets occurring between occluder and valve ring. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Flachskampf FA, Guerrero JL, O'Shea JP, et al. Patterns of normal transvalvular regurgitation in mechanical valve prostheses. *J Am Coll Cardiol* 1991;18:1493–1498, with permission.)

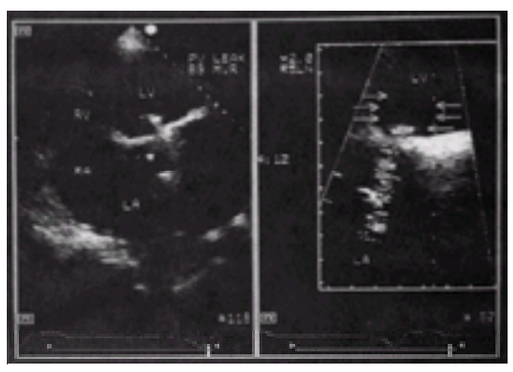
In the presence of mitral valve replacement, in particular if a mechanical prosthesis is present, the left atrium is obscured by artifacts and shadowing; therefore, special attention has to be paid to a parasternal or subcostal view, and transesophageal echocardiography should be considered. The assessment of severity follows the principles outlined for native mitral regurgitation. The occurrence of a clearly visible proximal convergence zone on the ventricular side of a mitral prosthesis indicates substantial regurgitation even if the atrium itself is not visualized; severe regurgitation by angiography corresponded to a maximal acceleration zone averaging 1 cm (2,72) (eFig. 51.16.1).



***e*FIGURE 51.16.1** Proximal convergence zone in a paravalvular leak of a Björk-Shiley mitral prosthesis. The regurgitant jet in the left atrium (*right*) is obscured by prosthetic artifacts. However, the proximal convergence zone (*arrows*) is clearly visible on the ventricular side. Modified apical four-chamber view. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Although aortic regurgitation is more easily identifiable, aortic prostheses are less well examined even by transesophageal echo than mitral prostheses. The principles outlined for the assessment of native aortic regurgitation apply.

CONGENITAL HEART DISEASE

Stenotic and Regurgitant Lesions

Congenital valvular lesions are evaluated in the same way as acquired valvular disease. It should be noted, however, that in serial or tunnel-like obstructions, the simplified Bernoulli equation may not apply. In general, however, the recorded flow velocities give a good idea of how significant an obstruction is and are clinically accepted by pediatric cardiologists to grade stenotic lesions.

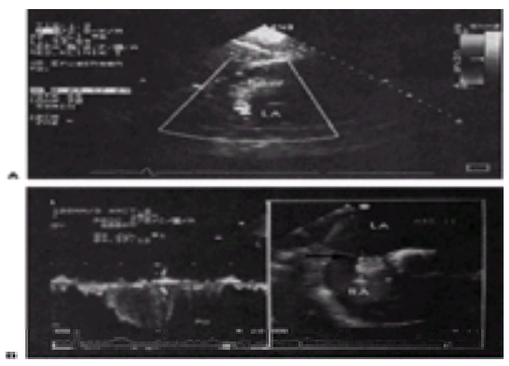
Shunt Flow

Atrial and ventricular septal defects mostly can be directly detected by color Doppler displaying the pathologic flow (*e*Fig. 51.16.2). Atrial septal defects are best examined from the subcostal window. Sinus venosus defects, however, may be overlooked and in doubtful cases may necessitate transesophageal echocardiography. Pulsed Doppler recordings of left-to-right shunt usually show a biphasic, mid-systolic to mid-diastolic, and late diastolic flow from the left to the right atrium, with a short reversal of direction (right to left) in early systole. Highest left-to-right velocities occur in late systole and rarely exceed 1 m per second. Atrial left-to-right shunt decreases in inspiration and increases in expiration.



***e*FIGURE 51.16.2** Atrial septal defect, secundum type. **A:** Subcostal color Doppler. **B:** Transesophageal color and pulsed Doppler recording of atrial septal defect (*arrow*). Note left-to-right flow velocities (downward in the transesophageal image orientation) in late systole and early diastole, followed by a smaller late diastolic wave. Ventricular septal defects are best detected by color Doppler; membranous defects usually are identified in parasternal views, and muscular defects either in parasternal views or in the apical or subcostal four-chamber view (*e*Fig. 51.16.3). Continuous wave Doppler tracings showing high systolic flow velocity toward the right ventricle allow one to calculate the maximal systolic pressure difference between left and right ventricle. This value should roughly match the difference between systemic arterial pressure and right ventricular systolic pressure calculated from tricuspid regurgitation. A patent ductus arteriosus is best visualized in suprasternal, parasternal, or subcostal views displaying a long axis of the pulmonary artery (*e*Fig. 51.16.4). Continuous wave Doppler reveals the shunt pattern, which in left-to-right shunt is systolic-diastolic with a late systolic peak. By color Doppler, a diastolic flow convergence region in the proximal descending aorta may be seen. In right-to-left shunts, maximal velocities are recorded at the aortic end of the duct, and retrograde flow in the descending aorta may be seen.

***e*FIGURE 51.16.3** Ventricular septal defect. **A:** Parasternal long-axis view with color Doppler depiction of a small congenital ventricular septal defect immediately below the aortic valve. Note the proximal convergence zone on the left ventricular side. **B:** Ventricular septal defect complicating anterior myocardial infarction. To calculate the left-to-right shunt ratio, the ratio of cardiac output (by multiplying the time velocity integral by the orifice area of the valve) at the aortic and the pulmonary valve level is validated (32). The estimation of maximal systolic pulmonary pressure from maximal tricuspid regurgitant velocity is described in the section Right-Sided Heart Function and Pulmonary Hypertension, later in this chapter.

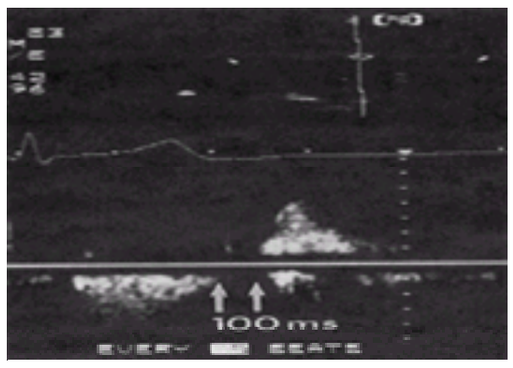
EVALUATION OF CARDIAC FUNCTION

Systolic Left Ventricular Function

The most straightforward Doppler parameter of systolic left ventricular function is cardiac output. In the presence of mitral regurgitation, the rate of increase of regurgitant velocities can be used to calculate the rise of the pressure gradient between the left ventricle and the left atrium throughout systole. This allows one to obtain an estimate of the rise of pressure in the left ventricle (dP/dT). However, since the pressure in the left atrium is not known, these values are an approximation. In practice, the time interval between the points where regurgitant velocity reaches 1 and 3 m per second is measured and the corresponding pressure drops (4 and 36 mm Hg) are used to calculate early systolic pressure rise as 32 mm Hg/D*t* (73). Note, however, that this is not necessarily *peak* dP/dT. Similarly, left ventricular pressure decline in late systole may be estimated, with the same caveat.

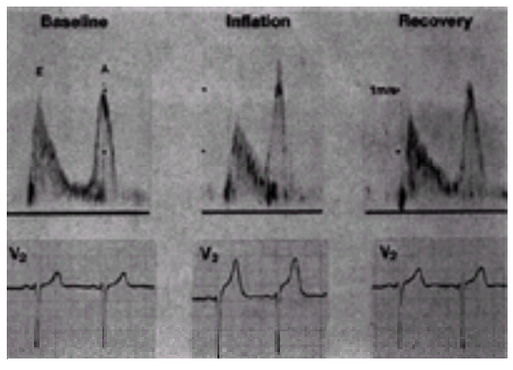
Diastolic Left Ventricular Function

Diastolic left ventricular function is in itself heterogeneous, comprising active (relaxation) and passive (chamber stiffness) characteristics of the left ventricle. It is characterized in classic hemodynamics by the diastolic time course of pressure and volume. Several parameters obtainable by Doppler have been proposed to evaluate left ventricular diastolic function (74,75). The most time honored is isovolumic relaxation time (the time from aortic valve closure to mitral valve opening; *e*Fig. 51.16.5), which depends on the velocity of myocardial relaxation (classically characterized by the time constant t), the end systolic pressure level of the aorta, and the early diastolic pressure level of the left atrium. Positioning the continuous wave Doppler beam in an apical long-axis view between left ventricular inflow and outflow, the end of outflow and the onset of inflow can be read from the spectral display.

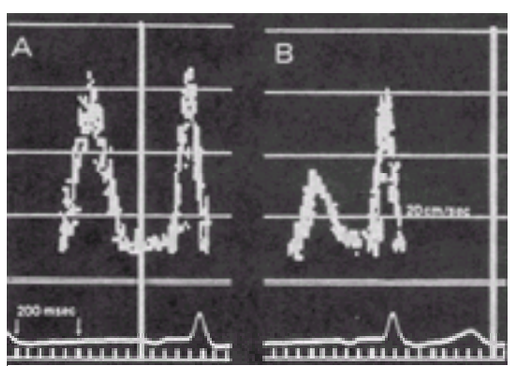


***e*FIGURE 51.16.5** Isovolumic relaxation time by continuous wave Doppler. The cursor is positioned between the left ventricular outflow and inflow tract. Isovolumic relaxation time is the time from cessation of outflow to beginning of inflow (between the arrows; 100 ms).

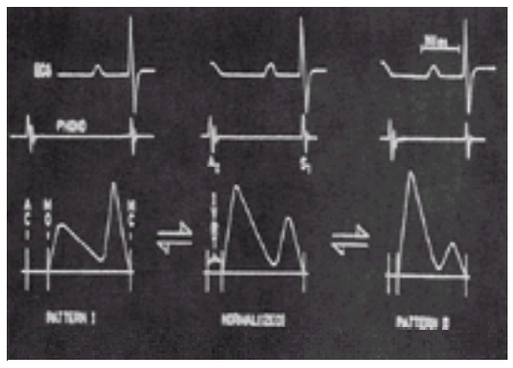
Intensive interest has focused on the characteristics of the mitral flow profile. Left ventricular filling in sinus rhythm occurs in two phases: an early E wave, which is caused by the pressure difference between the left atrium and the left ventricle, and a late A wave, which is caused by atrial contraction. In young healthy persons, maximal E velocity is slightly higher than A wave velocity. The following factors decrease the E wave: age, heart rate (in heart rates over 100 beats/min, there is generally E and A wave fusion), slowed left ventricular relaxation, and decreased left atrial pressure. Moreover, the site of measurement is important (E/A ratio is lower at the mitral annulus than at the leaflet tips). Increased left atrial pressure, conversely, increases maximal E wave velocity. Maximal A wave velocity depends on left atrial contraction and late diastolic left ventricular compliance. Because the E/A ratio is multifactorial, caution is necessary to interpret it, since *filling is not function*. It has been postulated that in early disease states with slowed relaxation, but normal left atrial pressures, the E/A ratio decreases (76). This, for example, has been demonstrated during acute ischemia during percutaneous transluminal coronary angioplasty balloon inflation (77) (*e*Fig. 51.16.6). However, this pattern can also be produced by preload reduction with normal relaxation (78) (*e*Fig. 51.16.7). If atrial pressure rises in the course of disease, the E/A ratio may again become normal: This has been termed *pseudonormalization*. In late disease states with high atrial pressures, the E/A ratio increases markedly, and isovolumic relaxation time is short, creating the so-called restrictive pattern (*e*Fig. 51.16.8 and *e*Fig. 51.16.9). These patterns of tran smitral filling can be found in different diseases, from coronary artery disease to dilated cardiomyopathy to amyloidosis. However, because of the preload dependency of the E/A ratio, interpretation of low or normal E/A ratios requires additional information. Such information can be gained from the study of pulmonary venous flow. Although the pattern of systolic and diastolic pulmonary venous inflow is not uniformly related to left atrial pressure (79,80), the size and duration of the reverse wave increases with left atrial pressure (81,82) (*e*Fig. 51.16.10). If the reverse pulmonary venous wave exceeds the transmitral A wave in duration, increased left atrial and left ventricular end diastolic pressures over 15 mm Hg are likely (67).



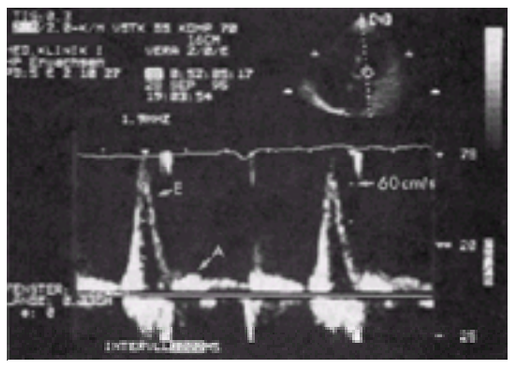
***e*FIGURE 51.16.6** Impaired relaxation pattern of transmitral flow during percutaneous transluminal coronary angiography of the left anterior descending artery (pulsed Doppler). At baseline and after recovery, there is a slightly decreased E/A ratio. During balloon inflation, there is a massive decrease of the E wave and some increase of the A wave, reflecting impaired relaxation by acute ischemia, also documented by ST elevation and high T waves in the electrocardiogram. (From Labovitz AJ, Lewen MK, Morton K, et al. Evaluation of left ventricular systolic and diastolic dysfunction during transient myocardial ischemia produced by angioplasty. *J Am Coll Cardiol* 1987;10:748–755, with permission.)



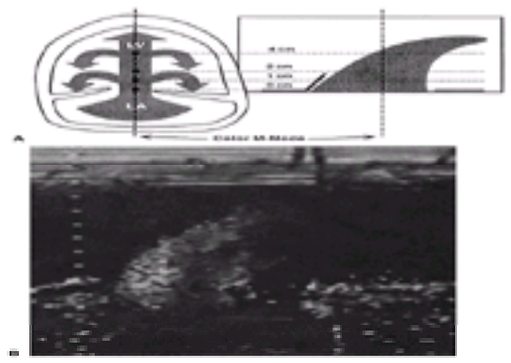
***e*FIGURE 51.16.7** Transmitral flow profile changes induced by changes in preload. Example from a patient before **(A)** and after **(B)** preload reduction by nitroglycerine. Pattern **B** is indistinguishable from “impaired relaxation” (see *e*Fig. 51.16.6). (From Choong CY, Herrmann HC, Weyman AE, et al. Preload dependence of Doppler-derived indexes of left ventricular diastolic function in humans. *J Am Coll Cardiol* 1987;10:800–808, with permission.)



***e*FIGURE 51.16.8** Schematic drawing of transmitral flow patterns and their relationship. Pattern I reflects “impaired relaxation” and is characterized by a prolonged isovolumic relaxation time (IVRT), a low E, and a high A wave. Pattern II reflects “restrictive physiology” and is characterized by a short IVRT, a high (and short) E wave, and a small A wave. Both patterns can be produced by cardiac diseases, and pattern I may change to pattern II, which is thought to represent advanced stages of disease, by going through a phase of pseudonormalization indistinguishable from the truly normal transmitral flow pattern. AC, aortic closure; MC, mitral closure; MO, mitral opening. (From Appleton CP, Jensen JL, Hatle LK, et al. Doppler evaluation of left and right ventricular diastolic function: a technical guide for obtaining optimal flow velocity recordings. *J Am Soc Echocardiogr* 1997;10:271–291, with permission.)



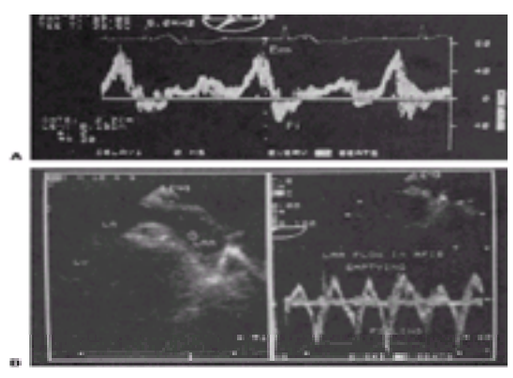
***e*FIGURE 51.16.9** Restrictive transmitral flow pattern. The pattern of high, short E waves and diminished A waves (E/A >2) with a short E-wave deceleration and short isovolumic relaxation time has been termed *restrictive*. It reflects high early diastolic filling pressure and low left ventricular compliance. This pattern has been observed in end-stage coronary heart disease, dilated cardiomyopathy, cardiac amyloidosis, and others.



***e*FIGURE 51.16.10** Flow propagation in the left ventricle. **A:** Schematic drawing. In diastole, blood from the left atrium propagates as a wavefront into the left ventricle. At the mitral valve level, this velocity corresponds to the E-wave velocity. Further into the left ventricle, propagation velocity continuously diminishes because of interaction with the stagnant ventricular blood pool. The velocity of flow propagation at each level can be measured from the slope of a transmitral color M-mode. **B:** Example of a transmitral color M-mode from the apical window showing diastolic flow propagation velocity into the left ventricle. Note curved outline of the color signal due to continuous decrease of propagation velocity toward the left ventricular apex. LA, left atrium; LV, left ventricle.

Presence of the restrictive mitral inflow pattern (E/A greater than 1.5), in particular presence of a short E wave deceleration time (less than 150 ms), has been convincingly shown to imply high pulmonary capillary pressure, impaired functional class, and bad prognosis in postinfarction patients (83,84), in dilated cardiomyopathy (85,86), in cardiac amyloidosis (87), and others (88). It can be shown theoretically that the slope of deceleration directly reflects the net compliance of the left atrium and left ventricle lumped together (36,37). Hence, a stiff diastolic ventricle leads to rapid E wave deceleration.

Another approach to the evaluation of diastolic function is to study the velocity of flow propagation into the left ventricle during diastole. This is the velocity with which the filling wave travels within the left ventricle from mitral annulus to apex (*e*Fig. 51.16.11). This velocity is less preload dependent than the E wave and can be measured as the slope of an apical color M-mode through the mitral valve during diastole. It has been shown in animal studies and in patients that flow propagation velocity strongly depends on left ventricular relaxation (89,90 and 91). However, reproducibility of this parameter is low.



***e*FIGURE 51.16.11** Left atrial appendage flow by transesophageal pulsed Doppler. **A:** Sinus rhythm. Note an emptying (Em, upward) wave before the R wave and a filling (Fi, downward) wave immediately thereafter. **B:** Atrial fibrillation. A fast succession of short emptying and filling waves is seen with maximal velocities greater than 50 cm per second, indicating preserved mechanical activity of the appendage.

Provided there is mitral regurgitation, an estimate of the rate of left ventricular pressure fall in late systole can be obtained. However, because mitral regurgitation velocities reflect the time course of ventriculoatrial pressure *difference*, these calculations only approximate the rate of left ventricular pressure fall.

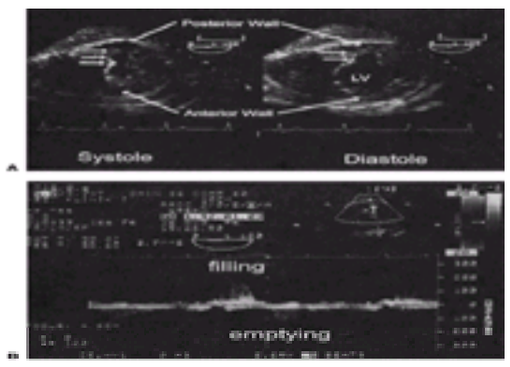
Right-Sided Heart Function and Pulmonary Hypertension

Right-sided heart output can be calculated at the pulmonary valve level by multiplying the pulmonary time velocity integral by the orifice area of the pulmonary valve ($pd^2/4$, where d is the diameter of the pulmonary annulus). The presence of pulmonary hypertension is easiest to assess from tricuspid regurgitation, which is present in almost all patients with pulmonary hypertension and particularly common in acute pulmonary hypertension due to pulmonary embolism. Peak tricuspid regurgitant velocity by continuous wave Doppler is converted to the maximal pressure drop during systole between the right ventricle and the right atrium by the simplified Bernoulli equation. Either this pressure drop can be taken as an estimate of pulmonary systolic pressure or an estimate of right atrial v wave pressure can be added by observing the collapse level of the jugular veins. Some echocardiographers simply add 10 mm Hg to the maximal ventriculoatrial pressure drop. Another useful index is pulmonary systolic flow acceleration time (the time from the onset of transvalvular flow to peak velocity). Acceleration time decreases with increasing pulmonary pressures from normal values of 130 ± 15 ms. The ratio of right ventricular preejection time (interval from Q wave to onset of pulmonary flow) to acceleration time has been shown to correlate well with mean pulmonary pressure, with values above 1.2 indicating pulmonary hypertension (92).

Left Atrial Appendage Flow

In sinus rhythm, the left atrial appendage shows four brief flow waves: a small emptying wave in early diastole and a larger one during atrial contraction after the P wave of the ECG. Both emptying waves are followed by a filling wave of similar velocity (*e*Fig. 51.16.12). Peak emptying and filling velocities occur immediately before and after the QRS complex and average 64 and 46 cm per second, respectively, in healthy individuals (93). These velocities can be recorded by transesophageal pulsed Doppler, with the sample volume well in the appendage cavity. In nonvalvular atrial fibrillation, although the transmitral A wave is absent and therefore there is no net effect of atrial contraction detectable at the mitral valvular level, emptying and filling velocities of the appendage still are well detectable in most patients. This is because the appendage encloses a small blood volume, on which the decreased wall motion during fibrillation still imparts enough acceleration to create inward and outward flow. In patients with large atria, especially in long-standing mitral stenosis, and apparently in rare cases of *left atrial appendage standstill* in sinus rhythm (94), these velocities are absent: The appendage is a static pouch, and these conditions are associated with frequent thrombus formation and thromboembolic events. Appendage flow velocities have been used with success retrospectively to stratify the thromboembolic risk of patients with nonvalvular atrial fibrillation, with peak

velocities less than 25 cm per second indicating a higher risk and therefore a strong argument for anticoagulation (95).



***e*FIGURE 51.16.12** Left ventricular pseudoaneurysm (*arrows*) after inferior infarction. **A:** Transgastric short-axis view in systole and diastole. **B:** Flow into (filling, upward, in systole) and out of the pseudoaneurysm (emptying, downward, in diastole) is detectable by pulsed Doppler. LV, left ventricle.

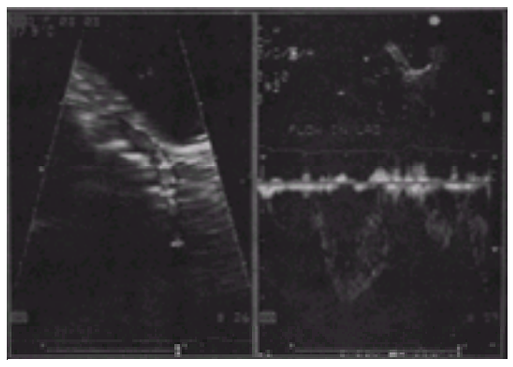
DOPPLER EVALUATION OF CORONARY ARTERY DISEASE

Impairment of left ventricular relaxation precedes systolic wall motion abnormalities in acute myocardial ischemia. Acute transmitral E/A ratio decrease has been documented during percutaneous transluminal coronary angioplasty balloon inflation (63). Similarly, during dobutamine stress echo, a decrease in peak E wave velocity and in E wave acceleration ratio was shown to be an excellent predictor of coronary artery disease superior to the detection of wall motion abnormalities (96). However, this has not been seen in exercise stress echo, presumably because after treadmill exercise the change to a supine position for the echo examination led to an increase in preload, blunting the response of filling parameters (97).

If depressed systolic left ventricular function is present after myocardial infarction, a decreased cardiac output can be measured. Doppler signs of impaired diastolic function are discussed in the section on Diastolic Left Ventricular Function, earlier in this chapter. The presence of a restrictive pattern (E/A greater than 1.5, E wave deceleration time less than 150 ms; eFig. 51.16.8 and eFig. 51.16.9) after myocardial infarction is associated with a poor life expectancy, even if controlled for systolic variables such as ejection fraction (74). Two large randomized placebo-controlled pharmacologic intervention trials in postinfarction patients with reduced systolic function have attempted to analyze diastolic function by echo. In the Studies of Left Ventricular Dysfunction (SOLVD) trial, a decrease in E/A ratio under enalapril was ascribed to a reduction in atrial pressure due to a favorable influence of enalapril on ventricular remodeling and hypertrophy (98). In the Doppler Flow and Echocardiography in Functional Cardiac Insufficiency: Assessment of Nisoldipine Therapy (DEFIANT) trial, a small increment in E wave velocity and a small reduction in isovolumic relaxation time were seen under the calcium antagonist nisoldipine, and this was ascribed to improvement in left ventricular relaxation (99). It is ironic that these trials interpret opposite echo findings as indicative of a favorable pharmacologic influence on diastolic function.

Doppler has an important role in the identification of some structural complications of myocardial infarction, especially in septal rupture leading to a ventricular septal defect located mostly in the apical half of the septum and in acute mitral regurgitation after papillary muscle rupture. In left ventricular pseudoaneurysm, Doppler recordings at the rupture site reveal biphasic flow, with flow into the pseudoaneurysm during both systole and after atrial contraction, and flow from the pseudoaneurysm into the ventricle during early to mid-diastole (100) (eFig. 51.16.12).

Transesophageal echocardiography can visualize flow in the proximal coronary arteries directly by color Doppler. The proximal left anterior descending artery often can be interrogated by pulsed Doppler, showing the typical coronary flow signal with diastolic predominance (eFig. 51.16.13). In one study, in patients without coronary stenosis, mean diastolic velocity increased on average by a factor of 3 after intravenous administration of the vasodilator dipyridamole, whereas it increased by only 1.5 in patients with left anterior descending stenosis (101). Significantly increased peak diastolic flow velocity after successful angioplasty of the proximal left anterior descending artery has been reported in another small series (102). However, small diameter and tortuosity of the coronary vessels unfortunately only allow limited visualization and often marginal image quality, and thus this approach at present has little value for the evaluation of coronary artery disease.



***e*FIGURE 51.16.13** Coronary flow recording by transesophageal color and pulsed Doppler in the proximal left anterior descending coronary. Predominantly diastolic flow velocities are recorded. LA, left atrium.

DOPPLER EVALUATION OF THE CARDIOMYOPATHIES, CARDIAC TAMPONADE, AND THE TRANSPLANTED HEART

Dilated Cardiomyopathy

Apart from measuring a reduced cardiac output, Doppler examination is useful to estimate systolic pulmonary pressure by the peak tricuspid regurgitation velocity (see Right-Sided Heart Function and Pulmonary Hypertension, earlier in this chapter), to assess mitral regurgitation, and to evaluate the transmitral filling pattern. A restrictive pattern (E/A greater than 1.5, E wave deceleration time less than 150 ms) indicates high filling pressures and a reduced left ventricular compliance and is associated with a poor prognosis (103,104). Because mitral annular motion is reduced, systolic pulmonary venous inflow is also reduced in comparison with diastolic inflow.

Hypertrophic Cardiomyopathy

The main task of the Doppler examination is to detect and assess left ventricular outflow obstruction. For this purpose, a continuous wave Doppler recording with the echo beam passing through the left ventricular outflow tract in the apical long-axis view should be obtained. Hypertrophic obstructive cardiomyopathy characteristically produces a sabre-shaped, late-peaking systolic velocity profile different from the (mostly also present) mitral regurgitation in the continuous wave Doppler examination, which begins earlier and exhibits an earlier steep velocity increase (Fig. 51.17). Because continuous wave Doppler has no range resolution, the diagnosis should be confirmed by moving the sample volume of the pulsed Doppler systematically along the interventricular septum from the midventricle to the aortic valve to map the velocities toward the aortic valve. If intraventricular obstruction is present, this is seen in the pulsed Doppler recording, as the systolic velocities at the location of the obstruction abruptly exceed the range limit of the pulsed Doppler. Color Doppler typically shows turbulence in the left ventricular outflow tract.

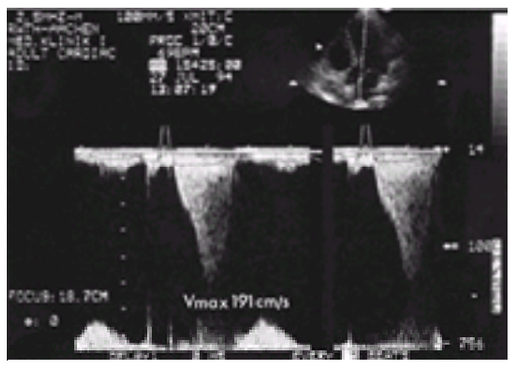


FIGURE 51.17 Left ventricular outflow tract obstruction in hypertrophic obstructive cardiomyopathy recorded by continuous wave Doppler from the apical window. A typical profile with a late systolic peak is recorded, which is well distinguished from the frequently concomitant mitral regurgitation.

A lowered E/A ratio of the transmitral filling pattern may be present because of impaired left ventricular relaxation, but because of concomitant mitral regurgitation and a possible increase in left atrial pressure, a normal E/A pattern does not exclude diastolic left ventricular dysfunction.

Constrictive and Restrictive Cardiomyopathy

The transmitral flow profile in constrictive and restrictive cardiomyopathies is frequently characterized by tall and short E waves and small A waves (the restrictive pattern) and a short isovolumic relaxation time. In constrictive pericarditis, but not in restrictive cardiomyopathy, accentuated influence of respiration on cardiac flow velocities is present during inspiration (a 10% inspiratory decrease in peak transmitral E wave velocity is seen in healthy subjects), transmitral flow velocities decrease, transtricuspid flow velocities increase, and left ventricular relaxation time also increases (Fig. 1.18). Recording is best done at a slow sweep speed to obtain several respiration cycles on one sweep. However, because inspiration image quality often is impaired, reliable documentation of this pattern frequently is difficult. The pulmonary venous flow in constrictive pericarditis decreases in inspiration, and this effect is more marked for diastolic than for systolic pulmonary venous inflow.

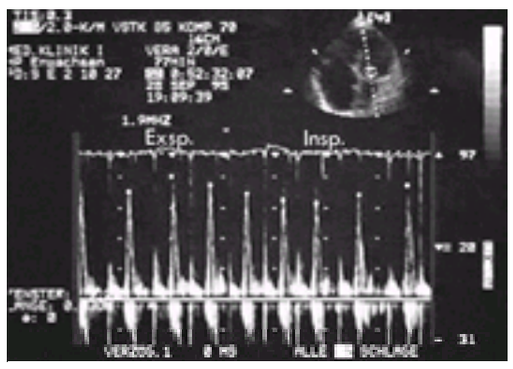

FIGURE 51.18 Transmitral flow profiles in constrictive pericarditis. A “restrictive” transmitral flow pattern with high and short E waves is seen. Peak E-wave velocities show pathologic respiratory variation (greater than 10%) with a decrease during inspiration (Insp.). Exsp., expiration.

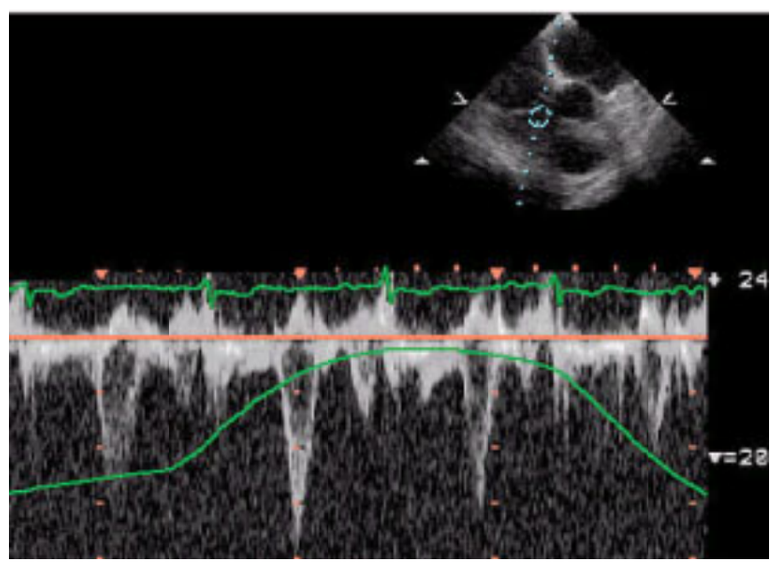
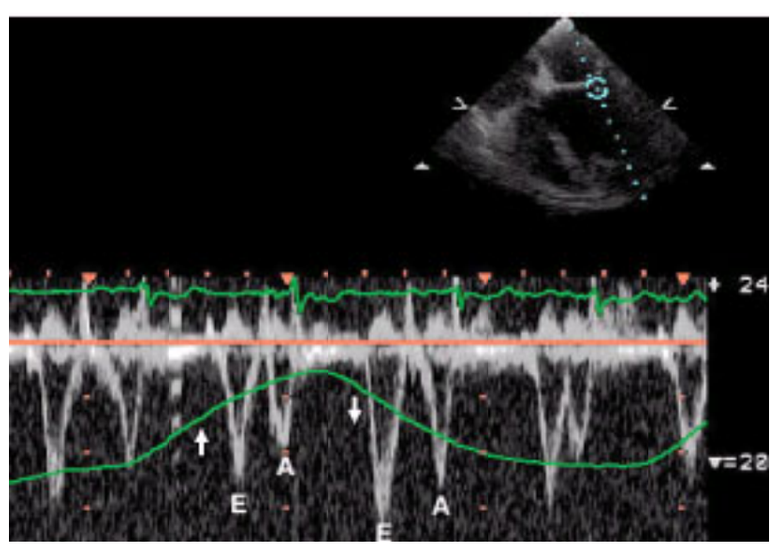
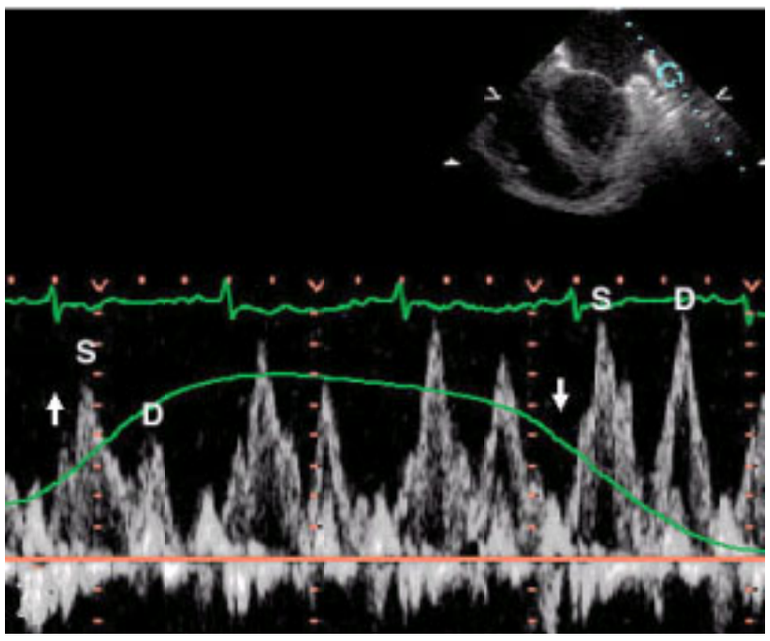


Pulsed wave Doppler through the tricuspid valve of a patient with constrictive pericarditis. Note the decrease of the E wave with inspiration due to interventricular dependence.



Pulsed wave Doppler of the mitral valve inflows of a patient with constrictive pericarditis. Note the decrease of the E wave during inspiration (*upward arrow*) due to interventricular dependence, and the increase in the E wave during expiration (*downward arrow*) for the same reason.



Pulsed wave Doppler of the pulmonary veins of a patient with constrictive pericarditis. Note the inspiratory decrease of the S and P waves and the expiratory increase due to interventricular dependence. (Inspiration is denoted by the upward arrow and expiration by the downward arrow).

Restrictive cardiomyopathy exhibits no marked respiratory variation in mitral flow velocities and is characterized by particularly short mitral and tricuspid pressure half-times. Often, systolic mitral and tricuspid regurgitation are present following the E wave (105). There is usually at least moderate pulmonary hypertension, and ventricular walls are frequently thickened (e.g., in cardiac amyloidosis), which represents the most frequent and classical form of restrictive cardiomyopathy.

Cardiac Tamponade

The Doppler characteristics of cardiac tamponade resemble those of constrictive pericarditis. There is a marked (30% to 40%) inspiratory decrease of transmitral, transaortic, and diastolic pulmonary venous inflow velocities (corresponding to the clinical finding of pulsus paradoxus), and an even more pronounced (greater than 80%) increase in transtricuspid (and transpulmonic) flow velocities. Left ventricular isovolumic relaxation time increases in inspiration.

Doppler Examination of the Transplanted Heart

Patients with a transplanted heart almost always present mild or moderate mitral and tricuspid regurgitation. If the residual native atria still are electrically and mechanically active, two distinct and dissociated A waves can be recorded on pulsed Doppler transmitral or tricuspid flow profiles, one representing contraction activity from the residual recipient atria and one from the donor atria (106).

The noninvasive detection of graft rejection by Doppler has gathered much interest. Because alterations in systolic function ensue only late in the course of rejection, several diastolic parameters have been analyzed for this purpose, in particular, a decrease in isovolumic relaxation time and a decrease in E wave deceleration time or pressure half-time (a misleading term, since in nonstenotic valves the simplified Bernoulli equation does not apply). Both lead to a restrictive inflow pattern (107,108), which has been associated with acute rejection, and both are reversible after treatment. In a small subset of patients, a chronic restrictive physiology develops. Because all of these parameters are multifactorial and especially preload dependent, there is no definitive set of values reliably identifying acute rejection, but serial follow-up in a given patient seems to allow the noninvasive detection of at least moderate acute rejection by observing changes in isovolumic relaxation time and in E wave deceleration with sensitivity and specificity in the 80% to 90% range.

CONTROVERSIES AND PERSONAL PERSPECTIVES

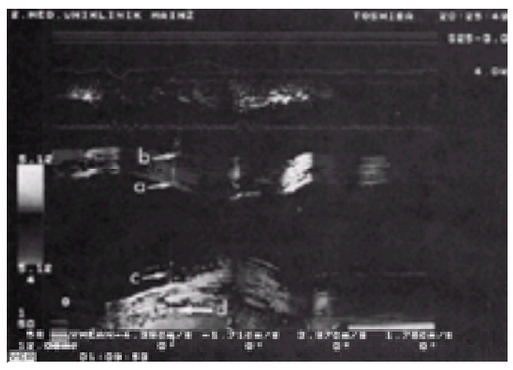
Although a tremendous success story, some problems in the echo-Doppler assessment of valvular stenosis and regurgitation remain. One fundamental limitation in the present quantitative Doppler approaches to regurgitation is the characterization of spatially complex three-dimensional flow velocity fields in the heart by severely limited data. For instance, a single pulsed Doppler sample volume is used in transvalvular flow rate calculations, or a 2-D color Doppler map in the proximal convergence method. These problems may ultimately be overcome by real-time, three-dimensional, multigated, pulsed Doppler. In the assessment of stenotic lesions, future three-dimensional echo capabilities could help solve the pressure recovery dilemma and reconcile the discrepancies between effective and geometric orifice areas by combining spatial morphologic and functional data. However, it is mostly the effect on myocardial function rather than the valvular lesion per se that clinically matters most, in particular in chronic regurgitant lesions. Thus, the quest for the single magic number representing the severity of a valvular lesion is misleading. A set of parameters measuring both valvular and myocardial function will be needed to fully characterize such lesions.

Much interest has focused on Doppler parameters of diastolic left ventricular function. A set of Doppler parameters (isovolumic relaxation time, E/A ratio, E deceleration, A wave duration, pulmonary venous reverse flow, and so forth) used cautiously together with other echo data generally allows prediction of elevated diastolic left ventricular pressures. However, because systolic and diastolic myocardial function are interrelated and both pervasively load dependent, the search for the one parameter exclusively reflecting *diastolic function* (itself an ill-defined term) is inadequate, and data should always be viewed in clinical and hemodynamic perspective.

FUTURE DIRECTIONS AND EMERGING TECHNICAL INNOVATIONS

Tissue Doppler and Strain Rate Imaging

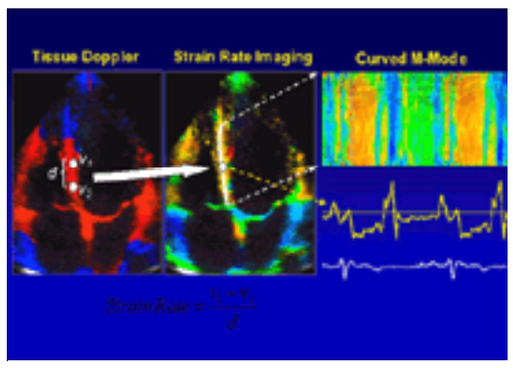
In conventional Doppler, filter settings are such that the low-amplitude, high-velocity signals from blood are recorded and the high-amplitude, low-velocity signals from solid cardiac structures such as the walls are suppressed (the low-velocity filter is appropriately named the *wall filter*). If this setting is reversed, the velocity of solid structures, especially the myocardium, can be recorded by pulsed or color Doppler (109,110) (*e*Fig. 51.18.1). They compare well with velocity measurements derived from sonomicrometry, M-mode, or 2-D echo registrations of moving solid structures. However, as in all Doppler measurements, only the velocity component in the direction of the echo beam is measured accurately.



***e*FIGURE 51.18.1** Example of tissue Doppler. Parasternal color M-mode at the left ventricular level. Note low velocities (±5 cm per second) on color bar on the left, coding the velocity of solid structures. Systolic contraction of the posterior wall is coded in yellow-red and of the septum in blue. After aortic valve closure (see second heart sound on phonocardiogram tracing), the posterior wall is coded in blue due to thinning of the wall. The transmural myocardial velocity gradient is represented by different color hues (the subendocardial posterior layer shows a bright yellow and the subendocardial layer a red hue in systole) and by intramyocardial pulsed Doppler measurements. These show local myocardial velocities of –4.4 cm per second (a, right ventricular half of septum), –1.7 cm per second (b, left ventricular half of septum), 4.0 cm per second (c, subendocardial layer of posterior wall), and 1.8 cm per second (d, subepicardial layer of posterior wall), respectively. (Courtesy of Uwe Nixdorff, MD, Erlangen, Germany.)

Interest has focused so far on regional analysis of myocardial wall motion (111). From the parasternal window, radial (inward and outward) motion of posterior and anterior segments is measured, and from the apical window longitudinal motion of left ventricular wall segments can be analyzed. There is a systolic contraction wave, leading to positive velocities toward the transducer, and two diastolic elongation waves, leading to negative velocities away from the transducer.

A derived measure is strain rate, which extracts the local deformation rate in the direction of the ultrasound beam (percentage elongation or contraction divided by time). Strain rate, and its temporal integral, strain, can be calculated by subtracting the simultaneous velocities at two myocardial points along a scan line and dividing the results by the distance between the two points (eFig. 51.18.2). These techniques can be used in several ways to analyze *regional* left ventricular systolic and diastolic function:



***e*FIGURE 51.18.2** Strain rate imaging. **Left:** Systolic color tissue Doppler image of a normal apical four-chamber view. Segments of the heart moving toward the transducer (upward) are depicted in red, apical segments moving away from the transducer (downward) are shown in blue. From the tissue Doppler velocity data, strain rate is calculated by subtracting two tissue velocities along a scanline (in this example, v_1 and v_2 from the midseptum) and dividing by their distance *d* (see formula). The strain rates are displayed again in color format in the mid-figure. Yellow-red depicts local tissue contraction, and blue local tissue elongation. Strain rate data from an arbitrary line in the tissue can be plotted over time as curved M-mode (*upper right*), showing periodic contraction and lengthening at the locations covered by the line. From each single point of the strain rate image, strain rate over time can be extracted (*lower right*). (From Voigt JU, Arnold MF, Karlsson M, et al. Assessment of regional longitudinal myocardial strain rate derived from Doppler myocardial imaging indexes in normal and infarcted myocardium. *J Am Soc Echocardiogr* 2000;13:588–598, with permission.)

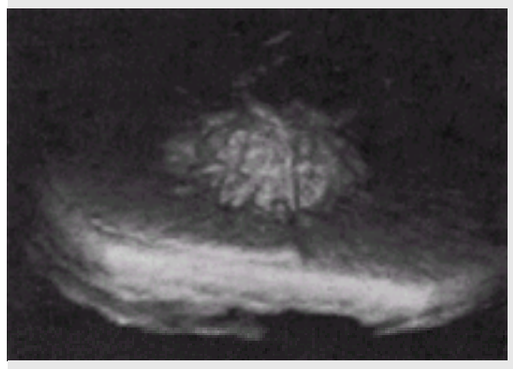
1. From an apical window, longitudinal contraction and elongation velocities can be measured in the left ventricular walls. Regional wall motion abnormalities (e.g., in ischemic, stunned, hibernating, or scarred myocardium) exhibit lower than normal velocities (112). Stress-inducible wall motion abnormalities lead to lower than normal contraction and lengthening myocardial velocities. Furthermore, in ischemia, there may be shortening extending from late systole into early diastole (*postsystolic thickening*). Unfortunately, discrimination of normal and abnormal velocities is not easy, because longitudinal contraction velocities decrease from base to apex, are age and heart rate dependent, vary by segment, and are subject to tethering by the physical continuity between segments and walls. Theoretically, measurement of strain or strain rate is more attractive (113), because it largely eliminates tethering and translational effects, truly reflecting local myocardial deformation (although only in the direction of the echo beam).
2. The subendocardial layer of the myocardium contracts more and more rapidly than the subepicardial layer. This transmural velocity gradient, which by definition is the same as radial strain rate, is a measure of contractile myocardial function. It is diminished in dilated cardiomyopathy and abolished in scar tissue, but not in viable myocardium. It can be analyzed by tissue Doppler, although so far only in parasternal views.
3. Evaluation of diastolic function benefits from tissue Doppler parameters. In the presence of normal relaxation, there is an early diastolic outward and lengthening motion of the myocardial walls slightly preceding the transmitral E wave, and a second outward and lengthening motion following the transmitral A wave. While in healthy hearts transmitral early filling follows early diastolic tissue elongation (active ventricular suction), in ischemic or scar tissue, this sequence is reversed, because filling is largely passive. Pseudonormalized transmitral flow patterns can be unmasked using this technique (114).
4. Tissue Doppler can locate preexcitation bundles by mapping the course of ventricular contraction. A further refinement comes from strain rate imaging. This is an imaging modality based on tissue Doppler, which instead of displaying local tissue velocities shows local tissue deformation or strain rates.

Strain rate (equivalent to myocardial velocity gradient) is calculated as the difference in velocities over a given distance, typically 1 cm or less; its unit is Hz (s^{-1}). Integrating strain rate over time yields strain, a dimensionless number indicating the fractional elongation or contraction (e.g., a strain of +0.3 means that the tissue has elongated by 30% compared with baseline). Strain rate imaging and strain calculations have the advantage of being unaffected by movements of the heart as a whole with respect to the transducer or by tethering from adjacent regions, because these cancel out when looking at the small distances over which these parameters are obtained. Therefore, strain rate is a truly regional parameter. Note, however, that so far strain or strain rate can only be directly measured in the direction of the ultrasound beam, while it is known (and can be visualized by magnetic resonance imaging) that myocardial tissue deformation in reality occurs in all three dimensions of space.

The potential of measuring these regional myocardial contraction and relaxation parameters for the characterization of regional myocardial contractility, ischemia, and viability is under investigation.

THE FUTURE

Several developments in particular will permit better calculation of flow rates. *Unwrapping* of high velocities will enable full mapping of the velocity field of regurgitant jets. Thus, jet momentum could be calculated, and because momentum is conserved in the cross sections of a jet, flow rate at the regurgitant orifice can be derived. Moreover, the length of the jet's laminar core has a fairly constant relationship with the diameter of the regurgitant orifice; measurement of the length of the laminar core would therefore allow estimation of regurgitant orifice size and, hence, severity of regurgitation (21). Automated integration of color Doppler velocities in two or three dimensions and three-dimensional Doppler of the proximal convergence zone are two other developments (eFig. 51.18.3), and use of Doppler power (amplitude squared) for flow calculations is a third (115).



***e*FIGURE 51.18.3** Three-dimensional reconstruction of color flow signals from the proximal convergence zone of a jet (*in vitro*). Color pixels are reconstructed as gray voxels. The approximately hemispheric shape of the proximal convergence zone is recognizable.

*In cardiology, *pressure gradient* is an unerasable misnomer for *pressure drop*. Both expressions are used synonymously in this text.

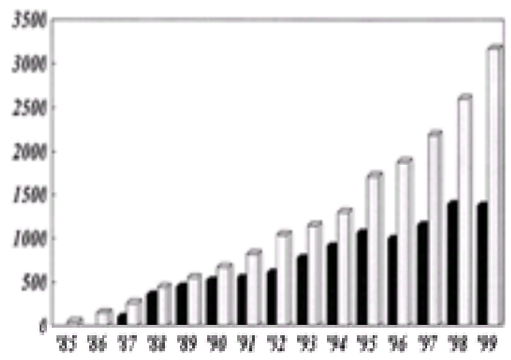
OVERVIEW

Transesophageal echocardiography (TEE) is an important tool in the evaluation of cardiac structure and function and for assessing the thoracic aorta. With TEE, images are acquired from an esophageal or gastric imaging window rather than from the chest wall (*e*Table 52.0.1). This is advantageous as the heart and aorta lie very close to the esophagus throughout much of its course. Esophageal imaging is therefore possible with a higher frequency transducer than is usually possible with transthoracic imaging. This and the absence of air-filled lung tissue in the imaging window allow improved image resolution. TEE images the heart from behind, which allows excellent resolution of posterior structures such as the atria, interatrial septum, and aorta as compared with transthoracic imaging. The posterior imaging approach is also advantageous in circumventing acoustic shadowing from strong reflectors of ultrasound such as prosthetic valves.

***e*TABLE 52.0.1** COMPARISON OF TRANSTHORACIC AND TRANSESOPHAGEAL ECHOCARDIOGRAPHY

	Transthoracic echocardiography	Transesophageal echocardiography
Imaging location	Chest wall, subcostal	Esophagus, stomach
Transducer frequency	2.0–5.0 MHz	3.5–7.0 MHz
Examination preparation	None	Sedation, anesthesia
Advantages	Widely applicable, noninvasive, multiple imaging windows, complete Doppler evaluation	High-resolution images, circumvents prosthetic shadowing, posterior structures (aorta, atria) well imaged
Disadvantages	Often suboptimal images, far-field structures (aorta, atria) and prostheses poorly imaged	Semiinvasive, imaging windows highly variable
Indications	Usually first-line cardiac ultrasound modality	When transthoracic echocardiography fails to adequately answer clinical question

TEE is invasive, as the transducer must be inserted into the esophagus and stomach. This usually requires local anesthesia and intravenous sedation. It is more consumptive of physician time, more expensive, and has less patient acceptance than transthoracic imaging. Transthoracic echocardiography (TTE) can provide adequate clinical information in many instances and is therefore usually acquired first. TEE is performed if additional information is required or if transthoracic image quality is suboptimal. In most adult echocardiography laboratories, less than 10% of all studies are performed by the transesophageal approach (*e*Fig. 52.0.1) (1,2). Major current indications for TEE are shown in *e*Table 52.0.2.



***e*FIGURE 52.0.1** Bar graph of transesophageal echocardiograms performed at The Cleveland Clinic Foundation from 1985 to 1999. Intraoperative studies are shown as stippled bars, and other transesophageal echocardiography examinations are shown as black bars.

***e*TABLE 52.0.2** INDICATIONS FOR TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Nondiagnostic transthoracic echocardiography images	Chronic obstructive pulmonary disease, obesity, dressings prevent adequate transthoracic echocardiography images

Atrial pathology and function	Atrial thrombus, spontaneous contrast, tumor
Interatrial septum	ASD, PFO, atrial septal aneurysm
Disease of thoracic aorta	Dissection, intramural hematoma, aortic trauma, atheroma
Endocarditis	Small vegetations, abscess, fistulae, prosthetic endocarditis
Native-valve disease	Flail valves, severity of mitral regurgitation, aortic valve morphology
Prosthetic valves	Prosthetic regurgitation, thrombosis, suspected dysfunction
Source of embolus	Atrial thrombus, PFO, atrial septal aneurysm, vegetation, valve strand, aortic atheroma, tumor
Coronary disease	Coronary anomalies and fistulae, stenoses, flow reserve, stress imaging
Critical care unit	Unexplained hypotension, complications of myocardial infarction, pulmonary emboli, post surgical tamponade
Congenital heart disease	Atrial situs, straddling atrioventricular valves, follow-up of Senning, Mustard, and Fontan procedures, pulmonary venous anomalies
Interventional procedures	Percutaneous mitral valvuloplasty, ASD, or ventricular septal defect closure, septostomy
Miscellaneous indications	Pulmonary vein pathology, assess hemodynamics, masses

ASD, atrial septal defect; PFO, patent foramen ovale.

HISTORICAL PERSPECTIVE

The close anatomical relationship of the esophagus to the heart has been used for many years to optimize cardiac physiological signals. Experimental esophageal ultrasound probes developed in the 1970s established the potential usefulness of the esophageal imaging window (3,4 and 5). The modern era of TEE began in 1980, when Hanrath and colleagues attached a phased-array ultrasound transducer to the tip of a flexible gastroscope (*e*Table 52.0.3) (6,7). Standard planes in which cardiac structures could be imaged from the esophagus and stomach were developed. Widespread use of TEE in the ambulatory setting occurred with the development of smaller transducers capable of imaging at a higher frequency and with full Doppler capabilities (pulsed, continuous-wave, and color-flow mapping) (8,9). Recent developments include smaller transducers for pediatric use and multiplane transducers capable of imaging in more than one plane (10,11).

ANATOMIC CONSIDERATIONS

The esophagus is approximately 25 cm in length and extends from the pharynx to the stomach (Fig. 52.1). The esophagus is narrowest at the junction with the pharynx. This is the most difficult area to cross when passing a transesophageal transducer. The esophagus descends vertically and slightly to the left, passing behind the trachea, left mainstem bronchus, left atrium, and left ventricle before passing through the diaphragm. The ascending aorta and arch lie anterior to the esophagus (*e*Fig. 52.1.1). The air-filled trachea and left mainstem bronchus interpose between the esophagus and portion of the ascending aorta and ascending arch and cause a “blind spot” in imaging the aorta from the transesophageal window. The esophagus twines around the descending aorta. It lies medial to the aorta in the midthorax, whereas the aorta lies behind it at the level of diaphragm. Therefore, the esophageal transducer must be rotated while imaging the descending aorta to keep it in view.

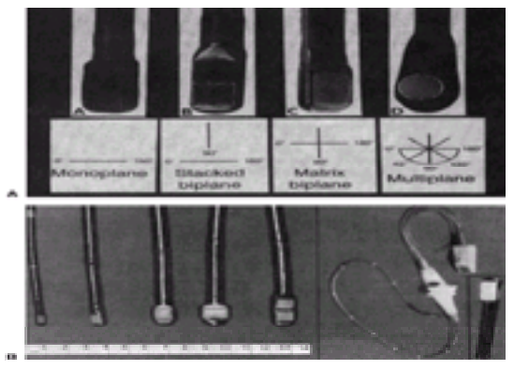
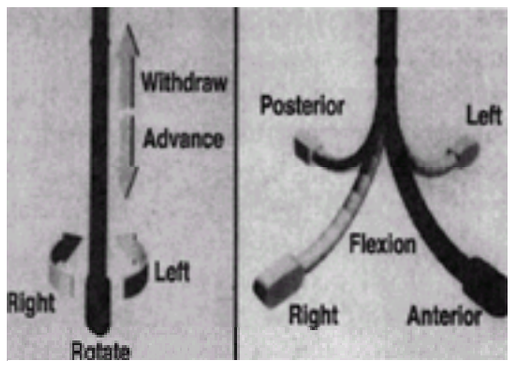
TECHNOLOGY: TRANSDUCERS AND PROBES

TEE requires the use of a special esophageal probe that interfaces with a conventional cardiac ultrasound system. The esophageal probes currently in use consist of an ultrasound transducer(s) mounted at the end of a flexible gastroscope from which the fiberoptic cables and suction capability have been removed (*e*Fig. 52.1.2). The transducers typically used are phased-array and multielement and operate at multiple frequencies from 3.5 to 7.0 MHz. These probes are capable of performing all Doppler modalities, and M-mode, and two-dimensional imaging. The length of the gastroscope is typically 100 cm. The transducer represents the fixed portion of the probe. Adult transducers vary in length from 27 to 45 mm, are 14 to 17 mm wide, and are approximately 11 mm thick. The gastroscope cable is approximately 10 mm wide in adult probes. TEE probes 7 mm in diameter are now available and allow imaging even in infants as small as 3 kg (12). Esophageal probes have the standard gastroscope controls that allow remote movement of the transducer at the tip anteriorly, posteriorly, and to both sides. Specific positioning of the probe requires (a) advancing or withdrawing the probe within the esophagus, (b) rotation of the esophageal probe, and (c) manipulation of the tip of the probe using the controls described above (*e*Fig. 52.1.3).



***e*FIGURE 52.1.2 A:** Evolution of transesophageal ultrasound transducer technology. A, Monoplane device is a single-plane transducer typically perpendicular to the shaft. B, In stacked biplane device, the distal transverse plane is complemented by a separate proximal longitudinal plane parallel to the long axis of the scope. C, In a matrix biplane device, transverse and longitudinal planes array are interdigitated into a single footprint. D, Multiplane device uses a single array that can be rotated though 180 degrees so that a continuum of orientations relative to the shaft of the scope may be produced. **B:** Photograph of array of commercially available transducers.



***e*FIGURE 52.1.3** Flexion, extension, and lateral rotation of transducer. The tip of the scope may be advanced, withdrawn, rotated to the left or right, and flexed in four directions (anterior, posterior, left, and right).

Initially, esophageal probes consisted of a single transducer (*e*Fig. 52.1.2) mounted perpendicular to the long axis of the gastroscope. With this monoplane probe, cross-sectional or horizontal images of the heart are obtained, although additional imaging planes are possible by manipulation of the transducer tip. Biplane probes consist of two transducers mounted orthogonally on the probe (13). Multiplane probes are now standard with the major ultrasound systems (14,15). With this probe, the transducer is rotated either mechanically or electronically around a central axis through 180 degrees (Fig. 52.2). The horizontal transducer position is, by convention, at 0 degrees, whereas the longitudinal position is at 90 degrees. Planes not easily available with either the monoplane or biplane probe are available at intermediate degrees of rotation. The precise degree of rotation of the transducer is displayed graphically on the image.

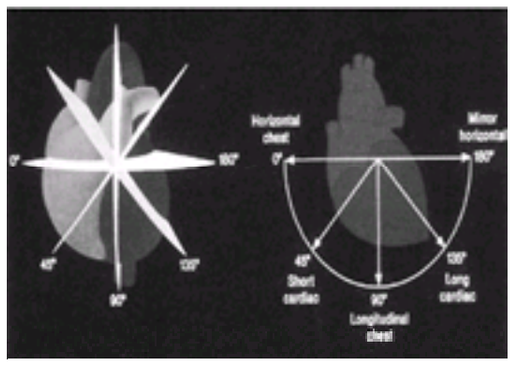


FIGURE 52.2 Scan planes of biplane and multiplane transducers. With the monoplane probe, the transducer is usually fixed and can image only in the transverse plane at zero degrees. Biplane probes have an additional transducer mounted to image in the longitudinal orientation at 90 degrees. In multiplane imaging, the transducer may rotate so that many additional imaging planes in between the transverse and longitudinal and mirror image of the transverse planes may be obtained. (From Khandheria BK. Transesophageal echocardiography in the evaluation of prosthetic valves. *Cardiol Clin* 1993;11:427–436, with permission.)

TECHNIQUE OF TRANSESOPHAGEAL ECHOCARDIOGRAPHY

TEE is performed in a manner similar to upper gastrointestinal endoscopy and requires experience in the safe intubation of the esophagus and stomach. Only operators who have adequate training in esophageal intubation and in echocardiography should perform this procedure.

Patient Selection

Patients should fast for at least 4 hours before the procedure (*e*Table 52.0.4). A detailed history should be obtained first, paying attention to a history of dysphagia, esophageal problems, and drug allergies. As the esophageal probe is passed blindly in TEE, any disorder of the esophagus that might interfere with the passage of the probe or that may lead to injury by the probe is considered a contraindication (Table 52.1). All oral prostheses and dentures are removed, and intravenous access is acquired. Blood pressure and electrocardiographic monitoring and oximetry are undertaken throughout the study. Resuscitation equipment, suction, and oxygen should be readily available. Although TEE may be performed without either pharyngeal anesthesia or sedation, both of these increase patient comfort and facilitate a thorough examination (16).

***e*TABLE 52.0.4** TRANSESOPHAGEAL ECHOCARDIOGRAPHY PROCEDURE
1. Appropriate indication
2. Informed consent
3. No specific contraindication or allergy to drug used in the procedure
4. Fasting >4 h
5. Monitoring of electrocardiogram, blood pressure, and oximetry
6. Pharyngeal anesthesia with topical lidocaine
7. Intravenous sedation with meperidine and midazolam
8. Left lateral decubitus position

1. Significant dysphagia of unknown origin
2. Significant esophageal pathology
Esophageal diverticulum (Zenker's)
Invasive esophageal tumor
Esophageal stricture—undilated
Esophageal tear, fistula, or rupture
Severe esophagitis or ulceration
Esophageal varices especially if recent bleed
3. Instability of the cervical vertebrae
4. Fasting <4 h
5. Uncooperative patient

TABLE 52.1 CONTRAINDICATIONS TO TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Anesthesia and Sedation

Pharyngeal anesthesia helps reduce retching and gagging on probe insertion. The pharynx is sprayed with lidocaine or benzocaine. The patient may also gargle viscous lidocaine 2% for additional anesthetic effect. The effects of anesthesia are apparent within a few minutes and persist for 30 to 45 minutes after the procedure. Patients should not eat or drink during this period because of the risk of aspiration. At The Cleveland Clinic, we use both a narcotic and a benzodiazepine agent for sedation. Meperidine at a dose of 12.5 to 50.0 mg is given intravenously for its anxiolytic action. We usually start by giving 12.5 or 25.0 mg, increasing the dose as necessary while monitoring the effects on heart rate, blood pressure, and oximetry. For additional sedation and amnestic action, we give midazolam in an initial dose of 0.5 to 1.0 mg. Incremental doses are given every 3 minutes until the required effect has occurred or the vital signs suggest that further medication is contraindicated. Midazolam is a short-acting drug that has a half-life of 1 to 4 hours and that is active within 5 minutes. It can cause respiratory depression. Specific antagonists are now available: Reversed for midazolam and Naloxone for meperidine. These should be available for use in the event of significant respiratory depression or other adverse event. Additional sedative medication may be required throughout the procedure to maintain patient comfort. Ambulatory patients should be accompanied so that they do not have to drive home under the influence of sedative and narcotic drugs.

Need for Antibiotic Prophylaxis

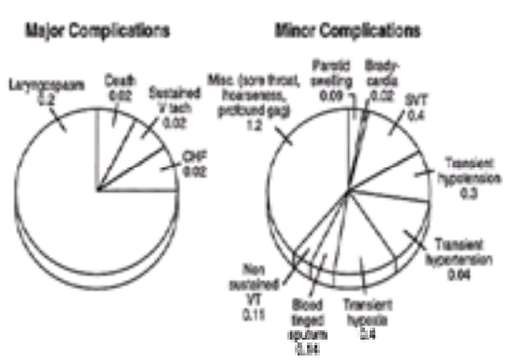
Upper gastrointestinal endoscopy is associated with bacteremia in 4% to 8% of reported series and in 45% of patients after esophageal dilatation (17). Many patients undergoing TEE have valvular or other lesions that pose a risk for endocarditis. Individual case reports have suggested that TEE was a causative factor in the development of endocarditis (18). Several studies involving a total of 522 patients have failed to detect significant bacteremia of oral flora associated with the TEE procedure or of clinical infection at follow-up (19,20 and 21). Therefore, the risk of endocarditis with TEE in experienced hands seems low. Routine prophylaxis for the procedure is not indicated. We do not routinely give antibiotic prophylaxis for patients with valve prostheses. Antibiotic coverage may be considered if the intubation is unexpectedly difficult or traumatic.

Probe Insertion

The probe is usually inserted by having the patient assume a lateral decubitus position while maintaining flexion of the neck. The probe is guided into the upper esophagus, and then the patient is asked to swallow. As the patient swallows, the probe is gently but firmly advanced into the distal esophagus. A bite block is inserted between the teeth to protect the probe, except in edentulous patients. Probe insertion in the ventilated patient is performed with the patient in the supine position. Probe passage is facilitated by removing nonessential tubes in the oropharynx, flexion of the neck, and manual advancement of the tongue and anterior pharyngeal wall in an anterior direction. The probe should never be forcibly advanced because this risks causing an esophageal tear. If the probe does not pass smoothly, assistance from an endoscopist should be sought. At the end of the procedure, the patient should be monitored until vital signs have returned to basal or at least normal values and the sedation has begun to wear off. The probe is washed and then sterilized by immersion in an antimicrobial solution (Cidex, Surgikos Inc.) for 20 minutes. The probe is rinsed and allowed to air dry.

SAFETY AND COMPLICATIONS OF TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Although TEE is invasive and is often performed on critically ill patients, successful intubation is possible in more than 98% of appropriately selected patients, and complications are uncommon (eFig. 52.2.1) (1,2). Inability to pass the probe is most often due to operator inexperience, patient noncompliance, and, rarely, pathologic lesions in the esophagus. Once successful probe passage has occurred, early cessation of the procedure occurs in less than 1% of cases. This is most often due to patient intolerance of the probe rather than the onset of a complication (1). The complication rate of TEE varies with the setting in which it is performed and the experience of the operator. TEE in the emergency room is reported to have a higher complication rate, likely due to the acuity of illness in this setting (22).



***e*FIGURE 52.2.1** Complications of transesophageal echocardiography depicted as percentages of the total number of transesophageal echocardiography procedures (q = 7,134) performed at the Mayo Clinic from 1988 to 1993. CHF, congestive heart failure; misc, miscellaneous; SVT, supraventricular tachycardia; VT or V tach, ventricular tachycardia. (From Khandheria BK, Seward JB, Tajik AJ. Transesophageal echocardiography. *Mayo Clin Proc* 1994;69:856–863, with permission.)

Major Complications

Major complications such as death, esophageal perforation, serious arrhythmia, congestive heart failure, and laryngospasm are uncommon and occur in less than 0.3% of patients (1). One death was reported out of 3,827 consecutive patients examined in one series. This was due to arrhythmia after the procedure in a patient with autopsy-proven myocarditis (2). Another death was reported in a series of 10,419 patients. This was due to esophageal perforation in a patient with unsuspected neoplasm that had invaded the esophagus (1). A third death after TEE has been reported in a patient with acute aortic dissection in whom aortic rupture occurred during a bout of severe retching and nausea after probe insertion (23). Serious esophageal injury may occur, and both esophageal perforation and tear have been reported (24). Absence of significant damage to the mucosal lining of the esophagus after prolonged TEE examination has been demonstrated in animals (25). Laryngospasm and severe bronchospasm occasionally occur because of aspiration of anesthetic agents or lubricants used for probe insertion and rarely from inadvertent passage of the probe into the airway (26).

Minor Complications

Minor complications such as transient hypoxia, hypotension, hypertension, angina, bronchospasm, atrioventricular block, supraventricular tachycardia, and nonsustained ventricular arrhythmia occur in less than 3% of cases (2). Transient vocal cord paralysis has been noted in patients undergoing neurosurgical procedures who were studied in the upright position (27). Compression of anomalous vascular structures by the esophageal probe has also been reported (28). Sore throat and mild dysphagia is common after the procedure and rarely is prolonged for more than 24 hours. Toxic and allergic reactions to the drugs used in patient preparation

occur but are uncommon. The most common reaction encountered is methemoglobinemia in susceptible subjects receiving topical anesthesia (29).

Technical Problems

A number of technical factors may affect the quality of the TEE examination. These include air in the esophagus and stomach and poor contact between the probe and the esophagus. Distorted anatomy from prior surgery, a tortuous aorta, or a large hiatal hernia may also interfere with imaging. Problems with the probe during the procedure such as mechanical or electronic failure occur but are uncommon (1,30).

IMAGING PLANES

The esophageal window imposes a number of challenges in imaging the heart and related structures in a standard format. The esophagus is not usually precisely aligned with the true long and short axis of the heart (Fig. 52.3). Furthermore, the relationship between the esophagus and cardiac structures is variable. Standard imaging planes have been described for TEE. However, the maneuvers required to acquire them are not always predictable but are facilitated by multiplane technology. Interpretation of esophageal images is often challenging initially despite their high quality. The orientation of the images is different to TTE, as the images are acquired from behind rather than from the front of the heart. The multiple imaging planes available and the ability to resolve structures rarely visible with other imaging modalities add to the initial difficulty. TEE requires a familiarity with the three-dimensional anatomy of the heart and aorta as imaged from the esophagus. This can best be obtained by performance of multiple procedures while supervised by an experienced operator. The transesophageal examination is usually goal-oriented. Specific questions unanswered by the prior transthoracic study are first addressed, followed by a comprehensive evaluation of other structures. It is important to follow a standard examination format encompassing all major cardiac structures and the aorta so that a complete examination is always performed.

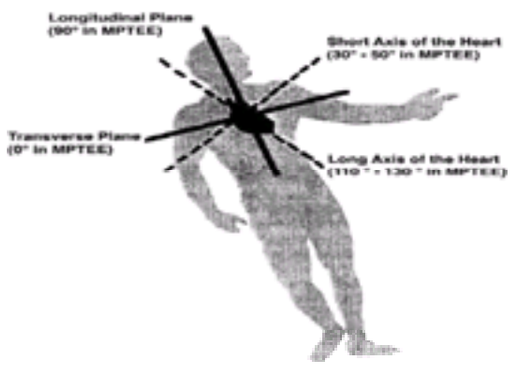


FIGURE 52.3 Relationship of horizontal and vertical vectors of the heart to those of the body and esophagus. The transverse (0-degree) and longitudinal (90-degree) esophageal imaging planes do not parallel the true short and long axis of the heart, which are imaged at 30 to 50 degrees and 110 to 130 degrees, respectively. The true short and long axis varies with individual habitus. MPTEE, multiplane transesophageal echocardiography. (From Schneider AT, Hsu TL, Schwartz S, Pandian NG. Single, biplane, multiplane, and three-dimensional transesophageal echocardiography. Echocardiographic-anatomic correlations. *Cardiol Clin* 1993;11:361–387, with permission.)

Base of the Heart

At approximately 30 cm from the incisors, the probe lies behind the left atrium and the base of the heart. In the transverse plane at this level, the aortic valve is seen in cross-section, with portions of the left and right atrium and interatrial septum (Fig. 52.4). Withdrawing the probe slightly from this view allows imaging of the left atrial appendage, the superior vena cava, the right ventricular outflow tract, ostia of the coronary vessels and the main pulmonary artery to its bifurcation, and a portion of the right pulmonary artery. The proximal portion of the ascending aorta is imaged in this view but it and the distal portions of the left pulmonary artery are difficult to image because of the interposition of air-filled large airways. The longitudinal imaging plane at this level provides important images of the great vessels, interatrial septum, left atrial appendage, and pulmonary veins. When the transducer is rotated to the left, a two-chamber view of the left atrium and left ventricle is seen. The left atrial appendage and the left pulmonary veins are often most easily imaged in this view. The mitral valve is also well seen in this view, and mitral regurgitation may be sought here. With clockwise rotation of the probe around its long axis, the right ventricular outflow tract, pulmonary valve, and main pulmonary artery may be imaged. With additional clockwise rotation, the aortic valve and ascending aorta are seen. This view is important in the evaluation of the ascending aorta particularly with regard to dissection and in assessing aortic regurgitation. Finally, with further clockwise rotation, the right atrium, interatrial septum, and superior vena cava may be imaged. This plane is important in the detection of a communication at the atrial level and in assessing pathology of the superior vena cava. Multiplane imaging is especially useful at this level in allowing the true long and short axis of the aortic valve and ascending aorta to be obtained. Typically, the true short axis is seen at approximately 30 to 60 degrees and the true long axis at 120 to 150 degrees (eFig. 52.4.1).

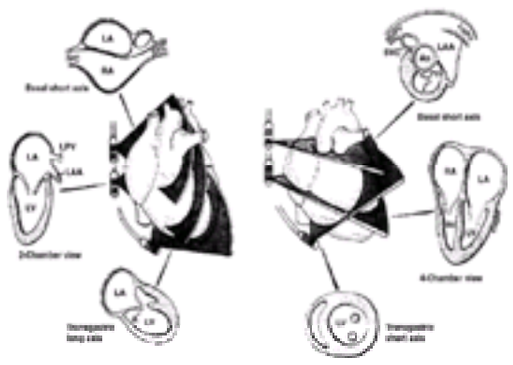

FIGURE 52.4 Transverse **(A)** and longitudinal **(B)** imaging planes at base of the heart, midesophagus, and transgastric windows. Video 52.1 A 60-degree transesophageal short-axis view **(A)** of the aortic valve demonstrating a quadricuspid (as opposed to the typical trileaflet) valve. Note the presence of four leaflets and four commissures. The second video shows a 60-degree transesophageal short-axis view of quadricuspid aortic valve with color Doppler demonstrating moderate central aortic insufficiency. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

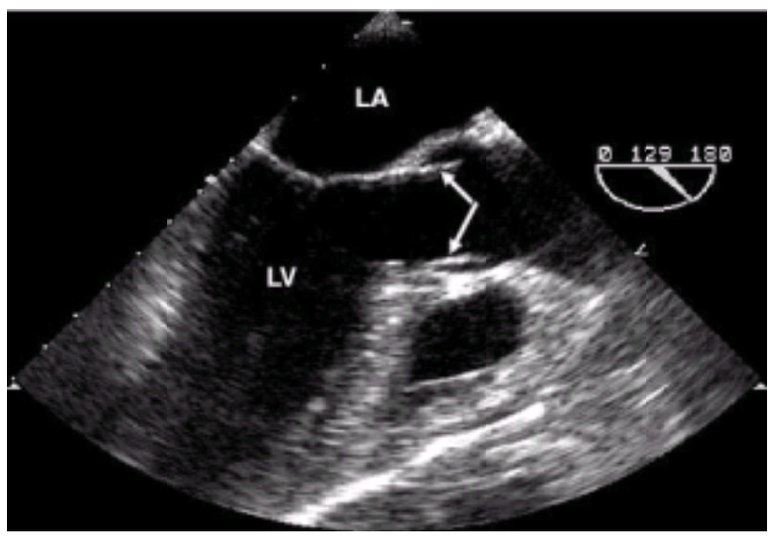
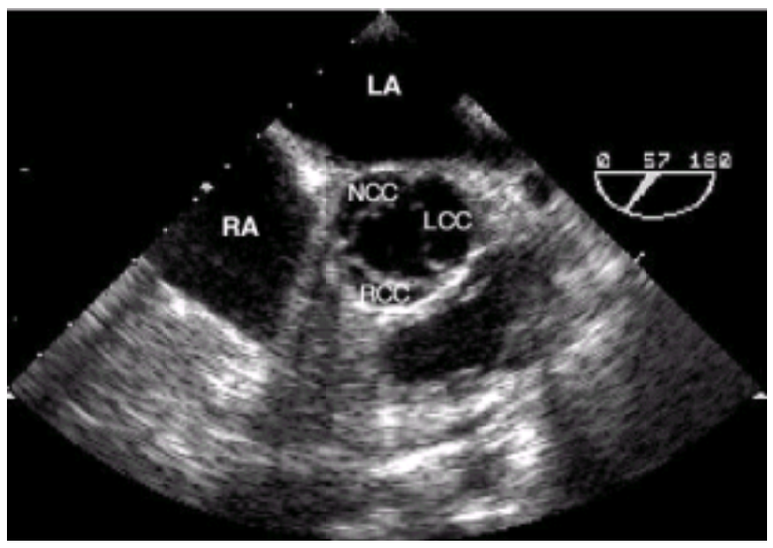
Video 52.2 A 60-degree transesophageal short-axis view **(A)** of the aortic valve demonstrating a quadricuspid (as opposed to the typical trileaflet) valve. Note the presence of four leaflets and four commissures. The second video shows a 60-degree transesophageal short-axis view of quadricuspid aortic valve with color Doppler demonstrating moderate central aortic insufficiency. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.3 A normal 120-degree transesophageal echo demonstrating a normal aortic valve in long-axis view and a normal mitral valve. The posterior mitral leaflet is towards the left of the screen, and the anterior mitral leaflet is in the center of the screen. The anterior/anteroseptal wall of the left ventricle is in the center of the screen, and the posterior wall is to the left. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

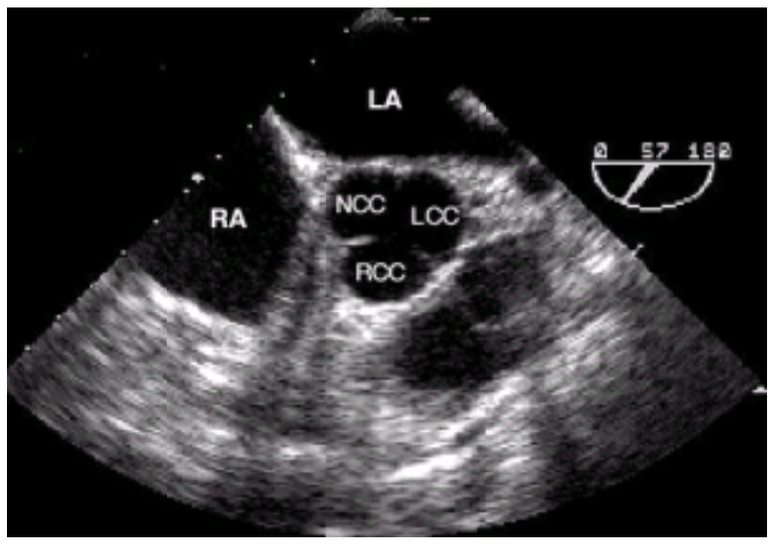
Video 52.4 A short-axis 60-degree transesophageal echo view of a normal, tri-leaflet aortic valve. The noncoronary cusp of the aortic valve is located toward the upper left of the screen, the left coronary cusp is towards the upper right, and the right coronary cusp is towards the bottom. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Systolic frame of a 120-degree transesophageal echo view demonstrating the long axis of the aortic valve. The aortic valve (*double arrow*) is open while the mitral valve to the left of the screen is closed.



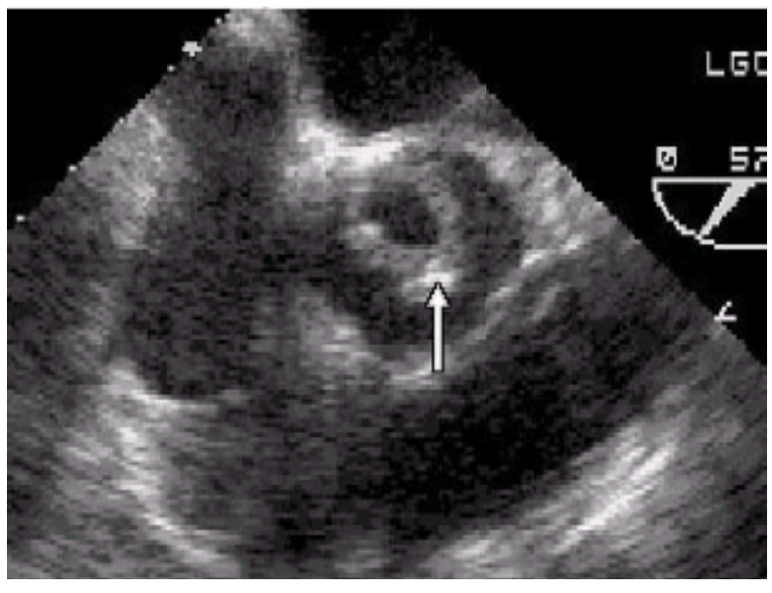
Short-axis transesophageal view demonstrating the aortic valve in systole. The noncoronary cusp is in the upper left of the screen and the left coronary cusp is in the upper right of the screen and the right coronary cusp at the bottom of the screen.



Short-axis transesophageal echo view of the aortic valve seen in diastole. Note the closed leaflets of the aortic valve.

Midesophageal Views

By advancing the probe into the midesophagus beyond the base of the heart, portions of both atria and ventricles, the interventricular septum, and the mitral and tricuspid valves are seen in the transverse imaging plane (Fig. 52.4). A four-chamber view is acquired at this level by flexing the probe posteriorly. This view is similar to the apical four-chamber view acquired transthoracically, except that the imaging plane does not cut through the true apex. This represents an inherent limitation of transesophageal imaging in the acquisition of ventricular volumes and in the detection of apical thrombus. This imaging plane is helpful in detecting regurgitation at the mitral and tricuspid valves and in global assessment of ventricular function. With slight counterclockwise rotation of the transducer, the left ventricular outflow tract and the proximal ascending aorta are seen. Longitudinal imaging at this level produces a two-chamber image of the heart already described. Multiplane images at this level are useful in distinguishing the individual leaflets of the mitral valve and the scallops of the posterior leaflet and in detecting eccentric jets of mitral regurgitation. Optimal differentiation between anterior and posterior mitral leaflet pathology is at approximately 140 degrees, whereas the full extent of the mitral closure line, from medial to lateral commissure, is at approximately 50 degrees.



Short axis transesophageal view of a unicuspid aortic valve with aortic stenosis. The arrow designates the single commissure present in this aortic valve. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)

VIDEO

Video 52.5 A normal 60-degree transesophageal echo view of a mitral valve demonstrating the medial commissure (*left*) and the lateral commissure (*right*). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 52.6 A 90-degree transesophageal echo view (with the probe rotated to the left) demonstrating a normal mitral valve and the left atrial appendage. The anterior mitral leaflet is towards the right of the screen, and the posterior leaflet is towards the left. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 52.7 Transesophageal echo view (90-degree with probe rotated to the right) demonstrating the right atrium with the inferior vena cava entering from the upper left and the superior vena cava from the right of the screen. The interatrial septum is at the top of the screen with the left atrium located superiorly. This view is useful to look for patent foramen ovules, atrial septal defects, and masses entering the right atrium from the inferior vena cava or attached to the septum. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 52.8 This 45-degree transesophageal echo view demonstrates the pulmonary artery bifurcation in the center of the screen and the aorta in cross section to the left. This can be useful to see a large saddle pulmonary embolus at the bifurcation. However, smaller, more distal emboli would be missed. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 52.9 A 90-degree transesophageal echo view of the left ventricle demonstrating the anterior wall on the right and the inferior wall on the left. The anterior mitral leaflet is to the right, and the posterior leaflet is to the left. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Transgastric Views

To obtain the transgastric series of views, the probe is advanced into the stomach. Generally, the tip of the probe must be flexed to bring the transducer in contact with the mucosa of the gastric fundus. In the transverse plane, a short-axis view of the left and right ventricle is acquired (Fig. 52.4). With increased anteflexion of the probe, the base of the heart and the mitral and tricuspid valves are imaged, whereas lesser degrees of anteflexion bring the image more toward the apex. This view allows an assessment of regional and global left ventricular function. The mitral valve apparatus and leaflets are also well seen in this view. This view is most often used when ventricular function is being monitored. A longitudinal view at this level allows the mitral valve and the left ventricle to be imaged in long axis. The anterior and inferior walls are well seen, as are the papillary muscles and chordae. The true apex of the heart is most likely to be displayed in this view. Rotation of the probe in the long axis frequently allows the left ventricular outflow tract to be aligned with the Doppler cursor so that a Doppler evaluation of the aortic valve and left ventricular outflow tract may be performed. Further rotation allows examination of the right ventricle and outflow tract. Multiplane imaging at this level facilitates the evaluation of the left ventricular outflow tract and examination of the tricuspid valve and its component leaflets. Another series of images is frequently possible by passing the probe further into the stomach and anteflexing (the deep transgastric view). In this view, the transducer is close to the apex, and the images obtained simulate those acquired in a transthoracic five-chamber or subcostal view. This view often optimizes Doppler interrogation of the aortic valve and outflow tract.

If you do not have QuickTime you may download it here.*

VIDEO

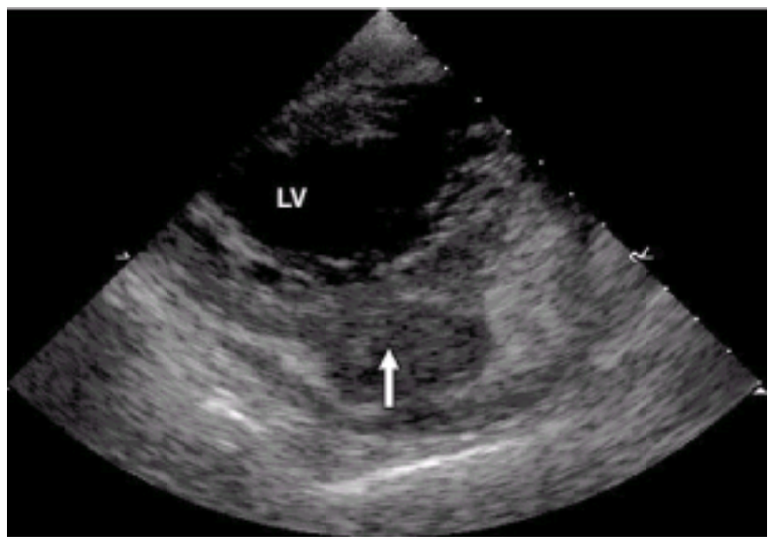
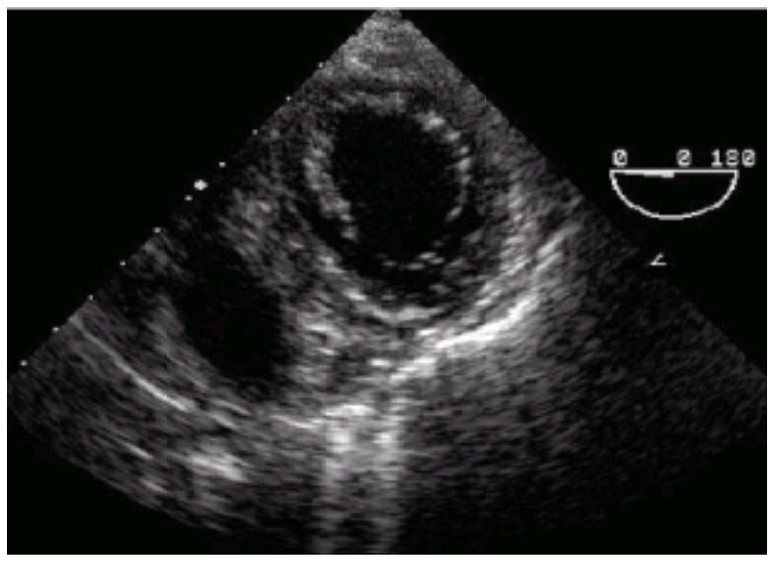
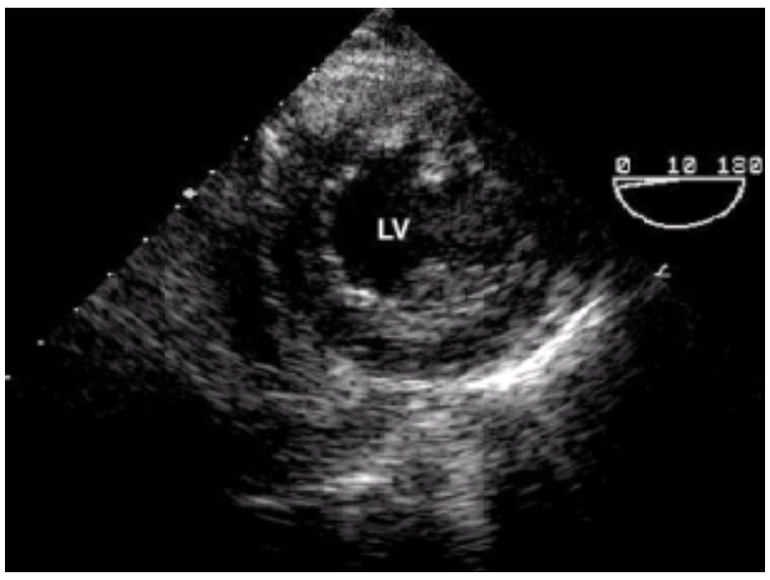
Video 52.14 Deep 90-degree transgastric view of the aortic valve obtained by starting with the transgastric long-axis view of the left ventricle and advancing the probe and retroflexing. This view is useful to measure aortic valve gradients. This patient has a heavily calcified aortic valve seen at the center of the screen. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



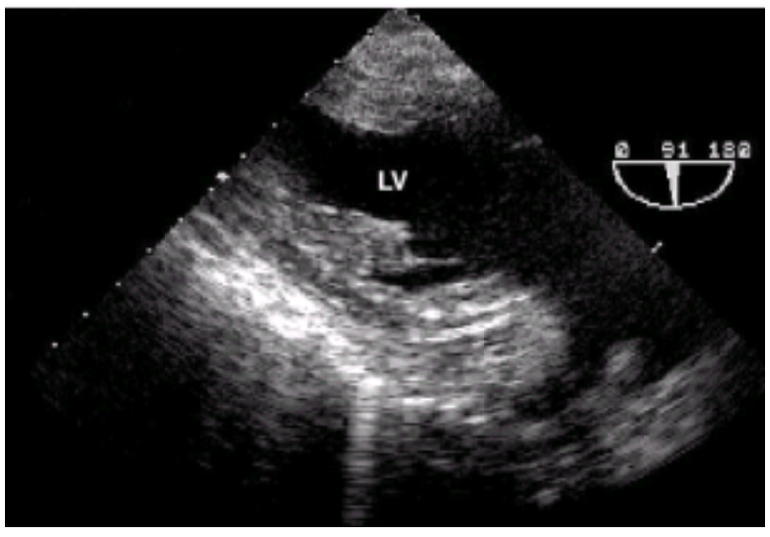
Transgastric long-axis view of a metastatic sarcoma within the anterior wall of the left ventricle at the bottom of the screen (designated by the arrow).



Transgastric transesophageal echo demonstrating the mitral valve in short axis. The anterior mitral leaflet is to the left of the screen and the posterior leaflet is to the right. The medial commissure is at the top while the lateral commissure is at the bottom of the screen.



Transgastric short-axis transesophageal view of the left ventricle. The inferior/posterior walls are at the top of the screen, the lateral wall to the right, the anterior wall at the bottom, and the septum to the left.



Transgastric transesophageal view of the left ventricle in long axis. The inferior wall is at the top of the screen, apex to the left, mitral valve to the right, and the anterior wall at the bottom of the screen.

Aorta

The aorta may be examined from the ascending aorta to below the diaphragm (Fig. 52.5). The examination of the ascending aorta has already been described. The distal portion of the ascending aorta cannot be examined using the transverse plane because of the interposition of the trachea. The longitudinal and multiplane imaging planes may allow an additional area of imaging, but not all of the ascending aorta can be identified. The descending aorta is evaluated by rotating the probe to the left and posteriorly at midesophageal level. The aorta is seen in cross-section using the transverse transducer at this level and in long axis using the longitudinal transducer. More distal portions of the aorta are examined by advancing the probe, whereas the proximal portions of the descending aorta are imaged by withdrawing the probe and rotating anteriorly and to the left to keep the aorta in view. As the probe is withdrawn to approximately 20 to 25 cm, the transverse arch and distal portions of the ascending aorta are seen. The transverse plane cuts the arch in long axis at this level, and the longitudinal plane provides a short-axis view. The proximal portions of the left subclavian and other head and neck vessels may be imaged with a longitudinal or multiplane transducer. Examination of the aortic arch is usually performed last, as the probe often elicits a gag reflex at this level, even in well-prepared patients.

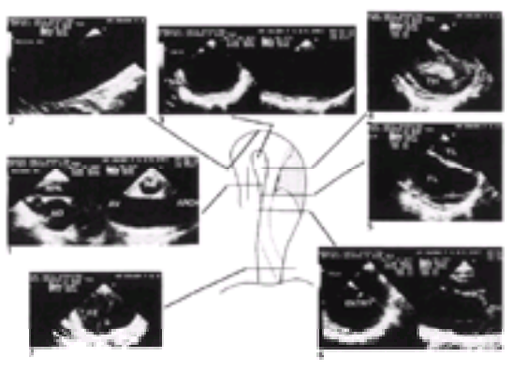


FIGURE 52.5 Imaging planes of aorta. Biplane imaging planes of the aorta illustrated in a patient with dissection flap confined to the distal aorta. **Panel 1:** Transverse (*left*) and longitudinal plane (*right*) images of the ascending aorta. **Panel 2:** Transverse plane image of the aortic arch. **Panel 3:** Transverse (*left*) and longitudinal (*right*) plane images of the proximal descending aorta at the junction with the arch. **Panels 4–7:** Transverse (**panels 4–7**) and longitudinal (**panel 6**, *right*) plane images of the aortic dissection flap and its variable orientation in various portions of the descending aorta. This short-axis view of the descending aorta is seen by intraoperative transesophageal echo showing the distal end of the aortic graft following the first stage of an elephant trunk procedure. Note the circular appearance of the graft within the aneurysmal descending aorta. The arrow demonstrates the diameter of the descending aortic graft.

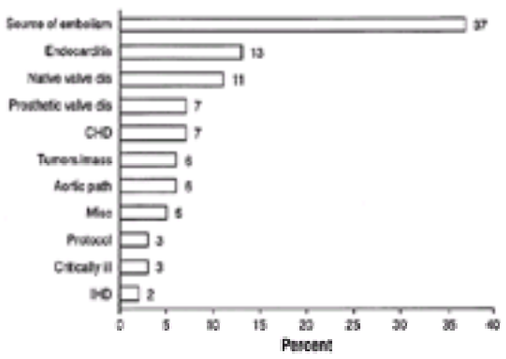
Intraoperative echo demonstrating the distal end of the aortic graft after the first stage of an elephant trunk procedure seen in long axis. Note the tubular free end of the graft within the aneurysmal descending aorta. CO designates the diameter of the conduit.

INDICATIONS FOR TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Left and Right Atria

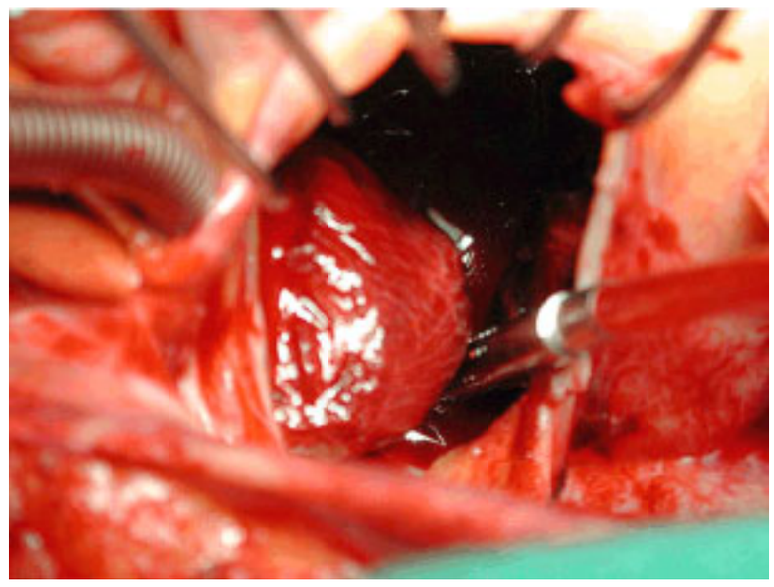
Atrial Thrombus

TEE is now the technique of choice in the evaluation of atrial thrombus (eFig. 52.5.1 and Fig. 52.6) and is superior to TTE in detecting atrial appendage thrombus (31,32). Left atrial thrombus is associated with mitral stenosis, atrial dilatation, atrial fibrillation, left ventricular dysfunction, or a combination of these factors (33) and is an independent risk factor for thromboembolism (34). The sensitivity and specificity of TEE in the detection of thrombus in both the body and appendage (32) of the left atrium are excellent and have exceeded 90% in a number of large series with surgical validation (35), as compared with less than 50% for TTE. TEE has shown that patients with atrial flutter are also at risk for development of atrial thrombus and are thus at risk of embolization especially with cardioversion (36). Patients with atrial fibrillation and mitral valve disease frequently undergo ligation of the atrial appendage. TEE has shown that flow may persist into the atrial appendage despite surgical ligation in more than one of three patients and who therefore remain at risk of thrombus formation and embolization from the atrial appendage. (37). TEE is also superior to TTE in the detection of right atrial thrombus (38).

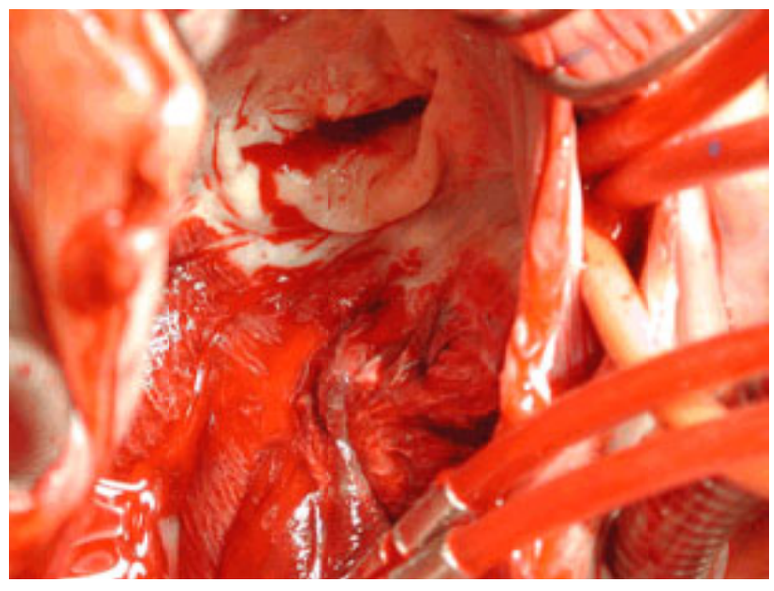


***e*FIGURE 52.5.1** Bar diagram of indications for 7,134 transesophageal echocardiography examinations performed at the Mayo Clinic from 1988 to 1993. CHD, congenital heart disease; IHD, ischemic heart disease; Misc, miscellaneous cardiac conditions; Path, pathologic conditions. (From Khandheria BK, Seward JB, Tajik AJ. Transesophageal echocardiography. *Mayo Clinic Proc* 1994;69:856–863, with permission.)

FIGURE 52.6 Left atrial appendage thrombus (*arrow*). LA, left atrium.



Intraoperative field looking into the left atrium of a patient with severe mitral stenosis who developed extensive clot within the left atrium. Notice the large mass in the center of the field, to the left of the opening within the left atrium. This is the largest portion of the left atrial thrombosis.

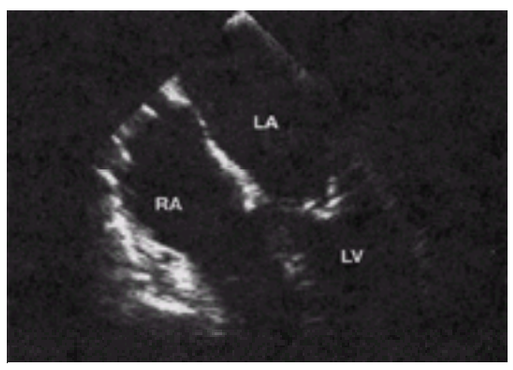


Intraoperative field looking into the left atrium after the large left atrial thrombus was resected demonstrating the rheumatic mitral valve at the top of the screen. Note the scarred, thickened, restricted mitral leaflets. This patient had severe mitral stenosis with a mean pressure gradient of 20 mm Hg across the valve and a mitral valve area of 0.7 cm^2.

Surgical specimen of the large left atrial mass explanted at the time of surgery. Note its somewhat pale, glistening surface, suggesting that the thrombus is not fresh and possibly endothelialized.

Spontaneous Contrast

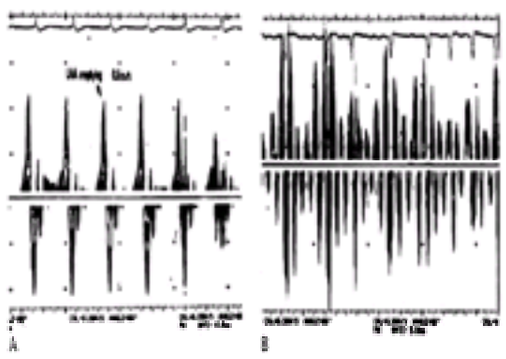
TEE often identifies swirling echoes of spontaneous contrast in the left atrium or appendage, especially in those with atrial fibrillation or atrial thrombus (eFig. 52.6.1) (39). This is reported in as many as 20% of all patients undergoing TEE but is rarely seen in TTE (39,40). The level of intensity of the contrast varies within the atrium and appendage and is most dense in areas of lowest flow such as the atrial appendage. The precise mechanism of its generation is uncertain but is thought to relate to rouleaux formation of red blood cells in areas of low flow (40,41). This theory is supported by the reduced incidence of this phenomenon after successful dilatation of stenotic mitral valves (42). Anticoagulation has not been shown to affect the prevalence or intensity of spontaneous contrast (40,41). Spontaneous contrast in the left atrium is an independent risk factor for systemic embolization in both mitral stenosis and nonvalvular atrial fibrillation (41,43). Spontaneous contrast occurs in 2% of patients with sinus rhythm and is an independent risk factor for stroke (44).



***e*FIGURE 52.6.1** Swirling echoes of spontaneous contrast in left atrium (LA) in a patient with mitral stenosis. LV, left ventricle; RA, right atrium.

Atrial Mechanical Function

TEE provides a unique window to atrial mechanical function (45). Investigators have measured the velocity and pattern of left atrial and appendage blood flow (46). Characteristic patterns of flow have been described in sinus and atrial rhythms (eFig. 52.6.2) (45). Reduced or absent flow and a fibrillatory pattern are most often associated with spontaneous contrast and thrombus formation (45). Others have noted that reduced velocity of flow in the posterior portion of the atrial body is associated with thrombus formation and systemic embolization (47). A reduction in appendage flow velocity immediately after cardioversion has also been noted (48). Atrial appendage velocity has been used to predict likelihood of successful cardioversion, maintenance of normal rhythm, and risk of thromboembolism, with variable results (49,50). A left atrial appendage emptying velocity of less than 20 cm per second is associated with poorer atrial function, greater likelihood of thrombus and spontaneous contrast, and a greater likelihood of subsequent events (51). Reduced left atrial appendage velocity is determined by factors such as hypertension, atrial size, atrial fibrillation, ischemic heart disease, and age (51) but remains an independent risk factor for embolism even when these factors are accounted for.



***e*FIGURE 52.6.2** Patterns of flow in atrial appendage by transesophageal echocardiography pulsed Doppler. **A:** Normal sinus rhythm. **B:** Atrial fibrillation.

Transesophageal Echocardiography Screening before Mitral Valvuloplasty and Cardioversion

Atrial thrombus poses a risk for embolization during percutaneous mitral valvuloplasty and electrical cardioversion of atrial fibrillation (52). TEE has been used to screen for atrial thrombus before these procedures. TEE detected atrial thrombus in 26% of 19 patients being considered for balloon valvuloplasty of the mitral valve, only one of which was detected by TTE (53). Patients with atrial thrombus detected by TEE were excluded from the procedure. TEE has also been used to allow early cardioversion of patients with chronic atrial fibrillation without the standard 3 to 4 weeks of systemic anticoagulation. In one prospective study of TEE cardioversion, left atrial thrombus was found in 15% of 233 patients with atrial fibrillation of unknown or prolonged duration (39). Cardioversion was performed without a prolonged interval of anticoagulation in those without evidence of atrial thrombus and no embolic complications were recorded (39). A prospective randomized trial of prolonged anticoagulation versus TEE cardioversion (Assessment of Cardioversion Using Transesophageal Echocardiography study) (54) has been completed. The embolic event rate in both the TEE and conventional group were lower than expected and similar. Although inadequately powered to show a difference between the two strategies, this study convincingly demonstrates a low embolic event rate associated with TEE-guided cardioversion. TEE cardioversion was associated with a shorter duration of anticoagulation but not with a greater likelihood of remaining in sinus rhythm (55). TEE cardioversion appears to be particularly cost-effective in patients with increased risk of hemorrhage with anticoagulation (56). Thromboembolic complications have been reported in patients who were cardioverted despite TEE results that were negative for atrial thrombus but who were inadequately anticoagulated (57). Temporary deterioration of atrial function after return of normal sinus rhythm with subsequent thrombus formation and embolization is postulated to account for these embolic events rather than embolization of thrombus undetected by TEE (46,48,58). The deterioration in atrial function occurs even with chemical cardioversion (59) and does not occur after delivery of a shock to the atrium in patients with normal sinus rhythm (60). The deterioration in atrial function is less after atrial flutter conversion as compared with atrial fibrillation (61). Anticoagulation for a number of weeks is indicated after cardioversion even when TEE does not show atrial thrombus to minimize the risk of embolism after the procedure.

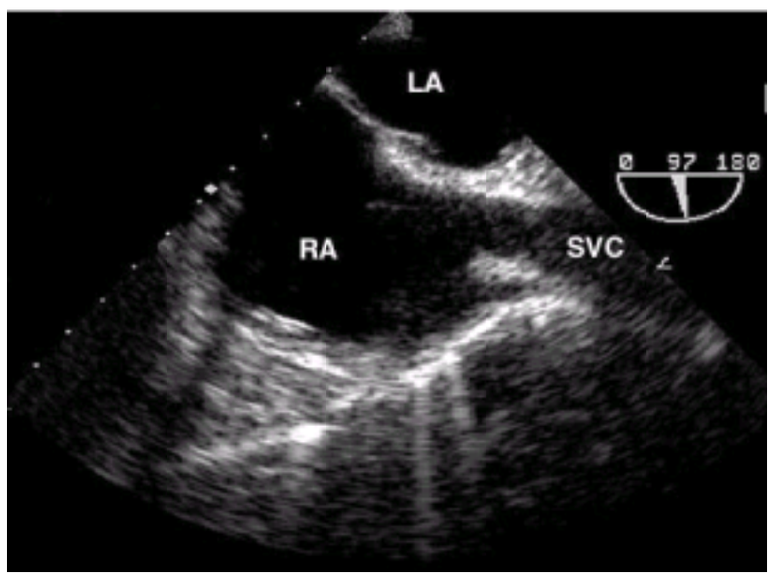
Interatrial Septum

Atrial Septal Defect

TEE is the technique of choice in the diagnosis of abnormalities of the interatrial septum. The atrial septum is visualized in the long-axis view of the base of the heart. TEE is especially useful in the detection of small atrial septal defects (less than 5 mm) (62) and of sinus venosus defects. In one study, TEE detected all sinus venosus defects, whereas only 25% were detected by TTE (63). Anomalous drainage of pulmonary veins, which often accompanies sinus venosus–type defects, is also reliably detected by TEE (63). TEE measurements of anatomic size and shunt flow compare well with those measured at the time of surgery (64).

VIDEO

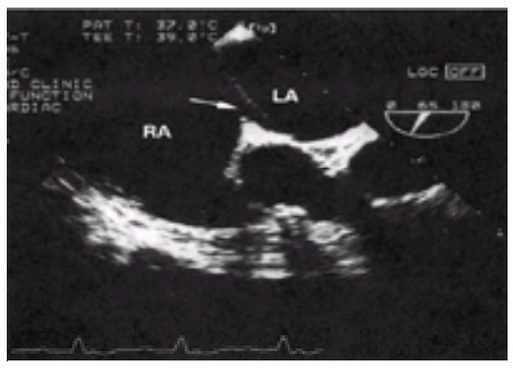
Video 52.16 Transesophageal echo with color Doppler flow demonstrating a secundum atrial septal defect with left-to-right flow. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Transesophageal echo demonstrating the right atrium with the inferior vena cava entering from the upper left and the superior vena cava from the right of the screen. The interatrial septum and left atrium are located superiorly. This view is useful to evaluate patent foramen ovales, atrial septal defects, or masses entering the right atrium from the inferior vena cava or attached to the interatrial septum.

Patent Foramen Ovale

Patent foramen ovale occurs in 25% to 30% of the normal population and is more commonly found in those with unexplained stroke (eFig. 52.6.3) (65,66). The latter finding and the TEE demonstration of passage of a paradoxical embolus through a patent foramen ovale support its causative role in cerebral embolism (Fig. 52.7) (67). TEE is highly sensitive and specific in the detection of patent foramen ovale and is superior to TTE (68). In one study, TEE detected all of the defects subsequently found at autopsy (69). In another study, patent foramen ovale was detected by TEE in 22% of patients and only in 8% by TTE (70). Contrast venous injection is useful in the detection of right-to-left shunting, whereas color-flow imaging is the method of choice in detecting left-to-right shunting (71). Both color-flow and contrast techniques are performed in practice. Characteristics of patent foramen ovale by TEE that predict an increased likelihood of embolic event include larger size and increased shunt flow across the defect (72).



***e*FIGURE 52.6.3** Patent foramen ovale by multiplane transesophageal echocardiography (*arrow*). LA, left atrium; RA, right atrium.

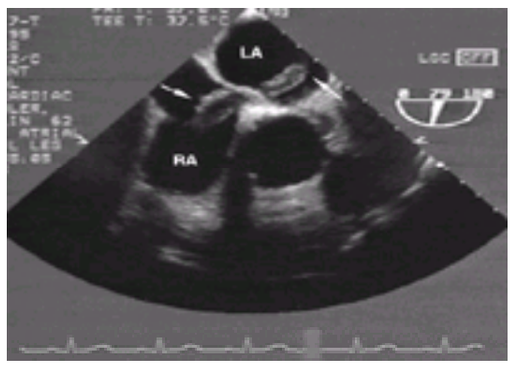


FIGURE 52.7 Embolus in transit across a patent foramen ovale (*arrows*). LA, left atrium; RA, right atrium.

Atrial Septal Aneurysm

Atrial septal aneurysm (ASA) is also a risk factor for cerebral embolism and is detected more frequently by TEE than by conventional echocardiography (73). ASA occurs in 2.2% of the population and is associated with a single patent foramen ovale or rarely with multiple fenestrations (74,75). It is three times more common in those with a history of cerebral ischemia (74). The embolic risk of this condition is due to the associated shunt or rarely to thrombus formation within the aneurysm, which occurs in 1% of patients with ASA (76). An ASA is recognized by the finding of a redundant highly mobile outpouching of the atrial septum that is at least 10 mm wide and 15 mm long. (Fig. 52.8). In a multicenter study, TEE detected 195 patients with this entity, whereas only half of these were detected by TTE (76). Half of the patients had evidence of an atrial shunt, whereas embolic events had occurred in 44%.

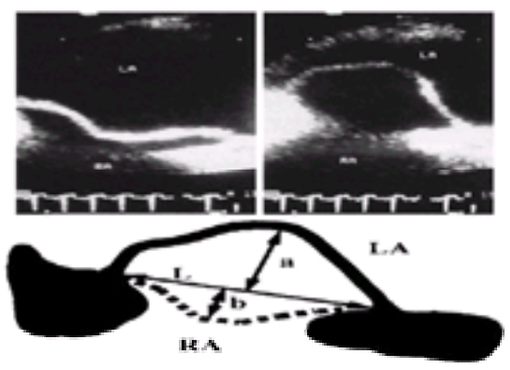

FIGURE 52.8 Mobile atrial septal aneurysm by transesophageal echocardiography. Other Atrial Abnormalities

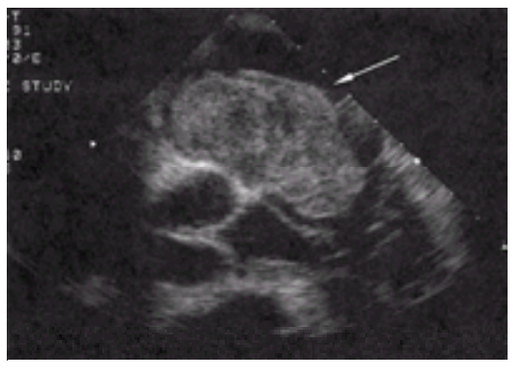
The membrane of cor triatriatum is particularly well-delineated by TEE. Atrial tumors such as myxomas are usually well-characterized by TTE. TEE is useful when there is diagnostic uncertainty and is superior in detecting the site of attachment to the wall and the composition of the tumor (eFig. 52.8.1) (77). It is also useful in elucidating the nature of other masses suspected by TTE and in distinguishing them from normal variants.

Video 52.17 Transesophageal view demonstrating the right atrium with the inferior vena cava off to the left of the screens, the superior vena cava to the right, and the left atrium at the top, with the interatrial septum in the middle. This view shows a hemangioma in the interatrial septum found incidentally at the time of preoperative transesophageal echo for mitral valve replacement for severe mitral regurgitation. Intraoperatively, the mass was highly vascular as expected and was resected. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



***e*FIGURE 52.8.1** Large left atrial myxoma (*arrow*) prolapsing through mitral valve.

Endocarditis

Diagnosis

Echocardiography is now an integral part of the evaluation of suspected endocarditis (78). TEE is more sensitive in diagnosing endocarditis, as it provides better resolution of vegetations than TTE. In one study, TTE detected 63% of vegetations, whereas TEE detected all of them (Fig. 52.9) (79). In that study, TTE had equivalent diagnostic accuracy to TEE in detection of vegetations greater than 11 mm but only detected 25% of vegetations less than 5 mm in size and 69% of vegetations of a size between 6 and 10 mm. In other studies in which the ability of TEE and TTE to detect vegetations has been compared, the sensitivity of TTE has varied from 25% to 60%, whereas that of TEE has varied from 87% to 100% (79,80 and 81). Both TEE and TTE have a reported specificity in the diagnosis of vegetations of more than 90% (81,82). The superiority of TEE in the detection of prosthetic endocarditis is even greater than for native-valve disease (*e*Fig. 52.9.1). The sensitivity of TEE and TTE in detecting prosthetic endocarditis is more than 80% and less than 45%, respectively (83,84). Vegetations on the tricuspid valve are detected with equal frequency by TEE and TTE (85). However, endocarditis of the pulmonary valve is more often recognized by TEE than by TTE (86), as is endocarditis at unusual sites such as on pacemaker wires (87).

Complications

TEE is more reliable than TTE in detecting perforation of a valve leaflet in endocarditis (88). TEE can detect pyogenic complications of endocarditis such as abscess and fistula formation (Fig. 52.10 and *e*Fig. 52.10.1) more readily than TTE (89,90). These complications are associated with increased mortality, usually require operative intervention for successful treatment, and occur in approximately one-third of endocarditis cases. They occur most often with staphylococcal infections of the aortic valve and in prosthetic endocarditis (89,91,92). The sensitivity of TEE in the detection of abscess or infected pseudoaneurysm has been reported at 87% to 100%, whereas that of TTE has varied from 28% to 43% (89,92) (Fig. 52.10). TEE is more reliable (100% sensitive) than TTE (32% sensitive) in the detection of endocarditis in patients with *Staphylococcus aureus* sepsis. Endocarditis may exist in 25% of such patients and when present carries a fivefold increase in mortality as compared with sepsis without endocarditis (93). TEE has also been shown to be both useful and cost-effective in following patients with catheter-associated sepsis to determine the duration of antibiotic treatment (94).

Predictive Value and Usefulness of Transesophageal Echocardiography in Endocarditis

Failure of TEE to detect vegetations in suspected endocarditis has a high negative predictive value. In one study, no evidence of endocarditis was noted on TEE in 65 of 105 patients with suspected endocarditis (95). Of these 65, definite endocarditis developed in only five (7%) on subsequent follow-up. However, TEE may fail to detect endocarditis early in the course of the illness or after embolization of a vegetation. Serial studies are indicated if the clinical suspicion is high despite an initially negative TEE. Many findings on native and prosthetic valves may simulate vegetations. These include degenerative changes such as Lambl's excrescences on the aortic valve or suture material in the case of prostheses. Comparison with prior studies is very useful in these instances. Because of the high sensitivity, specificity, and negative predictive value of TEE in the detection of endocarditis, it has been advocated as the technique of choice in the evaluation of this condition. In one study, the addition of TEE to clinical criteria increased the case detection rate from 50% using clinical criteria to 100% with TEE (96). In a study addressing the incremental usefulness of transthoracic and TEE over clinical criteria in the diagnosis of endocarditis (97), TEE was incrementally useful in patients with intermediate or high probability of disease based on clinical criteria and TTE and in those with suspected prosthetic endocarditis. TEE and TTE were equivalent in excluding endocarditis in patients with a low likelihood of endocarditis on clinical grounds. Another study has indicated that in native-valve endocarditis, an adequate TTE without evidence of

endocarditis was highly accurate in excluding this diagnosis (98). TEE has been shown to improve the diagnosis of native-valve endocarditis based on the Duke criteria and TTE in 11% of the study patients, most of whom had an intermediate likelihood of disease (99).

Guidelines for Use of Transesophageal Echocardiography in Endocarditis

TEE is indicated in all cases of suspected endocarditis involving prosthetic valves or cardiac devices such as pacemakers or defibrillators. TEE is also indicated in staphylococcal sepsis or in endocarditis in which pyogenic complications are common or suspected based on the clinical course. TEE should be considered if TTE imaging is inadequate or where the likelihood of endocarditis is of at least intermediate probability despite a negative TTE. TEE, because of its risk and invasiveness, should not be the primary method of excluding endocarditis when this is unlikely clinically. However, in certain situations in which a missed diagnosis might be catastrophic, such as in a patient with immune compromise, TEE should be considered, given its excellent negative predictive value. TEE may also be of value even in patients in whom a vegetation is evident on TTE in defining the presence of other complications and in helping decide the need for surgery. In one study in which patients with vegetations were subjected to serial TEE (100), failure of a vegetation to decrease in size on appropriate antibiotic therapy was associated with a significantly more complicated course.

Disease of the Aorta

TEE has become the technique of choice in many institutions in the diagnosis of acute dissection because of its high sensitivity, portability, and speed with which the diagnosis may be made (101). It is also used in diagnosis of aortic trauma and aortic atheroma. TEE is less often used as the primary diagnostic technique in evaluating other aortic pathologies, such as saccular aneurysm, which are effectively imaged by competing technologies such as computed tomography scanning and magnetic resonance imaging (MRI).

Aortic Dissection

TEE has been used as the sole diagnostic tool in the evaluation of suspected dissection, with excellent results (102). In one study of 45 patients who underwent TEE for evaluation of suspected dissection, only one required a further study for additional information (103). None of the 24 patients without evidence of dissection on their initial examination required additional investigation of their aorta over 2 years of follow-up. Other imaging modalities used in the assessment of aortic dissection include MRI, angiography, and computed tomography scanning (104). *e*Table 52.1.1 provides a summary of the relative strengths and weaknesses of these imaging tests in the diagnosis of dissection and its complications.

Diagnosis of Dissection

TEE has been reported to be more than 95% sensitive in the detection of aortic dissection in multiple studies (Fig. 52.11) (105,106 and 107). The detection rate reported is somewhat less for dissection involving the ascending aorta mainly because of the blind spot in the distal ascending aorta and proximal arch already described (105,108). The detection rate is also lower in patients who have had prior surgery of the aorta (109), when the dissection flap is very localized, or when the false lumen is thrombosed (110,111). The reported specificity of TEE in the detection of aortic dissection has varied from 68% to 100% (105,106 and 107,112). Studies that have shown perfect specificity have generally included only patients in whom the diagnosis was already established, whereas those with low specificity have used monoplane probes or less stringent criteria for diagnosis (106). False positives are most common in the ascending aorta and are often due to reverberation simulating a dissection flap (106,113). These may be minimized by the use of a biplane or multiplane probe (114). M-mode echocardiography is useful in timing and localizing reverberation (115). The presence of a flow disturbance on color-flow mapping at the site of the supposed dissection flap increases the likelihood of a true diagnosis. Recourse to other confirmatory techniques such as MRI or angiography should be made if the diagnosis is indeterminate by TEE (104). Operator experience is an important determinant of overall specificity.

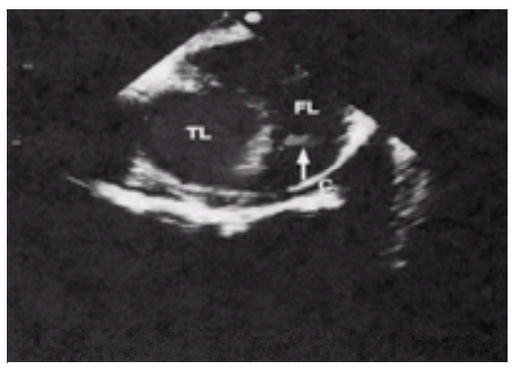
Assessment of Prognostic Features and Complications of Dissection

TEE provides important information concerning prognosis, complications, and surgical intervention in aortic dissection. Aortic dissection is most conveniently classified based on the presence (type A) or absence (type B) of a dissection flap in the ascending aorta. This classification is important prognostically. Type A aneurysms are considered for urgent surgery, whereas type B aneurysms are initially treated medically. The accuracy of classification of dissection by TEE has varied from 89% to 100% (102,112). Detection of the primary tear between the true and false lumen is important, as surgical plication of this communication may reduce and even obliterate flow in the false lumen and thus reduce the risk of late rupture. The primary entry site is most often in the ascending aorta and is detected in 73% to 89% of type A dissections (102,107). Other sites of communication between true and false lumen are frequently detected by TEE (eFig. 52.11.1).



***e*FIGURE 52.11.1** Communication (C) between true (TL) and false (FL) lumen in dissection involving the descending thoracic aorta.

Thrombus in the false lumen, a favorable prognostic feature, is also accurately detected by TEE. Important complications of dissection such as pericardial effusion, cardiac tamponade, the mechanism and severity of aortic regurgitation, and involvement of the coronary ostia are also accurately diagnosed by TEE. In one study, TEE correctly identified six of seven dissections involving the coronary ostia that were confirmed surgically (112). TEE can also detect other causes of chest pain when dissection is excluded. These include other aortic abnormalities and myocardial ischemia or infarction (116).

Limitations of Transesophageal Echocardiography in Dissection

Side branches, the head and neck vessels, and involvement of the abdominal aorta and branches and the distal coronaries are often not visualized by TEE. These are rarely crucial to surgical intervention for acute type A dissection. Supplemental imaging of the abdominal and head and neck vessels is possible with subcostal and suprasternal TTE. In chronic dissection, angiography and other imaging studies such as MRI may be performed to define the coronary anatomy and involvement of other branch vessels if surgery is planned.

Intramural Hematoma

Intramural hematoma is a hemorrhage into and confined to the medial layer of the aortic wall. This is distinct from a true dissection, in which there is communication between the media and aortic lumen through an intimal tear. Intramural hematoma has a similar prognosis to aortic dissection and may develop into a dissection over time. It may involve any portion of the aorta (117). TEE is superior to angiography in its detection (118). It is recognized by TEE as a crescentic thickening of the aortic wall that extends for a variable length (119), with displaced intimal calcium. Intramural hematoma is most often seen in elderly patients and may be difficult to differentiate from atherosclerotic changes or thrombosis of a localized dissection.

Penetrating Atherosclerotic Ulcer of the Aorta

Penetrating ulcer is associated with hypertension and atheroma and may present with chest or back pain. It frequently coexists with intramural hematoma and a limited dissection. It is recognized by TEE as a localized outpouching of the aortic wall, which may be calcified (120). Pseudoaneurysm formation may also occur. TEE was recently shown to detect 88% of penetrating ulcers that were confirmed at surgery or by another imaging modality (121).

Aortic Trauma

TEE has become an important tool in the rapid evaluation of aortic injury after major trauma. Aortic trauma most often involves the aortic isthmus just distal to the ligamentum arteriosum. Subadventitial disruption requires immediate surgical intervention and is recognized echocardiographically as a dense, thick, mobile flap that represents the disrupted intima and media. Asymmetric aortic enlargement is seen in this area due to the formation of a pseudoaneurysm. TEE can be performed rapidly and safely in trauma patients and is accurate in the detection of significant aortic disruption (122). Sensitivity and specificity of more than 90% have been reported in a number of studies of TEE in aortic trauma patients (122,123).

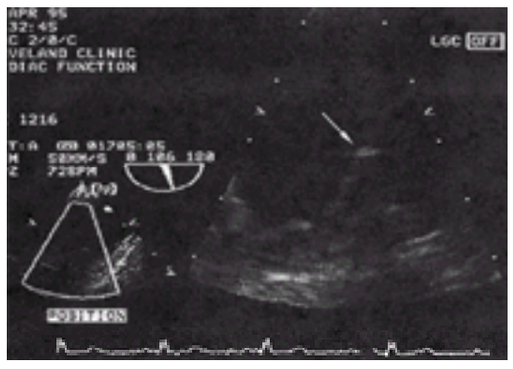
Video 52.32 A 120-degree intraoperative transesophageal echo of a patient with aortic insufficiency due to blunt trauma causing a flail left coronary cusp. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Aortic Atherosclerosis

Aortic atheroma is seen as echodense thickening of the intimal surface with superimposed thrombus or calcification in many instances. Involvement of the aorta varies from discrete plaques to diffuse thickening. TEE detection and classification of aortic atheromatous plaque shows good agreement with the pathologic findings (124). Aortic atheroma is most commonly seen in the descending thoracic aorta, less often in the aortic arch, and least often in the ascending aorta (125). Aortic atheroma on TEE is a sensitive marker of significant coronary disease (126) and of extensive peripheral vascular and carotid disease (127). Plaque in the aortic arch of more than 4 mm in thickness by TEE was an independent risk factor for ischemic stroke in one study (128). This risk appears to be lowered to a greater degree by oral anticoagulation rather than by antiplatelet drugs (129,130). Other studies have indicated that aortic atheroma on TEE increases the risk of perioperative stroke in patients undergoing bypass surgery and of atherogenic embolism after other procedures (131,132). The morphology of the plaque has independent predictive value. The likelihood of an embolic event is greatest with complex mobile plaque and least with sessile plaque (eFig. 52.11.2). In one study, complex atherosclerotic plaque was seen in 7% of 556 consecutive patients being evaluated by TEE. Systemic thromboembolism subsequently occurred in 73% of these patients but only in 12% of those with sessile plaque (133). Protruding atheroma was an independent risk factor for stroke in another study (134). Complex atheroma has been shown to be associated with a high prevalence of high-intensity transient signals in cerebral arteries, which further supports its role in cerebral embolism (135). The presence of spontaneous contrast in the aorta is an independent embolic risk factor (136) as well as a risk factor for cardiac mortality (137). Recently, mobile thrombus has been detected by TEE in younger patients with systemic embolism in the absence of diffuse aortic atheroma. Underlying atherosclerosis at the insertion site of the thrombus has been demonstrated histologically in patients who have undergone surgical removal of the thrombus (138).



***e*FIGURE 52.11.2** Mobile aortic atheroma (*arrow*).

Other Aortic Conditions

TEE can characterize thoracic aneurysms involving the sinuses of Valsalva and the ascending and descending aorta. It is useful in improving the resolution of sinus of Valsalva aneurysm and in detecting communication with individual cardiac chambers.

Video 52.33 A magnified 103-degree transesophageal long axis view **(A)** of a ruptured sinus of Valsalva aneurysm of the right sinus of Valsalva. Note the remnant thinned, aneurysmal wall of the sinus bowing into the right ventricle (towards the bottom of the screen). Color Doppler interrogation of the aortic valve with sinus of Valsalva in a transesophageal long-axis view **(B)**. Note there is moderate anteriorly directed aortic insufficiency at the top of the screen, and the aortic to right ventricular shunt through the ruptured sinus of Valsalva aneurysm is seen at the bottom of the screen. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.34 A magnified 103-degree transesophageal long axis view **(A)** of a ruptured sinus of Valsalva aneurysm of the right sinus of Valsalva. Note the remnant thinned, aneurysmal wall of the sinus bowing into the right ventricle (towards the bottom of the screen). Color Doppler interrogation of the aortic valve with sinus of Valsalva in a transesophageal long-axis view **(B)**. Note there is moderate anteriorly directed aortic insufficiency at the top of the screen, and the aortic to right ventricular shunt through the ruptured sinus of Valsalva aneurysm is seen at the bottom of the screen. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Native-Valve Disease

Transthoracic imaging can usually provide a complete anatomic and hemodynamic profile of abnormal valves. TEE is used in addition when improved resolution of valve structure is needed or when the hemodynamic severity of a regurgitant lesion is in question. Assessment of valve lesions to determine their suitability for repair or

reconstruction is an increasing indication for TEE during cardiac surgery.

Video 52.35 Transesophageal echo in a patient with a subvalvular membrane in the left ventricular outflow tract. Note the normal mobility of the aortic valve. This patient had a significant pressure gradient across the left ventricular outflow tract/AV. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.36 Four-chamber transesophageal view of a patient with a cystic-appearing mass on the tricuspid valve. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.37 Transesophageal four-chamber view focusing on the tricuspid valve showing myxomatous tricuspid valve disease with severe prolapse causing severe tricuspid regurgitation (pre-operative). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.38 Transesophageal echo of a patient with congenital pulmonary stenosis. Note the severe hypertrophy of the right ventricular outflow tract, causing infundibular pulmonary stenosis as well as valvular pulmonary stenosis. The pulmonic leaflets are thin and pliable; however, there is marked doming caused by tethering of the leaflet tips. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

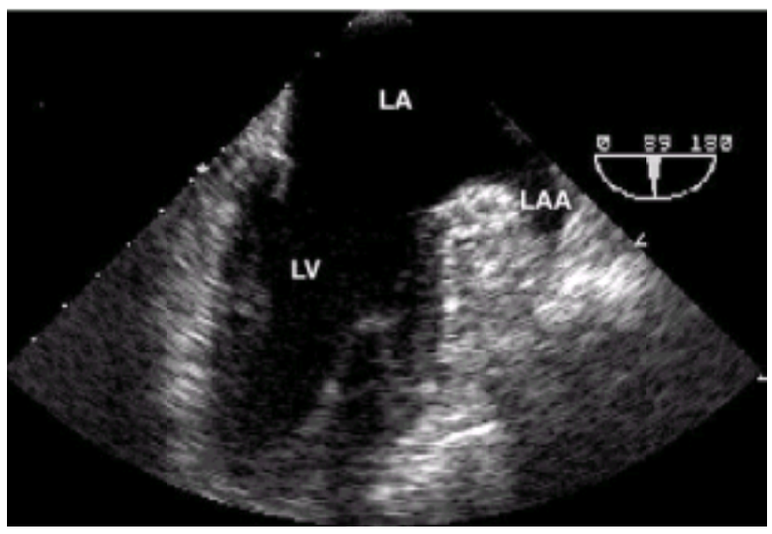
Video 52.39 Transgastric view (transesophageal echo) of the mitral valve in a patient with severe aortic insufficiency. Note the fluttering of the anterior mitral leaflet (*left*) due to the jet of aortic insufficiency hitting it (color flow seen on the left). (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.40 Long-axis 120-degree transesophageal view of a rheumatic aortic valve with central aortic insufficiency due to furled, restricted leaflets. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.41 Transesophageal echo with color Doppler showing tricuspid regurgitation after a myocardial biopsy of the right ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.42 Apical long-axis view of a patient with severe left ventricular dysfunction and annular dilatation causing 4+, centrally directed mitral regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 52.43 Transesophageal echo demonstrating a flail tricuspid valve after right heart biopsy in a transplant patient. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



A 90-degree transesophageal echo demonstrating the left ventricle and mitral valve in diastole. The anterior wall is to the right of the screen while the inferior wall is to the left and the mitral valve in the center and the left atrium at the top of the screen. The left atrial appendage (LAA) is at the far right of the image.

Mitral Valve

TEE is highly sensitive and specific in the detection of flail mitral valve leaflets and chordae and is superior to TTE in differentiating flail leaflets from vegetations (139,140). TEE is also superior in defining the mechanism of regurgitation, the site of regurgitation, the likelihood of repair, and a subset of patients at greatest risk for the development of complications such as systolic motion of the mitral valve after repair for myxomatous disease (141,142 and 143). It is more sensitive than either TTE or angiography in the detection of mitral regurgitation (Fig. 52.12). In one study, mitral regurgitation was present on TEE in 25% of patients in whom it could not be detected by TTE, and in 14% of these patients the regurgitation was at least of moderate severity (144). The superior ability of TEE to detect mitral regurgitation is most marked in critically ill ventilated patients with acute ischemia or infarction (145). TEE is superior to transthoracic echo in the detection of papillary muscle rupture in this population (146). Multiplane TEE is superior to TTE in the detection of eccentric regurgitant jets (114). The size of the regurgitant jet on color-flow mapping often appears larger by TEE than by TTE (147). This discrepancy is attributable to the proximity of the jet to the transducer and the higher carrier frequency of the Doppler used by TEE. When the area of high-velocity turbulent, or “mosaic,” flow alone is used in the assessment of regurgitant severity, a good correlation with angiographic grading is noted (148).

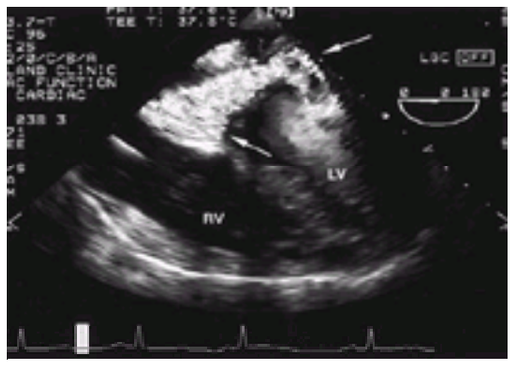


FIGURE 52.12 Severe anteriorly directed mitral regurgitation due to a flail posterior leaflet (*arrows*) imaged in the transverse four-chamber view. LV, left ventricle; RV, right ventricle.

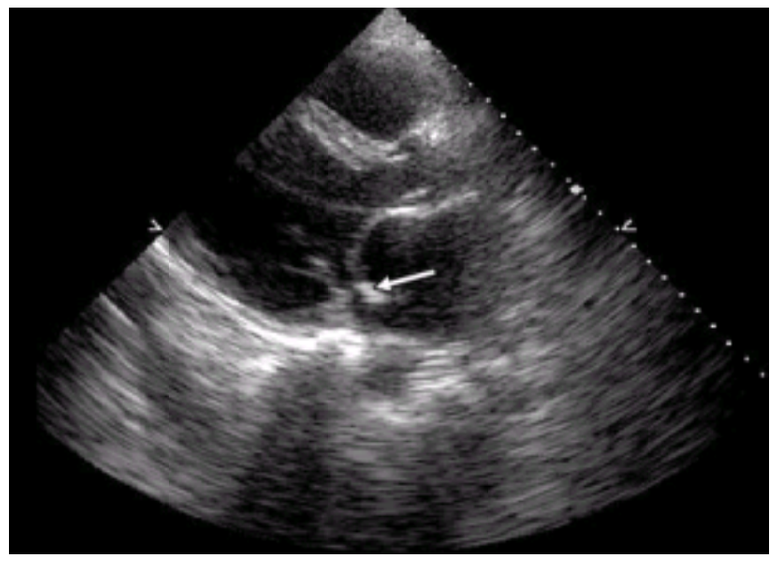
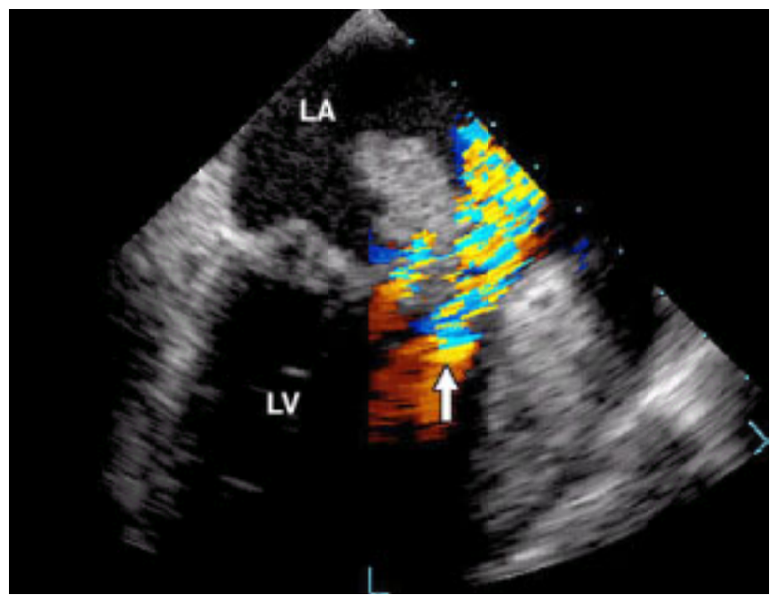
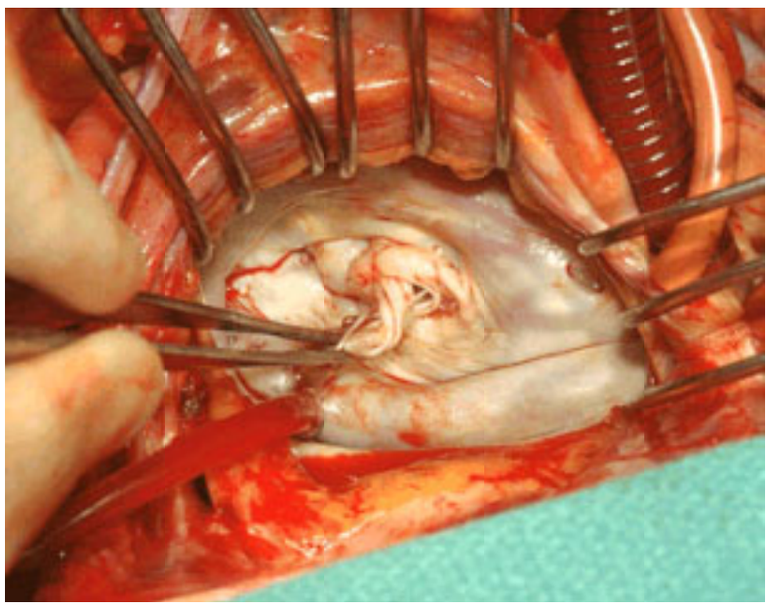
Video 52.44 Intraoperative 0-degree transesophageal echo showing a flail posterior mitral leaflet from a patient with myxomatous valve disease. Note the movement of the torn chordae attached to the tip of the leaflet (see color Doppler assessment). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Parasternal long-axis view of a papillary muscle rupture after myocardial infarction. Note the piece of papillary muscle attached to the tip of the anterior mitral leaflet as it flails into the left atrium (demonstrated by the arrow).



Color Doppler showing a perforation of the base of the anterior mitral leaflet from *Streptococcus* endocarditis. The patient’s underlying pathology was myxomatous mitral valve disease with mitral valve prolapse. The proximal flow convergence of the mitral regurgitation jet is demonstrated by the arrow at the orifice of the large perforation.



Intraoperative field demonstrating a mitral valve with a torn papillary muscle prolapsing across the mitral valve into the left atrium. The surgeon has the papillary muscle in forceps demonstrating the chordae attached to the posteromedial commissure, predominantly attached to the anterior mitral leaflet. (The patient's head is to the left of the screen and feet to the right.)

Surgical pathology specimen demonstrating a torn papillary muscle seen to the lower right of the screen, attached via chordae to a portion of the anterior mitral leaflet. Note the torn "ragged edges" at the bottom of the papillary muscle head.

VIDEO

Video 52.45 Color Doppler of 0-degree intraoperative transesophageal echo with prolapse and flail of the posterior mitral leaflet causing very eccentric, anteriorly directed mitral regurgitation. This valve was successfully repaired. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 52.46 Postpump echo (with color Doppler) after repair of the flail posterior mitral leaflet. There is a Cosgrove-Edwards annuloplasty ring in place. There is no residual mitral regurgitation and there is no systolic anterior motion of the mitral leaflets, which can sometimes complicate mitral valve repair. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 52.47 Intraoperative transesophageal echo showing bileaflet prolapse of the mitral valve. The color Doppler showed centrally directed mitral regurgitation. VIDEO

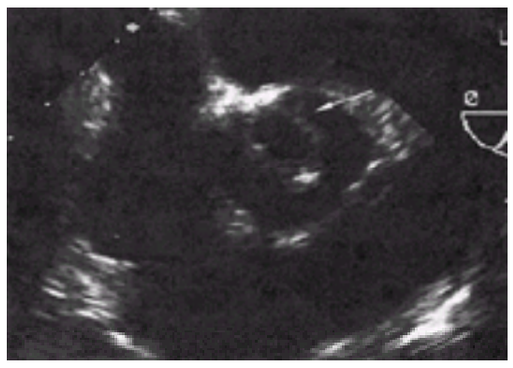
Video 52.48 Intraoperative 120-degree transesophageal echo of a flail posterior mitral leaflet prior to repair (two-dimensional). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Parameters other than regurgitant jet size are available with TEE in assessing severity of mitral regurgitation. These include the size of the regurgitant jet at its origin and the size of the area of flow acceleration just proximal to the regurgitant orifice (proximal flow convergence area). Both of these relate well to the size of the regurgitant orifice area and are less dependent on loading conditions than regurgitant jet area or length (149,150). Analysis of pulmonary vein flow is a useful parameter in confirming the severity of mitral regurgitation. High-quality Doppler recordings of both left and right pulmonary veins are readily obtained by TEE (151,152). Systolic flow reversal in a pulmonary vein is an accurate marker of severe mitral regurgitation. Blunting of the systolic flow is suggestive of significant mitral regurgitation in the setting of normal ventricular function and normal sinus rhythm but is unreliable otherwise (153). Quantification of mitral regurgitation is usually possible by TEE with methods based on both pulsed Doppler and the proximal flow convergence area with TEE (154,155). Planimetry of the mitral orifice in cross-section in mitral stenosis is more difficult with TEE than with TTE but is sometimes possible with multiplane imaging.

Aortic and Other Valves

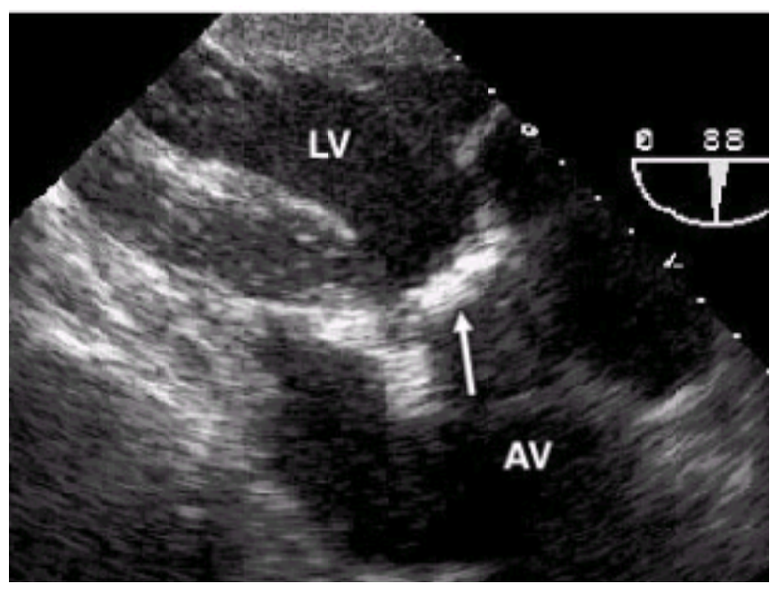
Multiplane TEE has facilitated imaging of the aortic valve and allows the true long and short axis to be acquired. High-resolution images obtained by this technique are useful in diagnosing a bicuspid valve or other structural abnormality when TTE is uncertain (eFig. 52.12.1). In a recent study with operative corroboration, multiplane

TEE was significantly better than TTE at detection of bicuspid aortic valves, with a sensitivity of 87% and specificity of 97% in their detection (156). Subaortic stenosis, especially subaortic membrane, is often better imaged by TEE than by TTE (eFig. 52.12.2) (157). Interrogation of the aortic valve with continuous-wave Doppler in the standard TEE imaging planes is more difficult than with transthoracic imaging. Planimetry of the aortic valve orifice is also feasible in many instances with multiplane transducers, and excellent agreement has been reported between the valve area planimetered by TEE and that measured at cardiac catheterization or by TTE (158). TEE provides excellent images of the tricuspid and pulmonary valve. However, the anterior situation of these structures in the chest allows adequate imaging in most circumstances by TTE, with little incremental benefit from TEE.

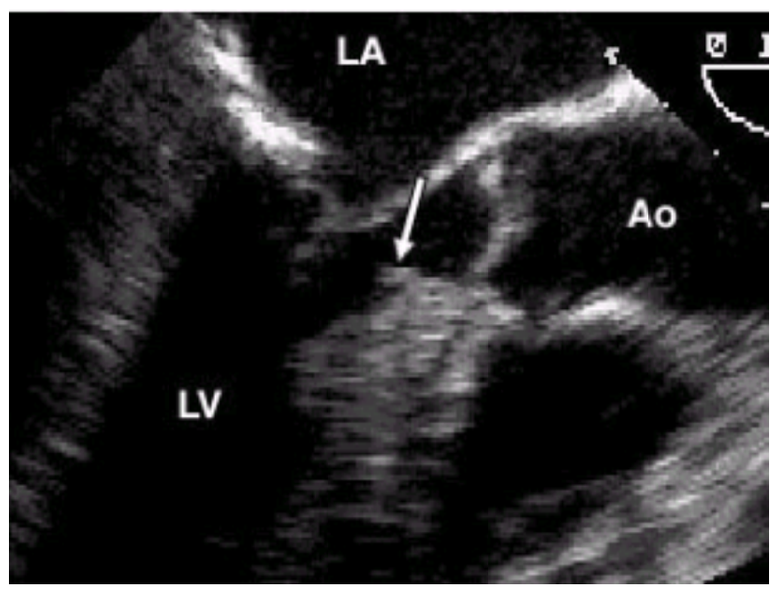


***e*FIGURE 52.12.1** Multiplane short-axis image of unicuspid aortic valve in systole (*arrow*).

***e*FIGURE 52.12.2** Narrowing of left ventricular outflow tract due to subaortic membrane (*arrow*). AO, aorta; LV, left ventricle.



Deep transgastric transesophageal echo view of the aortic valve in a patient with aortic stenosis. Note the heavily calcified aortic valve in the center of the screen (*arrow*), the posterior wall is at the top of the screen and the anterior/anteroseptal wall is towards the bottom. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)



Transesophageal echo at 120 degrees of the aortic valve with a subaortic membrane in the left ventricular outflow tract (designated by the arrow).

Prosthetic Valves

TEE allows improved resolution of prosthetic leaflets and regurgitation both at mechanical and bioprostheses as compared with TTE (83,159). In one study of 148 prosthetic valves (113 bioprostheses and 35 mechanical prostheses) in which abnormality was confirmed pathologically, TEE and TTE were 86% and 57% sensitive, respectively, in the detection of abnormalities (83). TEE was superior to TTE in the detection of abnormalities at mechanical prostheses (83% vs.22%), bioprostheses (87% vs. 65%), aortic prostheses (77% vs. 50%), and mitral prostheses (97% vs. 65%) (83). TEE may detect thrombus in patients with mechanical mitral valves that is clinically unsuspected but that is a risk factor for thromboembolic events (160).

Video 52.49 Transesophageal 138-degree view showing the Carpentier-Edwards mitral valve replacement with thickened leaflets with multiple mobile echo densities consistent with vegetations and a clot in a patient with prosthetic valve endocarditis. The mean transesophageal gradient was 20 mm Hg on surface echo. Note the

large left atrial thrombus to the right of the screen with significant spontaneous echo contrast in the left atrial cavity. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

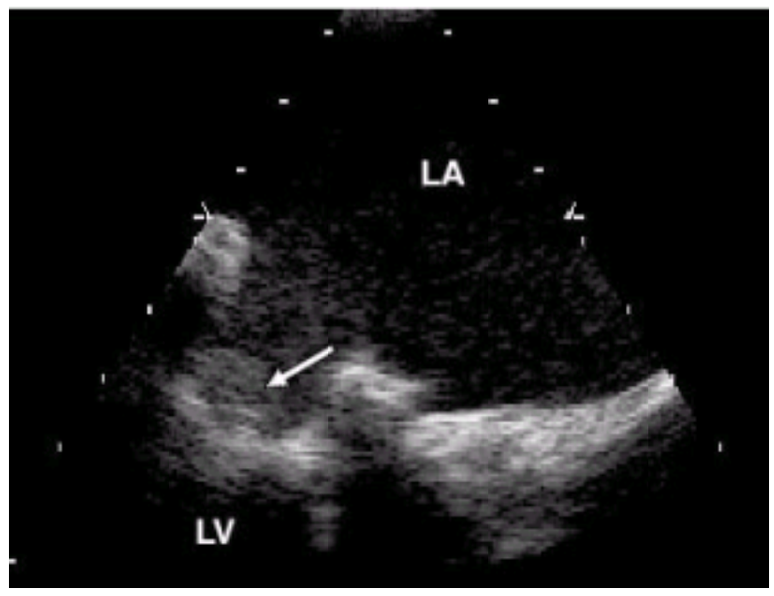
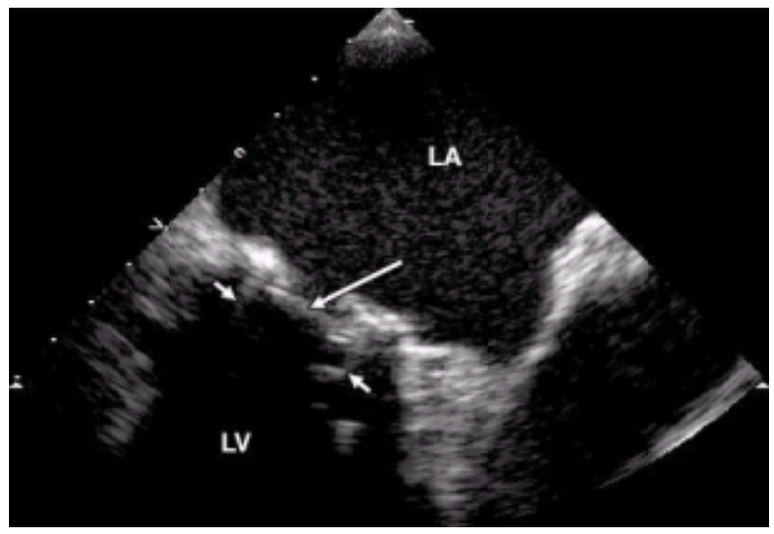
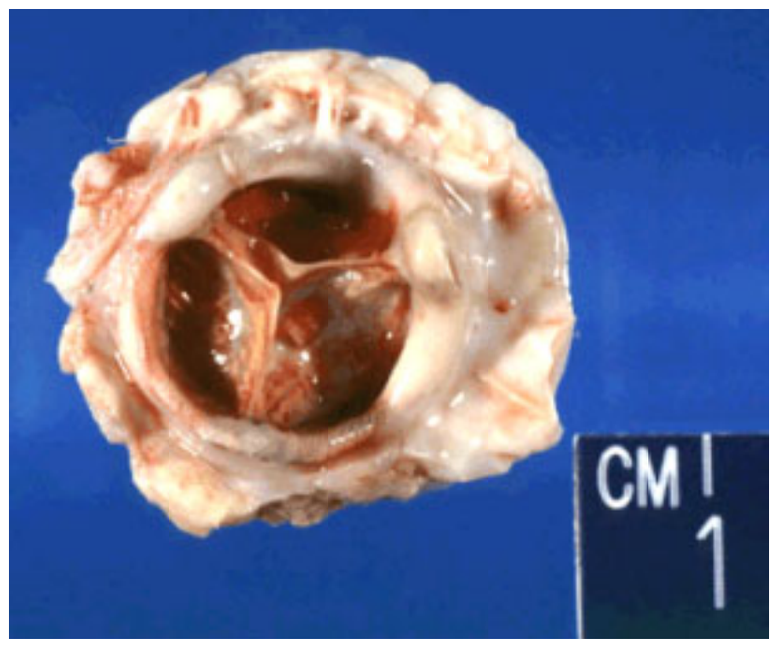
Normal St. Jude valve in the mitral position.



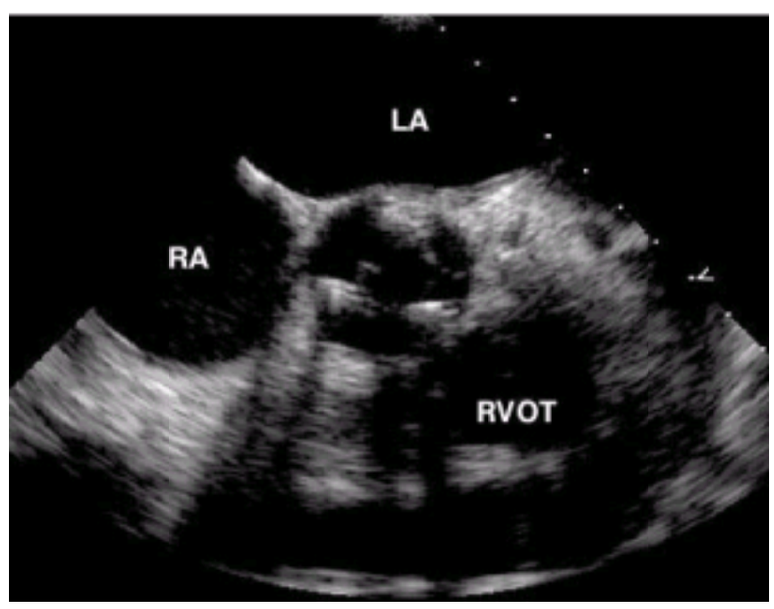
Magnified transesophageal view of a Starr-Edwards prosthesis (ball-and-cage valve) in the mitral position. This image was taken in systole with the ball (shown by the arrow) in the ventricular side of the cage.



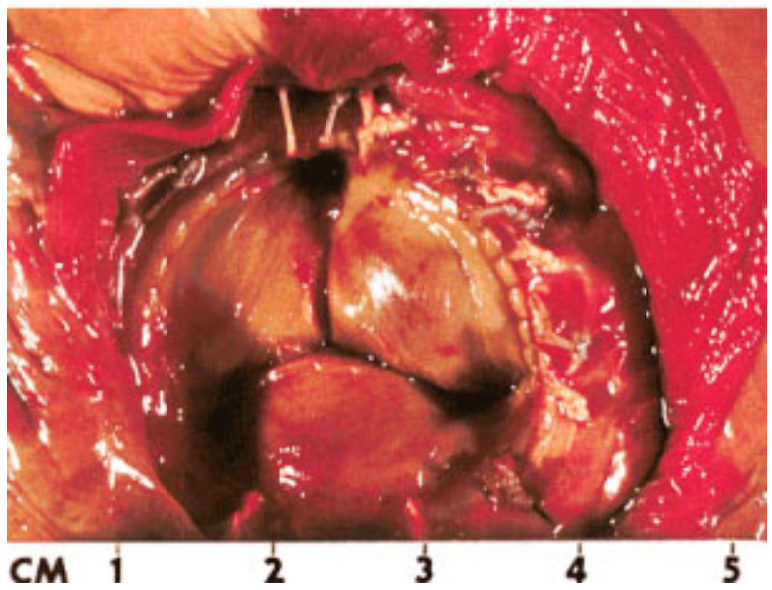
Beall mitral valve prosthesis showing the single disc within the cage in a 90-degree transesophageal view. The single arrow demonstrates the single disc of the prosthesis, and the two small arrows show the cage in which the disc is held.



Porcine prosthetic valve with severe fibrosis. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)



A short axis –60 degree transesophageal echo of a Carpentier-Edwards (CE) aortic valve. One can see the three mobile leaflets suspended from the struts.



Porcine prosthetic mitral valve. In this example, the valve is normal and the suture line is intact.

Prosthetic Regurgitation

A small amount of regurgitation occurs normally at mechanical prostheses by design. This is readily detected by TEE and less often by TTE. The pattern of regurgitation is specific to individual prosthetic types and is usually easily differentiated from abnormal regurgitation by the relative low velocity, short duration, and small size of the normal jets (161). Abnormal regurgitation at mitral prostheses is more reliably detected by TEE than TTE, but TEE's superiority in this regard is less for aortic prostheses (159,162). TEE is also more accurate than TTE in defining the origin of the prosthetic regurgitation (162,163). Prosthetic regurgitation, especially when paravalvular, is associated with intravascular hemolysis (Fig. 52.13). Regurgitant jets that produce a high shear stress on red blood cells and consequent hemolysis may be characterized using TEE (164). Structural abnormalities leading to regurgitation such as flail bioprosthetic leaflets are more also more reliably detected by TEE than by TTE (84).

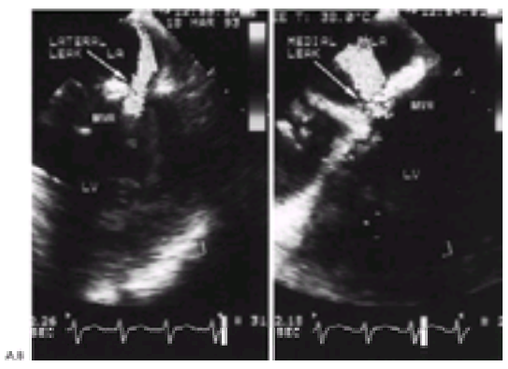


FIGURE 52.13 Two periprosthetic regurgitant leaks [lateral, **(A)**; medial, **(B)**] at a mitral mechanical prosthesis (MVR) demonstrated by multiplane transesophageal echocardiography. LA, left atrium; LV, left ventricle.

VIDEO

Video 52.58 Physiologic regurgitation of a St. Jude's mechanical valve in the mitral position. Transesophageal echocardiography demonstrates two converging regurgitant jets in the left atrium (LA). VIDEO

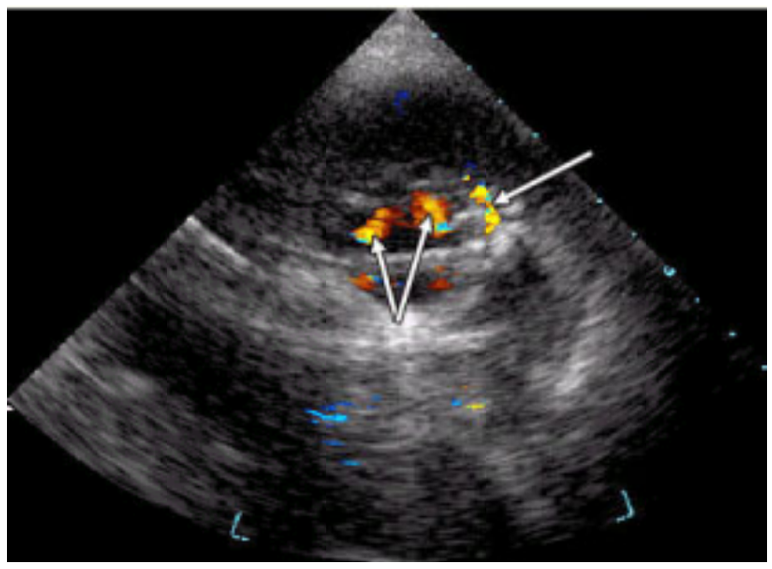
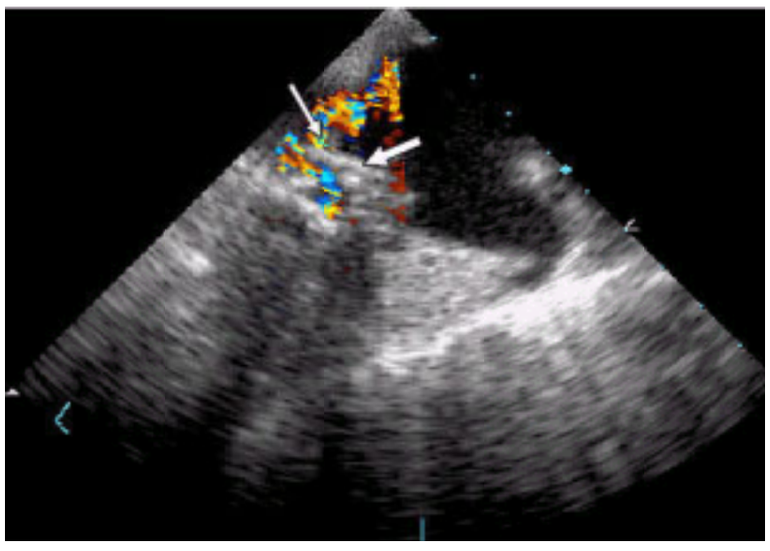
Video 52.60 Intraoperative transesophageal echo (transgastric short-axis view) of a CarboMedics mitral valve replacement with both physiologic prosthetic mitral regurgitation (two jets from within the sewing ring) and an abnormal, lateral paravalvular jet (outside the sewing ring to the right of the screen). Note that the paravalvular jet is arising between the sewing ring and an area of mitral annular calcification, making it difficult for the prosthesis to be in close contact with the annulus. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Transgastric short-axis view during intraoperative transesophageal echo of a paravalvular leak of a CarboMedics mitral valve replacement. Note the two normal physiologic prosthetic jets of mitral regurgitation (within the sewing ring) as designated by the double arrow and the one abnormal, laterally originating jet outside the sewing ring (to the right of the screen) designated by the single arrow. There was significant mitral annular calcification (MAC),

aking it difficult to achieve close contact between the annulus and the sewing ring.



Intraoperative transesophageal echo in a patient with a Carpentier-Edwards prosthesis in the mitral position with infectious endocarditis. There is a paravalvular jet of mitral regurgitation (*thin arrow*), and the mitral prosthesis (*thick arrow*) is rocking. (The left atrium is towards the upper right of the screen, and the left ventricle is to the lower left.)

Prosthetic Stenosis

TEE is an important diagnostic tool in the assessment of prosthetic stenosis, especially at mechanical valves. Although TTE is used to characterize the valve gradients, TEE provides incremental information on structural abnormalities of the valve leaflets or sewing ring once stenosis is suspected. TEE is especially useful in the detection of thrombus on the prosthetic leaflets (165). Thrombus may not be apparent on TTE and may occur despite normal prosthetic gradients. In one study, TEE detected thrombus on a mechanical valve in 13% of 114 patients in whom it was unsuspected by TTE (165). In another study, TEE detected all eight prosthetic thrombi (100%), whereas TTE detected only one (13%) of them (83). TEE is useful in prediction of the response of thrombus to thrombolytic treatment, which is more likely to be successful with nonobstructive thrombus rather than when the thrombus is completely occluding the prosthesis (166). It is also useful in detecting resolution of thrombus after thrombolytic infusion and the need for further thrombolytic infusion (167). TEE also helps in identifying thrombus from pannus at mechanical valve prostheses (168,169). The high resolution of TEE may detect features on prosthetic valves of uncertain significance, which are not seen with other imaging modalities. Microbubbles are frequently seen emanating from mechanical prostheses, especially at mitral tilting-disc prostheses. These are thought to be due to cavitation of erythrocytes and are often a normal finding (170). Filamentous strands have also been detected on mechanical and even biologic prostheses (171,172). The precise nature and significance of these strands are uncertain.

VIDEO

Video 52.61 Frozen St. Jude prosthetic valve leaflet **(A)**. Image was obtained 5 days postoperative with suspected prosthetic valve dysfunction by echocardiography. Transesophageal Echocardiography to Detect Source of Embolism

The leading indication currently for TEE in most medical centers is in the evaluation of source of embolism. The prevalence of potential source of embolism in those undergoing TEE for evaluation of prior embolic event compared with those without a history of embolism is shown in *e*Fig. 52.13.1.

Video 52.67 Thrombosis of bioprosthetic valves in the mitral and tricuspid position (*arrows*) in a patient with antiphospholipid syndrome in the early postoperative period demonstrated by transesophageal echocardiography. ***e*FIGURE 52.13.1** Bar diagram comparing prevalence of potential source of embolism in those with and those without a history of cerebral ischemia. ASA, atrial septal aneurysm; LASC, left atrial spontaneous contrast; LAT, left atrial thrombus; PFO, patent foramen ovale.

Incremental Value of Transesophageal Echocardiography over Transthoracic Echocardiography

The yield of TTE in the evaluation of cardiac source of embolism is greatest in those with known cardiac disease (173). One study found that a cardiac source of embolism was as likely to be detected by TTE in a matched control population without a history of embolism as in those with an embolic history (174). A number of studies have indicated that TEE is more likely than TTE to detect a potential cardiac source of embolism in patients with cerebral ischemia (68,175,176). Additional potential causes of embolism detected more often by TEE than TTE include left atrial thrombus, left atrial spontaneous contrast, patent foramen ovale, ASA, valvular strands, vegetations, and aortic atheroma. TEE is more likely than TTE to detect a source of embolism in patients without a prior cardiac history. In one study of 79 patients with cerebral ischemia in the absence of cerebrovascular disease, a cardiac source of embolism was detected in 15% by TTE and in 57% by TEE (68). In patients without a cardiac history, a potential source of embolism was detected by TEE in 39% and in 19% by TTE. In another study of 50 patients without cerebrovascular disease with recent stroke or transient ischemic attack, TEE detected a potential source of embolism in 52% of all patients and in 33% of those without a cardiac history whereas TTE failed to detect a cardiac source of embolism in any patient (176). The finding of a source of embolism on TEE may have prognostic value in predicting recurrent events. In a prospective study of 145 patients with cerebral ischemia, TEE detected a source of embolism in 45% of those with unexplained stroke or transient ischemic attack. Recurrent cerebral ischemia was more common in patients with a TEE-detected source of embolism over a follow-up period of 18 months (177). Stratification of risk after stroke by TEE was highly predictive of subsequent events and death in a study of a group of patients without major clinical cardiac risk factors such as severe left ventricle dysfunction and atrial fibrillation (178). However, in contrast, a multicenter study of the use of TEE to assess embolic risk in patients with atrial fibrillation found that on univariate analysis, atrial size and thrombus were predictors of subsequent embolic events but that in multivariate analysis none of the TEE predictors were included. Independent risk factors of subsequent events were age, prior stroke, and hypertension (179).

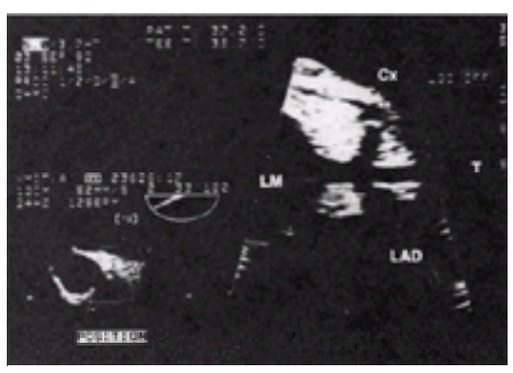
Indications for Transesophageal Echocardiography to Detect Source of Embolism

TEE is widely used in the assessment of cardiac source of embolism but its true usefulness in this setting is often in doubt. Many patients with unexplained embolic events are anticoagulated initially regardless of the echocardiographic findings. TEE, therefore, may be unnecessary in such patients. However, the usefulness of TEE as an initial diagnostic tool in patients with new-onset stroke has recently been supported by a cost-effectiveness study. A strategy in which TEE was used initially rather than TTE was more cost-effective in defining strategies that could reduce the risk of recurrent stroke (180). A number of small studies of the management implications of TEE in source of embolism have been reported. In one prospective study of 30 patients, TEE was thought to have changed management in only three of them (181). In another retrospective study of 39 patients with cerebral ischemia, TEE changed management in four (10%) and confirmed decisions about anticoagulation in 19 patients (49%). In 41% of patients, TEE had no effect on management decisions because of the overriding effect of other clinical information (182). Preliminary data from the VOTE study (Value of Transesophageal Echocardiography), which is investigating the usefulness of TEE in the management of cerebral ischemia, suggest that TEE alters the clinical management in 27% of patients and drug treatment in 16% (183). Prospective larger studies of the role of TEE in management of patients with suspected cardiac source of embolism are awaited (183).

TEE is unnecessary in the assessment of all patients with a potential cardiac source of embolism. Situations in which information from TEE is mostly likely to be of value include (a) younger stroke patients (younger than 60 years) without a history of cerebrovascular disease or obvious embolic source, (b) recurrent embolic events, (c) anticoagulation with a higher than normal risk due to comorbidities, (d) presence of prosthetic valve, and (e) suspected endocarditis.

Coronary Disease

TEE, although not a primary imaging modality for coronary disease, is capable of imaging the ostia and variable portions of the coronary tree. It can identify coronary anomalies and may detect and quantify coronary stenoses. The coronary vessels are most readily imaged in the basal short-axis view (*e*Fig. 52.13.2).



***e*FIGURE 52.13.2** Coronary vessels imaged by multiplane transesophageal echocardiography. Cx, circumflex; LAD, left anterior descending; LM, left main coronary; T, trification branch.

Imaging of Normal and Diseased Vessels

The left main coronary artery and proximal portions of the left anterior descending and circumflex artery are imaged in the majority of patients (184,185). The proximal right coronary artery is more difficult to image (184). Mid and distal portions of vessels are adequately imaged only in a minority, even with multiplane transducers (184). Coronary stenoses may be detected as areas of narrowing or of flow disturbance with Doppler (186). In one study, the left main coronary could be imaged in 90% of 67 patients. TEE identified 10 of 11 significant stenotic lesions, for a sensitivity of 91% and specificity of 100% (187). Other studies suggest that TEE can detect stenotic areas with reasonable accuracy in those portions of vessels that are adequately imaged (184,185). TEE is useful in confirming left coronary ostial stenosis when this is suspected at catheterization (188). It is also accurate in the detection and classification of anomalous coronary origin and fistula formation and of aneurysm formation (189,190).

Stress Imaging

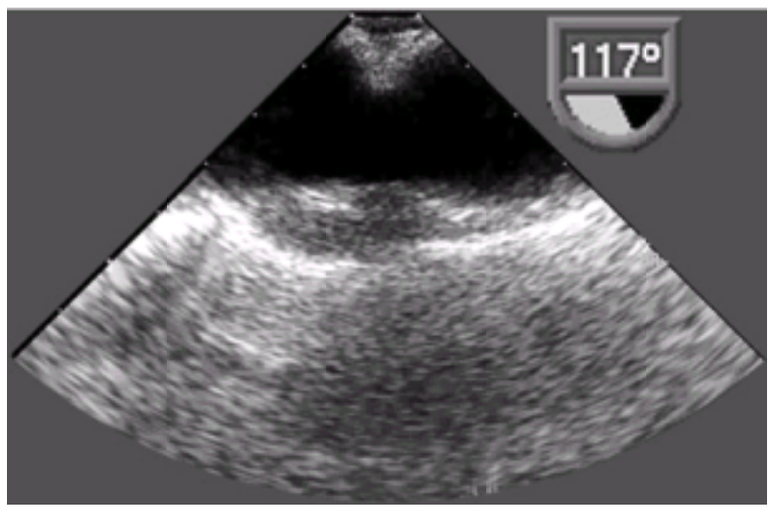
The transesophageal imaging window has been used to perform stress echocardiography. Excellent short- and long-axis images are obtained from the transgastric window, and all three major coronary territories are represented in this view (191). Excellent endocardial resolution is usually obtained, which facilitates detection of ischemic wall motion abnormalities. One limitation with TEE imaging is the evaluation of ischemia at the cardiac apex, which may be difficult to visualize even with multiple imaging planes. Esophageal pacing, intravenous vasodilators such as adenosine and dipyridamole (192), and inotropic agents such as dobutamine have been used to produce ischemia (193,194 and 195). A sensitivity and specificity of more than 80% in the detection of coronary disease have been reported for all of these stress TEE methods (193,194,196). The increased invasiveness of stress echocardiography from the transesophageal approach has limited its widespread application. Clinical use of TEE stress echocardiography has been confined to those in whom adequate images are not available from TTE, especially morbidly obese patients who cannot be evaluated by other methods (197).

Assessment of Coronary Flow Reserve

It is possible to measure flow velocity in individual large coronary vessels by pulsed Doppler (198). This is most often feasible in the left anterior descending artery and is facilitated by intravenous contrast agents, which cross the pulmonary circulation into the left heart (199,200). Coronary flow reserve has been estimated from the increase in flow produced by a coronary vasodilator such as adenosine or dipyridamole (198). Flow reserve in other disease states such as hypertrophic cardiomyopathy, aortic regurgitation, and syndrome X has also been assessed by TEE (201,202).

Transesophageal Echocardiography in Pediatric Cardiology and in Adult Congenital Heart Disease

Excellent TTE images are usually available in children. Nevertheless, TEE may provide additional diagnostic information in specific instances. Difficulty in passing the TEE probe in the pediatric population may occur with congenital esophageal anomalies such as atresia or with vascular rings. A number of studies have indicated that TEE is safe in neonates and young children, although general anesthesia is usually required (203,204). TEE has represented a significant advance in the evaluation of adults with congenital heart disease with complex anatomy (205,206 and 207). TEE is more reliable than TTE in the determination of atrial situs (203), in defining abnormalities in the systemic and pulmonary venous connections (208), and in defining the morphology of the chordal apparatus of atrioventricular valves (209). TEE long-axis imaging planes of right and left ventricular outflow tract often provide better definition than TTE of the site and nature of obstruction in the subvalvar area and in the pulmonary artery or aorta (204,207,210). It is also superior to TTE in detecting abnormalities of flow or leaks across the atrial baffle after Mustard or Senning procedures (211) and in identifying complications of the Fontan procedure (212,213). Complications associated with ventriculopulmonary conduits such as stenosis, regurgitation, or endocarditis are often best detected by TEE, especially in adults (204).



A still frame of a transesophageal echo demonstrating a coarctation of the aorta. Note the local narrowing of the aorta located at the junction of the distal arch and descending aorta. There was a 100–mm Hg pressure gradient across the coarctation as determined by continuous wave Doppler.

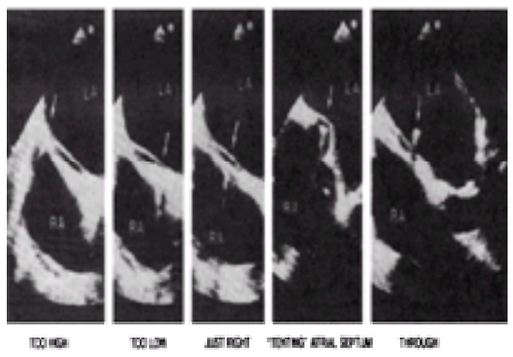
Transesophageal Echocardiography in Critically Ill Patients

TEE frequently provides vital information in the critically ill patient (191). Such patients often have inadequate TTE windows because of mechanical ventilation or dressings and may be too ill to undergo alternative imaging procedures such as computed tomography scanning or MRI. In one study, TTE was inadequate for diagnosis in 64% of intensive care unit (ICU) patients, whereas TEE was suboptimal in only 3% (214). The major indications for TEE in the critically ill patient include diagnosis of unexplained hypotension, suspected endocarditis, native and prosthetic valvular dysfunction, complications of myocardial infarction, source of embolus, pulmonary embolization, suspected dissection, and suspected tamponade (215,216). TEE may add information to TTE in between 25% to 59% of critically ill patients and alter the treatment plan in up to 25% of patients (215,217,218). In ICU patients with hypotension, TEE diagnosis of the cause of hypotension is prognostically powerful. Patients with reduced cardiac output because of valvular or pericardial disease have the best prognosis, whereas those with noncardiac disease or ventricular failure have a poorer outcome (214). TEE may also be of value in hemodynamic assessment in the ICU setting. Chamber volume can be estimated on a beat-to-beat basis using automated border detection algorithms based on changes in chamber area (219). Quantification of ejection fraction (220) and other volumetric indices using automated edge detection techniques has shown reasonable correlation with reference techniques.

Specific critical care situations in which TEE is superior to TTE include the detection of thrombus behind the right atrium that is compromising filling after open-heart surgery (221), the exclusion of significant cardiac abnormalities in potential cardiac donors (222), and the detection of the cause of a new systolic murmur in acute myocardial infarction. TEE is also highly sensitive in the detection of cardiac abnormalities in patients with blunt chest trauma (223). TEE has been used during cardiopulmonary arrest to determine the cause of the event and to evaluate the mechanism and adequacy of closed-chest compression in providing a forward cardiac output (224,225).The accuracy of TEE in diagnosis of the cause of the event is reported at 87%, and it may alter management in up to one in three cases in which it is used (226). It is also often diagnostic in patients with suspected acute pulmonary embolism (227,228). Thrombus in transit in the right heart and proximal pulmonary vessels is accurately detected, but distal pulmonary thromboembolism is not. TEE is reported to be 97% sensitive and 88% specific in the detection of central thromboembolism (227). However, artifact simulating thrombus in the pulmonary arteries is common, and the diagnosis of pulmonary thromboembolism should be entertained only in the appropriate clinical setting and after scanning in multiple planes. TEE may also detect thrombus *in situ* in the central pulmonary arteries of patients with significant chronic obstructive pulmonary disease in the absence of both pulmonary hypertension and pulmonary embolism, which are presumed to be a consequence of atherosclerotic disease in the pulmonary arteries of these patients (229).

Transesophageal Echocardiography in Interventional Cardiology

TEE has been used as a monitoring and diagnostic tool during many types of interventional procedure, although it is not absolutely required for any of these. Its major advantage is that it allows continuous imaging of structures of interest without interfering with the procedure. Although it is performed in awake patients in the supine position who are lightly sedated, it is well-tolerated, and few complications have been reported. The major indication for TEE in interventional cardiology is balloon valvuloplasty of the mitral valve (230). TEE is of value in optimizing the site of septal puncture and balloon placement within the mitral valve (eFig. 52.13.3). It can also determine the immediate effect of sequential balloon inflation on mitral valve structure, gradient, area and mitral regurgitation. Periprocedural complications may be rapidly detected. These include thrombus formation on catheters or at the site of endothelial injury, valve disruption, and pericardial effusion and tamponade (231). TEE is more sensitive than either oximetry or TTE in detecting a residual arterial septal defect after the septal puncture (64). TEE is also useful in percutaneous catheter closure of septal defects and patent ductus arteriosus (232,233). The exact position of the closure device can be ascertained and positional adjustments made to minimize residual shunt flow. Other interventional techniques in which TEE has been used include endomyocardial biopsy, electrophysiologic ablation procedures, and septostomy and other procedures in the pediatric group (234,235 and 236). TEE can assess the results of balloon dilatation of coarctation and intimal dissection, which commonly occurs with this procedure (237). It may be used instead of fluoroscopy in positioning catheters or pacemakers when radiation exposure is best avoided, such as in pregnancy (238).



***e*FIGURE 52.13.3** Transesophageal echocardiography–guided needle puncture of the interatrial septum. The arrows point to the transseptal needle in each panel. The corresponding description of the needle placement appears below each panel. LA, left atrium; RA, right atrium. (From Goldstein SA, Campbell AN. Mitral stenosis:

evaluation and guidance of valvuloplasty by transesophageal echocardiography. *Cardiol Clin* 1993;11:409–425, with permission.)

CONTROVERSIES AND PERSONAL PERSPECTIVES

A major controversy with regard to TEE is when should it be used as a primary diagnostic modality. TEE provides incremental information to that obtained by clinical examination and TTE in many selected instances of endocarditis, source of embolism, prosthetic dysfunction, disease of the aorta, native-valve disease, and atrial fibrillation. As outlined already, in specific situations such as suspected prosthetic endocarditis, the value of a TEE is such that it should be considered part of the normal workup. In other situations, such as in patients with stroke and atrial fibrillation, although TEE may detect a potential embolic source, it is unlikely to alter management, as the patient will most likely require chronic anticoagulation anyway. The usefulness and need for TEE in such situations are highly controversial. For instance, in the setting of embolic stroke, cost-effectiveness models have supported the use of TEE as a primary diagnostic modality (180). However, clinical variables have proven more predictive of outcome than TEE information in other studies of stroke in atrial fibrillation (179). TEE is an extremely accurate diagnostic tool. However, because of its invasiveness and cost, both economically and in physician time, it should be reserved for those situations in which information from it will likely alter patient management substantially. This will vary with the competency of the operator both in TTE and TEE in an individual institution and with variation in management algorithms in different institutions. Currently, TEE represents less than 10% of all studies performed in echocardiography laboratories. Although the indications for TEE have grown, improvement in TTE technology such as in contrast agents and harmonic imaging have reduced the need for TEE in many other situations such as the difficult-to-image patient. The proportion of echocardiograms being performed as TEE has not changed substantially over the last number of years, and this trend seems likely to continue.

THE FUTURE

Three-Dimensional Reconstruction

Multiple high-quality tomograms of the heart and aorta may be sequentially acquired with multiplane transesophageal transducers. Technological advances have led to the more rapid acquisition and reconstruction of images (239). These may be reconstructed by computer to derive a three-dimensional dataset. Three-dimensional reconstruction is of most value in the assessment of complex structures such as the mitral valve and in congenital heart disease (240) and in accurate estimation of chamber volume. Three-dimensional TEE may be especially useful in percutaneous interventional procedures such as closure of complex congenital shunts (241) and in assessing the mitral orifice in balloon valvuloplasty (242). The complex anatomy of the regurgitant orifice in myxomatous mitral valve disease may be reliably demonstrated and measured with three-dimensional TEE (239,243). Real-time acquisition of three-dimensional images is currently under investigation. This has the potential to greatly facilitate volumetric evaluation of the patient and to accelerate image acquisition. Once the three-dimensional dataset has been obtained, multiple tomograms through the heart may be generated later. Three-dimensional color Doppler is currently under investigation and appears to have potential in improving the detection and quantification of eccentric regurgitant jets (244). Although three-dimensional TEE is of great potential use, its diagnostic usefulness in a clinical setting is not sufficiently well-established for it to be used in routine clinical practice.

Miniaturization

The progress of TEE has been marked by increased miniaturization of the transducer and probe. Pediatric probes capable of imaging even neonates are currently available. Recently, transducers capable of passage through the nasopharynx have become available. Because of size constraints these have limited capabilities and are under investigation as an adjunct to monitoring left ventricle function in the ICU setting (245). Smaller transducers have the advantage of easier passage and have the potential to increase the patient acceptability of transesophageal imaging and reduce the need for conscious sedation in its use.

GLOSSARY

Attenuation: The reduction in the intensity of radiation that occurs when it passes through matter.

Background subtraction: Subtraction of nontarget counts from the target area; for example, left ventricular counts – background counts = background subtracted left ventricular counts.

Becquerel (Bq): The SI unit of radioactivity, equal to 1 disintegration per second. 1 mCi = 37 mBq.

Biologic half-life: The time interval over which the body eliminates one-half of a given amount of substance through biologic processes.

Compton scattering: The loss in photon energy that results from scattering by collision with electrons.

Effective half-life: The combined half-life of physical decay and biologic elimination.

mCi: The unit of activity that gives 3.7×10^{10} disintegrations per second.

Physical half-life: The time interval over which radioactivity decreases to exactly one-half.

Rad: Radiation absorbed dose.

Radioactive disintegration or decay: A process whereby an unstable nucleus becomes more stable by emitting charged particles.

Radionuclide generator: A system for producing short-lived isotopes by eluting a daughter radionuclide with short half-life from a parent radionuclide with a long half-life.

Rem: Roentgen equivalent, man. Dose in rem equals dose in rad for x-rays and for gamma rays.

Shielding: Any heavy materials used to block radiation.

Spatial resolution: Ability of a gamma camera to distinguish activities very close to each other; for example, separating lines.

Temporal resolution: Ability of a system to separate activities sequentially; for example, framing rate in first-pass study.

HISTORICAL BACKGROUND

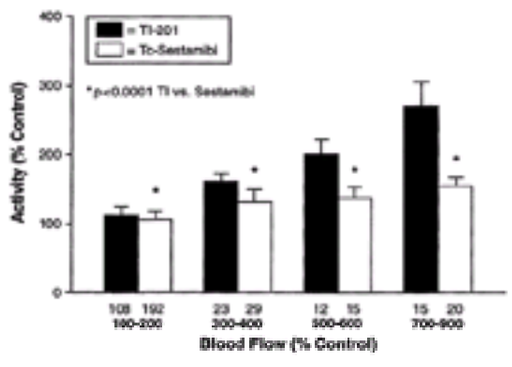
In the 1920s, nuclear techniques were applied for the first time to measure circulation time by injecting a radiotracer in one arm and monitoring the tracer's activity in the contralateral arm. Between 1950 and 1970, cardiac nuclear imaging techniques were used to detect pericardial effusion and pulmonary embolism. In the early 1970s, potassium-43 was used to study myocardial perfusion, radionuclide angiography (RNA) was used to study left ventricular function, and technetium-99m (Tc-99m) pyrophosphate was used to detect acute myocardial necrosis. In the mid-1970s, thallium-201 (Tl-201) was introduced for use in the study of myocardial perfusion. The U.S. Food and Drug Administration (FDA) approved two tracers (Tc-99m sestamibi and Tc-99m teboroxime) and a vasodilator stressor (dipyridamole) in 1991. Adenosine and Tc-99m tetrofosmin were approved in 1995, and indium-111 (In-111) antimyosin antibody was approved in 1996. In the late 1980s, a gradual shift from planar to single-photon emission computed tomographic (SPECT) imaging occurred. At the present time, gated SPECT perfusion imaging, attenuation/scatter

compensation, and SPECT fluorine-18-fluorodeoxyglucose (F-18-FDG) imaging are increasingly used. The first decade of contemporary nuclear cardiology can be characterized by its focus on diagnosis; the second decade, by its focus on risk assessment; and the third decade, by its focus on outcomes and cost-effectiveness. In 1993, the American Society of Nuclear Cardiology was created, and in September of 1996, the Certification Board of Nuclear Cardiology gave the first certification examination in nuclear cardiology.

TRACER KINETICS

Important differences exist between the kinetics of the current FDA approved perfusion tracers, Tl-201 and the three Tc-99m–labeled tracers [Tc-99m sestamibi (Du Pont Merck), Tc-99m teboroxime (Bracco Diagnostics), and Tc-99m tetrofosmin (Nycomed Amersham)] (1,2,3,4,5,6,7,8,9,10,11,12,13,14 and 15). Teboroxime is rarely used clinically at the present time. Tl-201 is a cationic element with low lipophilicity. Sestamibi is an isonitrile compound (2-methoxy-2-methyl propyl-isonitrile) and is marketed as Cardiolite. Tetrofosmin is a phosphine compound (1,2-Bis Bis 2-ethoxyethyl phosphine ethene) and is marketed as Myoview. Teboroxime is a Bato compound (boronic acid Tc dioxime) and is marketed as Cardiotec. Finally, Tc-99m-*N*-Noet (Cis bio), a cationic but neutral nitrido compound [Bis (*N*-ethoxy, *N*-ethyldithiocarbamato) nitrido], is undergoing clinical trials in Europe and the United States. The effective dose equivalent (rem/dose) is 1.05 for Tl-201, 1.06 for sestamibi, and 0.85 for tetrofosmin.

The kinetics of these tracers has been studied in cultured myocardial cells, in isolated perfused hearts, using *in vivo* animal models, and in humans (1,2,3,4,5,6,7,8,9,10,11,12,13,14 and 15). After intravenous injection, the blood activity decreases within minutes to a few percentage points of the initial concentration. In animal models of occlusion, reperfusion, stunning, and short-term hibernation, the uptake of Tl-201, sestamibi, and tetrofosmin reflects flow. The myocardial tracer concentration slightly overestimates flow in regions with low flow and underestimates it in regions with high flow. The trapping mechanism, which normally maintains the tracer inside the cell, disappears if necrosis occurs. Tl-201 is mostly localized in the cytoplasm, sestamibi and tetrofosmin in the mitochondria, and teboroxime on the cell membrane. The myocardial concentration of any tracer is a function of flow, extraction, and clearance. The extraction fraction of the available tracers is highest for teboroxime, followed by Tl-201, sestamibi, and tetrofosmin, in that order (9,10,13,14). There is a “roll off” in extraction as the flow rate exceeds 2.0 to 2.5 times the baseline level. The “roll off” is less severe for tracers with a higher extraction and more severe for those with a lower extraction (eFig. 53.0.1) (1,3,4,10). The myocardial clearance (washout) of teboroxime is faster than that of Tl-201. The clearance of sestamibi and tetrofosmin is negligible. Therefore, the myocardial retention—which is the net difference between extraction and clearance—for sestamibi and tetrofosmin is greater than that for Tl-201 and teboroxime. When the flow is very low, a slight increase in extraction fraction is noted with all tracers, as long as there is no myocardial necrosis. In the presence of myocardial necrosis, extraction diminishes, suggesting that these tracers are markers not only of flow, but also of viable myocardium.



***e*FIGURE 53.0.1** Bar graph showing mean myocardial thallium-201 (Tl-201, Tl) and technetium-99m sestamibi (Tc-Sestamibi) activities when these tracers were administered intravenously after intracoronary infusion of adenosine into the left anterior descending coronary artery of a patient (protocol 1). Activities are expressed as a percentage of control values and grouped by flow range. The numbers directly below each bar indicate the number of segments represented by each bar. Sestamibi activity was significantly less than that of Tl-201 in all flow ranges, and the difference between the tracers became progressively larger as flow increased. (From Glover DK, Ruiz M, Edwards NC, et al. Comparison between thallium-201 and Tc-99m sestamibi uptake during adenosine-induced vasodilation as a function of coronary stenosis severity. *Circulation* 1995;91:813–820, with permission.)

The myocardial uptake mechanism of Tl-201 is partly dependent on the sodium-potassium adenosinetriphosphatase system and is partly passive, dependent on concentration gradient, whereas the uptake of sestamibi and tetrofosmin essentially is passive, dependent on electric gradient. Tl-201 has an energy level in the range of 69 to 83 KeV and a smaller amount of gamma rays with energy levels of 165, 167, and 135 KeV. It has a half-life of 73 hours. Tc-99m has an energy level of 140 KeV and a half-life of 6 hours (eTable 53.0.1). Sestamibi and tetrofosmin are eliminated through the hepatobiliary and urinary systems. The hepatic clearance is faster with tetrofosmin than sestamibi, and lung activity is minimal with both in healthy subjects. A fatty meal after tracer injection does not affect the hepatobiliary clearance mechanism, although it may help to produce contraction of the gall bladder. The high energy level of Tc-99m, which labels sestamibi and tetrofosmin, produces less attenuation and scatter, improves spatial resolution, and allows simultaneous acquisition of perfusion and function by first-pass RNA or gated SPECT.

***e*TABLE 53.0.1** COMPARISON OF USE OF THALLIUM-201, SESTAMIBI, TEBOROXIME, AND TETROFOSMIN FOR CARDIOLOGIC IMAGING

Variable	Thallium-201	Sestamibi	Teboroxime	Tetrofosmin
Dose (mCi)	3.0	10–30	20–25	10–30
Energy (KeV)	80	140	140	140
Cyclotron product	Yes	No	No	No
Half-life	73 h	6 h	6 h	6 h
Extraction at normal flow	85%	65%	>90%	60%
Extraction at high flow	Lower	Lower	No change	Lower
Myocardial uptake	Adenosine triphosphatase	Unknown	Unknown	Unknown
Myocardial clearance	Fast, variable	Very slow	Very fast	Very slow
Hepatobiliary excretion	No	Yes	Yes	Yes
Perfusion-function studies[a]	No	Yes	Yes[b]	Yes
Gated perfusion	Possible	Yes	No	Yes
Stress redistribution	Yes	No	Possible	No
Stress rest	No	Yes	Yes	Yes
Time between injections (h)	NA	³2	³2	³2
Time to imaging (min)	<10	15–60[c]	<2	15–60[c]
Feasibility with pharmacologic stressor	Yes	Yes	Yes	Yes
Assessment of viability	Yes	Yes	Uncertain	Yes
Imaging protocol (d)	1	1 or 2	1	1 or 2

NA, not applicable.
[a]By first-pass RNA.
[b]Difficult because of high lung background.
[c]May be imaged up to several hours after the injection.

The myocardial washout (clearance) of Tl-201 depends on the gradient between its intracellular and intravascular concentrations (12). The clearance during stress imaging is more rapid in normal myocardium than in myocardium subtended by a diseased artery. The differential washout explains the disappearance of initial perfusion defects after 4 hours (redistribution). The washout is greater with exercise than with pharmacologic stress and is greater with maximal than with submaximal exercise (7). Minimal redistribution with sestamibi and tetrofosmin mandates the use of two separate injections to determine the nature of a perfusion abnormality (reversible or fixed).

IMAGING TECHNIQUES AND PROTOCOLS

The cardiac nuclear imaging techniques that have been applied to clinical imaging are summarized in eTable 53.0.2. At present, the most commonly used nuclear cardiac imaging procedure is myocardial perfusion imaging with the gated SPECT technique.

***e*TABLE 53.0.2** CARDIAC NUCLEAR IMAGING MODALITIES
Myocardial perfusion imaging

Thallium-201 chloride
Tc-99m sestamibi (Cardiolite)
Tc-99m tetrofosmin (Myoview)
PET (nitrogen-13 NH_3, oxygen-15 H_2O, rubidium-82)
Tc-99m teboroxime (Cardiotec)
Radionuclide angiography
First-pass
Blood pool (multiple-uptake gated acquisition)
Infarct-avid imaging (“hot spot”)
Tc-99m pyrophosphate
Indium-111 antimyosin antibody
Tc-99m glucarate
Ambulatory ventricular function (nuclear probes)
VEST
Cardioscint
Metabolic imaging
Fatty acids (iodine-123 IPPA, iodine-123 BMIPP)
Fluorine-18 (PET or SPECT)
Carbon-11 acetate (PET)
Sympathetic nerves
Iodine-123 MIBG (SPECT)
Carbon-11 hydroxyephedrine (PET)
Atherosclerosis imaging
Thrombus imaging

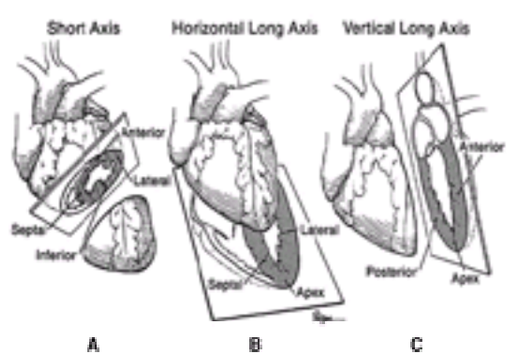
BMIPP, beta-methyl-*p*-iodophenylpentadecanoic acid; IPPA, iodophenylpentadecanoic acid; MIBG, metaiodobenzylguanidine; PET, positron emission tomography; SPECT, single-photon emission computed tomography; Tc-99m, technetium-99m; VEST, left ventricular function detector.

Principles and Instrumentation for Radiation Detection

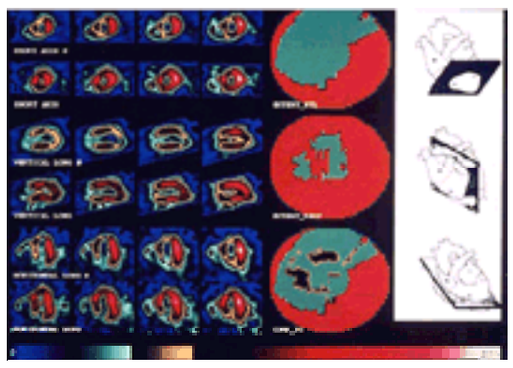
The basic principle of nuclear cardiac imaging is the detection of photons (gamma rays or x-rays) that are emitted from decay of radioactive tracers, by gamma cameras. These instruments use a large sodium iodide crystal at which the photons collide, producing scintillations. Several manufacturers now produce highly computerized digital gamma cameras with one, two, or three detector heads. Positron emission tomography (PET) cameras are designed to detect positrons (positively charged electrons) (see Chapter 55).

Acquisition Techniques and Views

Standard nuclear cardiology imaging uses either planar or tomographic (SPECT) techniques (16). During planar acquisition, images can be obtained in three or four different views. With SPECT imaging, sequential images can be acquired (32 or 64) at predetermined angular intervals. These individual images are then combined and reconstructed, followed by reorientation in three standard plans (eFig. 53.0.2), which allows a three-dimensional evaluation of the tracer activity in the heart. Most of the existing tomographic systems allow electrocardiographic (ECG) gating, dividing the cardiac cycle into 8 or 16 segments that, when viewed in cine mode, enable the interpreting physician to analyze the wall motion and systolic thickening in every segment of the left ventricle. Much of the currently available software allows quantification of the extent, severity, and reversibility of perfusion defects (eFig. 53.0.3). In addition, when gating is used, the left ventricular ejection fraction (LVEF) and left ventricular volumes can be calculated with well-validated software (17,18,19,20,21 and 22). The values of LVEF calculated by gated SPECT correlate well with those measured by cine magnetic resonance imaging, blood pool or first-pass RNA, contrast angiography, and echocardiography.



***e*FIGURE 53.0.2** Standard single-photon emission computed tomographic (SPECT) planes. Artist’s depiction of the three conventional planes during SPECT: short axis **(A)**, horizontal long axis **(B)**, and vertical long axis **(C)**. These three planes allow good visualization of all myocardial walls. (From Iskandrian AS, Verani MS. *Nuclear cardiac imaging: principles and applications*. Philadelphia: FA Davis, 1996, with permission).



***e*FIGURE 53.0.3** Single-photon emission computed tomographic images from a patient with high-grade left anterior descending artery stenosis in its proximal portion. A reversible defect during stress is depicted in the upper rows of each pair involving the anterior wall, septum, and apex. The polar maps on the right display the tracer activity during stress (*top*) and redistribution (*middle*). The lower polar maps localize the defect to the left anterior descending vascular territory.

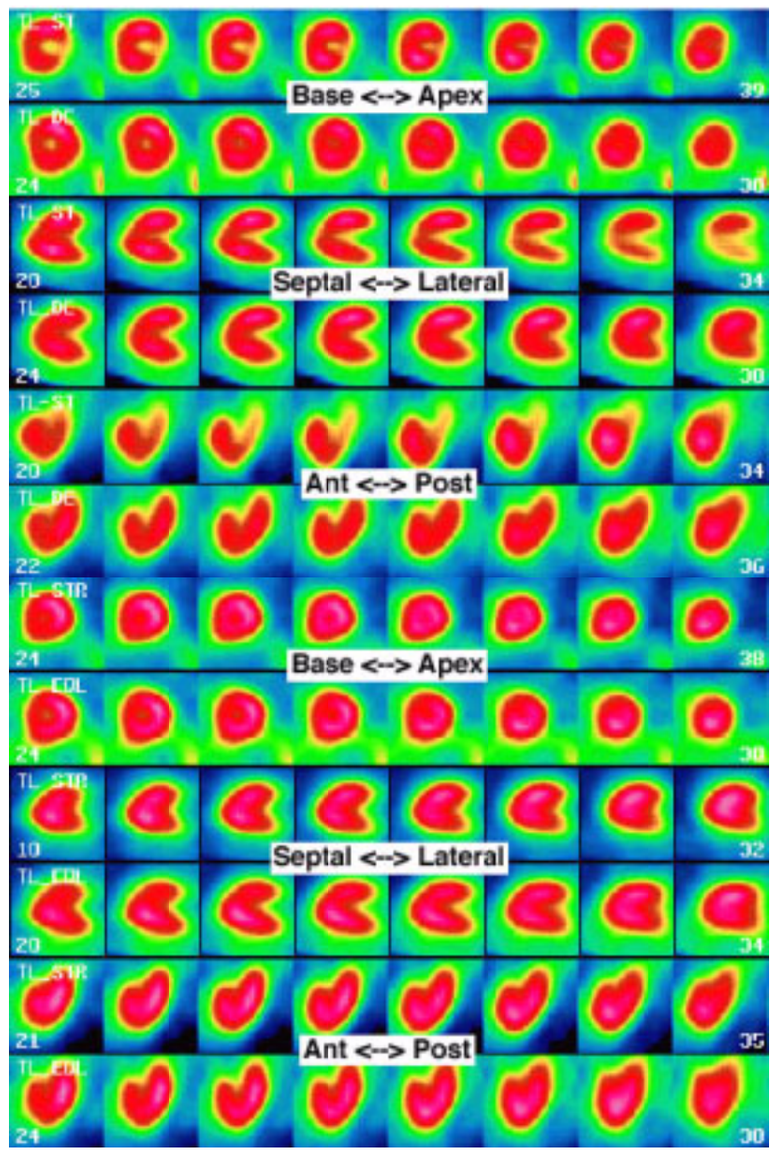
Radionuclide Angiography

RNA (16,23,24,25 and 26) can be performed using either a first-pass or a blood pool [also called *multiple-uptake gated acquisition* (MUGA)] technique (23). The first-pass technique is based on the fast acquisition of individual images as a bolus of a tracer (usually Tc-99m) traverses the central circulation. Ideally, it is done using a special camera with a high count rate (multicrystal camera). The gated blood pool technique is based on labeling of the red blood cells with Tc-99m. Images are obtained in three or four different positions and displayed in cine mode, where regional wall motion can be evaluated. Both techniques allow calculation of the left and right ventricular ejection fraction (EF), as well as left ventricular volumes. The EF measurements by RNA are computer-determined and, hence, extremely reproducible and accurate.

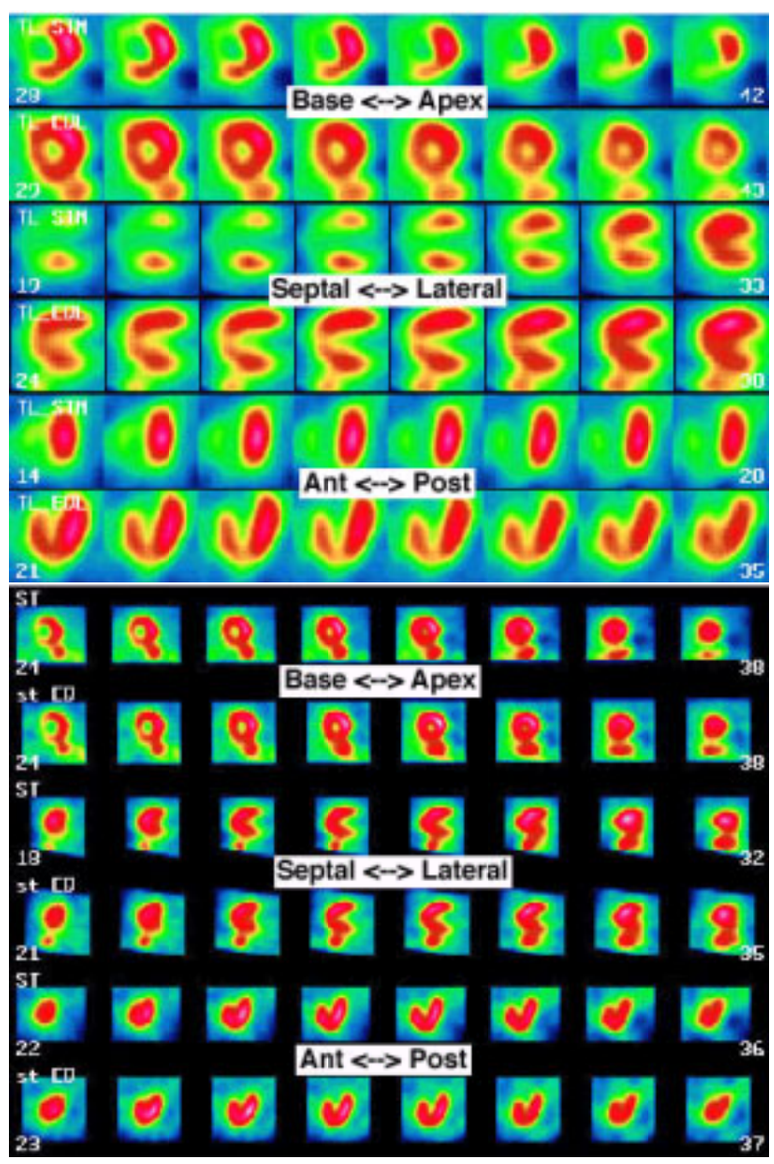
Imaging Protocols

Nuclear cardiac images can be acquired either at rest or during stress (exercise or pharmacologic). When the perfusion tracer is injected at peak stress, a separate rest

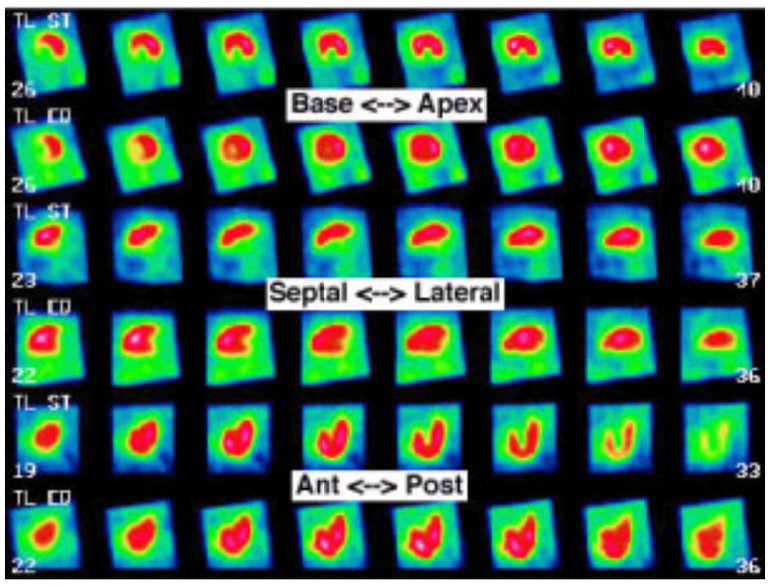
injection is often required if a Tc-99m labeled tracer (such as tetrofosmin or sestamibi) is used. Tl-201 images are obtained shortly after stress and repeated 4 hours later. Defects that are present during stress and improve 4 hours later (measured with Tl-201) or at rest (measured with Tc-99m tracers) denote myocardial ischemia, whereas lack of improvement denotes either scar or resting hypoperfusion. Reinjection of a small dose of Tl-201 (1 mCi) after the 4-hour redistribution images are taken as aids in distinguishing between ischemia and scar: Ischemic but viable areas improve after reinjection, whereas myocardial scar does not (27,28). A hybrid protocol (the dual isotope technique) uses a rest injection of Tl-201, followed by imaging, which is then followed by an injection within 1 hour of injection of a Tc-99m tracer during stress (29). In patients who are unable to exercise, pharmacologic stress with dipyridamole, adenosine, or dobutamine has been used successfully. With proper administration and monitoring, all three of these drugs are quite safe, although side effects are very common during the test (30,31).



Thallium-201 single-photon emission computed tomography stress and delayed images (A). Transverse, sagittal, and coronal plane images demonstrating lateral wall ischemia in a patient with severe proximal left circumflex artery stenosis. Thallium-201 single-photon emission computed tomography stress and equilibrium images (B). Transverse, sagittal, and coronal plane images obtained from a patient after successful intervention for severe proximal left circumflex artery stenosis (normal study).



Thallium-201 single-photon emission computed tomography stress and equilibrium images. A: Transverse, sagittal, and coronal plane images demonstrating anterior, septal, apical, and distal inferior ischemia in a patient with a severe proximal left anterior descending (LAD) artery stenosis in whom the LAD wraps around the left ventricular apex. B: Transverse, sagittal, and coronal plane images from the same patient as A after intervention for severe proximal LAD artery stenosis (normal study).



Thallium-201 single-photon emission computed tomography stress and equilibrium images. Transverse, sagittal, and coronal plane images demonstrating inferior and posterior wall ischemia in a patient with a severe proximal stenosis in a dominant right coronary artery

DETECTION AND EVALUATION OF CORONARY ARTERY DISEASE

In the past decade, myocardial perfusion imaging with SPECT has evolved into the preeminent noninvasive technique for assessment of coronary artery disease (CAD). Although RNA during stress remains a useful technique in selected patients, it is most often used in the risk-stratification of patients who have experienced myocardial infarction (MI) or heart failure.

Myocardial Perfusion Imaging

The basic principle underlying the detection of CAD by perfusion imaging is a differential blood flow distribution through the left ventricular myocardium, with a normal flow (and normal tracer uptake) in the myocardium perfused by normal coronary arteries and *relatively* diminished flow (and diminished tracer uptake) in regions perfused by stenotic vessels. A perfusion abnormality may be present at rest in patients with previous MI or fibrosis, or in patients with high-grade (>85% of the luminal diameter) coronary stenoses. However, most functionally significant coronary stenoses, including severe ones, are associated with normal resting myocardial blood flow and, hence, normal resting perfusion images. Consequently, to demonstrate these stenoses, it is necessary to perform imaging of these patients during stress.

During maximal exercise or pharmacologic stress, blood flow increases through the normal coronary arteries but increases less or even fails to increase (occasionally, it decreases) in vessels with significant (>50% of the luminal diameter) stenoses. This diminished coronary flow reserve in stenotic vessels is not an all-or-none phenomenon; rather, the flow reserve decreases gradually as the severity of the coronary stenosis progresses. The most severe stenoses (>85%) typically have no flow reserve left.

It is important to emphasize that the greater the flow differential between the normal arteries and the stenotic arteries, the greater the difference in tracer uptake and potentially the greater the likelihood that the stenosis will be detected. However, the relationship between myocardial blood flow and tracer uptake is only linear up to a flow of approximately 2.0- to 2.5-fold above the baseline values. Beyond these limits, the tracer uptake lags behind the flow (the so-called “roll-off” effect). This “roll-off” effect depends on two major factors: (a) the stress modality and (b) the flow tracer.

During exercise, the normal coronary flow increases approximately 2.5- to 3.0-fold over the baseline values. Although this is substantially less than the maximal normal coronary flow reserve in human beings, the relationship between flow and Tl-201 uptake remains approximately linear (12). During pharmacologic vasodilation induced by adenosine or dipyridamole, the coronary flow increases maximally or near-maximally (four- to sixfold above the baseline). However, when the flow is so high, tracer uptake diminishes considerably, so that the slope of the tracer uptake versus flow relationship becomes flattened. Tracers with high myocardial extraction, such as Tc-99m teboroxime and Tl-201, maintain a steeper slope, whereas tracers with lower myocardial extraction, such as Tc-99m sestamibi, Tc-99m tetrofosmin, and Tc-99m furofosmin, have a flatter slope. This nonlinear relation between flow and tracer uptake at high flow raises some theoretical concerns, especially about images acquired during pharmacologic stress. However, because the tracers with lower extraction fraction also have a longer residence time in the myocardium, it appears that the ability of pharmacologic stress to detect CAD is not compromised (24,32).

Exercise Myocardial Perfusion Imaging

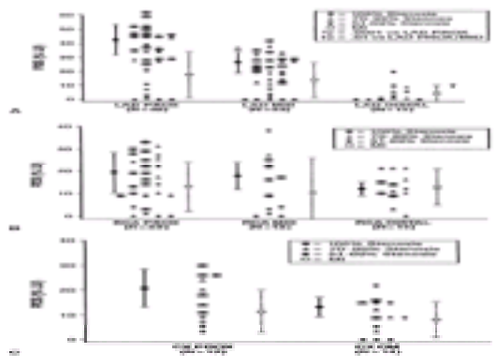
The most common indications for exercise perfusion imaging are listed in Table 53.1. Most studies are done to establish the diagnosis of CAD. The maximal diagnostic yield of SPECT imaging, according to Bayes’ theorem, is in patients with an intermediate likelihood (20% to 60%) of having CAD on the basis of their history. In patients with a very low pretest disease likelihood, a positive test is often false positive, whereas in patients with a very high pretest probability of CAD (e.g., middle-aged or older men with classical angina, in whom the pretest probability is ³80%), a negative test is often false negative. On the basis of these considerations, some authorities have suggested that perfusion imaging should not be applied to patients with a very low or a very high pretest likelihood of CAD. This line of reasoning, however, fails to consider the prognostic value of perfusion scintigraphy; that is, patients who have a low pretest disease likelihood but a large perfusion defect, especially with a multivessel distribution, may still be at increased risk, whereas patients who have a high pretest likelihood but a negative scan have a very low risk for future cardiac events, and, arguably, their condition could be managed medically without need for cardiac catheterization (33,34).

Diagnosis of coronary artery disease
Stable angina or chest pain of uncertain origin
Unstable angina, after initial stabilization
Positive exercise electrocardiogram without symptoms
Screening of high-risk, asymptomatic patients
Patients who are referred for exercise electrocardiographic testing but have an abnormal resting echocardiogram that hampers evaluation of ischemia
Prior nondiagnostic exercise electrocardiogram test
Assessment of functional importance of known coronary stenoses
Bordering stenoses (40% to 70%) by coronary angiography
Assessment of culprit lesion before coronary angioplasty
Stenoses of small branches or of distal location
Assessment of therapeutic benefits
After percutaneous coronary intervention
After coronary artery bypass surgery
After medical therapy
Risk-stratification
Stable angina
Unstable angina
Post-myocardial infarction
Preoperative risk
Demonstration of myocardial ischemia in patients with angiographically normal coronary arteries.

Modified from Iskandrian AS, Verani MS. Nuclear cardiac imaging: principles and applications. Philadelphia: FA Davis, 1996, with permission.

TABLE 53.1 INDICATIONS FOR EXERCISE PERFUSION SCINTIGRAPHY

Recent reports have confirmed the diagnostic utility of perfusion imaging in patients with normal and with abnormal resting ECG results (35). The information provided by myocardial perfusion scintigraphy during stress transcends the mere categorization of the test results as normal or abnormal. On the basis of the location of the perfusion abnormality, one can infer which arteries are involved. It has been shown that stenoses involving the left anterior descending artery generally lead to a larger perfusion defect than stenoses in the right coronary or circumflex arteries (36,37) (eFig. 53.0.4). Patients with multivessel CAD have larger perfusion defects than patients with single-vessel disease (38). In addition to the extent of hypoperfusion, the reversibility of the defects needs to be assessed during the redistribution (in the case of Tl-201) or the rest images (in the case of the Tc-99m tracers). It is important to assess also the severity of tracer uptake reduction in the stress and rest or redistribution images. Transient cavity dilation during exercise or pharmacologic stress and increased Tl-201 lung uptake during stress are powerful predictors of poor prognosis (25,33).



***e*FIGURE 53.0.4** Mean left ventricular perfusion defect size (PDS) in patients with (*solid line*) and without (*broken line*) myocardial infarction (MI) for the left anterior descending coronary artery (LAD) **(A)**, the right coronary artery (RCA) **(B)**, and the left circumflex coronary artery (CX) **(C)**, with proximal (PROX), middle (MID), or distal stenosis. Although LAD PROX stenosis generally led to a larger perfusion defect size than did LAD MID stenosis, significant individual vessel heterogeneity was seen. For the RCA, the mean perfusion defect size was similar whether stenoses were PROX, MID, or distal in location, although the range was wide. Similar heterogeneity was seen for the proximal and obtuse marginal (OM) CX stenosis. LV, left ventricle. (From Mahmarian JJ, Pratt CM, Boyce TM, et al. The variable extent of jeopardized myocardium in patients with single vessel disease: quantification by thallium-201 single photon emission computed tomography. *J Am Coll Cardiol* 1991;17:355–362, with permission.)

The use of exercise perfusion scintigraphy to screen asymptomatic patients is controversial. It certainly cannot be recommended across the board, but it may be very useful in selected populations who are at increased risk for CAD despite being asymptomatic (Fig. 53.1). For example, the test is useful in patients with a conglomerate of risk factors and in adolescents or young adults who have familial hypercholesterolemia (39). Middle-aged siblings of patients who have had an MI also are at increased risk for cardiac events and are good candidates for a stress perfusion study (40).

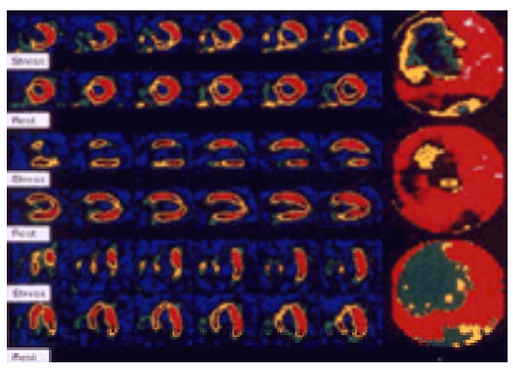


FIGURE 53.1 Technetium-99m single-photon emission computed tomographic images during exercise and at rest in a 52-year-old diabetic male who was asymptomatic. The images during stress depict large defects involving the anterior wall, septum, apex, and inferior and posterolateral walls, with substantial improvement at rest. Subsequent coronary angiography showed severe proximal left anterior descending (90%) and left circumflex (75%) stenoses.

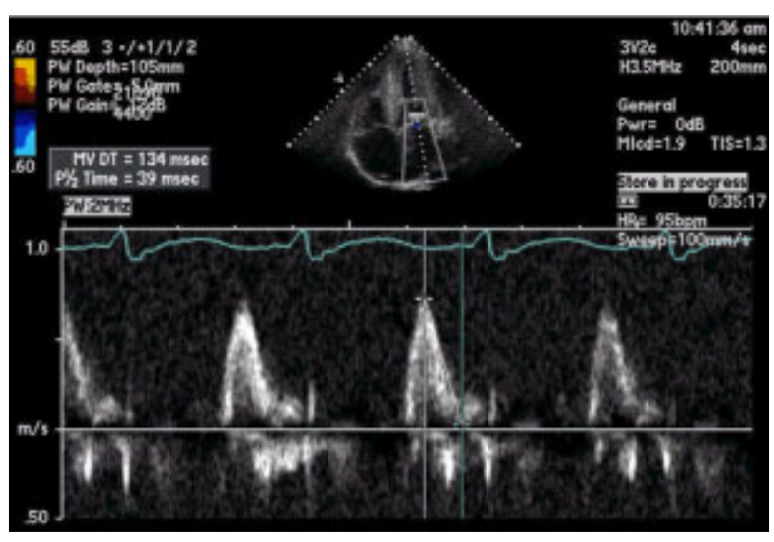
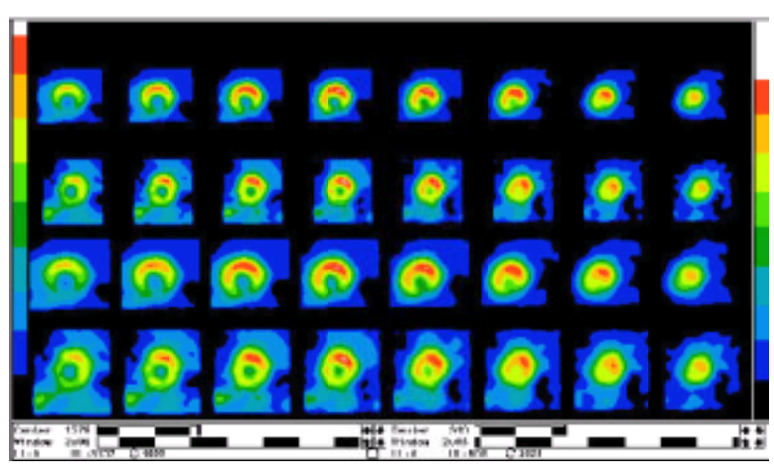
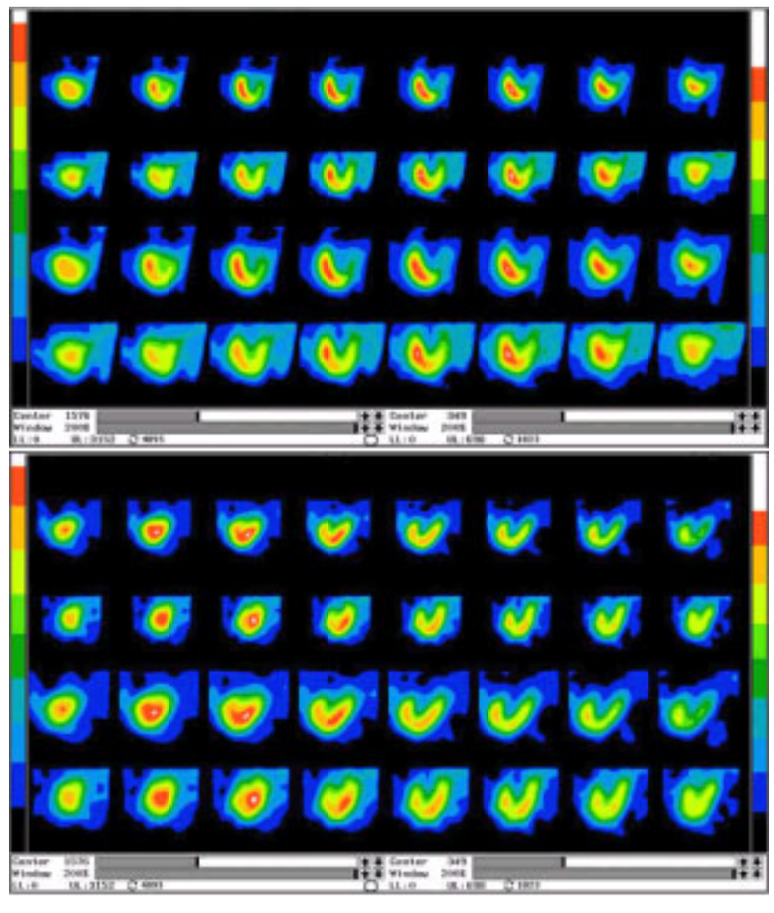
An extensive review of published studies that used exercise Tl-201 qualitative planar scintigraphy, which included 52 publications and 5,160 patients (41), shows an overall sensitivity and specificity of 83% and 88%, respectively. Several studies assessed the value of quantitative Tl-201 planar scintigraphy during exercise for the diagnosis of CAD (24). The mean sensitivity and specificity are 90% and 80%, respectively. With exercise Tl-201 SPECT, the average sensitivity and specificity are 89% and 76%, respectively, by qualitative analysis (24).



Pulsed wave Doppler of the mitral valve inflow in a patient with amyloidosis demonstrating a short deceleration time (134 ms) consistent with restrictive physiology.





Dual isotope resting thallium-201/stress technetium-sestamibi single-photon emission computed tomography transverse (*first image*), sagittal (*second image*), and coronal (*third image*) plane images demonstrating ischemia of the inferolateral, inferior, and proximal to mid inferoseptal walls. The left anterior oblique cranially angulated view (*video*) shows severe stenosis of the distal right coronary artery before the posterior descending and posterolateral arteries in the same patient.

Video 53.1 Dual isotope resting thallium-201/stress technetium-sestamibi single-photon emission computed tomography transverse (*first image*), sagittal (*second image*), and coronal (*third image*) plane images demonstrating ischemia of the inferolateral, inferior, and proximal to mid inferoseptal walls. The left anterior oblique cranially angulated view (*video*) shows severe stenosis of the distal right coronary artery before the posterior descending and posterolateral arteries in the same patient. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

A comparison between qualitative and quantitative analyses of Tl-201 SPECT images has not shown a major difference in sensitivity or specificity between these two techniques (38,42,43,44 and 45). However, detection of the individual coronary arteries involved may be moderately improved by quantitative analysis. This is particularly true for detection of circumflex artery stenoses and coronary stenoses of moderate severity (between 50% and 75% of the luminal diameter) (45).

Use of Technetium-99m Perfusion Tracers in the Diagnosis of Coronary Angiography Disease

The newer Tc-99m flow tracers represent a substantial improvement in nuclear cardiac imaging. The more favorable physical characteristics of Tc-99m, such as an optimal emission energy for imaging with gamma cameras, and less physical scatter and shorter half-life (which allows administration of a much higher tracer dose) than Tl-201, are definite advantages of these agents. Interestingly, the few studies that have directly compared Tl-201 with Tc-99m sestamibi, teboroxime, or tetrofosmin have not shown an overall superiority for detection of CAD with any of these newer agents. The overall sensitivity of Tc-99m sestamibi using planar imaging is 87%, with a specificity of 62% and a normalcy rate of 92%. When SPECT imaging is used, the overall sensitivity and specificity are 90% and 74%, respectively (24). As mentioned, Tc-99m sestamibi imaging during stress has also been used in combination with Tl-201 resting imaging (dual isotope imaging). With this strategy, a sensitivity of 91% and specificity of 75% have been found by Berman and coworkers (29).

Because the Tc-99m–labeled agents undergo less attenuation than agents labeled with Tl-201, they may be particularly useful for patients who are prone to attenuation artifacts, such as women with large breasts or breast implants and obese individuals (46). Tc-99m teboroxime has been used with planar imaging and with SPECT imaging. Despite its high myocardial extraction rate and its good correlation with determination of myocardial flow using microspheres, it has a very short residence time in the myocardium, rendering SPECT imaging a challenging proposition. The initial favorable reports (which indicated an average sensitivity of 87% and specificity of 62% with either planar or SPECT imaging) (47,48) notwithstanding, this tracer is not currently used for clinical imaging. New research has focused on the idea of measuring absolute myocardial blood flow using dynamic imaging with teboroxime (49).

Tetrofosmin is another attractive Tc-99m–labeled perfusion agent. A high concordance rate has been found between this agent and Tl-201, both with planar and SPECT imaging (50,51). As is the case for sestamibi, the sensitivity and specificity of tetrofosmin imaging appear to be comparable, but not superior, to those of Tl-201 imaging. In the largest reported series, from a phase III multicenter trial, that used planar imaging and included 252 patients from ten centers in the United States and Europe, tetrofosmin and Tl-201 had similar sensitivity and specificity for CAD detection. Other studies have confirmed the diagnostic accuracy of tetrofosmin (52,53,54 and 55) and confirmed that it is comparable to sestamibi (56).

Furofosmin is another Tc-99m–labeled compound that has been tested in the United States but has not received FDA approval. In a large multicenter trial comparing Tc-99m furofosmin SPECT with Tl-201 SPECT during exercise, an overall agreement in the results of 86% was found (57).

The principal advantage of the Tc-99m tracers is that they can be administered in higher doses, and, hence, high-quality images are feasible even for large or obese individuals and women with large breasts. Another very attractive feature is the ability to gate the SPECT images, which allows an evaluation of the global and regional ventricular function by observation of the motion of the perfused ventricular walls. These agents also enable assessment of left and right ventricular function during the injection of the Tc-99m tracers by first-pass RNA.

Pharmacologic Perfusion Imaging

Approximately 20% to 30% of patients with suspected or documented CAD are unable to perform an exercise stress test and, thus, are good candidates for pharmacologic stress imaging. Other clinical conditions for which pharmacologic stress imaging is appropriate are listed in Table 53.2. Adenosine produces maximal or near-maximal coronary vasodilation through its agonistic effect on the adenosine A2 receptors located in the coronary arterial wall. Dipyridamole has an indirect vasodilator effect, through the inhibition of the cellular reuptake and metabolism of adenosine (24,30), leading to an increase in the interstitial and perimembrane levels of adenosine. The principal difference between these two agents, which have similar hemodynamic effects (24), is the much shorter half-life of adenosine. Both produce frequent side effects, but the reported experience in large numbers of patients has indicated that both are quite safe when properly used (58,59 and 60). Investigators in Japan have used intravenous adenosine triphosphate as yet another option for pharmacologic stressor (61,62).

Patient unable to exercise
Preoperative risk-stratification
Early postinfarct risk-stratification
Left bundle branch block
Presence of fixed-rate ventricular pacemaker

TABLE 53.2 INDICATIONS FOR PHARMACOLOGIC PERFUSION IMAGING

Studies comparing dipyridamole or adenosine Tl-201 scintigraphy with exercise Tl-201 scintigraphy have indicated excellent agreement between these stressors. The overall reported sensitivity with dipyridamole Tl-201 planar imaging is 82%, with a specificity of 75%. These values are slightly higher with SPECT imaging (89% and 78%, respectively). The average sensitivity of adenosine Tl-201 SPECT is 88%, with a specificity of 85% (24,30). Clinical studies have shown similar values when adenosine or dipyridamole is combined with Tc-99m sestamibi or tetrofosmin (63,64 and 65). Both adenosine and dipyridamole can be combined with a submaximal exercise test. The main advantage of such a combination is the decrease in splancnic uptake, which improves the quality of the images, especially with Tc-99m agents (66,67).

Adenosine and dipyridamole are contraindicated in patients who have active asthma or severe chronic obstructive pulmonary disease with wheezing. In these patients, dobutamine is a proven adequate stressor, with reported sensitivity ranging from 80% to 97% and specificity ranging from 74% to 89%, in combination with SPECT (24). Although a curious antagonism has been described between dobutamine and sestamibi in animal experiments (68), the reported sensitivity of this combination of agents in clinical patients is high thus far (69,70).

Causes of False-Negative Results of Myocardial Perfusion Scintigraphy

Table 53.3 lists several of the possible causes of false-negative myocardial perfusion images. Among these, the most frequent are an inadequate exercise stress test and concomitant administration of antiischemic medications. It must be emphasized that the gold standard for determination of diagnostic accuracy of perfusion imaging has traditionally been coronary angiography. The potential weaknesses of this gold standard have long been emphasized (71). It is not unusual for lesions that are considered “significant” by angiography to have a normal flow reserve. It is thus not surprising that some of them are also associated with normal myocardial perfusion images.

Inadequate exercise stress
Administration of antiischemic medications
Non–flow-limiting coronary stenoses
Overlap circulation
Collateral circulation
Hypoperfusion in segments with attenuation
Incorrect interpretation of angiograms
Incorrect interpretation of scans
Poor-quality images
"Balanced" hypoperfusion
Delay in obtaining thallium-201 stress images

Modified from Iskandrian AS, Verani MS. *Nuclear cardiac imaging: principles and applications*. Philadelphia: FA Davis, 1996, with permission.

TABLE 53.3 CAUSES OF FALSE-NEGATIVE RESULTS OF SCANS

Causes of False-Positive Myocardial Perfusion Images

Table 53.4 lists some of the causes that may be associated with false-positive results of imaging. Among them, the most important is photon attenuation, which may have a different impact on different myocardial walls. For example, anterior wall attenuation is common in women with breast implants or large breasts, whereas diaphragmatic attenuation is frequent in obese, stocky patients (*e*Fig. 53.1.1). In individual patients, it may be extremely difficult to distinguish between attenuation artifacts and a true perfusion defect. The application of newly developed attenuation-correction techniques appears quite promising (72,73,74,75 and 76). Among the causes listed on Table 53.4, conduction defects are particular important, because they are potentially preventable. Patients who have a left bundle branch block often have perfusion defects involving the interventricular septum, which may be totally or partially reversible at rest, thus mimicking left anterior descending artery stenosis. These defects are much less frequently seen when dipyridamole or adenosine stress testing is used, and pharmacologic imaging with one of these agents is therefore preferable to exercise testing in patients with a left bundle branch block (22,24,30,77).

Regional photon attenuation
Poor technique
Conduction abnormalities*
Cardiomyopathies*
Coronary vasospasm*
Coronary anomalies*
Microvascular disease*

RISK ASSESSMENT

Risk Assessment in Patients with Stable Symptoms

The composition of atherosclerotic lesions varies considerably; some are rich in cholesterol (soft), and others are fibromuscular. The soft lesions are more likely to fissure or rupture. Plaques that are predominantly fibromuscular do progress, but rather slowly, and when they finally occlude the vessel, they may not precipitate acute MI, possibly because of the development of collaterals. There are trigger mechanisms that precipitate fissuring or rupture, such as unusual stress, hypertension, and a rise in catecholamine levels (78,79). Frequent episodes of sudden cardiac death shortly after the powerful earthquake in the Los Angeles area in 1994 were assumed to be the result of such a mechanism (80). It is estimated that only 10% of these plaques are predominantly lipid rich. Yet it is these plaques that most likely fissure and are followed by thrombosis and acute complications. The degree of underlying coronary stenosis in many patients with acute MI is only mild or moderate, and in patients with severe CAD, the artery responsible for the acute ischemic syndromes is not necessarily the artery with the most severe stenosis (24).

Cardiac events are defined either as “hard” (death or MI) or “soft” (e.g., increasing angina, the need for coronary revascularization, or the need for hospitalization). The predictors of hard and soft events may be different—in fact, the predictors of death may also differ from those of MI. For example, ischemic manifestation may predict an ischemic event such as acute MI or unstable angina, and left ventricular function or the overall extent of perfusion defect may predict death (81). Clinical, angiographic, and exercise variables have been identified that separate high- and low-risk groups for cardiac events. Califf and associates developed a risk-factor prediction chart that used age, gender, lipid profile, smoking history, systolic blood pressure, presence of diabetes or left ventricular hypertrophy, and fibrinogen level to separate patients into those with <1% risk of events and those with a 25% probability of having events during the 5 years after assessment (82).

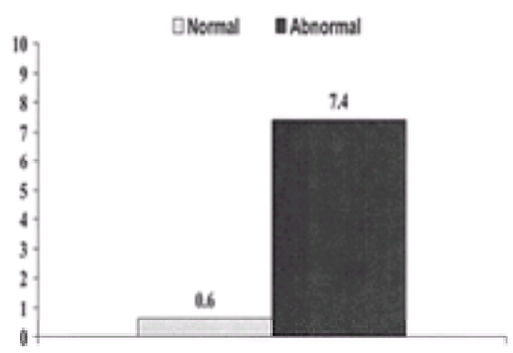
Early planar imaging and subsequent SPECT (using Tl-201– and Tc-99m–based tracers) in thousands of patients in multiple trials has yielded a strong message regarding the prognostic value of such tests. The message is consistent whether the imaging is done with exercise or with pharmacologic stress testing. Simply stated, perfusion imaging can separate patients at low risk from those at high risk. The relevance of such a conclusion on patient management is equally strong, because the condition of patients at low risk may be managed conservatively, without the need of coronary angiography or coronary interventions, whereas at least subgroups of high-risk patients may benefit from coronary revascularization (34,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101,102,103,104,105,106,107,108,109, 110,111,112,113, 114,115,116,117,118 and 119).

The major prognostic variables are listed in Table 53.5. The available data strongly suggest the following ten points:

Large zone of ischemia
Large zone of fixed defects
Perfusion abnormality in more than one vascular territory
Increased lung uptake
Left ventricular dilation (transient or fixed)
Left ventricular ejection fraction (by gated single-photon emission computed tomography)

TABLE 53.5 STRESS PERFUSION PREDICTORS OF RISK IN MEDICALLY TREATED PATIENTS WITH STABLE ANGINA

1. Normal stress images have a very high negative predictive value; hard event rate (death or nonfatal MI) is less than 1% per year (87,88,96,101,104,105).
2. Accordingly, the rate of coronary angiography is often very low in patients who have normal results of imaging (86,89,95,96,99,105).
3. The event rate is significantly higher (mean, 12-fold) in patients with abnormal results of imaging, based on review of data from more than 12,000 patients (*e*Fig. 53.1.2) (96,105).

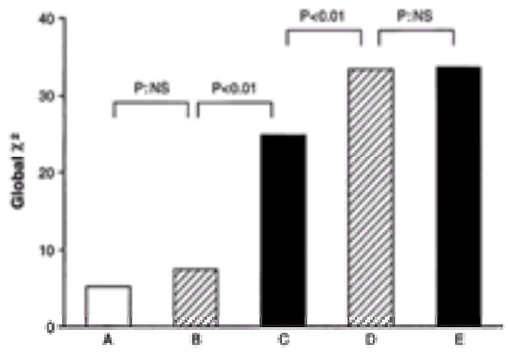


***e*FIGURE 53.1.2** Annual rate of death or myocardial infarction in patients who have normal and abnormal single-photon emission computed tomography sestamibi images. (Reproduced from Iskander S, Iskandrian AE. Risk assessment using single-photon emission computed tomographic technetium-99m sestamibi imaging. *J Am Coll Cardiol* 1998;32:57–62, with permission.)

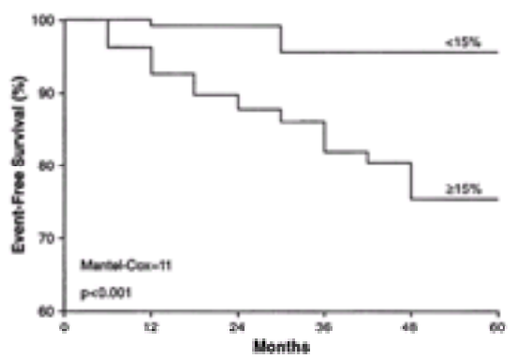
4. The event rate among patients who have abnormal results of imaging increases as a function of the severity of the perfusion abnormality. Patients with severe abnormality are at higher risk than patients with mild abnormality (85,96,105,109). The results are true in men and in women (90,102,115).
5. The results of exercise and pharmacologic stress testing using Tl-201, sestamibi, or tetrofosmin are comparable (96,105). The risk may be slightly higher among patients with normal results of dobutamine sestamibi imaging, possibly because ischemia is underestimated or because of a higher risk among the patient population in whom the use of dobutamine was studied (68).
6. Stress perfusion imaging provides statistically significant incremental information to support that provided by clinical evaluation, treadmill exercise testing, and coronary angiography (34,85,96).
7. The use of gated SPECT perfusion imaging enhances the prognostic power of imaging by incorporating left ventricular functional data, such as LVEF and left ventricular volumes, with perfusion data.
8. Diagnostic strategies based on the use of stress perfusion imaging as the initial test followed by selective referral of high-risk patients to coronary angiography are more cost-effective than routine use of coronary angiography on all patients. This advantage is accompanied by at least similar outcome (113,114 and 115).
9. The perfusion pattern may predict the type of subsequent events. Large fixed defects often predict cardiac death, and large reversible defects predict MI and total hard events (death plus MI) and, as expected, the need for coronary revascularization (34,104,105).
10. The “warranty” period associated with normal or mildly abnormal results of imaging depends on pretest likelihood of CAD; in high-risk patients and patients with established CAD, the test needs to be repeated at 18 to 24 months after revascularization, or earlier if symptoms change. In low-risk and intermediate-risk groups, the test needs to be repeated at 5 and at 3 years, respectively (85,96,105).

Pollock et al. (93) evaluated the hierarchical order of tests in terms of their prognostic importance. These tests were clinical evaluation, treadmill exercise stress testing, planar thallium imaging, and coronary angiography. When the perfusion data were considered, coronary angiography did not contribute additional prognostic value. We reached a similar conclusion using SPECT imaging (*e*Fig. 53.1.3). Importantly, when the catheterization data were not included and the model was based on clinical, exercise, and SPECT variables alone, the predictive power was as strong as when the catheterization data were included (85). Of all the variables analyzed, the size of the perfusion abnormality was the single most important discriminator between high- and low-risk groups. Patients with a large abnormality had a tenfold

higher event rate (death or MI) than did patients with small defects (eFig. 53.1.4). Similar results were observed in women (90). Despite a concern that the sensitivity of stress testing may be lower in women than men, SPECT imaging provides similar, if not better, risk assessment strategies for women (90,102). The receiver operating characteristic analysis by Hachamovitch and colleagues (102) showed superior discrimination in women than men in identifying high-risk patients by the results of stress SPECT imaging (area under the curve of 0.84 in women vs. 0.71 in men). Amanullah and coworkers (107) reported 0.9%, 4.1% and 7.5% event rates in women with mild, moderate, or severe perfusion abnormalities, respectively. Other groups have published similar results (109).



***e*FIGURE 53.1.3** Independent and incremental prognostic power of clinical, exercise, catheterization, and single-photon emission computed tomographic (SPECT) thallium variables. Data shown represent the c^2 statistic for clinical data (A); clinical and exercise data (B); clinical, exercise, and catheterization data (C); clinical, exercise, and SPECT thallium data (D); and clinical, exercise, catheterization, and SPECT data (E). The SPECT data provided incremental prognostic information. NS, not significant. [From Iskandrian AS, Chae SC, Heo J, et al. Independent and incremental prognostic value of exercise single-photon emission computed tomographic (SPECT) thallium imaging in coronary artery disease. *J Am Coll Cardiol* 1993;22:665–670, with permission.]



***e*FIGURE 53.1.4** Actuarial event-free survival curves in patients with perfusion defect ³15% or <15% of the left ventricular myocardium. The prognosis is worse in patients with large perfusion defects. [From Iskandrian AS, Chae SC, Heo J, et al. Independent and incremental prognostic value of exercise single-photon emission computed tomographic (SPECT) thallium imaging in coronary artery disease. *J Am Coll Cardiol* 1993;22:665–670, with permission.]

The group of patients with intermediate Duke scores—which often is the larger group—is problematic. Gibbons and associates (101), using data from four institutions, reported that the 5-year event-free survival rate among almost 5,000 patients was 99% among patients who had an intermediate Duke score and normal SPECT images. Shaw and coauthors (114) reported similar results: an annual mortality rate of 2.5% among patients with intermediate Duke scores in whom multivessel abnormality was seen on imaging versus 0.5% among patients whose scans were normal.

Diabetic patients pose a special problem because ischemia may be silent and autonomic neuropathy and peripheral vascular disease may affect exercise performance. Kang and colleagues (106) found a higher annual mortality rate among diabetic patients than among nondiabetic patients (4.3% vs. 2.3%). The annual mortality rate among diabetic patients was 1% to 2% in those with normal scans, 3% to 4% among patients with mildly abnormal scans, and >7% among patients with severely abnormal scans.

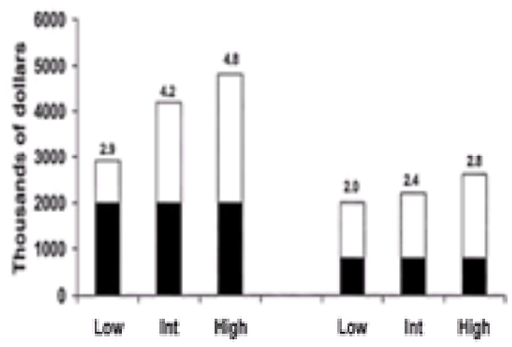
Vanzetto et al. (117,119) found that imaging results and the inability to exercise were the two most important predictors of outcome among diabetic patients. Patients with large defects had a 22% annual event rate, compared with 3% among those with normal results of imaging. In addition, the odds ratio for cardiac events was 6.8 among patients who had exercise limitations compared with patients who could exercise. Our experience supports these observations. The role of imaging in diabetes is being actively studied in two large studies (the Detection of Ischemia in Asymptomatic Diabetics trial and the Bypass Angioplasty Revascularization Investigation 2 Diabetes study).

Patients who have good exercise tolerance are often considered to be at low risk for cardiac events. Chatziioannou and colleagues (100) reported that even among this group of patients, SPECT imaging was able to discriminate between high-risk and low-risk patients (relative risk, 8.0). It should be noted, however, that 16 of the 21 events included in this study were soft events in the form of coronary revascularization.

The ability to perform gated SPECT perfusion imaging is a clear advantage in further improving the prognostic value of SPECT imaging. Sharir et al. (112) showed the importance of EF, end systolic volume, and the presence of ischemia. Patients with large areas of ischemia, low EF, and large end systolic volume are at the highest risk, whereas patients without ischemia who have normal EF and normal end systolic volume are at the lowest risk.

O'Keefe and associates (110) found a low event rate (2%) after 3 years among medically treated patients with mild perfusion abnormality, and only a few of these patients (9%) crossed over to coronary angiography. Other studies also show no advantage to the use of coronary revascularization rather than medical therapy in patients who have normal or mildly abnormal results of imaging (120,121). On the other hand, coronary revascularization proved superior to medical therapy among patients who had intermediate or large abnormalities (104). These results should be accepted with caution; they are not based on randomized studies, and the medical therapy was not optimized. Marie and colleagues (108) showed that beta-blocker therapy lowered the expected high event rate in patients with initially large defects who received medical treatment. Other studies also show that aggressive antiischemic therapy and statin therapy may decrease defect size and affect outcome. These observations are now being tested in randomized studies (the Intravascular Ultrasound Study of Predictor of Restenosis trial and the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation trial).

A large observational study involving 11,372 patients who had stable symptoms showed that the initial and follow-up costs were 30% and 41% higher for patients in whom coronary angiography was initially performed than for patients who underwent stress SPECT imaging and were selectively referred to undergo coronary angiography (113). The higher cost was not associated with a corresponding reduction in the mortality rate (3.3% vs. 2.8%) or MI (3.0% vs. 2.8%). The diagnostic costs were $1,320, $1,275, and $1,229 higher, respectively, for low-, intermediate-, and high-risk patients undergoing initial cardiac catheterization than for patients undergoing stress SPECT imaging as the initial test for detection of CAD (eFig. 53.1.5). Such a cost minimization approach has also been reported to be successful for women.



***e*FIGURE 53.1.5** Overall diagnostic and follow-up costs of care for direct catheterization and initial stress perfusion imaging. Diagnostic and follow-up costs were 30% and 41% higher for patients undergoing direct cardiac catheterization. Diagnostic costs are represented by solid bars; follow-up costs are represented by open bars. Low, intermediate, and high refer to pretest likelihood of coronary artery disease. Int, intermediate. [Reproduced from Shaw LJ, Hachamovitch R, Berman DS, et al. The economic consequences of available diagnostic and prognostic strategies for the evaluation of stable angina patients: an observational assessment of the value of precatheterization ischemia. Economics of Noninvasive Diagnosis (END) Study Group. *J Am Coll Cardiol* 1999;33:661–669, with permission.]

From the extensive reported experience, it can be concluded that stress perfusion imaging may serve as a gatekeeper in a system in which referral to cardiac catheterization is based on the presence and severity of ischemia. Such a strategy could reduce health care costs, because coronary angiography could be avoided in patients who are shown to be at low risk by the results of imaging studies, regardless of clinical presentation and treadmill exercise test results. This recommendation is justified because of the low event rate among patients who have normal results of tests or small defects; it is unlikely that coronary interventions could lower the already low risk.

Recent data indicate that patients who have microvascular disease or endothelial dysfunction may not have as benign an outcome as was once thought, even in the absence of epicardial coronary disease (121,122 and 123). This became apparent when the follow-up period for such patients was extended to 7 to 10 years, rather than the usual 1 to 4 years used in most of the studies cited previously. Some of these patients are known to have reversible perfusion defects, which may suggest that at least some false-positive scans are not really false and may, in fact, identify endothelial dysfunction and possibly high patient risk for future events.

Risk Assessment: Noncardiac Surgery

Two issues are important with regard to patients who will undergo noncardiac surgery: (a) which patients need stress testing and (b) which patients need coronary angiography and coronary revascularization. Mangano and Goldman (124) used a scoring system to define the risk based on several clinical descriptors. Based on the total points, the patients are divided among four classes. The probability of perioperative complications increased from class I (low score) to class IV (high score) and was higher among patients undergoing major vascular surgery or urgent surgery than among patients undergoing minor surgery or elective surgery. Lee and coworkers (125) suggested a simple scoring system to predict outcome. They assigned 1 point to each of the following factors: high-risk surgery, history of CAD, history of heart failure, history of cerebrovascular disease, insulin-dependent diabetes, and creatinine level >7.0 mg per dL. The major complication rates were 0.4%, 0.9%, 7.0%, and 11.0% for 0, 1, 2, and >3 points, respectively.

The American College of Cardiology (ACC)/American Heart Association (AHA) Task Force report on guidelines for perioperative cardiovascular evaluation for noncardiac surgery reaffirmed the importance of clinical evaluation in risk assessment (81). Major predictors of increased perioperative risk include recent acute MI, unstable angina pectoris, decompensated congestive heart failure, significant arrhythmias, high degree of atrioventricular block and severe valvular disease. Intermediate predictors include mild angina pectoris, prior MI, compensated or prior congestive heart failure, and diabetes mellitus. Minor predictors include advanced age, abnormal resting ECG, normal rhythm on ECG, low functional capacity, history of stroke, and uncontrolled systemic hypertension.

High-risk surgical procedures include a major emergency operation, such as aortic and other major vascular surgery, and peripheral vascular surgery, especially in elderly patients. Intermediate-risk procedures include carotid endarterectomy, head and neck surgery, and intraperitoneal, intrathoracic, orthopedic, and prostate surgery. Low-risk procedures include endoscopic procedures, superficial procedures, cataract removal, and breast surgery.

Patients who are at low risk, especially if they are undergoing a low-risk surgical procedure, may not need preoperative stress testing. Surgery should be avoided, whenever possible, in patients who have experienced recent MI or unstable angina pectoris, until the clinical condition has been stabilized; if surgery must be performed, then coronary angiography is recommended. In many other patients, stress testing is indicated. The greatest amount of experience by far is in the use of pharmacologic perfusion imaging with dipyridamole or adenosine (126,127,128,129,130,131,132,133,134,135 and 136). Mangano and Goldman (124) summarized the results of large studies published in the literature (*e*Table 53.5.1). The results show that among patients in whom no evidence of ischemia is found, the event rate is extremely low (2%); on the other hand, among patients who have reversible defects, the event rate is 18% (relative risk, 9.0). These general conclusions are concordant with those of multiple other studies that involved smaller number of patients. Most of these studies did not include quantitative analysis to assess the size of jeopardized ischemic myocardium, although Brown and Rowen (134) demonstrated that the risk of perioperative events increased in proportion to the degree of abnormality (assessed as the number of abnormal segments on dipyridamole planar Tl-201 imaging).

***e*TABLE 53.5.1** PREDICTIVE VALUE OF DIPYRIDAMOLE-THALLIUM SCINTIGRAPHY IN PREOPERATIVE RISK-STRATIFICATION[a]

[a]The definition of *cardiac complication* varied among studies but included preoperative myocardial infarction and death due to cardiac causes. The relative risks shown are the risk of a major cardiac event among patients with a positive test result divided by the risk among those with a negative test result.
Reproduced from Mangano DT, Goldman L. Preoperative assessment of patients with known or suspected coronary disease. *N Engl J Med* 1995;333:1750–1756, with permission.

The ACC/AHA guidelines recommend coronary angiography should be performed in patients for whom the results of noninvasive testing indicate a high risk of cardiac events (presence of a large area of ischemia, perfusion defects in multiple vascular territories, left ventricular dilatation, or increased lung Tl-201uptake) or who have angina pectoris that is unresponsive to medical therapy (class I indication) (81). Among other patients, either coronary angiography is not indicated or there is a divergence of opinion about whether such testing is indicated. Patients in whom left ventricular dysfunction is demonstrated by clinical evaluation or by the results of measurement of EF and patients who have extensive fixed perfusion defects are at risk of developing congestive heart failure or serious ventricular arrhythmias during the perioperative period. The risk of ischemic events in these patients is low, but the long-term outcome is poor because of the underlying left ventricular dysfunction. Thus, extensive fixed perfusion defects do not have the same implication as reversible defects in the short run, but they do have an impact on long-term prognosis (24,81).

A randomized study showed that bisoprolol (a selective $beta_1$-blocker) reduced the perioperative (137) death/MI rate from 34% in the control group to 3.4% in the treatment group for high-risk patients with ischemia who are undergoing high-risk vascular surgery.

In summary, coronary revascularization should be performed before noncardiac surgery only in a small subset of high-risk patients, whereas preoperative testing should be limited to circumstances in which the results will affect patient treatment and outcome. It should be noted that patients with vascular disease have a substantial risk of MI and cardiac death over the next 5 to 10 years. Accordingly, these patients should be carefully evaluated by noninvasive testing to determine the extent of ischemia and left ventricular function, and some of these patients may benefit from coronary revascularization procedures after the major noncardiac surgery.

PATIENT EVALUATION AFTER PTCA AND CABG

Nuclear techniques are very useful in the selection of patients for whom coronary revascularization is appropriate, in the evaluation of the results of revascularization interventions, and to ascertain the presence of recurrent myocardial ischemia early or late after revascularization. Ideally, coronary revascularization should be reserved for patients in whom myocardial ischemia has been documented, especially those patients who have large ischemic areas involving multiple vascular territories and patients who have transient cavity dilation or increased lung uptake of Tl-201 during stress testing; these are the characteristics that identify patients who are at high risk for future events if they do not undergo revascularization. Conversely, patients who have normal myocardial perfusion during stress testing or who have only small perfusion defects involving one vascular territory (especially if the defect is fixed) are not in a high-risk category; in general, the condition of these patients should be managed medically. However, patients who present with heart failure or angina in whom the perfusion scans show only fixed defects should undergo reinjection of Tl-201 (or a separate rest redistribution protocol), because some of these defects may further improve after reinjection, which is characteristic of myocardial ischemia and viable myocardium (138). Fixed defects accompanied by mild to moderate reduction in tracer activity are consistent with viable myocardium and often improve after revascularization (139).

Substantial resolution of myocardial ischemia with amelioration of perfusion defects is the rule after successful percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass graft (CABG) surgery (140,141,142,143,144,145,146,147 and 148). However, residual perfusion defects are common after coronary revascularization. The possible mechanisms of these defects are summarized in Table 53.6. The indications for perfusion imaging after PTCA or CABG are summarized in Table 53.7.

After PCI
Residual stenosis of dilated artery
Restenosis
Side-branch occlusion
After CABG
Graft disease (occlusion or stenosis)
After either PCI or CABG
Remote or periprocedure infarct
Incomplete revascularization
Disease progression

TABLE 53.6 MECHANISMS OF PERFUSION DEFECTS AFTER REVASCULARIZATION

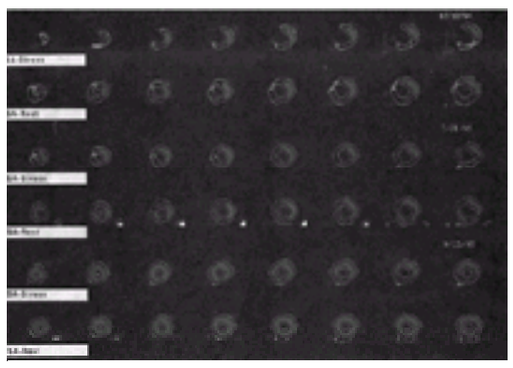
PCI
Early (<2 wk)
Uncertain or suboptimal results
Symptoms
Late (>2 wk)
Recurrence of symptoms
Silent ischemia before PCI
Multivessel disease with incomplete revascularization
High risk of coronary lesions
CABG
Recurrence of symptoms
Incomplete revascularization
Poor distal run-off
Silent ischemia before CABG surgery
Patient asymptomatic 3 to 5 yr after revascularization

CABG, coronary artery bypass graft; PCI, percutaneous coronary intervention.

TABLE 53.7 INDICATIONS FOR POSTREVASCULARIZATION PERFUSION IMAGING

Myocardial Perfusion Imaging after Percutaneous Transluminal Coronary Angioplasty

The ideal time to perform stress perfusion imaging after PTCA is controversial. Some authors have suggested that defects that occur very early after successful PTCA may later resolve (145). Others, however, have suggested that perfusion defects that appear early after PTCA are in fact highly predictive of late restenosis (143,146). It may be appropriate to delay myocardial perfusion imaging for 2 to 4 weeks after angioplasty. Alternatively, only patients with recurrent symptoms could be targeted for repeat myocardial perfusion imaging, although Hecht and colleagues (147) showed a similar rate of restenosis (61% vs. 59%) in asymptomatic and symptomatic patients, respectively, after PTCA (*e*Fig. 53.1.6). In both groups of patients, exercise perfusion imaging was highly accurate for detection of restenosis.



***e*FIGURE 53.1.6** Short-axis (SA) single-photon emission computed tomographic images from a patient with severe left anterior descending and circumflex artery stenoses before coronary angioplasty of both vessels (*top two rows*), 7 months after angioplasty and 2 months after coronary stenting of the left anterior descending artery. Perfusion defects involved the anterior wall, apex, and postero-inferior wall in the first study and clearly improved after angioplasty (*middle two rows*), although residual defects were still evident. After stenting of the left anterior descending artery, the images were normal (*bottom two rows*).

Myocardial Perfusion Imaging after Coronary Artery Bypass Graft Surgery

Contrary to PTCA, in which restenosis usually occurs within the first 3 to 6 months after the intervention, patients with CABG have a high early patency rate (90% at 1 year), with an attrition rate of 2% per year from years 1 to 7 and then 5% per year for years 7 to 12. At the end of 10 years, only approximately 40% of saphenous vein grafts are open and have a normal appearance. In contrast, internal mammary grafts have a patency rate of 85% to 95% after 7 to 10 years. Improved myocardial perfusion with normalization of ischemic perfusion defects is the rule after CABG (148), although residual defects after CABG resulting from the mechanisms listed in Table 53.6 are not infrequent. Myocardial perfusion imaging is also an effective way to assess graft patency after CABG. A new perfusion defect early (within the first 1 or 2 years) after CABG suggests a graft problem or incomplete revascularization, whereas defects appearing late (>5 years after CABG) suggest either graft disease or CAD progression (148). Tl-201 SPECT is very useful in the prognostic evaluation of patients who are examined late after CABG (149,150,151 and 152). The indications for perfusion imaging after CABG are listed in Table 53.7.

ACUTE CORONARY SYNDROMES

The main indications for nuclear imaging in acute coronary syndromes are listed in Table 53.8. Although Tc-99m pyrophosphate was introduced in the 1970s to detect acute myocardial necrosis, it is now rarely used, because positive results within the first 24 hours are unusual. In-111–labeled antimyosin antibody imaging is also likely to have limited clinical use for the same reason (images obtained earlier reflect blood pool activity). This tracer, however, has other useful clinical applications, such as the detection of myocarditis (which may occasionally need to be differentiated from acute infarction) and detection of anthracycline-induced cardiotoxicity. A new radiotracer (Tc-99m glucarate) is available that may permit early imaging; positive scans can be demonstrated within 1 to 2 hours of acute infarction, even in patients who did not receive thrombolytic therapy (153). This tracer is expected to undergo clinical trials in the near future. Infarct avid imaging and RNA are also helpful in detecting right ventricular infarction. Although RNA can be used to detect a left-to-right shunt (resulting from a ruptured ventricular septum) or mitral regurgitation (resulting from ruptured papillary muscle), these complications, as well as thrombus in the left ventricular cavity caused by large infarcts, are best detected by two-dimensional echocardiography. The issue of viability is discussed later in this chapter.

Detection of acute MI
Measurement of the size of MI
Assessment of myocardial salvage in response to thrombolytic therapy or primary angioplasty
Measurement of left ventricular ejection fraction
Identification of the culprit artery in patients with unstable angina pectoris
Triage of patients who present with chest pain in the emergency department
Risk assessment in patients with unstable angina pectoris
Risk assessment after acute MI
Detection of complications of acute MI
Viability assessment

MI, myocardial infarction.

TABLE 53.8 USES OF NUCLEAR IMAGING IN ACUTE CORONARY SYNDROMES

Because of the associated long myocardial retention and slow washout, Tc-99m–labeled tracers have been used to measure the size of MI and myocardial salvage. Injection of the tracer before thrombolytic therapy or primary angioplasty is initiated defines the area of myocardium at risk, even when the images are obtained several hours later. These images can be compared to a second set of images obtained several days later. The defect size reduction reflects the degree of myocardial salvage, and the final defect size reflects the area of residual necrosis. Further reduction in the size of a perfusion defect has been reported in approximately 70% of patients after 6 months, even without coronary intervention (154). Several studies have shown substantial variability in both the area at risk and the degree of salvage in patients with acute infarction. In general, both the area at risk and the absolute amount of salvaged myocardium are larger in patients with anterior than inferior or posterior MI (although, in relative terms, the percentage of salvage may be similar). The size of the defect seen on predischarge scan correlates well with indices of left ventricular function such as EF and end systolic volume and is also an important predictor of survival (155,156).

An emerging use of cardiac imaging in many institutions is in the triage of patients with chest pains who are seen in the emergency department (157,158,159,160,161,162,163 and 164). It is estimated that 36 million patients per year visit emergency departments in the United States for evaluation of chest pains. Although only 10% to 15% of these patients have acute MI, approximately 40% to 50% are admitted to the coronary care units to rule out acute infarction. Ironically, despite this high admission rate, approximately 5% of patients discharged from the emergency department will have acute MI, and of those, 15% to 25% will die. This misdiagnosis now accounts for the largest segment of malpractice lawsuits aimed against emergency departments. At the same time, the estimated cost for admitting patients for the purpose of ruling out acute MI is in the range of $13 billion per year. In any health system, unnecessary admissions amount to financial liability and, at the same time, reduce the availability of vital coronary care unit beds. Goldman et al. (165) developed a model based on resting ECG, systolic blood pressure, rales, and symptoms of unstable angina that helped to stratify patients into very low-risk, low-risk, moderate-risk, and high-risk groups (0.8%, 3.6%, 8.1%, and 21.5% event rate, respectively) for major events (i.e., serious arrhythmias, cardiogenic shock or recurrent ischemia requiring revascularization).

In many institutions, chest pain units have been established within the emergency department to screen for patients who need admission and monitoring and to identify those who may be discharged or need early stress testing. The precise algorithm varies from center to center, but generally patients with nondiagnostic ECG ST/T changes undergo clinical evaluation and serial cardiac enzymes measurements (including creatine kinase/MB and troponin I or T). When the results of these tests are negative, the patients undergo rest or exercise perfusion imaging (or both), depending on the probability of CAD. Injection of a tracer during chest pain or shortly after has shown perfusion defects in many patients with acute MI or unstable angina pectoris and nondiagnostic ECG changes. Varetto and colleagues (162) observed perfusion defects in 27 of 30 patients who subsequently were demonstrated to have acute coronary syndromes, but in 0 of 34 patients who subsequently showed no evidence of CAD. Hilton et al. (160) reported events in only 1 of 70 patients who had normal scans but in 71% of 32 patients with abnormal scans. The group of investigators (164) at the Medical College of Virginia have reported their extensive experience with emergency department imaging. Their pioneering work suggests that acute perfusion imaging may be an important addition to current screening modalities in the acute setting.

Risk Assessment

The risk among patients with acute MI for future cardiac events depends on the size of the infarction, clinical findings (e.g., third heart sound gallop, age, gender, presence of diabetes mellitus, rales, hypotension, serious ventricular arrhythmias, recurrent ischemia, infarction extension), LVEF and the results of coronary angiography (extent of CAD), exercise results, and imaging variables. Several studies made in the 1980s concluded that stress perfusion imaging (exercise or pharmacologic) (166,167) and the LVEF determined by RNA (168) performed in patients who had uncomplicated acute MI could stratify patients into low- and high-risk groups. These studies were carried out in the prethrombolytic era. For example, Gibson et al. (166) reported that 50% of patients who had multiple perfusion defects in more than one vascular territory or abnormal lung Tl-201 uptake on predischarge exercise testing subsequently experienced cardiac events. On the other hand, the event rate was only 6% in patients who had either a normal scan or fixed defects in the territory of the infarction. Other studies have also shown that stress perfusion imaging is clearly superior to ST segment changes in detecting multivessel disease in such patients. One of the most important markers of prognosis, judging by the results of the Multicenter Postinfarction Research group (168), has been the radionuclide-measured resting LVEF. In this study, patients with an EF >40% had a low event rate, whereas patients with an EF <40% had a significantly higher event rate, especially those with an EF <30%. In more recent studies involving patients who received thrombolytic therapy, the LVEF was still a strong predictor of outcome, but fewer patients had left ventricular dysfunction (Fig. 53.2) (169,170 and 171).

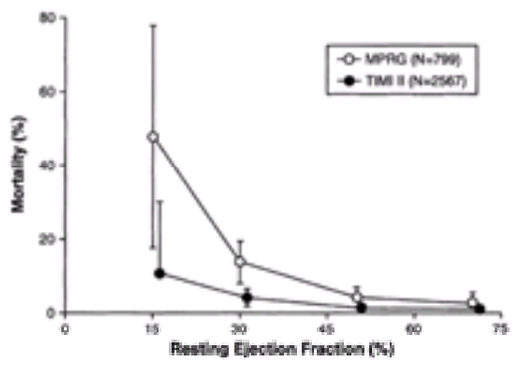


FIGURE 53.2 The relationship between resting left ventricular ejection fraction and survival in patients who have experienced acute myocardial infarction. The results from patients who received thrombolytic therapy [Thrombolysis in Myocardial Infarction phase II study (TIMI II)] are contrasted with those from the Multicenter Postinfarction Research Group (MPRG). [From Zaret BL, Wackers FJ, Terrin ML, et al. Value of radionuclide rest and exercise left ventricular ejection fraction in assessing survival of patients after thrombolytic therapy for acute myocardial infarction: results of Thrombolysis in Myocardial Infarction (TIMI) phase II study. *J Am Coll Cardiol* 1995;26:73–79, with permission.]

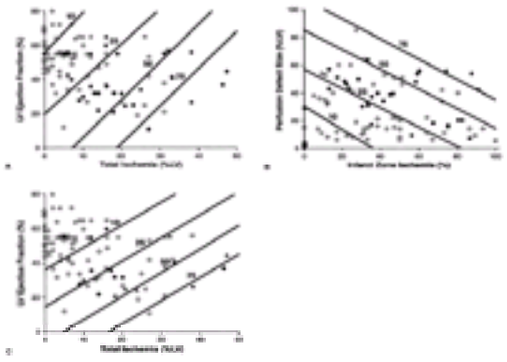
In the thrombolytic era, early studies have suggested that SPECT perfusion imaging is less accurate in risk assessment (172,173). However, more recent studies using exercise testing combined with quantitative Tl-201 imaging have shown that the size of the perfusion defect as well as the extent of ischemia and the LVEF are independent predictors of cardiac events. The perfusion data had incremental value to the LVEF (174). In nonselected patients who had acute infarcts, one-half of

whom had thrombolytic therapy, Mahmarian et al. (175,176) showed that traditional variables of perfusion imaging, such as the size of the perfusion abnormality and the extent of reversibility during adenosine SPECT Tl-201 imaging, were still important predictors of prognosis. Another important observation from the latter study is that the LVEF provided incremental value to the size of the perfusion defect (*e*Fig. 53.2.1). This observation is pertinent because the Tc-99m–labeled tracers allow simultaneous assessment of both the perfusion defect and the LVEF. Several studies have shown that pharmacologic vasodilatation with adenosine or dipyridamole is safe as early as 48 hours after an acute MI. A recent comparison between dipyridamole and submaximal exercise testing, both associated with SPECT imaging, showed the pharmacologic approach to be at least as good as exercise imaging, if not better (177). Another recent report has suggested that aggressive antiischemic therapy involving either revascularization or medical therapy substantially reduces perfusion defect size and may improve outcomes in these patients (178). Early testing may expedite the decision-making process and decrease hospitalization time. The relative value of vasodilator perfusion imaging compared with early exercise perfusion testing, however, remains unclear. There are no data on the safety of high-dose dobutamine perfusion imaging in risk assessment. The importance of perfusion imaging in risk assessment is emphasized in the new ACC/AHA guidelines on management of the condition of patients who have acute MI (179). The VANQWISH trial, which involved patients with non–Q-wave MI, used Tl-201 imaging as a risk-stratifying modality to identify patients randomly assigned to a conservative strategy who might have a high risk for cardiac events. These patients could cross-over to revascularization. The results of the Veterans Affairs Non-Q-Wave Infarction Strategies in Hospital trial suggested that a noninvasive strategy, in which assessment was performed by perfusion imaging, led to better outcomes than an invasive strategy (180). Recently published guidelines for management of non–Q-wave MI and unstable angina suggest that a noninvasive risk assessment strategy is appropriate for stable patients (181).



***e*FIGURE 53.2.1** Cox regression models displaying 1-year risk for a cardiac event according to left ventricular (LV) ejection fraction and total left ventricular ischemia **(A)** or infarct ischemia **(B)**. **C:** Regression model for predicting infarct-free survival. Diagonal lines indicate representative isobars of percentage risk. Patient risk for any cardiac event **(A,B)**, or specifically for death or nonfatal reinfarction **(C)**, increases as total LV ischemia increases and ejection fraction decreases. **A,B:** ●, events; ○, no events. **C:** ▲, death; ●, nonfatal myocardial infarction; ○, neither. (From Iskandrian AS, Verani MS. *Nuclear cardiac imaging: principles and applications*. Philadelphia: FA Davis, 1996; and Mahmarian JJ, Mahmarian AC, Marks GF, et al. Role of adenosine thallium-201 tomography for defining long-term risk in patients after acute myocardial infarction. *J Am Coll Cardiol* 1995;25:1333–1340, with permission.)

Unstable Angina Pectoris

The indications for nuclear testing include differentiation between cardiac and noncardiac chest pains in patients with equivocal presentations, and risk assessment. Injection of Tc-99m–labeled tracers while the patient is at rest during or shortly after chest pain can be very helpful in determining the cardiac etiology of pain and, more specifically, the culprit vessel (Fig. 53.3). According to Bilodeau et al. (157), this method had a sensitivity of 62% and a specificity of 88% (ST segment shifts had a sensitivity of 38% only).

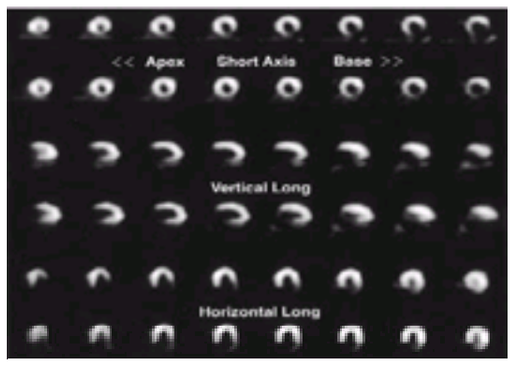


FIGURE 53.3 Resting single-photon emission computed tomographic technetium-99m sestamibi images obtained during spontaneous chest pain in a patient with unstable angina pectoris. The images show a large perfusion defect in the inferolateral regions (*first, third, and fifth rows*). The second set of images, obtained 24 hours later during an angina-free period, show partial redistribution (*second, fourth, and sixth rows*). Each set shows short-axis, vertical long-axis, and horizontal long-axis slices.

The guidelines on unstable angina pectoris suggest that in the following patients coronary angiography may be indicated: patients with previous MI or revascularization, those who fail to stabilize on medical therapy, those with high-risk clinical findings seen on noninvasive testing, and those with significant heart failure or left ventricular dysfunction (182). For patients who can be stabilized with medical therapy, a more conservative approach, using noninvasive testing, is generally preferable (181,182,183,184,185 and 186). Routine use of coronary angiography for all patients is not only expensive but also exposes many patients to unnecessary risk and interventions. Noninvasive risk-stratification can identify the patients most likely to benefit from additional invasive procedures.

Several studies have shown that myocardial perfusion imaging appears to be superior to ST segment response. For example, Brown et al. (183) found that the cardiac event rate was 26% in patients with reversible defects and 3% in those with no reversible defects; Stratmann et al. (184) found that the cardiac event rate was 25% in patients with reversible defects and 2% in those with normal scans; Madsen et al. (186) found a cardiac event rate of 21% in patients with reversible defects and 3% in patients with no reversible defects. Therefore, stress perfusion imaging may be used to risk-stratify patients with unstable angina who had no occurrence of ischemia for 48 to 72 hours while receiving medical therapy. Patients who are classified as high risk on the basis of scan results need coronary angiography, and patients classified as low risk can be treated medically.

RADIONUCLIDE ANGIOGRAPHY

The RNA techniques for assessing left ventricular and right ventricular functions include gated equilibrium (or MUGA) and first-pass methods. With gated RNA, Tc-99m pertechnetate is used to label the red blood cells, whereas with first-pass RNA, Tc-99m bound to pertechnetate, human serum albumin, DTPA (diethylenetriamine penta-acetic acid), or sulfur colloid can be used. Both the first-pass and MUGA techniques can be performed while the patient is at rest and during stress (exercise or pharmacologic). First-pass studies are usually obtained either in the anterior or right anterior oblique projection. Gated RNA images are obtained usually in three views, and with the dual head 90-degree detector systems, biplane studies may be carried out, providing four projections during two acquisitions. Both techniques allow measurement of LVEF (global and regional), volumes, wall motion, diastolic indices, and right ventricular EF and wall motion (*e*Fig. 53.3.1 and *e*Fig. 53.3.2). The EF is derived on the basis of count changes rather than geometric assumptions; this makes RNA probably the most reliable and reproducible method for EF measurement. A method of SPECT-gated RNA was used for the first time in 1980. The availability of multihead detector systems and high-performance dedicated computers that shorten the acquisition and processing time has renewed interest in the use of tomographic techniques (187,188). The advantages of tomographic MUGA are the abilities to avoid superimposition of different structures and to improve quantitative measurements. The images are displayed either as cineloops of multiple slices at end diastole and end systole or as a three-dimensional presentation showing the entire left ventricular silhouette and other cardiac structures. The left ventricular diastolic function can also be assessed using RNA. Some of the most common indices used include the peak filling rate, the time to peak filling rate, and percentage of left ventricle filling during early diastole compared to that during late diastole (due to atrial contraction). Abnormalities in diastolic indices have been found in patients with CAD (even in the absence of systolic dysfunction), in older patients, and in patients with hypertension, hypertrophic cardiomyopathy, and a number of other

cardiac disorders. As is true of systolic dysfunction, the diastolic dysfunction can be regional rather than global (23,24,25 and 26).

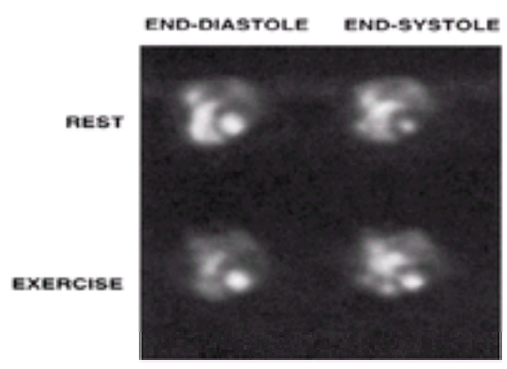
***e*FIGURE 53.3.1** First-pass radionuclide angiograms in a healthy subject (NL) show increases in ejection fraction (EF), end diastolic volume (EDV), stroke volume (SV), cardiac output (Co), and heart rate (HR) and a decrease in end systolic volume (ESV). There are no regional wall motion abnormalities at rest or during exercise. Responses from a patient with coronary artery disease (CAD) with exercise-induced wall motion abnormality show a decrease in EF and an increase in ESV between rest and exercise. The response from a patient with chronic aortic regurgitation (AR) shows a decrease in EDV. SBP, systolic blood pressure. (From Iskandrian AS, Verani MS. *Nuclear cardiac imaging: principles and applications*. Philadelphia: FA Davis, 1996, with permission.)



***e*FIGURE 53.3.2** Rest- and exercise-gated equilibrium radionuclide angiography in a patient with coronary artery disease. Resting left ventricular function is normal, but with exercise, wall motion abnormality and a decrease in ejection fraction are seen.

One of the chief advantages of exercise RNA has been in risk assessment. The Duke investigators have described the prognostic implication of exercise EF in patients with chronic CAD and have shown that exercise RNA variables provide independent and incremental prognostic value in addition to those obtained by clinical evaluation, exercise testing and cardiac catheterization (*e*Table 53.8.1) (189,190,191 and 192). In fact, measurement of the EF during exercise yielded most of the information provided by cardiac catheterization. Patients with an exercise EF >50% had a very low event rate; those with an exercise EF <35% had a high event rate; and those with an EF between 35% and 50% had an intermediate event rate. Shaw et al. (193) demonstrated that the prognostic power of a model based on clinical variables and RNA was slightly better than that of a model based on clinical variables and cardiac catheterization (c^2 = 83 vs. 74) (*e*Fig. 53.3.3). Other groups have shown similar results (194,195,196,197 and 198). The RNA predictors of risk are listed in *e*Table 53.8.2. Supino et al. (199) showed that the benefit of CABG was greatest in patients who had the greatest amount of ischemia before surgery, reflected in the change in EF from rest to exercise. Borer and colleagues (200) reported that the change in EF from rest to exercise, adjusted for end systolic wall stress, predicted long-term outcome in patients who had aortic regurgitation with no or minimal symptoms.

First-pass RNA can be obtained with a multiwire gamma camera (Proportional Technologies, Inc., Houston, TX), which uses a proportional counter detector with a high count rate and improved image resolution (201). This system uses low-energy radionuclides such as tantalum-178, with energy of 55 to 65 KeV and a half-life of approximately 9 minutes. There is also a nonimaging nuclear probe (known as *VEST*), that allows beat-to-beat measurement of LVEF and relative volume over the course of relatively extended periods of observation in ambulatory patients, very much as a Holter monitor does (202).

MYOCARDIAL VIABILITY

It has long been recognized that some patients who have ischemic heart disease and depressed left ventricular function may exhibit improved function after CABG or PTCA enhances the coronary flow. The preoperative identification of myocardial viability is particularly important in patients with congestive heart failure and depressed LVEF, because these patients may improve remarkably after surgery if they have chronic myocardial hypoperfusion of otherwise structurally viable myocardium (hibernating myocardium). Conversely, revascularization carries a higher risk and would be expected to result in minimal, if any, benefits for patients who have extensive myocardial scarring.

Physiologic Basis

Although the myocardial uptake of all available myocardial perfusion tracers is directly proportional to myocardial blood flow (within physiologic limits), both extraction and retention depend on active metabolic processes. Tl-201 extraction, for example, depends in part on the sodium-potassium adenosinetriphosphatase pump, whereas retention depends on an intact cell membrane. Tc-99m sestamibi and Tc-99m tetrofosmin are extracted predominantly on the basis of a negative cellular transmembrane potential and a negative mitochondrial transmembrane potential. Maintenance of these transmembrane potentials requires active metabolic processes. Disruption of the cell membrane or of the mitochondrial function affects tracer extraction, retention, or both.

Clinical Use of Nuclear Imaging in the Assessment of Myocardial Viability

Several different tracers and protocols can be used for the assessment of myocardial viability (eTable 53.8.3). The presence of redistribution on Tl-201 images taken 4 hours after stress is indicative of myocardial ischemia and hence viability. However, regions with absent or incomplete redistribution may still be viable and may improve after revascularization (139,140). Early attempts to overcome this problem used 12- to 36-hour delayed imaging after the stress Tl-201 injection (203). Although filling in of defects in this late redistribution image identifies additional areas of viable myocardium, a considerable number of viable regions are still missed. Moreover, because of the typically poor count statistics associated with the 24-hour delayed Tl-201 images, interpretation of these studies may be difficult.

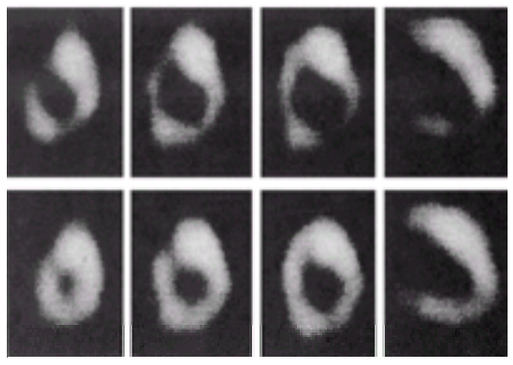
***e*TABLE 53.8.3** NUCLEAR METHODS OF ASSESSING MYOCARDIAL VIABILITY

Tl-201 stress-redistribution
Tl-201 reinjection
Tl-201 rest redistribution
Technetium-99m sestamibi stress-rest
Nitrate-augmented perfusion imaging
Fatty acids (I-123 IPPA, I-123 BMIPP)
Positron emission tomography: flow/fluorodeoxyglucose; rubidium-82 washout
Low-dose dobutamine SPECT

I-123 BMIPP, iodine-123-beta-methyl-*p*-iodophenylpentadecanoic acid; I-123 IPPA, iodine-123 iodophenylpentadecanoic acid; SPECT, single-photon emission computed tomography; Tl, thallium.

Tl-201 reinjection after the redistribution images may circumvent some of the deficiencies of the latter. As initially described by Dilsizian et al. (27), approximately 50% of defects that may appear fixed at 4 hours improve after reinjection, and most of these regions also show improved function after revascularization.

Although the identification of stress-induced ischemia is a superior indication of viable myocardium (204), incompletely resolved ischemia may also present as a persistent defect (scar) (139,140,203)—hence the current use of resting 4-hour redistribution Tl-201 imaging. It is recognized that asynergic myocardial regions perfused by coronaries with high-grade stenosis may display resting hypoperfusion (hibernating myocardium) during resting Tl-201 imaging (27,28,205,206). These defects may fill in over the course of the next several hours, thereby demonstrating viable myocardium (eFig. 53.3.4). It has also been shown that the higher the regional uptake of Tl-201, the more likely it is that the region is viable. Conversely, regions with very low uptake during rest redistribution or stress reinjection are likely to contain predominant scarring. An arbitrary 50% or 60% Tl-201 uptake, relative to that in normal regions, is a clinically useful threshold to differentiate between viable and nonviable myocardium (28,206,207 and 208). However, the identification of viable regions by rest redistribution Tl-201 imaging is still less than ideal, and positive and negative predictive accuracies range from 45% to 79% and 62% to 80%, respectively (205,209,210).



***e*FIGURE 53.3.4** Rest-redistribution single-photon emission computed tomographic thallium imaging showing severe reversible perfusion defects in multiple segments. The ejection fraction in this patient showed marked improvement after coronary artery bypass grafting. (From Iskandrian AS. Thallium reinjection imaging: the search for an optimal protocol. *J Nucl Med* 1993;34:743–746, with permission.)

Clinical Use of Technetium-99m Sestamibi in the Assessment of Myocardial Viability

Because Tc-99m sestamibi undergoes only minimal redistribution at 4 hours after the injection, sestamibi has been considered by some to be less useful for detecting viable myocardium than Tl-201 (211,212). More recently, Udelson and associates (207) and Kauffman and coauthors (213) compared sestamibi uptake, after a resting injection, with Tl-201 uptake in the rest redistribution images. Under those conditions, these authors found very similar sestamibi and Tl-201 activities. A sestamibi

activity >60% of maximal uptake had a positive predictive value of 80% and a negative predictive value of 96% for improvement in regional dyssynergy after revascularization. Dilsizian and colleagues (28) have also compared sestamibi uptake at 1 hour and 4 hours after a resting injection and observed that 40% of the segments had improved uptake over the course of time. These authors also compared sestamibi and Tl-201 uptakes by quantitative analysis, which markedly improved the concordance between these two tracers for viability detection. Recent investigations comparing the levels of Tc-99m sestamibi in perfusion defects with the extent of historically viable myocardium have indicated a high degree of correlation between the uptake of this tracer and the amount of viable myocardium (214,215).

Nitrate-Augmented Perfusion Imaging

Nitroglycerin administration may improve myocardial perfusion either by increasing coronary collateral flow or by dilating the stenosis slightly. Thus, it is not surprising that administration of nitroglycerin may improve perfusion defects. Galli et al. (216) reported that administration of nitroglycerin before sestamibi injection while the patient was at rest improved detection of myocardial viability. It has also been shown that nitrate administration before Tl-201 reinjection improved detection of viable myocardium (217). Therefore, nitroglycerin administration before either sestamibi or Tl-201 injection may further improve detection of myocardial viability (217,218).

Clinical Use of Fatty Acids for Detection of Myocardial Viability

Recent reports have suggested that iodine-123 iodophenylpentadecanoic acid (I-123 IPPA) may be a good marker for use in detection of myocardial viability (219,220). Iskandrian et al. (220) have reported a 91% agreement between IPPA and rest redistribution Tl-201 SPECT (Fig. 53.4). A recent multicenter trial (221) evaluated the utility of I-123 IPPA for predicting substantial increases in LVEF (=10%) after CABG in patients with a depressed preoperative LVEF (<40%). On multivariate analysis, the number of segments that were viable by IPPA was the most important predictor of recovery of function after revascularization.

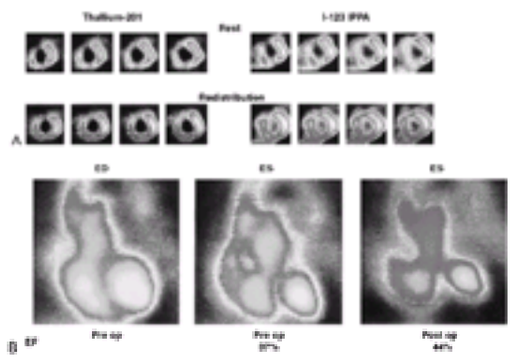


FIGURE 53.4 A: Rest-redistribution thallium-201 tomographic images and 5- and 30-minute iodine-123 iodophenylpentadecanoic acid (I-123 IPPA) tomographic images from a patient with severe three-vessel disease and left ventricular dysfunction. The thallium-201 and I-123 IPPA images reveal reversible defects. The reversibility is better seen with I-123 IPPA. **B:** This patient had improvement in left ventricular function after coronary artery bypass grafting. ED, end diastole; EF, ejection fraction; ES, end systole. (From Iskandrian AS, Powers J, Cave V, et al. Assessment of myocardial viability by dynamic tomographic iodine 123 iodophenylpentadecanoic acid imaging: comparison with rest-redistribution thallium-201 imaging. *J Nucl Cardiol* 1995;2:101–109, with permission.)

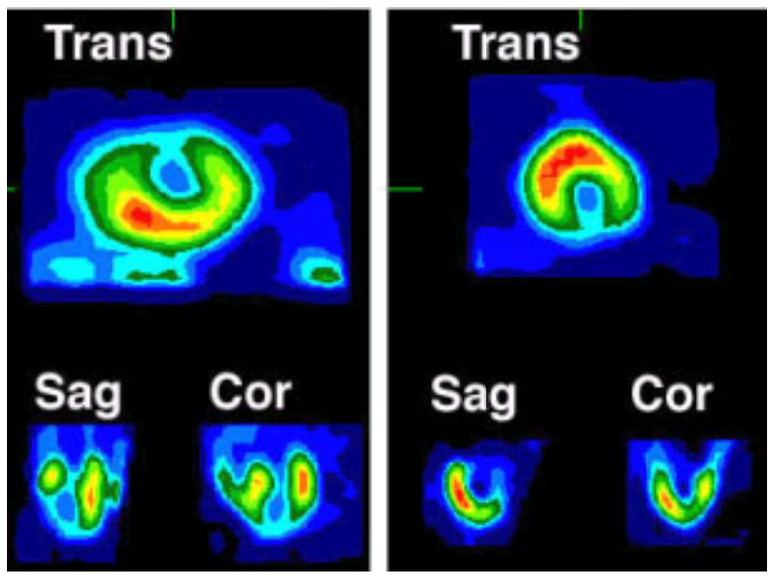
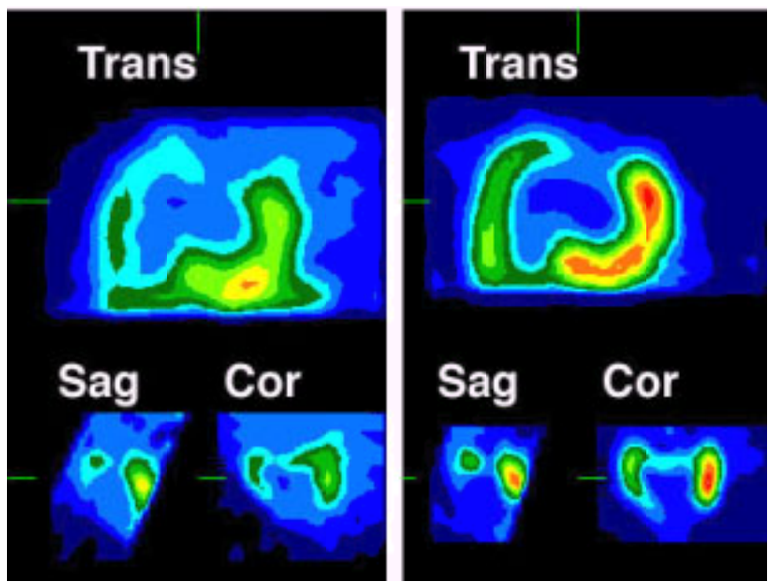
Another fatty acid that has been used, especially in Japan, for evaluation of myocardial viability is I-123-beta-methyl-*p*-iodophenylpentadecanoic acid (I-123-BMIPP). This agent has a structure that is remarkably similar to IPPA, with the addition of a methyl radical. However, it possesses a longer residence time intracellularly and therefore allows more convenient imaging. Although I-123-BMIPP has not yet been well studied as a viability marker, it has been suggested that areas with discordant BMIPP/Tl-201 uptake (greater decrease in BMIPP than Tl-201) are likely to show increased F-18-FDG uptake, a marker of myocardial viability (222).

Clinical Use of Positron Emission Tomography for Assessment of Myocardial Viability

At the present time, PET is probably the best technique for the assessment of myocardial viability. The best predictor of viable myocardium is a mismatch between flow (measured by oxygen-15 H_2O, nitrogen-15 NH3, or rubidium-82) and glucose metabolism (assessed by F-18-FDG) (208,223). Recently, F-18-FDG has been successfully imaged using standard SPECT cameras mounted with a special high-energy (511-KeV) collimator (224). Although the feasibility of this technique has been demonstrated, the quality of the F-18-FDG SPECT images is not as good as that of images obtained with PET. Moreover, the radiopharmaceutical cost remains a serious impediment to widespread clinical use of F-18-FDG.



Matched resting rubidium (*left set*) and radiolabeled fluoro-deoxyglucose positron emission tomographic (*right set*) images. Transverse, sagittal, and coronal positron emission tomographic images demonstrating myocardial hibernation in the left anterior descending artery territory.



Matched resting rubidium (*left*) and radiolabeled fluoro-deoxyglucose (*right*) positron emission tomographic images. Other investigators have used PET imaging with carbon-11 acetate as an indicator of myocardial oxidative metabolism, which potentially could be a good marker of viability (225). The clearance of rubidium-82 has also been proposed as a marker of viability, but there is limited experience with this approach (226). A new protocol has been proposed to assess myocardial viability with low-dose dobutamine sestamibi SPECT (227,228). At this time, only preliminary data have been reported with this technique (229).

RECENT DEVELOPMENTS IN NUCLEAR CARDIOLOGY

A number of guidelines on training, competency, certification, and accreditation of radionuclide users and laboratories are now available. A variety of educational programs are also sponsored by the American Society of Nuclear Cardiology, including an annual scientific meeting. The new developments are summarized in Table 53.9. Newer generations of solid-state gamma cameras, nonimaging detectors, and micro-PET and micro-SPECT will enhance clinical and research applications of nuclear cardiology, including the ability to study myocardial metabolism and gene expression in small animals. Improvements in software to correct for attenuation, scatter, and depth resolution have been made, and such methods may be used at the present time (Table 53.9).

Hardware and software
New tracers
New stress agents
Molecular and vascular imaging
New applications

Adapted from Iskandrian AE, Verani MS, eds. Bar Harbor Invitation Meeting 2000. *J Nucl Cardiol* 2001;8(2):224–316, with permission.

TABLE 53.9 RECENT DEVELOPMENTS IN NUCLEAR CARDIOLOGY

Clinical studies on a number of compounds, such as Tc-99m Noet (for myocardial perfusion), Tc-99m glucarate (for acute MI), Tc-99m annexin V (for apoptosis and transplant rejection), Tc-99m nitro imidazole (for myocardial hypoxia), I-123 meta-iodobenzylguanidine (for sympathetic innervation), and a number of selective A_2 receptor agonists (used as vasodilators), are ongoing (119,230,231,232,233,234 and 235).

There is a heightened interest in molecular imaging, angiogenesis, and vascular imaging and gene expression. Significant strides continue to be made in this field in automation and quantification, including the possibility of absolute measurements such as the myocardial blood flow, which is now only possible by use of PET.

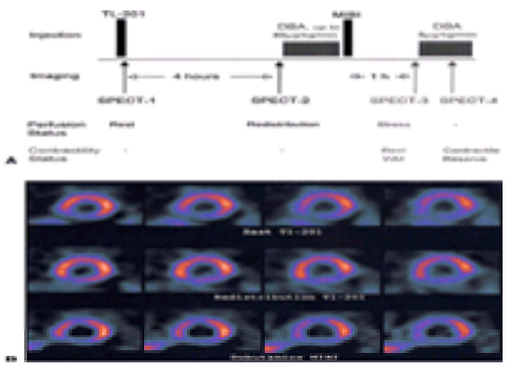
New applications are currently emerging, such as the use of acute imaging in emergency departments and in cases of sudden death and heart failure. Finally, there is a heightened interest in the detection of early atherosclerosis and characterization of unstable atherosclerotic plaques. These and other anticipated developments are likely to contribute to the continued growth of the field in the new millennium (234).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Three perfusion tracers are currently approved for routine clinical use: Tl-201, Tc-99m sestamibi, and Tc-99m tetrofosmin. All three tracers are useful in the assessment of diagnosis, risk-stratification, and myocardial viability.

The Tc-99m–labeled tracers provide significantly better image quality than Tl-201 and allow attenuation/scatter correction and first-pass RNA studies. The results with attenuation/scatter correction with Tl-201 are not yet convincing. The importance of EF measurement suggests that gated SPECT should be used in all patients. Today, >70% of perfusion studies are performed using Tc-99m–labeled tracers, and >90% are performed using gating; this is a remarkable change in a relatively short period of time.

For viability assessment, rest redistribution Tl-201 imaging provides a measure of hibernation (rest hypoperfusion) that, arguably, is not obtainable by Tc-99m–labeled tracers. The role played by ischemia in recovery of function, however, suggests that a stress rather than a resting study is needed for these patients. A hybrid protocol using rest redistribution Tl-201 and stress Tc-99m–labeled tracers may provide a complete assessment (eFig. 53.4.1) (235).



***e*FIGURE 53.4.1 A:** The methodology of a novel imaging protocol to assess myocardial viability using gated single-photon emission computed tomography (SPECT) that allows characterization of dysfunctional myocardium as stunned, hibernating, remodeled or infarcted. **B:** Selected SPECT slices showing rest-redistribution thallium and dobutamine (DBA) sestamibi (MIBI). The baseline and low-dose dobutamine functional images are not shown. Resting and stress-induced reversible defects are present. Tl-201, thallium-201; WM, wall motion. (From Narula J, Dawson MS, Singh BK, et al. Noninvasive characterization of stunned, hibernating, remodeled and nonviable myocardium in ischemic cardiomyopathy. *J Am Coll Cardiol* 2000;36;1913–1919, with permission.)

The strongest asset of nuclear imaging is the ability to provide quantitative measurements (e.g., EF, area of myocardium at risk, and infarct size). This is best achieved by tomographic imaging enhanced by gated perfusion imaging and by performing attenuation/scatter depth resolution compensation. Emerging techniques are likely to expand the applications beyond perfusion and function to include metabolic, receptor, and atherosclerosis imaging, and ultimately the ability to identify unstable plaques and gene expression.

Some argue that nuclear testing is prohibitively expensive, which it is in comparison to exercise ECG. However, cost is a market-driven value, and cost-effectiveness is a better index than cost.

Regarding the choice of stress modality, exercise continues to be preferred because of the known prognostic variables associated with stress ECG and exercise tolerance. From the standpoint of diagnostic accuracy, however, pharmacologic stress imaging appears to be at least equivalent to exercise imaging. Moreover, the image variables that indicate increased risk by exercise stress (e.g., large defects, multivessel defects, transient ischemia dilation, and LVEF and left ventricular size) are also powerful risk predictors when observed with pharmacologic imaging.

THE FUTURE

We believe the future will bring about important changes in the way that nuclear cardiology is practiced. First, newer tracers will be available that will allow imaging to be target-specific for studying myocardial perfusion, myocardial hypoxemia, myocardial necrosis, myocarditis, myocardial metabolism, sympathetic innervation, ventricular function, and coronary atherosclerosis. Targeting gene expression with specific nuclear markers will allow imaging of genetically engineered animal models and, later, of human beings. It may become possible to image vulnerable plaques in diverse arteries. Second, SPECT imaging will be used routinely with attenuation/scatter and depth resolution compensation, as well as with gating, three-dimensional imaging, and absolute quantification. These advances will increase the precision of the technique and improve quantification. Third, there will be increased applications of nuclear imaging in other groups of patients, such as patients with life-threatening ventricular arrhythmias, patients with congestive heart failure, asymptomatic patients who are at high risk, and in the evaluation of effects of therapeutic interventions such as gene therapy, lipid-lowering therapy, antianginal medications, and hormone-replacement therapy. Fourth, the quality of the nuclear images will improve through standardization of procedures, quality assurance measures, and certification and credentialing programs. Last, managed-care organizations will recognize that nuclear procedures are cost-effective for selecting patients who will benefit most from coronary angiography and percutaneous procedures and patients in whom routine coronary angiography is not justified.

OVERVIEW

Cardiovascular (CV) magnetic resonance imaging (MRI) is uniquely well suited for the morphologic and physiologic evaluation of a wide range of acquired and congenital disease processes affecting the heart, pericardium, and great arteries and veins of the thorax. Its technological diversity permits MRI to provide four-dimensional (three spatial dimensions over the dimension of time) imaging of the CV system based on definition of high-detail anatomy, histologic characterization, intracardiac or intravascular blood flow, cardiac chamber contraction and filling, regional myocardial mechanics, and tissue perfusion. Already, CV MRI has established itself as a valuable noninvasive diagnostic imaging tool within the clinical arena, with its application largely limited by actual or perceived expense, lack of availability of dedicated CV MRI services compared with other imaging services (e.g., echocardiography), unportability of equipment to ill patients, difficulty in monitoring patients on life support or during induced stress, and contraindication to imaging certain implanted devices (e.g., pacemaker). Nevertheless, CV MRI has evolving roles being established in the following groups of CV diseases: (a) thoracic aortic disease (e.g., aortic dissection); (b) ischemic heart disease [e.g., determination of viability and post–myocardial infarction (MI) complications]; (c) myocardial disease [e.g., right ventricular cardiomyopathy (CM)]; (d) pericardial disease (e.g., constrictive pericarditis); (e) thrombi and masses (e.g., cardiac tumor); (f) adult congenital heart disease (CHD) (e.g., great vessel abnormality); (g) valvular heart disease (e.g., aortic regurgitation); and (h) pulmonary artery disease (e.g., pulmonary hypertension). The future of CV MRI will depend on (a) establishment of an important role in the evaluation of ischemic heart disease or related conditions (e.g., possibly by providing comprehensive profiles of the pertinent parameters); (b) unique definitions of aspects of CV diseases (e.g., myocardial characterization, load-independent measure of myocardial function, noninvasive arterial wall imaging), leading to high morbidity and mortality in this country; (c) cooperative efforts between services dealing with diagnostic imaging of CV diseases; or (d) all of these.

GLOSSARY

Cine: A dynamic gradient-echo imaging technique involving the rapid acquisition of multiple sequential images (10 to 20 images per cycle) at an anatomic level over the cardiac cycle, resulting in an image loop.

Delayed-enhancement technique: An MRI sequence (Turbo FLASH with inversion recovery) used to evaluate myocardial necrosis and viability without pharmacologic stress. Approximately 15 to 30 minutes after the injection of gadolinium-diethylenetriaminepentaacetic acid, hyperenhancement is visible in areas of myocardial necrosis because of concentration or retention of agent, whereas signal nulling occurs in viable regions because of lack of contrast agent.

Echo-planar imaging: A form of near real-time MRI, allowing the acquisition of images in approximately 50 ms using a single pulse repetition and rapid switching of a strong phase-encoding gradient in the presence of a weaker readout gradient to produce a series of echoes. As a result, this technique has the ability to acquire a complete image set of the heart within a breath-hold period.

Echo time (TE): The time between the initial radiofrequency perturbation and the return of the echo signal in an MRI pulse sequence.

Even-echo rephasing: The flow phenomenon in which the net spin phase associated with constant velocity flow is theoretically zero on even-numbered images from a multiple spin-echo sequence with balanced and symmetric gradient structures. It represents enhancement of spin-phase coherence and reduction of signal cancelling effects of proton spins in regions of nonturbulent, slow blood flow with even-numbered refocusing pulses with fixed –180 to +180 intervals and results in an absolute increase in signal intensity in regions of constant velocity on magnitude data images.

Gadolinium chelates: The only contrast agents approved for use in clinical MRI; they are paramagnetic.

Gating: The process of temporal referencing of image-data acquisition to the points of the cardiac and respiratory cycles to overcome blurring related to physiologic motion. In CV MRI, gating based on the electrocardiogram is almost universally used and is accomplished with an MRI-compatible sensing device to synchronize the phase-encoding steps in the image-data acquisition with a specific segment of the cardiac cycle.

Gradient-echo imaging: A common form of MRI using a low flip angle of 20 to 60 degrees for the initial radiofrequency pulse, which is followed by reversal of the polarity of the gradient to recall the gradient-echo signal; the low flip angle of the slice-selective radiofrequency pulse allows a sufficient number of spins to relax by T1 decay back to equilibrium in a short period of time, so that a rapid succession of such pulses with shortened repetition time (TR) can be applied while maintaining signal intensity for faster imaging. It results in the "bright blood" appearance.

k-space (Fourier space): The platform onto which MRI data are acquired, positioned, and then transformed into the desired image; data are acquired at discrete intervals to fill k-space as signal amplitude is stored as a function of the spatial frequencies along the readout and phase-encoding directions.

Longitudinal relaxation time (T1): A measure of the exponential rate of growth of the magnetization vector along the direction of the external magnetic field after perturbation of the nuclei by the radiofrequency pulse, thereby enhancing the signal.

Magnetic resonance angiography (MRA): An MRI technique for angiographic imaging that relies either on signals generated by the flow of fully magnetized protons into an imaging region or on phase shifts that are observed with moving protons during the application of magnetic field gradients.

Magnetic resonance imaging (MRI): The imaging modality using high-power static magnetic fields, low-power changing magnetic fields, and radiofrequency pulses to generate tomographic images from the inverse Fourier transform of the sampled k-space.

Nuclear magnetic resonance: A phenomenon in which atomic nuclei with odd numbers of protons or neutrons have magnetic moment (i.e., spin about an axis) aligned along the direction of a main magnetic field, causing them to precess when tipped from alignment with the main field.

Paramagnetic contrast agents: By virtue of possessing unpaired electrons with unopposed spins, these agents generate strong, fluctuating magnetic fields at nearby nuclei, thus stimulating relaxation; they predominantly shorten T1, and less so T2.

Phase-change effect: The signal-canceling effect of relative phase differences imparted to proton spins moving at different velocities through a magnetic gradient field. The range of velocities and the associated spin-phase shifts across a vessel lumen increase with rising mean flow velocity, as well as with voxel size.

Phase contrast: An MRI approach using subtraction to qualitatively or quantitatively register motion spatially; it exploits the fact that spin phase of moving protons (usually those in flowing blood) is sensitive to magnetic gradients and varies according to proton position in the gradient fields. While stationary protons accumulate phase during the first lobe of a bipolar gradient with known amplitude, they lose the phase change during the second lobe, which is symmetric but opposite in polarity to the first; moving blood protons gain phase during both lobes, resulting in a net phase accumulation. It is the basis for the qualitative phase-display and the quantitative phase-tracking and velocity mapping techniques.

Phase display: A qualitative phase-contrast technique for registration of motion-dependent phase changes corresponding spatially to the standard magnitude data image.

Phase tracking: The technique applying velocity mapping for the identification of movement of myocardial elements.

Prospective gating: Gating with the initiation or repetition of the MRI sequence being triggered by the physiologic marker (e.g., R wave).

Repetition time (TR): The duration between repeated applications of the initial radiofrequency perturbation pulse in an MRI sequence.

Retrospective gating: Gating in which the MRI sequencing is machine dependent, but the data are later referenced to an independently monitored physiologic signal; with this strategy, image-data sampling occurs at arbitrary points in the cardiac cycle, which then must be interpolated relative to a fixed reference time point in the physiologic recording.

Segmented k-space approach: Method for more rapid filling of k-space in which phase-encoding steps are covered in groups (segments).

Signal-loss cloud: The diffuse areas of intermediate flow-signal loss in regions of slow flow; this results from saturation effects as slowly moving proton spins remain in the imaging volume over a longer period of time and, hence, experience a greater number of excitation pulses.

Signal-void jet: The discrete areas of pronounced flow-signal loss on gradient-echo imaging resulting from complex flow, especially turbulent.

Spatial modulation of magnetization: The technique whereby tissue is tagged, before otherwise normal dynamic MRI, by a pair of nonselective radiofrequency pulses separated in time by the application of appropriate magnetic field gradient pulses to label myocardial proton spins for the purpose of assessing motion. It can be used to produce a parallel stripe pattern, which, when used in combination with a set of stripes directed perpendicularly to the first set, can result in a grid pattern in the myocardium.

Spin-echo imaging: The most common form of MRI in which images are produced after an initial slice-selective 90-degree radiofrequency pulse, followed by one or more 180-degree pulses for refocusing of the spin-echo signal. It results in the “dark blood” appearance.

Spin tagging: The most common approach to assessing myocardial mechanics by MRI. It involves the use of sequences applied once at the start of each cardiac cycle to directly label myocardial units during systole or diastole. In the simplest version, direct radiofrequency saturation is used to produce dark bands of myocardium that can be followed through time and space during dynamic MRI; another commonly used version is spatial modulation of magnetization.

T1 weighting: Imaging in which the intensity of image voxels depends greatly on the T1 relaxation time of tissues. For spin-echo imaging, this is accomplished with a short TR and TE.

T2 weighting: Imaging in which the intensity of image voxels depends greatly on the T2 relaxation time of tissues. For spin-echo imaging, this is accomplished with a long TR and TE.

Time of flight: An approach to MRI of flow that relies on signals generated by the flow of fully magnetized protons into an imaging region.

Transverse relaxation time (T2): A measure of the rate at which nuclear magnetic resonance–sensitive nuclei lose coherence with each other in the transverse plane following their perturbation by the radiofrequency pulse, thereby degrading the signal.

Ultrafast: An MRI technique using gradient-echo pulse sequences (i.e., Turbo FLASH) with extremely short TR and TE to acquire a cardiac image within 100 to 300 m per second. Thus, a snapshot of a portion of a single cardiac cycle can be obtained for the assessment of patterns of blood flow and tissue perfusion.

Velocity mapping: A quantitative phase-contrast technique to encode flow velocity either perpendicular or parallel to the imaging orientation; knowledge of the gradient structure allows for the spin-phase shifts detected with velocity mapping to be converted to absolute velocity values.

View sharing: A method used with segmented k-space cine acquisition in which a portion of the image data from one cardiac phase, represented by a segment, is combined with a portion of the data from an adjacent cardiac phase to form an image intermediate to the two phases. This effectively doubles the temporal resolution.

HISTORICAL PERSPECTIVE

Nuclear magnetic resonance is a phenomenon exhibited by certain atomic nuclei. Independently introduced by Block (1) and Purcell (2) in 1946, this technology was subsequently employed as a spectroscopic tool to analyze molecular structures (3). In 1973, Lauterbur (4) first described a method for producing images using related techniques and, as early as 1977, human whole-body images were already being produced by MRI (5), although diagnostically valuable images of the central CV system had to await solutions to motion-related degradation. By the early 1980s (6,7), high-quality static anatomic imaging of the central CV structures was being accomplished by electrocardiogram (ECG)-gated MRI, but the orientation of imaging was limited to the axes of the MRI scanner. However, capabilities for oblique imaging soon followed, permitting acquisition of images oriented along the axes of the CV structures (8). The mid- to late 1980s saw the development and clinical implementation of dynamic MRI techniques allowing physiologic assessment of cardiac function and blood flow (9,10); this was promoted by the use of the more rapid acquisition techniques (11). Since then, CV MRI has profited from technical advancements allowing the following capabilities: ultrafast/near real-time imaging (12,13), tissue tagging and tracking (14,15), and three-dimensional (3-D) acquisition and display (16); the result has been improvement in the assessment of myocardial physiology and complex and fine-detail anatomy of the CV system. Despite this rapid development of technology and associated clinical research, the routine implementation of CV MRI has been delayed for a variety of reasons (17). However, increasing awareness of the capabilities, as well as the limitations, of this imaging modality has created new momentum to promote the practical application of CV MRI.

In adults, the diagnostic information provided about CV disease by transthoracic echocardiography (echo) is often incomplete because of the larger body and the paucity of adequate imaging windows. Although this provides the incentive for using MRI, computed tomography (CT), and transesophageal echo, MRI has the advantage of providing imaging in any desired plane chosen by the operator. All the structures in the thorax are equally accessible to MRI without the CT limitations of x-ray exposure and need for contrast administration and the echo limitations of restrictive windows of access. Additional advantages of MRI include high spatial resolution and excellent soft tissue definition. The advantages of MRI may be offset, however, by the following factors: (a) high cost, (b) longer imaging time, (c) immobility of the scanner, and (d) the restricting physical environment of MRI.

PRINCIPLES AND TECHNIQUES

Detailed descriptions of the basic principles of MRI are available elsewhere (18) but are reviewed in this chapter. Although closely related to and, at times, intertwined with the technological development of MRI, spectroscopy is beyond the scope of this chapter.

Magnetic Resonance Imaging Principles

Atomic nuclei with odd numbers of protons or neutrons have a magnetic moment (i.e., spin about an axis), which can be aligned along the direction of a magnetic field. This characteristic is vital for nuclear magnetic resonance phenomena, because it causes nuclei to precess when tipped from alignment with the main magnetic field. Among nuclei sensitive to nuclear magnetic resonance (e.g., ^{31}P, ^{23}NA, ^{13}C), the proton (i.e., ^{1}H) has been most widely applied in MRI because of its natural abundance; therefore, this discussion refers to hydrogen-based MRI.

The MRI signal originates primarily from the hydrogen of water and less so from the small hydrogen content of lipids. However, the actual appearance of the image is affected by a variety of physical parameters. Some of these parameters are characteristic of the tissue sampled, and others relate to the MRI sequences.

An essential difference between MRI and other modalities is the control that the user has over how data are used. The agent of this control is k-space (Fourier space), the platform onto which data are acquired, positioned, and then transformed into the desired image (19). Raw image data are obtained during sampling through k-space, which depicts the spatial frequency domain. High spatial frequencies encode fine details, whereas overall contrast is encoded in the lower frequencies. Data are acquired at discrete intervals to fill k-space, as signal amplitude is stored as a function of the spatial frequencies along the readout and phase-encoding directions. An image is simply the inverse Fourier transform of the sampled k-space (20).

MRI uses high-power static magnetic fields, low-power changing magnetic fields, and radiofrequency (RF) pulses to generate tomographic images. Application of weak RF-modulated pulses of a specific frequency partially aligns the magnetic moments of protons within the tissue sample against the magnetic field and induces their resonance; the effect of this RF field is maximal when the nuclei have been deflected by 90 degrees. When the RF pulse ceases, the protons return to equilibrium. During this process, they emit the RF energy of the same frequency, which is then Fourier transformed by a computer into a spatially accurate image whereby differences in signal intensity result in differences in gray levels. The signal intensity is not only dependent on hydrogen density, but also on their longitudinal relaxation time (T1), reflecting the rate of realignment with the external magnetic field (enhancing the signal), and on their transverse relaxation time (T2), indicating the rate at which nuclei lose coherence with each other (degrading the signal). In normal myocardium, T2 is much shorter (i.e., 60 ms at 1.5 Tesla) than T1 (i.e., 500 ms). The characteristic T1 and T2 relaxation times are exploited to distinguish between normal tissues and to characterize disease processes. In general, MRI contrast improves with increasing hydrogen density, shortening of T1, and lengthening of T2.

Externally, MRI scanners have changed little over the past two decades, although the internal architectures have evolved. Basically, an MRI scanner consists of five major parts: magnet, transmitter, antenna, receiver, and computer. Most modern clinical MRI scanners have magnets, consisting of liquid helium–cooled, superconducting solenoids, operating at a field strength of 0.1 to 3.0 Tesla and with a bore size of approximately 1 m; MRI is best performed with a magnet with higher field strength and homogeneity to improve the signal-to-noise ratio. The transmitter is used for transmitting RF pulses to an antenna or coil, which in turn transmits RF power to the patient, and also receives the returning signal. The coil usually surrounds the patient or may be placed directly on their surface, depending on whether information is required from the whole body or from a selected organ of interest. Although surface coils provide higher sensitivity and, therefore, excellent spatial localization of signal, they have the disadvantage of an inhomogeneous RF field, which produces an inhomogeneous signal intensity distribution on images. The receiver amplifies the signal picked up by the coil, and the signal is processed by a computer, which is also needed to operate the entire MRI system.

Magnetic Resonance Imaging Techniques

Current MRI exists in two basic forms: spin-echo (S-E) imaging and gradient-echo (G-E) imaging. With an S-E sequence, images are produced after an initial slice-selective 90-degree RF pulse followed by one or more 180-degree pulses to refocus the S-E signal. The G-E technique uses a lower flip angle of 20 to 60 degrees for the initial RF pulse, which is followed by reversal of the polarity of the gradient to recall the G-E signal; the low flip angle of the slice-selective RF allows a sufficient number of spins to relax by T1 decay, back to equilibrium in a short period of time, so that a rapid succession of such pulses can be applied while maintaining signal intensity, for faster imaging.

In addition to flip angle, these sequences are described in terms of repetition time (TR), referring to the duration between repeated applications of the initial RF perturbation pulse, and echo time (TE), which refers to the time between the initial RF perturbation and the return of the echo signal. For multilevel S-E or G-E imaging and for dynamic G-E imaging, the TR is dependent on the gating strategy used, as described in this section. TE values for S-E imaging typically range from 15 to 60 ms depending on the tissue contrast sought, whereas the TE range for G-E imaging is only 4 to 15 ms.

Because the echo signal from the resonating protons recorded during MRI data collection is a vector defined uniquely by magnitude (i.e., intensity) and phase (i.e., direction) components, different types of reconstructions can be performed. The magnitude data are used to produce an anatomy-based image, whereas the phase component can be used to generate a motion-based image that reflects the movement of proton spins during the time interval between the RF excitation pulse and the center of the signal-sampling window (i.e., TE).

CV images are usually acquired as two-dimensional (2-D) tomographic slices of 1 cm thickness or less, although volume or true 3-D MRI is becoming more practical as the speed of imaging increases. Regardless of the form of MRI, temporal referencing of image-data acquisition to the points of the cardiac cycle (gating) is crucial to CV MRI; not only does it overcome blurring related to cardiac motion, it provides a basis for dynamic imaging.

For static S-E or G-E imaging, a multilevel acquisition may be used for production of a series of images of adjacent parallel anatomic levels; because of the time needed for data sampling at a level, each image in the series represents a slightly earlier point (e.g., 50 ms) in the cardiac cycle than the next image in the series (21). Thus, the first image usually represents the onset of systole and the last image, late diastole. Using standard phase-encoding schemes, a static multilevel series requires 5 to 7 minutes of imaging time, depending on desired image quality and heart rate. This type of acquisition can be significantly reduced with new approaches to phase encoding, including a segmented k-space approach, in which phase-encoding steps are covered in groups (segments), or partial k-space sampling (12,19). In addition, turbo S-E sequences have been employed to allow rapid static imaging within a breath-hold period (22). One of these sequences is considered a “snapshot” because it acquires each image slice in a single heartbeat (23).

Dynamic G-E imaging, also referred to as *cine*, involves the rapid acquisition of multiple sequential images (10 to 20 images per cycle) at an anatomic level over the cardiac cycle, resulting in an image loop with good temporal resolution. The repetition time used depends on the gating strategy used, but usually ranges from 20 to 50 ms (24). An image loop set can be produced within a breath-hold period with the segment k-space approaches (24) with a good temporal resolution (e.g., 25 ms).

On even-numbered images from a multiple S-E sequence with balanced and symmetric gradient structures, the net spin phase associated with constant velocity flow is theoretically zero. It represents enhancement of spin-phase coherence and reduction of signal-canceling effects of proton spins in regions of nonturbulent, slow blood flow with even-numbered refocusing pulses with fixed 180- to 180-degree intervals throughout. Such even-echo rephasing results in an absolute increase in signal intensity in regions of constant velocity on magnitude-data images, so that the intensity of the signal from blood moving at constant velocity resembles that of stationary blood (25). Application of gradients for flow compensation also produce the even-echo rephasing effect for constant velocity flow in G-E MRI (26). Because the rephasing occurs for a unique timing and amplitude relationship between gradient pulses applied along a given direction, a slight time shift can be introduced into the bipolar gradient to make the pulse sequence velocity sensitized, so that the associated signal becomes valuable for quantitative velocity measurements (27).

The spin phase of blood protons is sensitive to magnetic gradients, and it varies according to the position of the proton in the gradient fields. Phase-contrast sequences involve the application of a bipolar gradient of known amplitude (10,27). Stationary protons accumulate phase during the first lobe of the gradient, and then lose phase during the second lobe that is symmetric but opposite in polarity to the first. Although moving blood protons also accumulate phase during the first lobe, they will be in a different position during the second lobe, which results in a net phase accumulation. It is possible to use this velocity mapping technique to encode flow velocity either perpendicular or parallel to the imaging orientation. Knowledge of the gradient structure allows for the spin-phase shifts detected with velocity mapping to be converted

to absolute velocity values (centimeters per second) (28). Ultimately, the velocity value can be represented by a level on a gray scale on a voxel-by-voxel basis, building a map corresponding spatially to the magnitude-data image.

Furthermore, dynamic S-E or G-E techniques have been developed for assessment of cardiac wall mechanics. Of the two, spin tagging (14) and phase tracking (15), spin tagging has, to date, received the greatest attention. The spin-tagging sequences are applied once at the start of each cardiac cycle to label myocardial units during systole or diastole. In its simplest form, direct RF saturation is used to produce dark bands of myocardium that can be followed hrough time and space during dynamic MRI; a distinctive tagging pattern that has resulted involves radially oriented bands, extending outward from the center of the cavity of the left ventricle (LV) on transaxial or short-axis images (14). Another commonly used form of spin tagging has been spatial modulation of magnetization (SPAMM) (29). By SPAMM, the myocardial tissue is tagged before otherwise normal dynamic MRI by a pair of nonselective RF pulses separated in time by the application of appropriate magnetic field gradient pulses to label proton spins within the myocardium. It has popularized the parallel stripe pattern (5 to 10 mm separation), which, when used in combination with a set of stripes directed perpendicularly to the first set, can result in a grid pattern for orthogonal or oblique imaging. Phase tracking applies the aforementioned velocity mapping technique to the identification of movement of myocardial elements (15).

Ultrafast G-E pulse sequences, with extremely short TR and TE, have also been employed. The most commonly used of these sequences (i.e., Turbo FLASH) acquires a cardiac image within 100 to 300 ms; thus, a snapshot of a portion of a single cardiac cycle can be obtained (30). This technique, from here on referred to as *ultrafast*, allows the assessment of patterns of blood flow and tissue perfusion (31).

Another form of near real-time MRI, referred to as *echo-planar imaging* (EPI), allows the acquisition of images in approximately 50 m per second by rapidly switching magnetic field gradients (13). As a result, this technique has the ability to acquire a complete image set of the heart within a breath-hold period. Although this technique has great potential for evaluating cardiac function on a beat-to-beat basis, currently it is limited by relatively less spatial resolution, problems with flow quantitation, difficulties in performing oblique imaging, potentially adverse biologic effects (e.g., muscle stimulation), and the need for additional expensive hardware and software (32). EPI is currently available at only a few centers and is discussed in detail in this chapter.

Physiologic Demands

Motion degrades image quality in MRI. As a result of cardiac and respiratory activity, MRI of the CV system is particularly susceptible to motion artifacts. Therefore, it is critical to freeze frame the beating of the heart and moving thoracic vasculature to avoid blurring.

Gating to the cardiac cycle is recognized as being an essential component of all commonly used CV MRI techniques (21). Of the physiologic markers investigated for gating, the ECG markers for points in the cardiac cycle have been the most useful (33). While the ECG recordings may become degraded by magnetohydrodynamic effects and MRI-induced currents, these problems can be overcome by careful positioning of the leads and by electronic filtering of the signal. ECG gating is accomplished with an MRI-compatible sensing device to synchronize the phase-encoding steps in the image-data acquisition with a specific segment of the cardiac cycle.

Such gating is usually performed prospectively, with initiation or repetition of the MRI sequence being triggered by the physiologic marker (e.g., R-wave); the TR is then defined by the RR interval (33). With a standard multilevel series, image data from the first anatomic level is obtained before the second, which is before the third, and so forth, for a fixed amount of time that must not exceed the RR interval (21). This delay represents the time required for RF excitation pulsing and echo-signal acquisition at a particular level before the same process is executed at the next level.

An alternative used primarily for dynamic imaging of the complete cardiac cycle is retrospective gating, in which the MRI sequencing is machine dependent, but the data are later referenced to an independently monitored physiologic signal (26). With this gating strategy, image-data sampling occurs at arbitrary points in the cardiac cycle, which then must be interpolated relative to a fixed reference time point in the ECG recording. The maximum number of frames in an image loop corresponds to the number of sequence-TR intervals that can be inserted into the cardiac cycle. With this form of cine, the rapid repetition rates allow for one or several anatomic levels to be imaged at multiple nearly identical segments of the cardiac cycle during a single series. Because multiple levels of the CV system may need to be evaluated, simultaneous acquisition of image loops from more than one anatomic level is desirable because it reduces total imaging time; this is possible, but only with a decrease in temporal resolution. The interpolated data are reconstructed into a user-selected number of images, which then form an image loop in a manner resembling gated blood pool ventriculography.

Prospective gating can also be used to perform dynamic multiphasic imaging (21,26), with repetitive scanning at the same level or few levels, so that the inherent delay in the sequence leads to uniformly delayed images covering end diastole through systole into at least early diastolic filling. The prospective strategy for gating in cine has the advantage of being simpler than the retrospective strategy and obviating the need for postprocessing, thus allowing immediate use of the image loops. This has been the approach to segmented k-space G-E acquisitions allowing fast, respiratory, artifact-free cine to be performed at one level during a single breath-hold (24). However, in general, breath-hold cine has inferior temporal resolution because of acquisition of image data over the duration of the segments. In addition, it is somewhat limited by incomplete representation of the entire cardiac cycle; this is because of a variable dead time between the end of the triggered image-data acquisition and the appearance of the next R-wave trigger. A postprocessing technique developed to overcome some of these limitations is view sharing (34). With this technique a portion of the image data from one cardiac phase, represented by a segment, is combined with a portion of the data from an adjacent cardiac phase to form an image intermediate to the two phases. This effectively doubles the temporal resolution, creating a smoother image loop, although it does not provide for additional images deeper into end diastole.

Like cardiac motion, motion related to the excursion of the thorax during normal respiration degrades MRI (35). Respiratory motion produces a form of coherent noise distributed across the image as a periodic artifact; however, it tends to be less degrading than cardiac motion. Nevertheless, some MRI systems incorporate respiratory-sensing devices that coordinate the changes in chest position with the ECG gating to minimize image artifacts (36). Respiratory gating has theoretical advantages as far as minimizing such motion artifacts, but the associated significant increase in imaging time limits its application. Consequently, alternative means of compensation for respiratory motion have been used, and they vary considerably in their sophistication. The simplest method is encouragement of voluntary slow and shallow breathing by the patient, followed by the use of a restraining belt around the thorax to restrict chest expansion. At the other end of the spectrum are methods using phase-encoding reordering to destroy the periodicity of the respiratory motion (37). This need has been largely remedied by the introduction of fast imaging techniques permitting imaging during breath-holding (12).

Image Orientation

The orientations traditionally used for CV MRI are the transaxial, sagittal, and coronal planes; they are orthogonal to the thorax but oblique to the heart and great vessels. Complete sets of these images are most useful in gaining a global perspective of the relationships of the cardiac chambers, great vessels, and adjacent structures. They also serve as important localizing images for oblique imaging along the natural axes of the CV structures, such as with the long axis of the thoracic aorta. With further axial rotation, double-oblique imaging also can be performed to acquire images of the heart equivalent to the 2-D echo short-axis and long-axis orientations (e.g., two-chamber, four-chamber, LV outflow) (8,38).

Morphologic images depicting the lumina of large central or smaller peripheral vessels may be obtained using a variety of techniques, termed *magnetic resonance angiography* (MRA) (16). MRA methods rely either on signals generated by the flow of fully magnetized protons into an imaging region [time-of-flight (TOF) MRA], or on phase shifts that are observed with moving protons during the application of magnetic field gradients (phase-contrast MRA) (39). MRA is increasingly being employed to evaluate the great vessels, especially the thoracic aorta (40). Traditionally, sequential 2-D TOF approaches have been employed. More recently, MRI contrast agents have been used in combination with rapid 3-D TOF sequences to acquire a volume of data (41). Data sets from either type of acquisition may be reconstructed into multiple projection or reconstructed tomographic images (40).

Safety Issues

A major safety consideration in MRI was initially the production of ventricular fibrillation through induction of a current into the patient by rapidly changing magnetic fields. Based on experimental studies, however, the threshold rate of change of the magnetic field to produce ventricular fibrillation is far in excess of those experienced in clinical MRI scanners, indicating a large safety margin for patients (42).

From the standpoint of implants in patients, some are absolute contraindications for MRI. MRI should not be used in patients with vascular clips used for cerebral aneurysm surgery because of the potential risk of dislodgement from the vessel (43). At the present time, implanted cardiac pacemakers, cardiac defibrillators, and neurologic stimulators represent contraindications, and patients with these electronic implants should not undergo MRI because of the risks from malfunctioning of the device or current induction (43).

On the other hand, most of the recent manufactured coronary arterial stents and all prosthetic heart valves, including the prosthetic valves containing large amounts of alloy (e.g., Starr-Edwards pre-6000 series, Edwards Lifesciences Corporation, Irvine, CA), are now considered to be compatible with MRI (44,45). Aside from local

imaging artifacts, hemostatic clips, metallic sternal suture wires, or retained surgical epicardial pacing wires are not known to lead to complications from MRI (43).

Critically ill patients are less than optimal candidates for MRI, either because they are dependent on life support or continuous monitoring systems that cannot be brought near the scanner, or their clinical condition is too fragile for the limited monitoring that is compatible with the MRI environment. Nevertheless, such patients can be safely evaluated if physiologic monitoring is supplemented by close observation by trained personnel.

Finally, claustrophobia may impede MRI in up to 5% of patients. This problem can be controlled by premedicating the patient with sedative agents.

GENERAL INTERPRETATION GUIDELINES

The appearance of an MRI is dependent on the interactions between the components of the imaging sequence and the physical system being imaged.

Appearances of Flow

An understanding of flow phenomena and their variable appearances with different types of sequences is essential in the interpretation of MRI. Blood flow phenomena assume great importance in the CV system because of the dynamic and complex nature of the relatively large volumes of moving blood (46). Basic descriptions of blood flow are typically based on laminar flow velocity profiles (25,47). Blood flow in the heart and thoracic vasculature, however, is complex as a result of both pulsatility and movement through curving and branching structures. This results in deterioration of laminar flow, development of turbulence, and generation of flow-related artifacts, all of which must be considered.

For the most part, the hemodynamics in the cavities of the cardiac chambers and lumina of the thoracic vasculature are such that little to no signal is received from the intracardiac or intravascular blood pools on magnitude-data images from static S-E MRI; this results in the characteristic dark blood appearance (48). The two major factors accounting for loss of blood signal on these images are TOF effects and phase-change effects, which primarily influence flow perpendicular and parallel to the imaging plane, respectively (25). TOF dictates that flowing protons that traverse the full thickness of the imaging level in the interval between the initial excitation pulse and the refocusing pulse on the S-E sequence (i.e., TE/2) will generate no signal (46,47). The phase-change effect refers to the relative phase differences imparted to proton spins moving at different velocities through a magnetic gradient field (25). The range of velocities and the associated spin-phase shifts across a vessel lumen increase with rising mean flow velocity, as well as with voxel size.

Consequently, S-E sequences generally produce excellent differentiation between intracardiac or intravascular blood pools and the surrounding myocardial or vascular walls (49). However, under circumstances of blood flowing below a critical velocity, whether physiologic or pathophysiologic, increased intracardiac or intravascular signal may be noted on S-E MRI. There is normal physiologic variation in the S-E blood signal with the phase of the cardiac cycle represented, and relatively slow diastolic blood flow may generate signal (49). When blood flow is exceptionally sluggish or stagnant because of CV disease, abnormal flow signal caused by the reduction of TOF and phase-change effects is frequently observed even on systolic S-E images.

To overcome diagnostic limitations from such unwanted intracardiac or intravascular signal on S-E MRI, several approaches can be used. The simplest is to increase the TE, thereby allowing slowly flowing blood more time to move out of the imaging plane and cause TOF effects; unfortunately, this approach also introduces more time for movement of the CV structures, which is manifested as a motion artifact (50). Another approach is to apply additional RF excitation at levels above or below the levels of interest to saturate in-flowing blood (51); with this approach, the quality of the image of the CV structures tends not to be degraded.

A characteristic of slower flowing blood on images from multiple S-E sequences is even-echo rephasing (52). This phenomenon is manifested as an increase in intracardiac or intravascular signal intensity, both in absolute values and relative to other tissues, from an odd-echo image to the subsequent even-echo image. Because this signal variation is true only of proton spins moving at constant velocity, slow flow can often be differentiated from fixed material (e.g., thrombus), which also causes abnormal signal but without even-echo rephasing (53). Variability of the signal intensity of the fixed material may, however, result from differences in composition of its tissue (54).

Constant velocity slow blood flow can also be differentiated qualitatively from intracardiac or intravascular fixed material, using reconstructions of the phase data from S-E sequences (53,55). Averaged proton spin phase can be interpreted on a voxel-by-voxel basis from odd-echo data and used to produce a phase-display image that corresponds spatially to the standard magnitude-data image. For protons in stationary structures (e.g., vertebral body), the phase change is zero and is, by convention, assigned an intensity in the middle of the gray scale. On the other hand, spin-phase changes for protons in moving tissues (e.g., flowing blood) are expressed as positive or negative degree values ranging from +180 degrees to –180 degrees; increasing positive or negative phase values are represented by increasing intensity of whiteness or blackness, depending on the assignment of the positive and negative values. A variation of the phase-display technique has been used to produce images in which the motion-dependent phase changes appear as a series of stripes displaced in the direction of the motion (56).

Because of its fixed nature, a large intracardiac or intravascular mass (e.g., thrombus) is usually represented with the same gray intensity on standard phase display as a stationary structure (53,55). On the other hand, slowly flowing blood, because of its moving protons, has an appearance that is different; it is represented by shades of white or black. Unfortunately, any structure that is moving during the application of the gradients, such as the heart or a highly mobile intracardiac mass, may produce an observable phase change that may lead to improper identification. In addition, technical factors (e.g., inhomogeneity in the static magnetic field) may alter local phase progression, which may be misinterpreted as phase change caused by motion (57).

In G-E MRI, including cine, normally flowing blood has a high signal intensity that exceeds that of the surrounding myocardial or vessel walls. The bright blood appearance is related to (a) short TR minimizing TOF effects, (b) short TE reducing phase dispersion, (c) single non–slice-selective RF excitation pulses allowing constant influx of fully magnetized protons into the imaging volume, and (d) frequently used flow-compensation schemes, capturing otherwise lost signal from spin dephasing (9,11,26).

Normal and abnormal patterns of intracardiac or intravascular blood flow are still reflected by variations in signal intensity on cine. Normally, the blood pools show almost uniformly increased signal intensity during most of the cardiac cycle, although increases in intraarterial flow rates in systole are represented by increased intensity (9). Local signal loss caused by dephasing effects of nonuniform flow may, however, be observed during the cardiac cycle (58).

Basic phantom work using cine has aided the understanding of the phenomena noted on clinical images. It is now recognized that signal intensity increases on such images with increasing flow velocity up to a point (i.e., 60 cm per second), because partially saturated protons are washed out of the imaging plane and completely replaced by fully magnetized protons at a rapid rate. Beyond this point, signal loss occurs primarily because of spin-dephasing effects that increase with increasing TE (59). Phase cancellation, exaggerated by turbulent flow, is a common cause of signal void on cine in the setting of pathology. A combination of these effects appears to account for the characteristic focal, pronounced “signal-void jet” that is found with conditions causing complex flow, especially turbulent. Although there is a relationship between the prominence of a signal-void jet and the extent of flow disturbance, there are pitfalls in clinical use of parameters based on jet size. Along with physiologic factors (e.g., transorifice gradient), the following factors have been shown to influence signal-void jet extent (61,62): (a) window level or width; (b) TE (increased size with increased TE up to approximately 12 m per second); (c) imaging orientation; (d) flip angle; (e) gradient field strength; and (f) degree of motion compensation. A more diffuse intermediate “signal-loss cloud” in regions of slow flow appears to result from saturation effects, as these slowly moving proton spins remain in the imaging volume over a longer period of time and, hence, experience a greater number of RF excitation pulses (63).

Anatomic Evaluation with Magnetic Resonance Imaging

Magnitude data from S-E or G-E sequences are used to produce the static images most often used for anatomic evaluation of CV diseases, as described in this section. The distinct appearance of blood flow allows the differentiation of solid tissues (e.g., myocardium), which are in the range of intermediate signal intensity, from moving intracardiac and intravascular blood. Thus, for definition of the anatomic abnormalities associated with various CV diseases, standard ECG-gated, multilevel, single-echo S-E or G-E series are appropriate (9,64).

MRA data sets from S-E or G-E imaging may be postprocessed into multiple projection or reconstructed tomographic images for anatomic evaluation of vasculature (16,40,41). However, significant pitfalls with such image acquisition and postprocessing must be recognized, making the experience of the interpreter critical to interpretation (65). For example, MRA tends to overestimate the degree of stenosis for lesions that exceed 70% of diameter partly because of signal loss caused by complex flow (60).

Because S-E imaging is sensitive to longitudinal and transverse relaxation parameters, as well as to hydrogen density, image contrast can be weighted either to T1 or T2 differences by varying the parameters of TR and TE. By using short TR and TE, a T1-weighted image yields more signal for tissues with shorter T1 (e.g., fat). A T2-weighted image, which uses a long TR and TE, provides a greater signal intensity for tissues with longer T2 (e.g., edema). Although this is the basis for the

traditional approach to tissue characterization, it has limited application to CV MRI because of dependency of TR on the cardiac cycle.

MRI contrast media may have been used to improve the differentiation between normal and hyperperfused or hypoperfused tissues. Two classes of such contrast agents have been used for CV imaging. The paramagnetic contrast agents, which predominantly shorten T1, and less so T2, are usually used in a dose range to cause a higher signal intensity on T1-weighted S-E and G-E MRI; currently, the paramagnetic gadolinium (Gd) chelates are the only contrast agents approved for use in clinical MRI (66). The second group includes the susceptibility agents that cause local variations in the magnetic susceptibility of tissue and thereby induce a decrease in signal intensity in relation to their distribution; this effect is observed on T2-weighted S-E or G-E images (66).

In addition to qualitatively delineating anatomic abnormalities, multiphasic S-E or cine MRI may be used for assessing ventricular mass (67,68). Because multilevel MRI is essentially a 3-D technique, the accuracy of myocardial mass determinations from anatomically accurate images is not dependent on geometric models and assumptions that can alter the accuracy of planar imaging techniques (e.g., ventriculography), especially in the presence of myocardial damage (69). MRI also has a distinct advantage in the quantitation of the dimensions of the right ventricle (RV), which is particularly limited with geometric models because of its complex shape (70). For ventricular mass determination from multiphasic MRI, the endocardial and epicardial surfaces of the ventricle are outlined at end diastole or end systole from each dynamic tomogram, and the volume of the myocardium at each anatomic level is calculated based on both the number of voxels in the region outlined and the known volume of each voxel; the myocardial volumes calculated for each anatomic level representing the ventricular wall are then summed to provide the total ventricular wall volume by Simpson's method and then converted to mass. Myocardial mass measurements by MRI correlate well with those obtained with echo and ventriculography (70,71 and 72).

Physiologic Evaluation with Magnetic Resonance Imaging

Evaluation of the physiologic aspects of CV disease by MRI has been an ongoing pursuit. This effort has resulted in the development and implementation of many interesting techniques; some use magnitude data for the production of anatomically accurate images representing the different segments of the cardiac cycle, whereas others use phase data to demonstrate physical changes reflecting motion or flow (63,69).

Contraction or Filling Evaluation

S-E MRI is not typically used to assess ventricular function. However, from end diastolic and end systolic S-E images acquired by a preset trigger-delay technique and obtained at a single long-axis level, volumes have been calculated using the area-length method and have correlated well with those from LV ventriculography (73). Nevertheless, the deficiencies of this oblique 2-D approach for volume determination have been described (74); the need for geometric assumptions has been cited as a major drawback of the 2-D MRI approach to evaluate ventricular volumes. Logically, a tomographic imaging technique should acquire a set of contiguous slices, encompassing the ventricles for determination of the total ventricular cavity volume using Simpson's method (75). Therefore, measurements of ventricular volumes for both LV and RV obtained by the multilevel MRI approach are generally more accurate than unilevel measurements (71,72,74,75).

For deriving information about cardiac chamber contraction or filling, the S-E MRI techniques are generally limited by their poor temporal resolutions and long acquisition times (21). Thus, cine is generally preferred for the MRI evaluation of ventricular function (9,63,69). Standard and segmented k-space versions of cine provide accurate and highly reproducible measurements of LV volumes (68,71,76). LV end diastolic and end systolic volumes and ejection fraction (EF) values from cine have correlated well with EF values from 2-D echo and LV ventriculography (77,78).

Ventricular volume measurements (i.e., myocardial and cavity volume, should be equally accurate with either orthogonal or oblique imaging when the multilevel approach encompasses the entire heart (69). In fact, ventricular volumes determined from images in the transaxial orientation and those in the short-axis orientation have been found to be nearly identical (76).

A complete cine examination of the two ventricles provides the basis for 3-D determination of stroke volume (75). In normal volunteers, measurements of stroke volume for the RV and LV, derived from a multilevel cine series using Simpson's method, have been nearly identical (70). Therefore, in the absence of more than one volume-overloading condition affecting the ventricles (i.e., valvular insufficiency or shunt), several quantitative measures of CV pathophysiology can be determined using cine (69). Along with EF, these stroke volume measurements can provide the basis for determination of regurgitant or shunt volume or fraction.

Although ventricular wall thickening may be determined with S-E imaging (79), regional wall motion and thickening are more reliably determined by cine. Cine measures of regional wall thickening correlate well with 2-D echo and LV ventriculography (80). However, cine may be more accurate for defining regional myocardial dysfunction than ventriculography, because the latter depends on the evaluation of wall motion only. Although heterogeneity of systolic wall thickening has been observed on cine in healthy people, absence of systolic wall thickening on MRI has been shown to be a specific marker of regional dysfunction (80). Limitations in the measurement of cardiac chamber wall and cavity dimensions from orthogonal MRI have been emphasized; oblique imaging related to the cardiac axes should improve the precision of linear dimension measurements (i.e., wall thickness and cavity diameter) (38).

A fundamental problem with ventricular volumes and EF as indices of yocardial performance is that they are both dependent on hemodynamic loading conditions (81). Of the approaches to load-independent evaluation of myocardial performance, MRI estimates of ventricular wall stress have received the greatest attention (71,82). The calculation of ventricular wall stress is simplest for meridional stress (the force applied along the length of the ventricle to achieve shortening of that length); an analogous calculation can be used for circumferential stress, the force applied in the circumferential direction in the short-axis plane to achieve circumferential shortening. Cine has been applied for reproducible quantification of LV wall stress at end systole and end diastole, using graphic recordings of the carotid pulse for timing of the cardiac cycle and systemic arterial or ventricular pressure recording (71,82,83). However, when applied to many conditions affecting the LV, the MRI wall stress construct has the following important limitations: (a) it assumes homogeneity of LV function and symmetric geometry, neither of which applies to LV inhomogeneously configured or damaged; (b) it represents a global estimate of average midwall stress, rather than regional pathophysiology; and (c) it overlooks the complexity of the material properties of the myocardium, which is composed of individual fibers with their distribution of orientation varying from region to region and across the wall so that myocardium is anisotropic in its mechanical properties (81).

At the same time, for assessment of regional LV function by MRI, conventional wall-thickening analysis has the following limitations: (a) thickening is not uniform across the wall, with a maximum found in the subendocardium; (b) fiber angle differs across the wall, so that the principal direction of shortening may also vary transmurally; and (c) cardiac motion is complex relative to any single imaging plane, with in-plane deformation, rotational and nonrotational translation, through-plane deformation, and complex translation causing the location of a given segment to change over the cardiac cycle (81). Therefore, both transmural heterogeneity within a wall segment and relocation of the myocardium present in the image plane from end diastole to end systole are important confounding factors in analyzing regional dysfunction by MRI.

Currently, the most precise method for monitoring myocardial motion by MRI is the technique of spin tagging, from which the pattern, amplitude, and rate of displacement of the tags during the cardiac cycle can be used to identify abnormalities in contraction or filling (14,29,81,84). It allows precise tracking of normal and abnormal in-plane rotation and myocardial twist within the wall of a ventricle. Therefore, measurements of wall motion and wall thickening and motion can be corrected for myocardial displacement in 2-D or 3-D space; the problem of through-plane movement can be addressed by 3-D tagging or by tagging in the orthogonal planes (85). In addition, the technique has been used to quantify myocardial deformation as a measure of regional strain (14,86); this provides a method to assess ventricular nonuniformity, and differences in subendocardial and epicardial wall motion, both in normal and abnormal myocardium (84,87).

In the normal LV, 1-D analysis of tag stripe separations has been used to demonstrate that circumferential shortening has a transmural gradient in which subendocardial shortening exceeds subepicardial shortening (84); in addition, the absolute area of 2-D triangular subendocardial elements markedly decreases during systole, probably reflecting phasic alterations in myocardial blood volume that may be a marker of tissue perfusion (81). Whereas there is also a long-axis gradient in circumferential shortening, with shortening greater at the apex than base, there is no transmural gradient for longitudinal shortening; shortening is uniform along the length of the septum and lateral walls. On the other hand, for physiologic LV hypertrophy, reduced circumferential and longitudinal shortening with no change in transmural gradient of circumferential shortening or reduction in EF has been observed. This suggests that analysis of segment shortening is more sensitive to altered myocardial function than are global chamber indices of LV pump function. The coexistence of reduced intramural segment shortening with normal chamber pump function probably relates to the increased ratio of wall thickness to chamber diameter; thus, less shortening per unit from more myocardium results in normal EF (81).

Excellent reproducibility of end diastolic and end systolic wall thickness and percent wall thickening measurements derived with spin tagging have been demonstrated (88). LV wall thickening by spin tagging, especially by the volume method, correlates well with sonomicrometer measurements (87). Epicardial and endocardial cross-fiber strains have been found to be closely related to total wall thickening (89).

One limitation of spin tagging is that it labels only a limited number of points in the myocardial wall. To overcome this limitation, myocardial function can also be examined using phase tracking to directly measure the velocity at each myocardial voxel in the wall (15). Phase-tracking measurements of myocardial displacement have been validated in an animal model using implanted tantalum markers (90). Phasic longitudinal velocity measured in short-axis images in humans has revealed

significant differences in LV myocardial velocity between healthy subjects and patients (91).

A major hindrance to the clinical application of quantitative spin tagging and phase tracking has been the often lengthy data analysis. To overcome this limitation, automated approaches to postprocessing are being developed (92).

Flow Evaluation

Early attempts at flow measurement using S-E MRI were based on the TOF phenomenon (25). In TOF flow quantitation, proton spins are labeled by a 90-degree RF excitation pulse at one level and monitored after a 180-degree refocusing pulse is applied downstream at another level. Consequently, a signal at the downstream level originates only from the labeled spins within the unit of blood that has moved the distance between the excitation and refocusing levels. With knowledge of the time between labeling and readout, the velocity of flow can be determined. This concept of flow quantitation is also used in the dynamic bolus tracking technique, whereby the ECG triggers an initial 90-degree RF excitation pulse for presaturation of a slab of blood flowing perpendicular to the eventual imaging plane (93). Image-data acquisition with an otherwise conventional cine sequence is then performed at an anatomic level oriented with the long axis of the vessel. Tracking of the distance of displacement within vessels during known time intervals permits flow-velocity calculation.

Because the proton spin phase of the MRI signal is directly related to motion, a more practical approach to blood flow analysis is achieved using phase-contrast techniques, especially the aforementioned velocity mapping (10,27,28). In the application of velocity mapping, velocity-encoding limits are set to correspond to 30% to 50% greater than the expected peak velocity in the vessel investigated. For normal arterial blood flow in the aorta and pulmonary arteries, velocity-encoding limits are set at 150 to 200 cm per second. In slow-flow states (e.g., congestive heart failure), these limits may be set lower. Alternatively, to examine areas of stenosis (e.g., coarctation), higher velocity-encoding limits corresponding to 400 or 500 cm per second may be needed; these higher velocity mapping sequences are typically more difficult to perform accurately because of the need for very short TE to overcome rapid phase dispersion in the setting of complex flow (94,95). Velocity mapping may also be used to measure flow in venous structures (e.g., superior vena cava) (96,97); the velocity-encoding limits used for this purpose are typically lower than for arterial studies (e.g., 50 to 75 cm per second).

Velocity mapping is most often used for the assessment of bulk flow. Volume-flow data can be obtained by determining the cross-sectional area of the vessel of interest and multiplying it by the mean instantaneous velocity recorded by velocity mapping within that region (10,27,28). A region of interest applied to encompass the vessel on a magnitude-data image allows determination of the intravascular area (cm^2); this same region of interest over the corresponding velocity mapping image allows direct assessment of the mean flow velocity. This calculation, when performed at each phase represented in the cardiac cycle, may be converted to a flow-volume curve for the vessel of interest (98). An ascending aorta volume-flow curve, for example, can be integrated over the cardiac cycle to calculate stroke of the LV, which can then be used to derive cardiac output (99).

Detailed information on blood velocity profiles in the great arteries can be obtained with velocity mapping (100). On velocity mapping, normal blood flow curves from the ascending aorta typically show systolic increase and then decrease in velocity, followed by reversal of flow in early diastole (98,99). Volume-flow curves of the thoracic aorta, when plotted for the ascending and descending portions, reveal smaller volumes for the descending aorta than those for the ascending aorta because of flow runoff to the head and arms. Measurements of normal volume flow in the ascending aorta and main pulmonary artery obtained with velocity mapping have demonstrated close agreement and have been validated against ventricular volume changes determined by cine (98,99). In addition, when comparisons have been made between velocity mapping determinations of both total systemic venous return per cardiac cycle measured from the venae cavae and stroke volume of the LV measured from the ascending aorta, the correlations have been strong (99).

A stenotic lesion may be assessed by measuring the flow velocity in the jet of blood passing through that stenosis; with a given flow, increasingly stenosis leads to a higher flow velocity at the orifice. The relation between the velocity of the flow jet and the difference in pressure across the stenosis can be approximated, assuming negligible proximal velocity, by the modified Bernoulli's equation (94,95,98,99). This approach can be used to determine the peak instantaneous gradient across the stenosis. However, signal loss on cine found in the presence of stenosis-related turbulence generally indicates insufficient signal for accurate velocity measurement by velocity mapping (60). Fortunately, when short TE velocity mapping sequences have been used, the quantification of jet velocity has correlated well with invasive and noninvasive hemodynamics (101). For this purpose, peak velocity measurements may be obtained by examining those phases corresponding to peak systole. As opposed to determining mean velocities over the entire luminal area, individual pixels or groups of pixels can be evaluated to reveal the peak systolic velocity across the stenotic orifice (99).

Perfusion Evaluation

The development of ultrafast allows the monitoring of the first-pass kinetics of distribution of MRI contrast agents to assess regional tissue perfusion (30). Because currently available Gd chelates equilibrate rapidly in the extracellular space, the demarcation between normally and abnormally perfused myocardium requires rapid imaging to monitor the first passage of the intravenously administered agent. Because of its inherently reduced cardiac motion and enhanced coronary flow, diastole is usually used as the imaging period for these sequences; acquisition of sequential images of diastole during the first pass of a Gd chelate bolus permits the assessment of patterns of myocardial perfusion (31). The feasibility of ultrafast, as well as EPI, for evaluation of myocardial perfusion has been shown in animals (102,103) and in patients (104,105).

Methods for quantifying regional myocardial perfusion by using data acquired during first passage of MRI contrast agent have been proposed (106). In animal models with various grades of coronary stenosis, and after augmentation of flow with a vasodilator, myocardial blood flow has been quantified by analysis of signal intensity versus time curves; the inverse mean transit time of the Gd chelate displayed a linear correlation with absolute blood flow in the myocardium, as measured by microspheres (102). Thus, by treating Gd chelates mainly as extracted tracers, it is possible to measure myocardial perfusion from the pattern of myocardial enhancement. While the model assumes a linear relationship between tracer concentration and signal enhancement, this is only true for these extracellular agents at low concentrations (0.05 or 0.10 mmol per kg), as normally applied in clinical practice (106).

SPECIFIC CLINICAL APPLICATIONS

For the purpose of this discussion, application of MRI to CV diseases presenting in the adult are addressed.

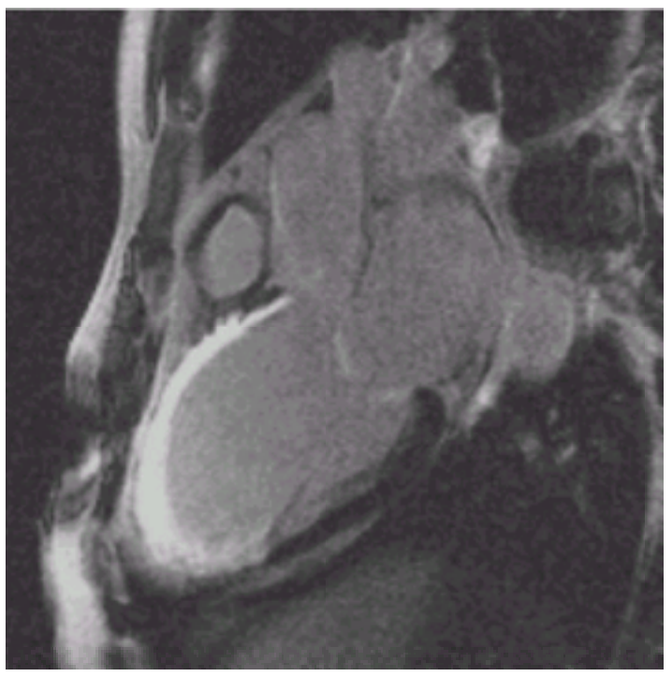
Ischemic Heart Disease

Assessment of Global Ventricular Function

Multiphasic MRI techniques have been used to estimate impaired EF as a result of ischemic heart disease. End diastolic and end systolic images of the LV have been obtained to evaluate EF and the resulting values derived, using the area-length method to correlate with those obtained by single-plane and biplane LV ventriculography (e.g., R = 0.79 and R = 0.95 for parallel and perpendicular to the interventricular septum, respectively) (73,74). Nevertheless, in the presence of LV asymmetry caused by MI with remodeling, formulas for calculating LV volumes by geometric models have serious limitations (107).

VIDEO

Video 54.1 Impaired systolic function and necrosis delineation in a chronic myocardial infarction region (long-axis). The SPAMM (spatial modulation of magnetization) video demonstrates contraction of the left ventricular inferior wall but akinesia of the anterior, apex, and infero-apical segments. The delayed-enhancement image demonstrates transmural hyperenhancement of the segments with impaired systolic function. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Impaired systolic function and necrosis delineation in a chronic myocardial infarction region (long-axis). The SPAMM (spatial modulation of magnetization) video demonstrates contraction of the left ventricular inferior wall but akinesia of the anterior, apex, and infero-apical segments. The delayed-enhancement image demonstrates transmural hyperenhancement of the segments with impaired systolic function.

After MI, LVEF values (determined from transaxial MRI, obtained using a multiphasic multilevel S-E technique) have been shown to correlate well with those from radionuclide or contrast LV ventriculography (108). However, the correlation varied with the damaged region, described by primary coronary artery distribution (e.g., R = 0.87 for right coronary artery and R = 0.48 for left anterior descending distributions). A semiquantitative measure of global post-MI LV function, based on segmental wall motion scoring from transaxial multiphasic multilevel images, also correlated regionally with ventriculographic EF values (e.g., R = 0.96 for left anterior descending and R = 0.62 for right coronary artery distributions) (38). Such regional variations have been attributed to the limitations of orthogonal imaging, including poor visualization of the undersurface of the LV adjacent to the diaphragm. This limitation is overcome when short-axis imaging is used.

Multilevel-multiphasic MRI for EF determination in patients with ischemic heart disease can be performed more efficiently and with better temporal resolution using cine (68,71,76). In patients imaged within 7 days of acute MI using cine, LVEF by MRI has been shown to correlate better with EF by contrast ventriculography (e.g., R = 0.94) than with EF by radionuclide ventriculography (e.g., R = 0.82) (109).

Despite its advantages, MRI continues to have difficulties in gaining acceptance in the assessment of ventricular volumes and function in patients with ischemic heart disease because of a lack of general availability of dedicated CV MRI services with full capabilities for performing the functional aspects of cardiac imaging, and the wider availability and general familiarity with echo (107). Although the precision and the reproducibility of echo measurements are less than those achieved with MRI, echo information generally can be relied on for clinical management.

Assessment of Regional Ventricular Function

Abnormal wall motion, and more specifically abnormal systolic thickening, in the LV indicates diminished regional myocardial function (110). Regional myocardial wall thickening abnormalities are frequently observed on MRI in association with ischemic heart disease, starting as early as 5 minutes after coronary artery occlusion (111).

Compared with other criteria, such as increased myocardial intensity and adjacent intracavitary blood signal, regional wall motion abnormality appears to be the most predictive and specific MRI finding associated with either a recent or remote MI (112). By analyzing the outline of the endocardial and epicardial borders on images acquired at various segments of the cardiac cycle using the different multiphasic MRI techniques, regions of hypokinesia, akinesia, or dyskinesia, accompanied by increasing degrees of impaired wall thickening, can be defined clinically (69,80,108). For the detection of a recent MI, using a multiphasic multilevel S-E MRI technique, sensitivity, specificity, and accuracy are improved when wall motion abnormalities are used along with myocardial intensity increase (e.g., 93%, 80%, and 87%, respectively) rather than intensity increase alone (e.g., 80%, 80%, and 80%, respectively) (113).

Regions of decreased LV systolic wall thickening caused by ischemic heart disease can be identified and quantitated using the various multiphasic S-E MRI techniques. Employing transaxial imaging and a multiphasic multilevel S-E MRI technique, absolute and percent wall thickening has been assessed in various cardiac diseases, including ischemic heart disease; MRI consistently demonstrated decreased systolic wall thickening measurements in regions damaged by MI when compared with normal myocardial regions in the same patients, and with the LV wall in normal individuals (38,79). When concurrent multilevel multiphasic S-E MRI and 2-D echo examinations of patients with a single MI were evaluated using a segment-by-segment point scoring of residual wall thickening, most of the LV segments, representing the left anterior descending distribution, showed significant agreement (38). In experimentally evaluating regional LV contractility in comparison with histochemical evidence of MI, determinations of mean maximal percent systolic thickening have been found to be significantly decreased in induced MI regions; with high sensitivity and moderate specificity, the same MRI approach identified reduced systolic wall thickening in segments recognized as akinetic or dyskinetic by LV ventriculography in patients with a history of MI (114).

More so than multiphasic S-E techniques, cine is suited to the evaluation of regional ventricular function in patients with ischemic heart disease (69,80,109,110). Assessments of LV wall motion by cine in patients with coronary artery disease (CAD) have correlated well with results of echo or LV ventriculography (80); impaired systolic wall thickening has proved to be a very specific marker of regional myocardial dysfunction (Fig. 54.1). Compared with contrast ventriculography, the concordance in regional wall motion has been similar for both cine (e.g., 69%) and radionuclide ventriculography (e.g., 65%) (109). Although a multilevel cine series gives the advantage of full representation of the ventricles, when patients with suspected CAD have been studied using only biplane cine and biplane LV ventriculography, 96% agreement in the right anterior oblique view and 92% agreement in the left anterior oblique view have been demonstrated (115).

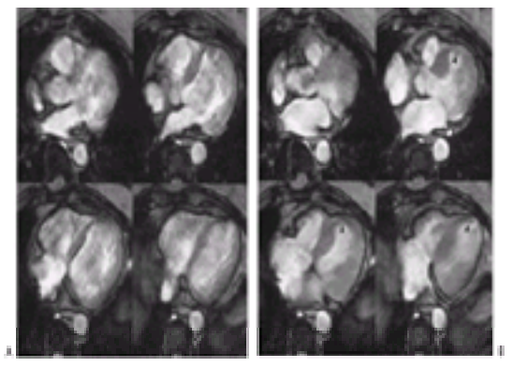


FIGURE 54.1 Regional myocardial dysfunction from coronary artery disease (cine; transaxial). From end diastole **(A)** to end systole **(B)**, four adjacent levels of the left ventricle reveal decreased anteroseptal and anteroapical wall thickening (*arrowheads*) from disease of the left anterior descending coronary artery.

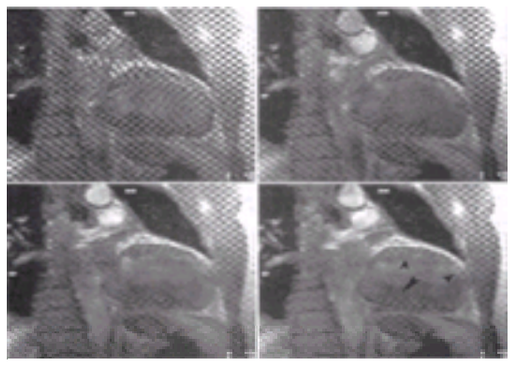
Absence of systolic wall thickening in the presence of passive inward wall motion, which is potentially mistaken for hypokinetic viable myocardium on ventriculography, is detectable in MI regions on MRI because of direct LV wall visualization. Wall thickening of greater than 2 mm has been measured in all regions of the normal LV on cine; less thickening has been demonstrated at sites of prior MI (80,116,117 and 118). Cine has proved to be more accurate than echo in the measurement of LV systolic wall thickening (119).

More recently, myocardial tagging has been used to provide unique functional information about regions of MI and compensatory changes of noninfarcted portions of the LV (eFig. 54.1.1) (120). In patients with one-vessel disease leading to an acute MI, reduced intramyocardial circumferential shortening has been noted throughout the LV, including remote noninfarcted regions (121). Using SPAMM, LV dilatation and eccentric hypertrophy from remodeling have been shown to be associated with

persistent differences in segmental function and wall stress between adjacent and remote noninfarcted myocardium (121).



***e*FIGURE 54.1.1** Impaired systolic function in myocardial infarction region and compensatory changes in noninfarcted regions (spatial modulation of magnetization, two-chamber long axis). Decreased grid deformation in the infarcted anterior wall (*small arrowheads*) contrasts with the noninfarcted, hypertrophic inferior wall where deformation is preserved (*large arrowhead*).

Although the determination of wall motion, thickening, and mechanics by these forms of multiphasic MRI may eventually play an important role in the accurate detection and functional characterization of myocardial ischemia in patients with suspected or known CAD (122), their routine clinical use has been limited because of the aforementioned reasons.

Complications and Natural History of Myocardial Infarction

Tissue characterization by MRI has shown an inverse relationship between relaxation times and flow during experimental coronary artery occlusion (123). Acute MI is characterized by prolonged T1 and T2 (111,112 and 113,124). The alteration in relaxation times, and the associated signal increase, in acutely infarcted myocardium seems to primarily represent edema resulting from acute, irreversible ischemia (125). In addition, following an acute MI, maximum T1 values are observed at 2 weeks after the event, suggesting that cellular infiltration also contributes significantly to the appearance (126). However, other factors (e.g., hemorrhage, loss of myocyte membrane integrity, increased triglyceride content, free radicals, changes in magnetic susceptibility) also presumably contribute to the prolonged relaxation times (127).

Although an *in vivo* determination of these relaxation times is calculated from signal intensities detected on MRI, intensity does not depend only on T1 and T2 but, rather, is related to other physiologic characteristics (e.g., movement). Therefore, image-derived quantitation of the relaxation times for clinical purposes is influenced by hemodynamics and by cardiac and respiratory motions; hence, the obtained values for relaxation times differ from *ex vivo* measurements and are less reliable (111,112 and 113).

Nevertheless, increase in relative myocardial intensity is routinely seen as early as 30 minutes, but almost certainly 3 to 6 hours, after coronary occlusion when MI has occurred (113,124). The intensity reaches a maximum after 3 days, but then tends to decline after 20 days (113,128). Because T2 is prolonged, helping to enhance intensity in the region of an acute MI, the contrast between the MI region and normal regions is optimized on T2-weighted images (113,124).

Regional increase in S-E myocardial intensity, indicating acute MI (Fig. 54.2), has corresponded with the ECG location of the MI (113), enzymatic indicators (129), the presence of hypokinetic segments on ventriculography (113,129), and nuclear perfusion defects at rest (130). Although this characteristic pattern of myocardial S-E intensity is often noted in clinical cases during the first 2 weeks after MI, there are pitfalls in the clinical application of alterations in signal intensity (112). Increased myocardial intensity on T2-weighted images may be difficult to distinguish from slowly moving intraventricular blood (131), and it has been noted that T2 prolongation might not be a specific marker for acute MI and can also be observed in abnormally perfused myocardial segments of patients with unstable angina (132). In addition, increased intensity may often be seen in normal individuals, thereby reducing its value as a marker of MI. Thus, although the increased intensity of MI regions on S-E MRI can be considered a sensitive finding, it is of low specificity (112).

FIGURE 54.2 Regional increase in myocardial intensity from acute myocardial infarction (T2-weighted spin-echo; transaxial). Increased myocardial signal intensity in interventricular septum and anterior wall (*asterisk*) is caused by edema from an acute myocardial infarction.

Findings consistent with hemorrhagic MI have also been detected *ex vivo* on S-E imaging (133). Regions of decreased signal intensity, histologically proven to be hemorrhage, have been noted adjacent to or within the central zone of increased intensity that represents acute MI; good correlation has been found between the volume of hemorrhage measured at postmortem examination and the volume of such decreased signal intensity. The decreased myocardial intensity results from T2 enhancement produced by deoxyhemoglobin (134).

The use of Gd chelates enhances the ability to visualize a region of MI on T1-weighted S-E images (66,135,136), and it may also result in a higher specificity in detecting MI (137). Gd chelates at lower doses mainly shorten T1 of the myocardium and, because of the different washout rates, increase the contrast between MI and normal regions on T1-weighted images. *Ex vivo* MRI of perfused hearts using Gd chelates has shown increased contrast between normal and reperfused ischemic myocardium, when compared with both nonreperfused ischemic hearts after Gd chelate administration and reperfused ischemic hearts not given Gd chelate (138). However, this distinction has been less evident on S-E MRI performed *in vivo*.

The appearance of an acute MI after the injection of contrast media is regulated by whether images are acquired during the initial or early passage of the contrast media through the heart or during the equilibrium phase (66). The appearance also depends on the age of the MI, the dose of the medium, and the sequences applied (107). During the first pass, there is delayed entrance of the contrast medium into the ischemic region. Consequently, the region supplied by an occluded artery shows lower signal intensity than normal myocardium during the first few minutes after injection of a Gd chelate (107) (eFig. 54.2.1). On the other hand, there is greater enhancement of intensity of the MI region using T1-weighted images acquired during the equilibrium phase of distribution, because of a delayed washout of the medium in the occluded area or the enlarged extracellular space of the MI region (135,136); the differentiation persists 30 minutes after injection (137).

***e*FIGURE 54.2.1** Impaired perfusion of myocardium (short axis). There is a rapid first-pass enhancement of right ventricle cavity, left ventricle cavity, and then left ventricle viable myocardium by a bolus of gadolinium-diethylenetriaminepentaacetic acid. A region of no enhancement is visible in the anteroseptal wall, representing impaired myocardial perfusion at rest caused by an occlusion of the left anterior descending artery.

Although in patients, significantly greater myocardial intensity enhancement results from Gd chelate (i.e., 66% to 70% increase) in regions of MI when compared with normal regions (i.e., 20% to 35% increase) on T1-weighted images (136,137), it is not true on T2-weighted images (139). Because contrast between acute MI and normal regions is increased (e.g., 6% and 39% before and after Gd chelate, respectively), improved clinical discrimination has been possible, allowing for a more accurate diagnosis of MI (135,137,138). A new delayed-enhancement MRI technique (Turbo FLASH with inversion recovery) has been applied to study both acute and chronic MI after the administration of Gd chelate and has shown an excellent correlation with TTC staining histology in animal models (139). The sequence is employed 15 to 30 minutes after the injection of a double dose (0.2 mmol per kg) of gadolinium-diethylenetriaminepentaacetic acid (Gd-DTPA), and the area of necrosis is delineated as an area of hyperenhancement and viable myocardium as an area of nulled signal (Fig. 54.3 and *e*Fig. 54.3.1).

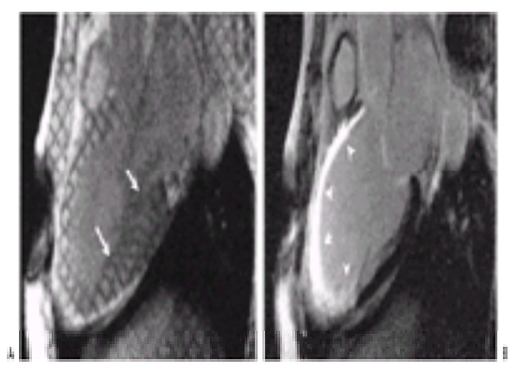


FIGURE 54.3 Delayed-enhancement magnetic resonance image of chronic myocardial infarction [spatial modulation of magnetization (SPAMM); Turbo FLASH with inversion recovery; long axis]. At end systole a SPAMM image **(A)** demonstrates contraction (*arrows*) (deformation of grid pattern with change from square to diamond shape) of the left ventricle inferior wall. Delayed-enhancement image **(B)** demonstrates transmural hyperenhancement of the anterior wall, apex, and apical inferior wall (*arrowheads*) caused by myocardial necrosis, corresponding to the area of absent contraction on the SPAMM image.

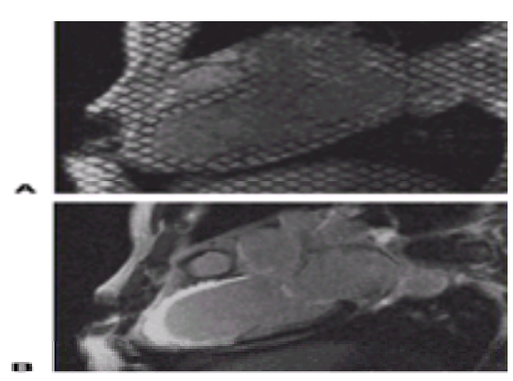

***e*FIGURE 54.3.1** Impaired systolic function and necrosis delineation in chronic myocardial infarction region (long axis). The spatial modulation of magnetization image **(A)** demonstrates contraction of the left ventricle inferior wall but akinesia of the anterior, apex, and inferoapical segments. The delayed-enhancement image **(B)** demonstrates transmural hyperenhancement of the segments with impaired systolic function.

Although a number of experimental and clinical studies have shown that MRI contrast agents improve the demarcation between acute or subacute MI and normal myocardium, it has been accomplished for a chronic MI (140). In addition, despite encouraging initial results, it has been shown that signal intensities measured 25 minutes after Gd chelate administration differentiate reperfused from nonreperfused MI when the delayed-enhancement technique is employed (140). In patients status-post thrombolytic therapy for acute MI, measured intensity ratios 6 to 8 minutes after injection of Gd chelate have been shown to be significantly different from those of MI regions subtended by occluded coronary arteries, indicating that assessment of the early dynamics of contrast enhancement using Gd chelates may identify successful reperfusion (138). It has also been shown that the morphologic appearance of contrast enhancement by Gd chelates may identify the presence or absence of reperfusion; reperfusion leads to no enhancement, whereas lack of reperfusion may be visualized as a hyperenhancement (140,141).

Chronic MI produces regions characterized by shortened T2 and decreased intensity on routine S-E and G-E imaging consistent with the replacement of myocardium with fibrous tissue (142). On ultrafast for first-pass assessment, 50% enhancement of chronic MI regions, compared with 134% in normal regions, has been observed after Gd chelate administration; the MI site on MRI corresponded with the location of wall motion abnormality on echo (143).

In addition to increased relaxation times, other morphologic MRI features of MI are valuable diagnostic parameters. Areas of thinning of the LV wall caused by remote MI are sharply demarcated from myocardium that is of normal thickness (130,142,144). Regional abnormalities are delineated better on systolic images than on diastolic images, because there is an accentuated disparity in the wall thickness. Compared with increased myocardial intensity and abnormal cavitary signal, relative regional wall thinning has been found to be the most predictive and specific marker for the presence of an acute MI during clinical evaluation by MRI (112).

Damage to the LV wall segments is often indicated by intracavitary stagnant blood and thrombotic material (*e*Fig. 54.3.2). These intracavitary areas appear as abnormal signal on S-E and cine MRI (49,77,145). With S-E MRI, the differentiation between these two causes of such signal may be made, as described earlier, from multiple S-E magnitude-data images or the corresponding phase-display images. The presence of even-echo rephasing or significant motion-dependent phase changes indicates slow blood flow; the absence of these changes accompanies thrombus (146). On cine, their differentiation is achieved by finding fluctuating areas of intermediate signal loss (i.e., indicating slow blood flow) or fixed lower intensity areas (i.e., indicating thrombus) on the image loop (63) (*e*Fig. 54.3.3).

***e*FIGURE 54.3.3** Post–myocardial infarction apical thrombus (long axis). Akinesia of thin apical wall with adjacent thrombus.

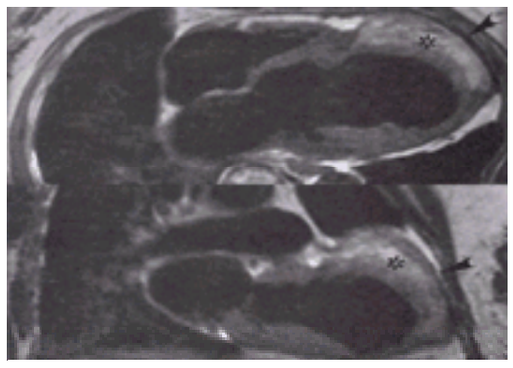
Because of its therapeutic and prognostic importance, MI sizing by MRI has been pursued. *Ex vivo* and *in vivo* measurements of relative MI size (i.e., percent LV), based on changes in myocardial signal parameters such as intensity on T2-weighted images after experimental coronary artery occlusion, have correlated closely with postmortem estimates (147). However, S-E imaging without the administration of contrast has tended to overestimate MI size and to demonstrate abnormal intensity extending well beyond the margins of the MI found on pathologic evaluation, suggesting that T2-weighted S-E MRI depicts not only MI damage but also some reversibly injured myocardium (148). In addition, MRI-determined MI size has correlated well with microsphere-determined reduction of blood flow of 25% or more (122). But with the new delayed-enhancement technique, an excellent correlation has been shown between MRI images and histology, either in acute or chronic MI (139).

Clinical MI size determinations, based on intensity at a mean of 9 days after the acute onset of symptoms, have been shown to correlate well with the region of severe hypokinesia visualized by ventriculography (113). Good agreement has been found between MI sizing based on T1 MRI maps and assessment by infarct-avid scintigraphy and ventriculography 5 to 7 days after MI (149). In addition, mean MI volume, based on signal changes, correlated well with segmentally quantitated dysfunction by ventriculography. In the setting of a recent MI, studied 5 to 20 days after the acute event, T2-weighted S-E MRI allows for the direct assessment of MI location and size (150).

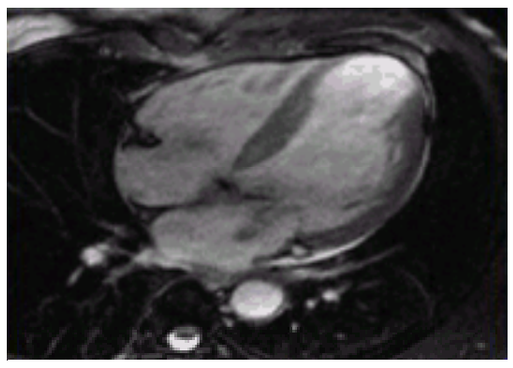
A good correlation between MI size measured with contrast-enhanced MRI and enzymatically determined MI size, 3 to 7 days after the acute event, has been demonstrated (151). Also, Gd chelates produce markedly increased myocardial intensity that correlates well with extent of acute or chronic MI on the delayed-enhancement MRI (139,140).

Another approach to evaluate MI may well be a correlation with the extent of regional wall thinning. Clinically, MI size has been measured based on regional LV wall thinning and dysfunction noted on multiphasic multilevel S-E MRI, and the resulting values correlated inversely with EF determinations by ventriculography (e.g., R = 0.88) (108). Nevertheless, significant reduction in MI size, based on myocardial signal on S-E MRI with (152) or without (153) contrast enhancement, has been shown in patients who did, compared with those who did not, receive intravenous streptokinase within hours of the onset of chest pain related to an acute MI.

MRI is also capable of detecting long-term sequelae of MI. Complications of acute MI including ventricular aneurysm (*e*Fig. 54.3.4), ventricular septal perforation (154), mitral regurgitation, and LV thrombus also can be readily demonstrated by MRI (107,122). Post-MI LV aneurysms are identified as outwardly protruding myocardial wall segments associated with marked transmural thinning and occasionally mural thrombus (142,144). A true aneurysm (i.e., relatively wide neck,) can usually be differentiated from a pseudoaneurysm (i.e., relatively narrow neck), based on the relative size of the communication between the aneurysmal cavity and the main LV cavity (155,156) (*e*Fig. 54.3.5 and *e*Fig. 54.3.6).



***e*FIGURE 54.3.4** Post–myocardial infarction left ventricle aneurysm (T1-weighted spin-echo; horizontal and vertical long axis). Aneurysmal bulging of the anteroapical region (*arrowheads*) of the left ventricle wall contains a layered thrombus of variable age (*asterisks*).



***e*FIGURE 54.3.5** Post–myocardial infarction true aneurysm (long axis). Dyskinesia and thinning of the left ventricle apex caused by an occlusion of left anterior descending artery.

Although therapy is focused on minimizing the deleterious remodeling process in the LV after MI, imaging modalities have not been routinely used to guide or to assess the effect of this therapy (107). MRI used to show remodeling of the LV after acute MI (157), and attenuation of the remodeling process in response to drug therapy has been documented experimentally (158). In patients, cine has provided accurate quantification of myocardial mass of the abnormally shaped LV caused by a transmural MI (159).

In spite of the recognition that MRI can be used to evaluate many aspects of MI, there has been limited clinical use of it for these purposes (107). Perhaps the reason for this is that LV shape changes and complications after acute MI are well shown by echo, although MRI is able to produce a 3-D view of the LV and define with extreme accuracy the extension and size of MI.

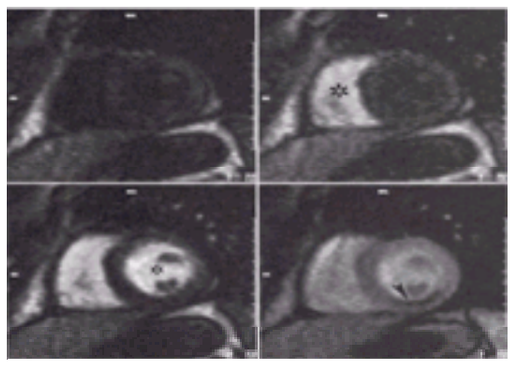
Assessment of Ischemia

Myocardial ischemia, like MI, is associated with increased myocardial signal as a result of prolonged relaxation times (160), and correlations have been observed between increases in T1 and T2 and the increase in tissue water content (161). However, in the clinical setting, the detection of myocardial intensity changes from induced reversible ischemia, moreover ischemia at rest, has not been reliable without the administration of Gd chelate. In contrast to irreversibly injured myocardium, reversibly ischemic myocardium does not necessarily alter myocardial relaxation times or intensity in the early phase. In unstable angina, S-E MRI has occasionally shown significantly increased T2 in reversibly ischemic myocardium. It also failed to distinguish reversibly from irreversibly ischemic regions, as determined by nuclear perfusion imaging (132). The detection of acute ischemia with unenhanced MRI does not occur until several hours after coronary occlusion.

The detection of myocardial ischemia by any imaging modality frequently requires some form of stress to induce disparity in blood flow between normal and potentially ischemic regions. In more recent years, pharmacologic stress has been applied in MRI for detection of functional abnormalities in patients with CAD, because physical exercise during MRI is difficult because of space restriction and it results in motion artifact. The agents used for this purpose increase flow by causing either direct coronary vasodilatation or secondary vasodilatation caused by augmented myocardial oxygen requirements, or both; regional myocardial dysfunction is then caused by either an absolute decrease in regional perfusion (i.e., coronary steal phenomenon) or inadequate increase in flow relative to augmented oxygen requirements (i.e., increased myocardial work) (107).

Using ultrafast, the assessment of myocardial blood flow in normal, reversibly ischemic and irreversibly ischemic myocardium, at rest and during dipyridamole-induced hyperemia, has been validated experimentally (102). With dipyridamole as the vasodilator, a direct relation has been found between myocardial blood flow and signal intensity after administration of Gd chelates (162). These experimental studies have stimulated the application of ultrafast in patients with CAD.

Applying ultrafast to patients with or without the use of pharmacologic stress, myocardial regions perfused by a severely stenosed coronary artery can be detected by an abnormal pattern of change in myocardial intensity. Several differences in intensity versus time curves between the normally perfused segments and the segments supplied by stenotic arteries have been observed after the bolus administration of Gd chelates (163). Some investigators have qualitatively observed an abnormal delay in signal increase of the hypoperfused myocardium; these areas have been shown to correlate well with abnormal areas shown on nuclear perfusion imaging (*e*Fig. 54.3.7) (106). Others have shown that regions with reduced perfusion can be quantitatively characterized on ultrafast, as areas of reduced peak intensity and diminished upslope of the intensity versus time curve compared with normal myocardium (163).



***e*FIGURE 54.3.7** Abnormal delay in signal increase of hypoperfused myocardium (ultrafast; short axis). First-pass enhancement of the right ventricle cavity (*large asterisk, top right*), followed by the left ventricle cavity (*small asterisk, bottom left*), and then the left ventricle myocardium by a bolus of gadolinium chelate is demonstrated on the sequential diastolic images. A region of delayed enhancement in the inferior wall (*arrowhead*) represents impaired myocardial perfusion at rest, caused by a high-grade stenosis of the distal right coronary artery.

Ultrafast for the resting assessment of patients with CAD before and after revascularization has demonstrated improvement in peak intensity and rate of signal increase in myocardium perfused by the treated vessel (163). However, ultrafast has more often been used during the peak effects of dipyridamole (Fig. 54.4) (164). When patients with CAD have been studied using Gd chelate-enhanced ultrafast and dipyridamole stress, sensitivity, specificity, and accuracy of 65%, 76%, and 74%,

respectively, have been noted (104).

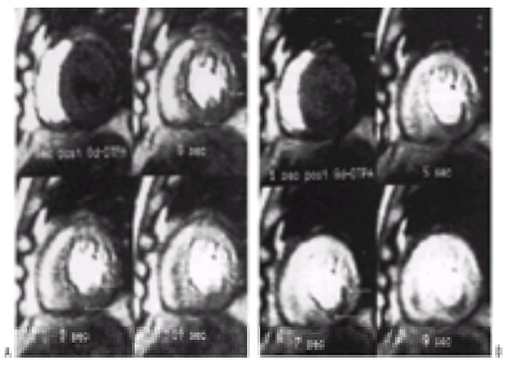


FIGURE 54.4 Dipyridamole-induced hypoperfusion in myocardial ischemia (ultrafast, short axis). On sequential diastolic images at rest **(A)**, only a moderate lack of signal enhancement is detected in the posterior wall of the left ventricle (*arrows*); this is caused by asymptomatic retrograde-filled occlusion of the right coronary artery. Following administration of dipyridamole **(B)**, resulting in angina, decreased signal intensity around the subendocardial layers (*arrows*) of the posterior wall is clearly differentiated from the higher signal intensity of the normal myocardium. Gd-DTPA, gadolinium-diethylenetriaminepentaacetic acid. (From Wilke N, Jerosch-Herold M, Stillman AE, et al. Concepts of myocardial perfusion imaging in magnetic resonance imaging. *Magn Reson Q* 1994;10:249, with permission.)

The limitation of all studies using ultrafast imaging is that the LV can be only partially sampled (usually 3 to 5 anatomic levels) while maintaining adequate temporal resolution (image at each level at 2- to 3-second intervals), whereas higher speed methods would allow multislice tomography to generate a 3-D perspective. Experimentally, EPI has been used to monitor the first pass of Gd chelates in hearts of normal animals and those with coronary occlusion (103) but has not yet been applied clinically. The results in animals and in humans suggest that perfusion imaging by MRI could become an important tool in the diagnosis of ischemic heart disease. A conclusion about the importance of perfusion MRI in relation to nuclear perfusion studies must await further publications (107).

An alternative to the assessment of perfusion abnormalities for the assessment of myocardial ischemia is the detection of reversible LV contractile dysfunction by multiphasic MRI. Multiphasic MRI may show regional LV dysfunction associated with induced reversible ischemia. In patients with known CAD and induced defects on nuclear perfusion examinations, corresponding regional LV functional abnormalities have been noted on MRI after administration of dipyridamole; these wall motion abnormalities occurred at the site of more extensive thallium defects and were associated with chest pain and more severe CAD (164). The 84% sensitivity and 89% specificity of dipyridamole-stress cine resembles that of stress nuclear perfusion imaging for detecting hemodynamically significant stenoses at coronary arteriography (165).

Compared with dipyridamole, dobutamine appears to be a more appropriate agent for eliciting wall motion abnormalities; dobutamine infusion is well tolerated during MRI (166). Cine has been used to visualize wall motion or wall-thickening abnormalities in the potentially ischemic myocardium provoked by dobutamine (Fig. 54.5) (117,166). In patients with CAD studied by both dobutamine-stress cine and nuclear perfusion imaging, comparison of perfusion defects and wall motion abnormalities showed 90% agreement (117,167). Studies of patients referred for coronary arteriography have shown that dobutamine-stress cine can identify wall motion abnormalities by such quantitative analysis with sensitivity, specificity, and accuracy of 91%, 80%, and 90%, respectively; the sensitivity for detection of one-vessel disease was 88%, two-vessel disease 91%, and three-vessel disease 100% (168). Dobutamine-stress MRI has been compared with dobutamine-stress echo and showed similar accuracy, but when echo images were suboptimal, the MRI accuracy was significantly higher than echo (169). Furthermore, dobutamine-stress MRI has been used in patients with poor acoustic window and not well suited for second harmonic stress echo, generating an accuracy of 83% when compared with coronary angiography (170).

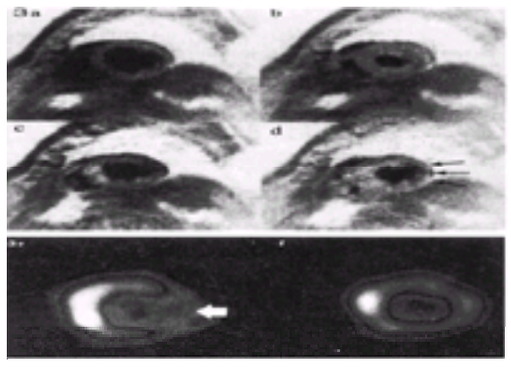

FIGURE 54.5 Dobutamine-induced contractile dysfunction in myocardial ischemia (cine and thallium single photon emission computed tomography, short axis). On end diastolic, **(left, 3a, 3c)** and end systolic **(right, 3b, 3d)** cine images (displayed in negative format) at rest **(above)**, baseline contraction is normal in all regions of the left ventricle. During dobutamine administration **(below, 3c, 3d)**, decreased systolic motion and wall thickening are noted in the lateral free wall of the left ventricle (*arrows*); these are caused by left circumflex coronary artery disease. Corresponding thallium single photon emission computed tomography images during stress **(3e)** and after redistribution **(3f)** demonstrate a reversible lateral free-wall perfusion defect (*large arrow*) corresponding to the wall motion abnormality on cine. (From Pennell DJ, Underwood SR, Manzara CC, et al. Magnetic resonance imaging during dobutamine stress in coronary artery disease. *Am J Cardiol* 1992;70:34, with permission.)

Myocardial tagging may improve the accuracy of MRI with dobutamine stress to detect regional dysfunction, including that limited to the subendocardium. However, to date, this application has been largely investigational in animal models.

Stress MRI is becoming an important tool for diagnosis of myocardial ischemia due to its capability of excellent spatial resolution and been able to define the endocardial border with high accuracy (166,167,168,169 and 170).

Assessment of Myocardial Viability

The distinction between viable and nonviable myocardium after MI is an important determinant of therapeutic options. The effectiveness of MRI in assessing the complete area at risk following acute coronary occlusion may depend on the use of MRI contrast agents to delineate the volume of jeopardized myocardium. Work in animal models has shown that the region of increased myocardial intensity correlates with the bed of myocardium at risk in reperfused myocardium, when Gd chelate is injected after 5 minutes of reperfusion (171). Also, with late injection (e.g., 15 to 30 minutes), an excellent correlation is noted if the delayed-enhancement technique is employed (139,140).

Ultrafast, during administration of Gd chelates, has been shown to provide clear differentiation between an occlusive (i.e., nonenhancing) and a reperfused (i.e., enhancing) MI (172) and between reversible and irreversible injuries in reperfused myocardium in experimental models (173). Although reperfused reversibly injured myocardium shows no significant difference in intensity compared with normal myocardium, irreversibly injured reperfused myocardium shows a substantial increase in intensity during equilibrium, probably as a result of greater distribution space for the contrast media in the jeopardized region because of expansion of the extracellular space (173). An occlusive MI shows a significantly greater enhancement of the peripheral zone than of the central zone, whereas reperfused MI shows homogeneous enhancement of the injured zone (173). EPI has also been used to compare the first pass of a Gd chelate in occluded and reperfused MI (174).

These studies performed in various animal models have been promising in characterizing different types of myocardial injuries, and studies in patients with an occlusive MI or a reperfused MI have shown that contrast-enhanced MRI with a delayed-enhancement technique is effective in differentiating between these two types of myocardial injury (175). When clinical results of delayed enhancement have been compared with positron emission tomography and dobutamine-stress echo, concordant results have been observed, and a correlation has been observed between the amount of enhancement transmurally and the percentage of nonviable segments determined by both techniques (176).

The capability of basic forms of MRI such as cine to provide functional information about myocardium in combination with assessment of diastolic wall thickness and systolic wall thickening makes it suitable for identification of myocardial viability (177). Regional end diastolic wall thickness of less than 6 mm and end systolic wall thickening of less than 1 mm on cine have been identified as features of nonviable myocardium, as defined by nuclear perfusion or metabolism imaging (178,179). A comparison of cine with low-dose dobutamine stress with positron emission tomography in patients with chronic MI showed that use of these parameters was accurate in assessing myocardial viability; wall thickening was found to be a better predictor (e.g., 96% positive predictive value) of residual metabolic activity than was end diastolic wall thickness (Fig. 54.6) (179). Cine and transesophageal echo with dobutamine stress have been assessed for their relative ability to detect induced contraction reserve; when results of each were compared against segmental assessments of viability by positron emission tomography, the sensitivities were 81% and 77% and the specificities were 100% and 94%, respectively (180).

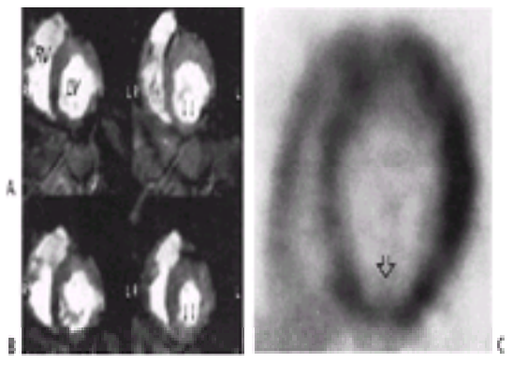

FIGURE 54.6 Post–myocardial infarction myocardial viability (cine and fluorine-18-fluorodeoxyglucose positron emission tomography; short axis). Despite an inferior myocardial infarction (*closed arrows*), viability in the injured region is represented on end diastolic **(left)** and end systolic **(right)** cine images by dobutamine-induced systolic wall thickening **(B)** of the akinetic-appearing inferior wall at rest **(A)**. The positron emission tomographic image **(C)** demonstrates preserved metabolism in the same region (*open arrow*). [From Baer FM, Voth E, Schneider CA, et al. Comparison of low-dose dobutamine-gradient-echo magnetic resonance imaging and positron emission tomography with (18F) fluorodeoxyglucose in patients with chronic coronary artery disease: a functional and morphological approach to the detection of residual myocardial viability. *Circulation* 1995;91:1006, with permission.]

Direct Assessment of Coronary Arteries

Noninvasive visualization of the coronary arteries is one of the ultimate challenges for MRI (122). Imaging of the coronary arteries by MRI has received a great deal of attention since the beginning of clinical CV MRI (181). Visualization of the coronary arteries with standard MRI approaches has been erratic and limited to the proximal segments of the vessels (181,182); only occasionally have readily recognizable vascular abnormalities been identified. Nevertheless, in the cardiac cycle between rapid filling in early diastole and atrial systole, there is a period of relative diastasis with high coronary flow; this has become a target for the many more recently introduced approaches to MRI of the coronary arteries employing static versus dynamic, structural versus flow-based, 2-D versus 3-D, and other variations (183).

Although angiographic forms of MRI are routinely used clinically for evaluation of the carotid and intracerebral vasculature, the great vessels of the chest and abdomen, and the arteries and veins of the extremities (40), angiography of the coronary arteries by MRI remains investigational. This is because of the greater technical difficulties related to the relatively small size of these arteries, their complex 3-D anatomy, normal cyclic variations in coronary flow, competing signal from neighboring blood pools, and their constantly changing position within the chest caused by cardiac and respiratory motion (107,122). To overcome these obstacles, several approaches have been proposed and have already achieved some success (183). To date, the greatest experience has been with 2-D G-E MRI with fat saturation to eliminate signal from adjacent adipose tissue and segmented k-space acquisition, allowing imaging at one level during a breath-hold to avoid excessive blurring from respiratory motion (184).

With the 2-D G-E approach, good visualization of all major vessels in healthy subjects has been reported (185), and good correlation between measurements made by MRA and coronary arteriography has been established (186). In patients with CAD, occluded coronary arteries have appeared on such MRA images as absent flow signal distal to the occlusion, while high-grade stenoses showed signal loss in the area of stenosis with visualization of the vessel distally (Fig. 54.7). Initial clinical work with the approach resulted in optimism about identifying hemodynamically significant stenoses (i.e., ³50% narrowing) of major coronary arteries. Using selective coronary arteriography as the gold standard, MRI-based angiography had 90% sensitivity and 92% specificity for identifying a diseased epicardial coronary artery on blinded analysis, although correspondence between lesion location within an individual coronary artery was not assessed; the corresponding positive and negative predictive values were 85% and 95%, respectively (187). The sensitivity and specificity of the technique were, respectively, 100% and 100% for the left main coronary artery, 87% and 92% for the left anterior descending artery, 71% and 90% for the left circumflex coronary artery, and 100% and 78% for the right coronary artery (187). Subsequent work, using the same approach (188) or a 3-D approach with respiratory compensation (189), however, showed much poorer results, which were attributable to patient selection biasing, independent evaluation, technique differences, and experience of the interpreter. More recently, contrast-enhanced 3-D approaches with breath holding have shown great promise (183).

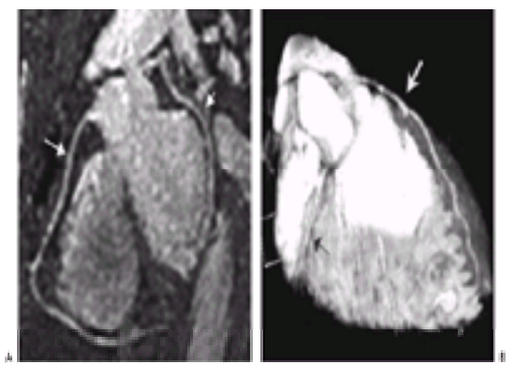

FIGURE 54.7 Magnetic resonance angiography of normal coronary artery (breath-hold, three-dimensional, segmented echo-planar imaging magnetic resonance angiography; maximal intensity projection). A maximal intensity projection image **(A)** demonstrates widely patent normal right coronary artery (*long arrow*) and left circumflex artery (*short arrow*). A volume-rendered reconstruction **(B)** of the same data set delineates the normal left anterior descending coronary artery (*white arrow*) and right coronary artery (*black arrow*). (Courtesy of Debiao Li, Ph.D., Northwestern University, Chicago, IL.)

The present spatial resolution and loss of signal caused by turbulence preclude accurate prediction of coronary artery stenosis severity by MRA. It has been shown that it is not possible to identify stenotic vessels based on quantification of signal intensity; no significant difference in signal was found between vessel segments of a normal coronary artery and vessel segments proximal to a significant stenosis (190). Nevertheless, MRA can be used to noninvasively identify patency of infarcted artery (191).

High-resolution MRI of the human coronary atheroma has developed significantly in the last years. The feasibility of imaging the coronary artery and determining the plaque content has been demonstrated (192). Although the plaque lipid material and the fibrous cap were identified in this preliminary work, further studies are needed to prove the applicability in a large population of this new and interesting technique to determine the morphology of the coronary plaques. In addition, its role relative to advancements in CT (subsecond multidetector scanning), which has also shown promise for plaque characterization, is unclear.

In addition to the morphologic approaches, an MRI method for evaluating flow in coronary vessels has been described (183,193). Results have indicated the feasibility of MRI for measuring flow in the native or simulated coronary arteries (194). Segmented velocity mapping has since been used to measure flow in the coronary arteries in healthy subjects; adenosine was used to increase coronary flow by several-fold, and an increase in velocity was shown (195). Others showed the feasibility of assessing increased coronary flow velocity using breath-hold velocity mapping or TOF EPI, during hand-grip exercise or after dipyridamole (196). Finally, coronary flow reserve in the left anterior descending coronary artery has been measured in an animal model (197) and in patients with CAD undergoing cardiac catheterization with

validation by intracoronary Doppler velocity and flow measurements (198). Thus, MRI may become a noninvasive technique to demonstrate reduced coronary flow reserve caused by hemodynamically significant coronary arterial stenoses.

Encouraging initial results with MRI evaluation of coronary artery bypass graft (CABG) patency has been noted. S-E MRI has been used to assess patency of CABGs; an accuracy of 84% to 95% for detection of graft patency and 72% to 85% for graft occlusion was demonstrated (199,200). After studies with the S-E technique, cine was used to assess CABG patency, with the expectation that the associated signal enhancement of flowing blood would improve evaluation. Cine achieved adequate sensitivities (88% to 93%), specificities (86% to 100%), and overall predictive accuracies (89% to 91%) for patency (201,202). Subsequently, velocity mapping was applied to the measurement of flow in internal mammary artery grafts (203) or aortocoronary vein grafts (204); the normal flow patterns for coronary artery grafts is biphasic with peaks in both diastole and systole. The potential of MRA to evaluate CABG patency has been recognized (Fig. 54.8).

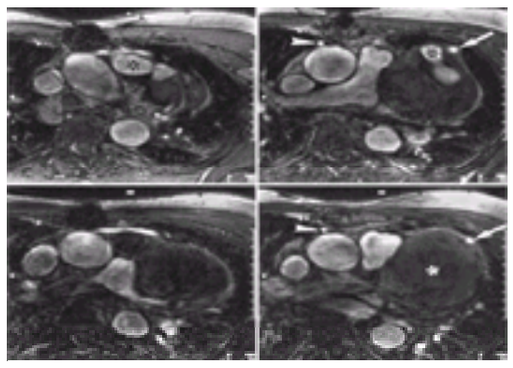

FIGURE 54.8 Coronary artery bypass graft patency and occlusion (contrast-enhanced, three-dimensional magnetic resonance angiography; oblique-transaxial). While patency of an internal mammary artery graft to the left coronary system (*arrows*) and a saphenous vein graft to the right coronary system (*arrowheads*) is confirmed, mid-graft occlusion of an aneurysmal, thrombus-filled saphenous vein graft to the left coronary system (*asterisks*) is detected.

MRA provides a new approach to the evaluation of the patency of coronary vessels. While preliminary work with small numbers of patients has been described, large population studies are needed to see how this new technique will ultimately perform. High-resolution coronary MRI is a new and exciting technique that might be able to discriminate the plaque content, but further studies in this area are also needed, including correlation with histologic specimens.

Valvular Heart Disease

Until the advent of the multiphasic techniques, MRI could provide little valuable information about valvular heart disease (64); for the most part, only indirect signs were offered by S-E MRI. Because of signal enhancement of the intracardiac and intravascular blood pools, morphologic changes of the leaflets may be demonstrated better on cine (63).

MRI generally produces less information about valvular disease than is offered by Doppler echo. However, MRI has the following advantages: Its 3-D nature makes it operator independent; it may be less susceptible to missing or underestimating eccentrically directed flow through a diseased valve; and it is free from geometric assumptions if cardiac chamber volumes are to be calculated (205). Echo has the advantage of providing true real-time imaging, whereas dynamic MRI techniques provide image loops composed of multiple averaged cardiac cycles. Nevertheless, in the setting of stenosis, thickening and calcification, decreased excursion or doming, and fusion of leaflets have been observed on MRI; predisposition to regurgitation, vegetation, prolapse, and flail can be detected on MRI (205).

Abnormalities of the adjacent chambers are easily detected with MRI. In the presence of stenosis (205), focal dilatation of the distal recipient chamber, concentric hypertrophy of a proximal ventricle, and generalized dilatation of a proximal atrium have been described; with regurgitation present (205,206), generalized dilatation of the proximal and distal chambers and eccentric hypertrophy of an associated ventricle have been noted.

The flow disturbances associated with valvular heart disease are also detectable by MRI. S-E MRI identifies abnormally increased signal caused by stagnant flow within a chamber proximal or distal to a diseased valve, especially an atrioventricular valve; on cine, the same flow disturbance creates an ill-defined cloud of low signal (49,63). On the other hand, in the setting of turbulence, a discrete jet of signal void extending from the diseased valve into the otherwise signal-enhanced recipient chamber characterizes poststenotic or regurgitant flow on cine (62,205,206). Such signal-void jets must be differentiated from physiologic signal loss from normal antegrade flow and from normal inflow, respectively (205,206 and 207). Jets from these valvular problems are easily detected and are distinguishable based on their direction of propagation and time of appearance (63).

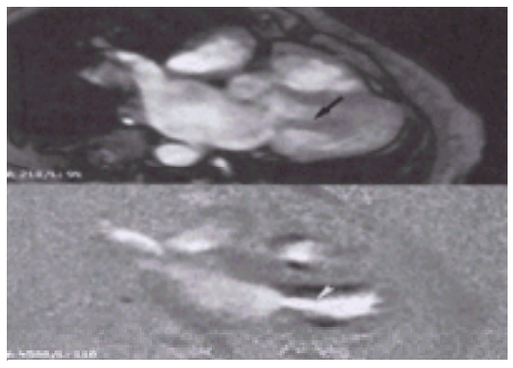
The semiquantitative or quantitative dynamic MRI assessment of the severity of flow disturbance caused by valve disease has been approached by several methods (205,206 and 207). The methods are based on the following measurements: (a) valve leaflet separation (208); (b) proximal convergent flow signal-void dimensions (209); (c) distal flow signal-void jet dimensions [e.g., length, area, or volume (absolute or relative to receiving chamber)] (207,210,211,212 and 213); (d) ventricular volumetrics (205,214); (e) transvalvular flow velocity (215); and (f) net volume flow (62,216).

Mitral Valve

Mitral Stenosis

The following anatomic abnormalities of mitral stenosis (MS) have been described by MRI: thickened leaflets with reduced diastolic opening, enlarged left atrium, abnormal left atrial signal, and abnormal diastolic transmitral signal (208,217).

A signal-void jet begins at the site of the mitral valve level and extends into the cavity of the LV during diastole on cine (205,206 and 207). More so than for the evaluation of regurgitation, evaluation of MS by cine is limited by the need for differentiation between the physiologic signal loss resulting from normal antegrade transvalvular flow and the abnormal flow through the stenotic mitral valve (eFig. 54.8.1). However, some studies indicate that significant MS can be easily detected and semiquantitatively evaluated using cine (208,217).



***e*FIGURE 54.8.1** Mitral stenosis (cine and velocity mapping; horizontal long axis). On cine (*above*), decreased diastolic opening of the mitral valve leaflets creates a jet of signal void (*arrow*) extending into the left ventricle cavity. A corresponding stream of high-velocity flow (*arrowhead*) is noted on velocity mapping (*below*).

Dynamic MRI has demonstrated its ability to quantitatively evaluate physiologic abnormalities associated with MS. The following have been assessed: valve leaflet separation (R = 0.81 vs. area by Doppler by pressure half-time method) (208), relative distal signal-void jet area (R = 0.77 vs. peak trans-valve gradient by

catheterization) (207), and peak trans-valve gradient (R = 0.89 vs. gradient by Doppler) (218).

Mitral Regurgitation

The anatomic abnormalities of mitral regurgitation on MRI resemble those of MS; however, dilatation of the LV is present (205,206 and 207).

Mitral regurgitation is readily identified on cine because of the signal-void jet of turbulent flow extending from the mitral valve level into the left atrial cavity during systole (Fig. 54.9). Based on the detection of a jet, mitral regurgitation is identified with a high degree of accuracy (94% to 100% sensitivity and 95% to 100% specificity vs. color Doppler) (210,219,220).

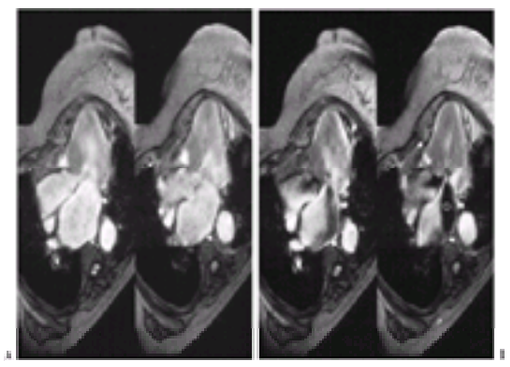


FIGURE 54.9 Mitral regurgitation (cine; left ventricle outflow tract). From end diastole **(A)** to mid-systole **(B)**, mitral regurgitation becomes identified by a signal-void jet of turbulent flow (*open circle*) extending from the mitral valve level into the left atrial cavity.

Quantitative physiologic assessment by dynamic MRI has included the following: distal signal-void jet grade [70% concordance vs. grade by color Doppler (221) and R = 0.77 vs. ventriculography (220)]; distal signal-void jet size [length, R = 0.74 vs. color Doppler (220); absolute area, R = 0.71 vs. color Doppler (220); relative area, R = 0.74 to 0.87 vs. color Doppler (219,220); volume, R = 0.84 vs. regurgitant volume by cine volumetric analysis (210,213)]; volumetric regurgitant fraction [R = 0.84 vs. ventriculography (221)]; volume-flow regurgitant fraction [R = 0.87 to 0.96 vs. grading by color Doppler (222,223)]; and combined volumetric and volume-flow regurgitant fraction [R = 0.96 vs. ventriculography (223)].

Aortic Valve

Aortic Stenosis

Anatomic abnormalities of aortic stenosis (AS) evaluated by MRI have included concentric LV hypertrophy, dilatation of the ascending aorta, reduced aortic valve area [R = 0.75 by S-E vs. catheterization or Doppler (224)], and mean difference by velocity mapping of 0.2 cm^2 versus catheterization by Gorlin formula and of 0.1 cm^2 versus Doppler by continuity equation (225). A double-oblique cine image taken through the aortic valve plane best demonstrates the cusps and their coaptation and serves to differentiate acquired AS from congenital AS with a bicuspid aortic valve. Because of its proven accuracy for quantifying LV mass (67,68), MRI may also be used to monitor the effects of AS on the LV before and after surgical repair or balloon valvuloplasty.

Video 54.4 Aortic stenosis and insufficiency (long-axis). A systolic signal-void jet of aortic stenosis is visible extending from the aortic valve into the ascending aorta. In addition, a diastolic signal-void jet of aortic insufficiency is seen extending from the aortic valve into the left ventricular cavity. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

On cine, a signal-void jet of AS extends from the level of the aortic valve outward until its hemodynamic effects are dissipated within the blood pool of the ascending aorta (Fig. 54.10 and eFig. 54.10.1). AS jets are usually observed on cine throughout most of systole; however, some physiologic signal-void jets normally appear transiently just beyond the aortic valve after the initial opening of its leaflets. Nevertheless, significant AS can be detected using cine, and when there is a pressure gradient across the aortic valve, the severity of pressure drop and the length of the area of signal loss on cine show significant correlation (205,206 and 207). Mild, moderate, and severe AS can be differentiated based on jet size, but at pressure gradients above approximately 60 mm Hg, no further size increase is noted (207).

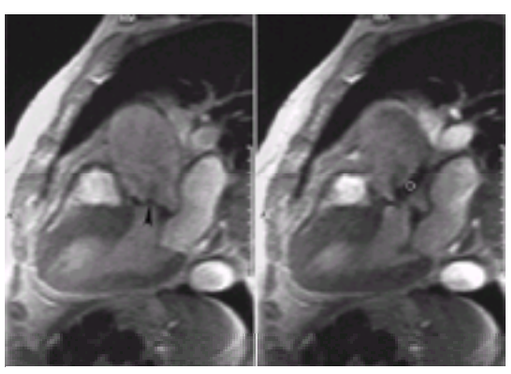

FIGURE 54.10 Aortic stenosis (cine; left ventricle outflow tract). From end diastole **(left)** to mid-systole **(right)**, a signal-void jet of turbulent flow (*open circle*), representing aortic stenosis, develops beyond the thickened aortic valve leaflets (*arrowhead*). HRA, high right atrium.

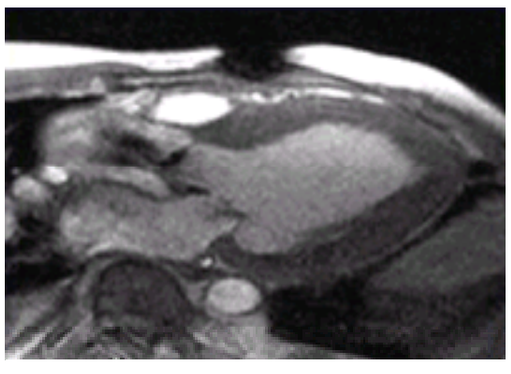

***e*FIGURE 54.10.1** Aortic stenosis and insufficiency (long axis). A systolic signal-void jet of aortic stenosis is visible extending from the aortic valve into the ascending aorta. In addition, a diastolic signal-void jet of aortic insufficiency is seen extending from the aortic valve into the left ventricle cavity.

Dynamic MRI has proved its ability to quantitatively evaluate physiologic abnormalities associated with AS. The following have been assessed: absolute distal signal-void jet length [R = 0.86 vs. peak trans-valve gradient by catheterization (207)] and peak trans-valve gradient [R = 0.96 vs. gradient by Doppler (225) and R = 0.67 to 0.97 vs. catheterization (225,226)].

Aortic Regurgitation

On MRI, the anatomic abnormalities of aortic regurgitation (AR) resemble those of AS, but instead of concentric hypertrophy, there is dilatation of the LV (205,206 and 207).

The signal-void jet of AR on cine has been fully described and evaluated for its potential to stage the severity of disease (Fig. 54.11 and *e*Fig. 54.10.1 and *e*Fig. 54.11.1) >(205,206 and 207). Qualitative assessment by cine has also involved proximal flow convergence detection (227) (87% sensitivity and 100% specificity vs. aortography) (209) and distal signal-void jet detection (89% to 92% sensitivity and 93% to 98% specificity vs. Doppler) (210). Velocity mapping has also received a great deal of attention for physiologic evaluation of AR, largely by assessing total reverse flow (62,205,206 and 207).

Video 54.5 Aortic insufficiency associated with annuloaortic ectasia of aortic root (oblique-coronal). An “onion-bulb” dilatation of the proximal ascending aorta and the sinuses of Valsalva is observed. A signal-void jet of aortic insufficiency is seen extending from the aortic valve into the left ventricular cavity during diastole. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

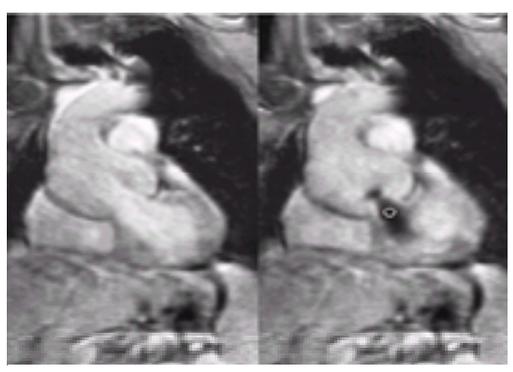

FIGURE 54.11 Aortic regurgitation (cine; oblique-coronal). A signal-void jet of aortic regurgitation (*open circle*) is seen extending from the dilated aortic root into the left ventricle cavity during diastole.

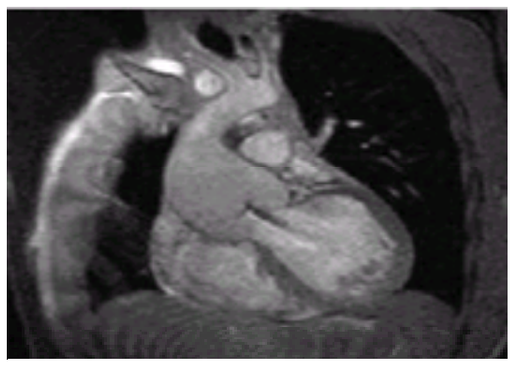

***e*FIGURE 54.11.1** Aortic insufficiency associated with annuloaortic ectasia of aortic root (oblique-coronal). An “onion-bulb” dilatation of the proximal ascending aorta and the sinuses of Valsalva is observed. A signal-void jet of aortic insufficiency is seen extending from the aortic valve into the left ventricle cavity during diastole.

For quantitative physiologic assessment, dynamic MRI has been used for proximal convergent flow signal-void area (significantly greater than for all grades by echo) (209); distal signal-void jet grade (93% concordance vs. grade by aortography) (228); distal signal-void jet size [area significantly greater than for moderate to severe vs. normal to mild 2-D echo grades (229)]; volume R = 0.84 versus regurgitant volume by cine volumetrics (210,212), significantly greater than for moderate versus mild and for severe versus moderate 2-D echo grades (210); volumetric regurgitant fraction (significantly greater than for moderate to severe versus normal to mild 2-D echo grades) (212); volume-flow regurgitant fraction [R = 0.97 to 98 vs. cine volumetrics (216,229); R = 0.80 vs. grading by aortography (230)] (Fig. 54.12).

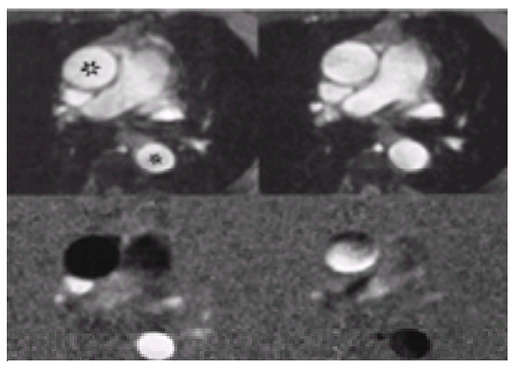

FIGURE 54.12 Aortic regurgitation (velocity mapping; oblique-transaxial). Corresponding to the magnitude data cine images (*above*) are the mid-systolic image (*left*) and mid-diastolic image (*right*) from velocity mapping (*below*). In systole, rapid antegrade-cranial flow in the ascending aorta (*large asterisk*) and antegrade-caudal systolic flow in the descending aorta (*small asterisk*) are represented by intense black and white shades, respectively. Because of significant aortic regurgitation, retrograde flow patterns are demonstrated in the thoracic aorta in diastole.

Tricuspid and Pulmonic Valves

Little work has specifically dealt with the issues of acquired right-sided valvular heart disease, although the value of MRI in assessing congenital tricuspid, including Ebstein’s anomaly or pulmonic valve disease, has been described (231). The principles correspond to the aforementioned for assessment of acquired left-sided valvular heart disease by MRI.

Volume-flow regurgitant fraction of pulmonic regurgitation has been validated (R = 0.93 vs. cine volumetrics) (232).

Prosthetic Valves

Normally Functioning Prosthesis

Studies *in vitro* and *in vivo* have shown that patients with artificial heart valves can be safely examined in high-field magnets (43,45). On MRI, little image distortion outside the immediate area of the prosthetic valve and no patient discomfort have been observed in related studies (233).

Abnormally Functioning Prosthesis

When the diagnostic value of cine for detecting regurgitation in prosthetic valves has been compared with that of transesophageal color Doppler echo, excellent (e.g., 96%) agreement between the methods in distinguishing physiologic from pathologic regurgitation was observed (234). In addition, quantitative physiologic evaluation of the severity of regurgitation has been promising [75% concordance of grade vs. grade by Doppler (234); R = 0.85 distal signal-void jet length, and R = 0.91 distal signal-void jet vs. Doppler (234)].

Myocardial Disease
