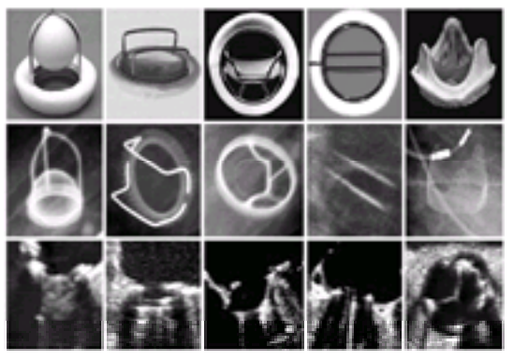
The undesirable thromboembolic complications of the mechanical valves raised interest in the development of tissue valves. The first tissue valve was an aortic homograft inserted by Ross in 1962 (9). The limited availability of fresh homografts made their use impractical until the development of cryopreservation in 1987. Advances in methods of preservation led to the development of the stented porcine valve xenografts, first implanted in 1965 by Carpentier (10) and later marketed as the Hancock and the Carpentier-Edwards valves. Although these valves eliminated the need for anticoagulation, they were limited to suboptimal hemodynamic performance at smaller sizes because of the bulk and position of their supporting stents. The Ionescu-Shiley (11) and the Carpentier-Edwards bovine valve, which were fashioned from bovine pericardium, were later developed to improve the hemodynamic profile of the tissue heterografts. Aortic homografts, aortic pulmonary autografts (12), and, more recently, stentless porcine valves are capable of providing hemodynamic performance comparable to that of native valves, although these are mostly available for use in the aortic position and have less durability than mechanical valves. A few institutions have limited experience with the use of a mitral valve homograft (13). The long-term results of this operation still need to be determined. Thus, efforts to improve the design and performance of prosthetic valves continue, because none of the options currently available can match the hemodynamic performance, durability, low risk of infection, and low thrombogenicity of native human valves.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

Prosthetic valves are classified into two major subgroups: mechanical prostheses and tissue prostheses. The predominant advantages of mechanical prostheses are higher durability and better hemodynamic performance. The main disadvantage is higher thrombogenicity, which necessitates the use of long-term anticoagulation. Each valve within these groups has unique design characteristics that convey specific differences in performance, durability, and thromboembolic risk. These variations in design translate into auscultatory, radiographic, and echocardiographic findings that make identification of these prostheses possible and, most important, permit recognition of changes that may represent prosthetic malfunction (eFig. 24.0.1).



***e*FIGURE 24.0.1** Photographic (*top row*), radiographic (*middle row*) and echocardiographic (*bottom row*) appearance of different mechanical and bioprosthetic valves. General Principles

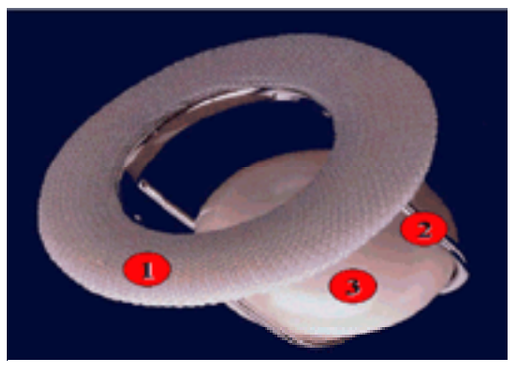
Valve prostheses have three main components: a sewing ring, a supporting strut, and an occluder device (eFig. 24.0.2). Sewing rings are constructed from metallic alloys or plastics and covered with a cloth through which sutures are passed to implant the valve to the annulae fibrosa. These rings are common to all prosthetic devices, with slight variations in the frame and cloth materials. The size of the prosthesis is determined by the diameter of the suture ring. The type of occluder determines the anatomic and functional characteristics of each valve type. The occluders may be composed of plastic balls or discs in a metallic cage, single or dual tilting discs, or biologic tissue mounted in a frame. Each type of prosthesis has specific features that may permit its recognition by means of auscultation, two-dimensional and Doppler echocardiography, or cinefluoroscopy.



***e*FIGURE 24.0.2** Basic components of a prosthetic valve: (1) sewing ring, (2) supporting strut, and (3) occluder. Example of a Starr-Edwards valve.

Magnetic resonance imaging can be performed safely in most patients with prosthetic valves (14). This test may be of clinical advantage in patients in whom valvular regurgitation is suspected when the results of Doppler echocardiographic studies are inconclusive (15,16). Uncommonly, invasively obtained catheter gradients are needed to determine prosthetic valve dysfunction. Retrograde catheter crossing of tissue prostheses and ball-and-cage prostheses may be performed safely to determine transvalvular gradients. Tilting-disc prostheses should not be crossed with these catheters because of the risk of catheter entrapment (17). Direct left ventricular puncture using a percutaneous approach may be performed in some cases to measure pressure gradients. Fortunately, in most instances, transvalvular gradients can be determined by Doppler echocardiography, obviating the need for catheterization.

When evaluating the function of prosthetic valves, the following general principles should be taken into consideration:

1. With the exception of the aortic homograft and stentless porcine valves, all currently available tissue and mechanical prosthesis have a smaller effective orifice than a native valve in the same position. This reduction in effective orifice is caused by the profile of the suture ring and the supporting stents in tissue valves or the occluders in mechanical valves. Thus, most tissue and mechanical prostheses in a semilunar position generate a systolic flow murmur. Diastolic murmurs in atrioventricular prosthetic valves are uncommonly heard unless prosthetic stenosis, high forward flow caused by severe valvular regurgitation, or patient-prosthesis mismatch is present (18). The normal auscultatory findings of prosthetic valves may be altered by factors such as chest wall thickness, emphysema, stroke volume, heart rate and rhythm, and the presence of other prostheses.
2. Transvalvular gradients may be estimated from continuous-wave Doppler velocities by means of the modified Bernoulli equation ($DP = 4V^2$), where *P* represents pressure and *V* represents velocity. Transvalvular gradients are determined by several factors: the effective orifice of the prosthesis, the stroke volume, and the presence of intravalvular obstruction. Thus, the published normal ranges of transvalvular gradients are only general guidelines that are applicable to normally functioning prostheses at average resting cardiac outputs. Transvalvular gradients are often higher in patients in high output states, such as in patients with anemia, hyperthyroidism, or pregnancy. Forward transvalvular flow may be increased also in the presence of large paravalvular regurgitant leaks. Doppler-derived and catheter-derived peak and mean gradients are comparable, with perhaps the single exception of small ball-and-cage and bileaflet tilting-disc valves that are in the aortic position, in which Doppler gradients have been shown to exceed transcatheter gradients by as much as 44 mm Hg (19). This discrepancy between catheter-derived gradients and Doppler gradients is the result of pressure recovery upstream from the prosthesis.
3. The ratio of Doppler velocity across the valve and velocity proximal to the valve orifice, or “dimensionless index,” is independent of flow and should remain relatively constant over time; thus, it is useful in detecting changes in effective valvular orifice (20). The continuity equation of flow (21) provides accurate estimates of the effective valve orifice in single-leaflet tilting-disc mechanical valves and in bioprostheses but underestimates the orifice of the bileaflet tilting-disc valves by approximately 0.5 cm^2 (20). A decrease in effective valve orifice is often seen in bioprosthetic valves at low flow rates, suggesting that bioprosthetic leaflets do not open fully in these cases because of the increased resistance (22).
4. All normally functioning mechanical prosthetic valves have a certain amount of intravalvular regurgitation. This regurgitation is generated by the closure flow backwash and by built-in mechanisms that prevent the deposition of thrombogenic material. Small paravalvular leaks are commonly detected intraoperatively by transesophageal echocardiography immediately after surgical implantation, most of which improve after reversal of anticoagulation (23).
5. Prosthetic valve suture rings, cages, discs, and stents may produce echocardiographic shielding or make it impossible to visualize structures or flow beyond the location of the ultrasound reflecting surface. This limits the ability to detect transvalvular or paravalvular regurgitation, thrombi, or vegetations of infective endocarditis in some prostheses by transthoracic echocardiography, particularly in prostheses that are in the mitral position (24). In those cases, transesophageal echocardiography offers a superior visualization.
6. Certain types of prosthetic valves and their locations may be identified using plain chest radiography (Fig. 24.1, eFig. 24.1.1 and eFig. 24.1.2). Suture rings are always radiopaque, as are prosthetic cages and some tissue valve supporting stents. Tilting discs may or may not be seen in a plain film, depending on the angle of the prosthesis, the construction material, and the radiographic penetration. Cinefluoroscopy may be useful in evaluating the mobility of the occluder of mechanical valves in patients in whom obstruction is suspected. This technique, however, may not necessarily detect subvalvular obstruction by pannus and cannot be used to assess valvular regurgitation.

Mechanical Valves

Ball-and-Cage Valves

The Starr-Edwards valve prosthesis consists of a metallic alloy ring attached to a cage in which either a metallic or a silastic ball moves from a closed position occluding the ring to an open position in the outer end of the cage. A cloth that allows suturing of the prosthesis to the annulus covers the outside edge of the ring. Flow across the prosthesis is directed circumferentially around the ball, assuming a lateral angle. Model 6120 is manufactured in several different diameters, from 26 to 34 mm, for implantation in the mitral or tricuspid position. Four equidistant struts joined at the distal end make the cage in this model. Model 1260 has three struts in its cage and is available in different diameters, from 16 to 27 mm, for use in semilunar positions. Other models of these valves that contain metallic balls or cloth covered struts were discontinued because of the rapid degeneration or embolic complications associated with their use (25). The Starr-Edwards ball-and-cage prosthesis has the longest proven durability, in many instances exceeding 30 years, of all the prosthetic valves (26). Mechanical failure of this valve is rare and is caused by either degeneration of the ball due to abrasion and lipid infiltration, also known as “ball variance” (27), or by obstruction by thrombus or pannus formation that results in valve incompetence.

One of the major disadvantages of ball-and-cage valves is their suboptimal hemodynamic profile. Because of their configuration, flow is obstructed between the ring and the ball and again between the ball and the left ventricular cavity in the mitral position or the aorta in the aortic position. In patients with a small ventricular cavity,

the mitral prosthesis may also partially obstruct and create a pressure gradient across the left ventricular outflow tract (28). The mean transvalvular gradient for Starr-Edwards ball-and-cage prostheses in the mitral position is 4.6 + 2.4 mm Hg, and the estimated effective orifice is 1.4 to 2.9 cm^2 (29,30,31,32 and 33). In the aortic position, the mean gradient is 23 + 8 mm Hg, and the estimated effective orifice is 1.2 to 1.6 cm^2 (34,35). On auscultation, ball-and-cage valves produce a loud opening click, followed by multiple clicks of variable intensity, produced by the ball bouncing in the cage and a flow murmur in the aortic position. A less intense click occurs with the closing of the valve. Frequently, a systolic ejection murmur may be noted in patients with a mitral prosthesis. This murmur is produced by turbulence in the left ventricular outflow tract. Small prostheses or high cardiac output may produce soft diastolic flow murmurs in the mitral position.

Radiographically, the support ring and cage can be detected in plain films (eFig. 24.1.2). In certain models of ball-and-cage prostheses, the ball is metallic or barium-impregnated, allowing visualization. Two-dimensional echocardiography can demonstrate the highly reflective echoes produced by the metallic struts and the less intense reflective echoes produced by the proximal surface of the ball. From the apical four- and five-chamber imaging views, M-mode echocardiography may detect the opening and closing displacement of the prosthetic ball. Doppler interrogation of forward flow velocities to estimate pressure gradients must be directed at a lateral angle between the prosthetic ring and the ball, where the highest velocities are expected (36). Color Doppler examination may be used to detect the direction of flow and to assess the presence of prosthetic regurgitation or flow turbulence in the left ventricular outflow tract with prostheses in the mitral position. In normal ball-and-cage prostheses, regurgitation is minimal and limited to the closure backflow (37). Other models of ball-and-cage prostheses, which were used in the 1960s and early 1970s, include the double-caged Cutter (38), Magovern-Cromie (39), and the cloth-covered Braunwald-Cutter (40) valves.

Tilting-Disc Valves

These valves consist of a metallic ring attached to one or two flat or concave discs that pivot from the occluded position to an open position at an angle of 60 to 85 degrees. The Björk-Shiley valve (5) has been manufactured in six different models, four of them available in the United States. The original models had a flat disc made of Delrin or pyrolytic carbon, which was later replaced with a convexo-concave disc. The disc tilts through the retaining welded or unwelded struts to an angle of 60 to 70 degrees, depending on the model. The occurrence of fractures of the welded struts and embolization of the disc resulted in the withdrawal of these valves from the market. The Björk-Shiley Monostrut model (41) has excellent hemodynamics and a low risk of mechanical failure and thromboembolism. The Omniscience tilting-disc valve (42) has a free-floating concave-convex disc in titanium housing. The Omniscience valve has a 3% risk of thrombosis, which is considerably higher than the risk associated with other tilting-disc valves, probably because of the smaller built-in volume of regurgitation (43). The Medtronic-Hall (7) valve has a one-piece housing that is manufactured from titanium and a rotatable Teflon sewing ring. A small orifice in the center permits regurgitant flow to “wash” potentially thrombogenic material from the disc. Currently available single-tilting-disc valves have excellent hemodynamics and low risk of mechanical failure.

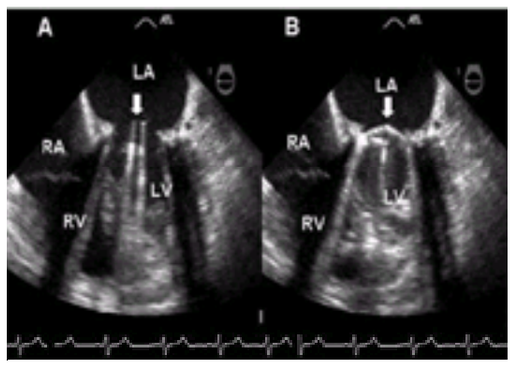
The St. Jude Medical (44) and the Carbomedics (45) valves are the only bileaflet tilting-disc valves. The leaflets of the St. Jude Medical prosthesis are manufactured

from pyrolytic carbon impregnated with tungsten for radiopacity. These semicircular leaflets open to an 85-degree angle, leaving two larger lateral orifices with a narrow rectangular slit between them (eFig. 24.1.3). The flow across bileaflet tilting-disc valves is symmetric, providing excellent hemodynamic performance (46). The rates of mechanical failure and thromboembolism associated with these valves are very low. Because of these favorable characteristics, this valve was the most commonly used mechanical prosthesis in the United States during the last decade. The Carbomedics bileaflet valve has characteristics and hemodynamic performance similar to those of the St. Jude's Medical valve, and it has also shown a low rate of mechanical failure and thromboembolism.



***e*FIGURE 24.1.3** St. Jude's valve in the mitral position shown by transesophageal echocardiography during opening **(A)** and closing **(B)**. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Tilting-disc prostheses are available in diameters from 19 to 33 mm for implantation in the mitral or aortic positions. Their mean transvalvular gradient is significantly lower than that of equally sized Starr-Edwards ball-and-cage valves, from 6 to 15 mm Hg in the aortic position and from 2 to 7 mm Hg in the mitral position. The estimated effective orifices range from 2.1 to 3.9 cm^2 for mitral prostheses and from 1.3 to 2.5 cm^2 for aortic prostheses. The Carbomedics "Top-Hat" valve is mechanically designed to increase the effective orifice in relation to the annular size, due to the supraannular location of the occluder (47). The auscultatory findings of tilting-disc prostheses include a loud single or double closing click and a soft mid-systolic ejection murmur in the aortic position or a low-frequency diastolic rumble in the mitral position. Tilting-disc prostheses also produce a softer opening click. The radiographic appearance of these valves differs according to the number and position of the struts and the tilting discs. In some valves, such as the Björk-Shiley valve and the Wada-Cutter valve, the discs may be radiolucent. The two half discs of bileaflet valves can be observed from a tangential plane. The motion of the valve ring and the opening angle of the discs can be evaluated under fluoroscopic guidance. The movement of the tilting discs also can be detected by two-dimensional echocardiography. Two-dimensional echocardiography frequently demonstrates microcavitations in the left ventricular cavity of patients with mechanical tilting valves in the mitral position (48). These microcavitations appear to be gaseous and do not cause any clinical symptoms. However, transcranial Doppler often detects these microembolic signals, and some cases have been reported in which this phenomenon appeared to be related to episodes of amaurosis fugax (49).

Color Doppler imaging may help to identify the type of prosthesis. The Medtronic-Hall tilting-disc valve has a characteristic regurgitant flow jet through its central orifice. The St. Jude's Medical valve has two central divergent and multiple peripheral convergent regurgitant jets that may be visualized depending on the imaging angle. The amount of intravalvular regurgitation may vary according to heart rate and cardiac output. The regurgitant fraction of single tilting-disc valves averages approximately 12% under normal hemodynamic conditions, but it may be as high as 37% at high heart rates and low cardiac output (50). Continuous-wave Doppler imaging is useful for estimating transvalvular gradients using the modified Bernoulli equation. Mean pressure gradients obtained by Doppler imaging generally have a good correlation with catheter-derived gradients (51). Doppler imaging may overestimate the gradient, however, in small prostheses in the aortic position, particularly in those with bileaflet valves. The mean Doppler gradient may be 10 mm Hg higher than the catheter gradient in these circumstances (52). This apparent overestimation is caused by the effect of pressure recovery, which determines that part of the kinetic energy present at the valve level is converted back to pressure distal to the valve if the geometry of the valve prevents turbulence (53). Thus, discrepancy exists because the Doppler imaging method measures the highest gradient at the intravalvular level, whereas the catheter method measures the gradient distal to the valve. Extended M-mode and Doppler recordings are important in excluding intermittent entrapment of the discs.

Tissue Valves

Heterografts

The biologic nonhuman tissue valves currently available are manufactured either from porcine valvular tissue or from bovine pericardium mounted in supporting stents or preserved *in situ* in a segment of the porcine ascending aorta. The Carpentier-Edwards porcine valve (54) consists of a cloth-covered silicone-rubber sewing ring attached to three cloth-covered steel alloy flexible stents and is available for both annular and supraannular implantation (55). The stents serve as a base for a porcine semilunar valve, which has been preserved in a glutaraldehyde solution to strengthen the tissue and to reduce its antigenicity. The Hancock valve has very similar characteristics, but the stents are manufactured of polypropylene. Early experience with other porcine valves more recently introduced to the U.S. market, such as the Medtronic Mosaic valve, has been favorable (56).

VIDEO

All bioprosthetic valves are structurally similar to human semilunar valves. A pressure gradient forces the movement of the three cusps to an open position, and flow occurs through the central orifice. A gradient reversal results in closure by backflow. Despite their resemblance to human anatomy, these valves have suboptimal hemodynamic performance in comparison to tilting-disc mechanical prostheses of the same diameter (57,58). This limitation results primarily from the reduction in their profile caused by the interposed stents and is more significant in valves smaller than 23 mm. The bioprosthetic leaflets are also stiffer than native human semilunar valves, exhibiting an incomplete opening at low flow rates. The durability of porcine bioprosthetic valves has improved significantly with newer changes in design and preservation techniques. Actuarial probability of freedom from structural valve degeneration at 5, 10, and 15 years has been reported at 99%, 79%, and 57%, respectively (59). According to this study, in patients younger than 50 years, freedom from structural valve dysfunction at 15 years was 16%, whereas in patients older than 70 years, the rate was 87%. The durability is reduced in mitral prostheses because of the greater closing pressure in this position, in younger patients, and patients with increased calcium metabolism (60,61).

Bovine pericardial bioprostheses were initially developed in an attempt to improve the hemodynamic profile of the porcine valves. The Ionescu-Shiley valve (62) was constructed from bovine pericardium preserved in glutaraldehyde mounted in a titanium frame with the cusps attached to the external surface of the stents to increase the internal diameter of the orifice. Although this design provided an improved hemodynamic performance (63), it also resulted in premature valve failure secondary to stress fracture of the cusps (64). The Carpentier-Edwards bovine pericardial valve (65) resembles structurally the porcine tissue valves and has comparable hemodynamics and durability.Advances in tissue valve preservation are expected to increase the longevity of these valves. Intermediate follow-up of the Hancock II porcine bioprostheses suggests that their durability will be superior to that of their predecessors. Freedom from reoperation has been reported to be 100%, 97%, and 89% after aortic, mitral, and combined valve replacement, respectively, after 7 years of follow-up (66).

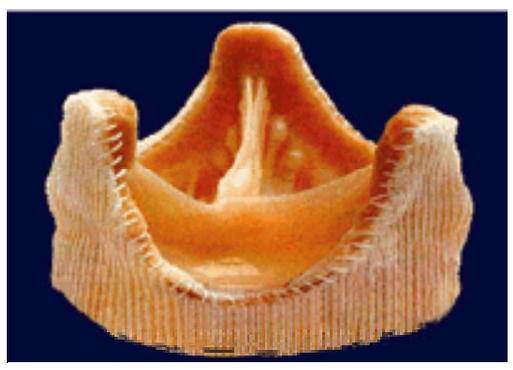
Bioprosthetic valves are available in diameters of 19 to 31 mm. The effective orifice area for bioprostheses ranges from 1.4 to 2.5 cm^2 in the mitral position and from 0.9 to 1.8 cm^2 in the aortic position. The auscultatory findings of bioprosthetic valves include a systolic ejection murmur in the aortic position and an opening sound in the mitral position. Frequently, a systolic murmur is heard in patients who have mitral bioprostheses, which is caused by turbulent flow in the left ventricular outflow track. The bioprosthetic valve sewing ring is radiopaque in radiographic films. In some models, wire-framed stents may also be seen. The three equidistant stents seen on two-dimensional echocardiography are the hallmark of bioprostheses. The three leaflets can also be imaged, although they are less echogenic than the native aortic valve. Normal bioprostheses showed no or minimal intravalvular regurgitation on color Doppler imaging.

Stentless heterograft prostheses consist of a tubular segment of a porcine proximal ascending aorta containing its *in situ* aortic valve, which is sutured proximally to the aortic annulus and distally to the mid-ascending aorta (eFig. 24.1.4). Although surgical implantation of these valves is technically more demanding, studies have failed to show higher in-hospital morbidity or mortality rates (67). Short and intermediate follow-up of stentless valves have, thus far, demonstrated better hemodynamics with smaller resting and exercise gradients and greater regression of left ventricular hypertrophy than stented tissue valves of similar size (68,69). One study suggested that patients with severe aortic stenosis and left ventricular dysfunction who receive a stentless valve demonstrate a greater early improvement in left ventricular systolic function than patients who receive a stented valve (70). Stentless aortic root bioprostheses can be used safely to replace the aortic root for aortic valve and aortic root pathology (71). Freedom from structural valve degeneration has been reported to be approximately 85% at 9 years (72).



***e*FIGURE 24.1.4** St. Jude Toronto stentless porcine valve.

Aortic Homografts

Human aortic valves are harvested from cadaveric hearts and cryopreserved (73). Like stentless heterografts, these valves are supported by a short segment of the donor's aortic root, in which the recipient's coronary arteries are reimplanted. The homograft endothelial cells and fibroblasts are antigenic (74) and are gradually destroyed by immunologic reactions. The antigenicity may be reduced by antibiotic sterilization and cryopreservation, resulting in a reduced rate of leaflet degeneration of approximately 2% to 10% by 10 years after implantation (75). Langley and associates recently reported freedom from structural valve degeneration at 10, 15, and 20 years of 81%, 62%, and 31%, respectively (76). The durability of the homograft is also influenced by the age of the donor. The incidence of valve degeneration at 10 years is 8% if the donor is younger than 20 years and 40% if the donor is older than 50 years (77). The flow characteristics, auscultatory findings, and radiographic appearance of aortic homografts are similar to those of native aortic valves. On echocardiography, the walls of a homograft may appear thicker at the level of the proximal anastomosis (78). Although the durability of homografts may be higher than that of heterografts in younger adults (79), the rate of degeneration has been shown to be similarly high in young children, particularly when grafts are used in the pulmonary position. Severe regurgitation may be detected in up to 50% of children

who are younger than 18 months at the time of implantation and in up to 15% of older children at 15 months' follow-up (80). Homografts have a reduced rate of reinfection when they are used to replace valves in patients with endocarditis (81). Langley and colleagues reported a freedom from endocarditis at 10, 15, and 20 years of 99%, 96%, and 95%, respectively (76).

Pulmonary Allografts

A healthy pulmonary valve may be transplanted to the aortic position to substitute for a diseased aortic valve, while a cadaveric homograft is placed in the pulmonary position. Late follow-up has shown no evidence of primary tissue degeneration and normal cusp cellularity. This evidence suggests that the cusps not only survive permanently but can grow with the patient, making the operation ideal for children. Among 339 operations performed from 1969 to 1991 in London, with a cumulative follow-up of 3,774 patient-years, freedom from reoperation was 85%, and the actuarial patient survival was 80% at 20 years after implantation (12). However, mild to moderate valvular regurgitation of the allograft is not uncommon and is usually associated with donor-recipient size mismatch. Degeneration of the implanted homograft in the pulmonary position and stenosis of the pulmonary trunk anastomotic site are also potential limitations and causes of reoperation in these patients. Most importantly, this operation is technically more demanding and thus requires longer circulatory arrest time, which could potentially lead to greater perioperative morbidity. In addition, longer follow-up is needed to determine whether reoperation after this surgery may be associated with greater morbidity.

Selection of Prosthetic Valve Type

Because each prosthetic valve type has specific advantages and disadvantages, the selection of a prosthetic valve should always be individualized to each patient on the basis of age, anatomic considerations, lifestyle, expected longevity, and relative risks of anticoagulation. The in-hospital mortality and complication rates after valve replacement are similar to the rates seen among patients with mechanical and bioprostheses (26,82) and therefore should not be considered determining factors in the selection of a valve. Several retrospective and prospective studies have shown that the risk of death and major complications, including systemic embolization, endocarditis, and valve thrombosis, are also comparable in long-term follow-up (eFig. 24.1.5).

AVR, aortic valve replacement; MVR, mitral valve replacement. (From Hammermeister KE, Sethi GK, Henderson WG, et al. A comparison of outcomes in men 11 years after heart-valve replacement with a mechanical valve or bioprosthesis. *N Engl J Med* 1993;328:1293, by permission of The Massachusetts Medical Society.)

In the Edinburg Heart Valve Trial (82), 541 consecutive patients undergoing valve replacement were randomly assigned to receive either a Björk-Shiley 60-degree spherical tilting-disc prosthesis or a Carpentier-Edwards porcine valve. A trend towards improved actuarial survival after 12 years was found in patients with Björk-Shiley valves, although this was not statistically significant. Reoperation was more frequent among patients with bioprosthetic valves (8.5% vs. 37.1%, p <.001), but bleeding complications occurred more frequently among patients with mechanical valves (18.6% vs. 7.1%, p <.01). No significant differences were seen in the rates of other complications, including embolism (mechanical vs. bioprosthetic valves, 21.1% vs. 26.4%) and endocarditis (3.7% vs. 4.6%).

In the Veterans Affairs Cooperative Study (26), in which 575 patients undergoing valve replacement were randomly assigned to receive mechanical valves (Björk-Shiley) or bioprostheses (Hancock), the risk of systemic embolism among patients with mechanical valves was 17% and the risk among patients with bioprostheses was 15% after a mean follow-up interval of 11 years. The risks of endocarditis were 8% versus 11%, respectively, and the risk of prosthetic valve thrombosis was 2% versus 1%. The most significant differences occurred in the incidence of structural failure, reoperation, and hemorrhagic complications related to the use of anticoagulant medication. Structural failure occurred in 21% of bioprostheses, and the rate was significantly higher among prostheses in the mitral position (36%) than among those in the aortic position (15%) (eFig. 24.1.6). Reoperation was required in 26% of the cases. In contrast, no cases of mechanical valve failure occurred, and only 11% of the patients in this group required reoperation, either because of periprosthetic regurgitation, valve thrombosis, or endocarditis (eTable 24.0.1). As anticipated, the risk of hemorrhagic complications was greater in patients with mechanical prostheses (42% vs. 25%).

Optimal oral anticoagulant therapy in patients with mechanical heart valves. *N Engl J Med* 1995;333:15, by permission of The Massachusetts Medical Society.)

***e*TABLE 24.0.1** CAUSES OF REOPERATION IN PATIENTS WITH MECHANICAL AND BIOPROSTHETIC VALVES

Cause	Mechanical prostheses	Bioprostheses
Operations	46	662
Prostheses	49	717
Structural valve degeneration	1 (2.0%)[a]	518 (72.2%)
Nonstructural dysfunction	32 (65.3%)	82 (11.4%)
Prosthetic valve endocarditis	9 (18.4%)	74 (10.3%)
Thromboembolism	5 (10.2%)	10 (1.4%)
Incidental removal	1 (2.0%)	31 (4.3%)
Miscellaneous	1 (2.0%)	2 (0.3%)

[a]Percentages relate to operations, not number of prostheses replaced.
Adapted from Tyers GF, Jamieson WR, Munro AI, et al. Reoperations in biological and mechanical valve populations: fate of the reoperative patient. *Ann Thorac Surg* 1995;60:S465.

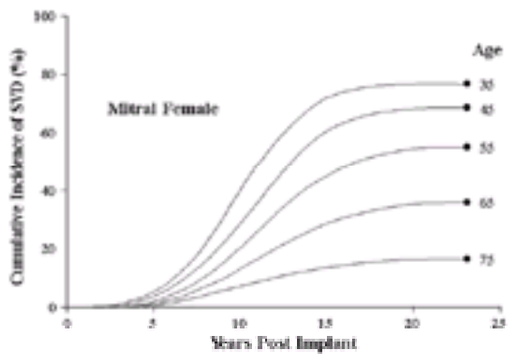
The slightly higher rates of death, endocarditis, and bleeding complications found in the Veterans Affairs Cooperative Study probably reflect an older population and a more intense anticoagulation regimen (prothrombin time, 2.0 to 2.5 times control, vs. 1.3 to 2.0 times control in the Edinburgh trial). The overall mortality rates for reoperation in the Edinburgh trial and the Veterans Affairs Cooperative Study were 30% and 25%, respectively. Other studies have reported valve reoperation mortality rates from 4.7% to 20.0% (83,84 and 85). The results of the Edinburgh Heart Valve Trial and the Veterans Affair Cooperative Study indicate that reoperation rates are higher among patients with bioprosthetic valves, and the risk of hemorrhagic complications is higher among patients with mechanical prostheses. The cumulative

mortality rate associated with reoperation in long-term survival is similar among patients with mechanical valves and patients with bioprostheses. Reoperation is performed less often in patients with mechanical prostheses, but it carries a higher individual mortality rate, because the cause of reoperation is more frequently endocarditis and abrupt mechanical failure.

It is important to consider, however, that significant advancement has occurred since these studies were conducted. The widespread use of anticoagulation clinics and, more recently, the introduction of home anticoagulation testing kits will likely result in a lower risk of embolic and hemorrhagic complications. At the same time, improved surgical expertise will likely reduce the relative risk of reoperation. Nevertheless, prosthetic valve durability and risks of hemorrhage remain the main determinants in the selection of heart valve prostheses.

Age

Children who require valve replacement benefit most from mechanical prostheses (86). Tilting-disc mechanical valves provide better hemodynamic performance than bioprostheses, particularly at smaller sizes, thus delaying the need for reoperation. Structural valve deterioration of bioprosthetic valves also occurs more rapidly in children and young adults (eFig. 24.1.7) (61,82,83,84,85,86 and 87). The main cause of dysfunction of porcine valves appears to be calcification of the leaflets. Premature calcification of porcine valves in children is thought to be caused by the patients' accelerated metabolism of calcium, reduced mobility of the leaflets due to lower cardiac output, and stronger immune reactivity to porcine valve tissue. The life expectancy of bioprostheses increases linearly with the patient's age at the time of implantation, from a mean of 6 years at age 20 years to 12 years at age 80 years. Approximately 60% to 80% of patients who are younger than 40 years at the time of bioprosthetic valve replacement will experience structural valve deterioration, versus 5% to 40% of patients older than 60 years (87,88). Therefore, as a general rule, mechanical valves are preferred in younger patients, and bioprosthetic valves are recommended in older patients, in whom the risk of anticoagulation therapy is higher. In young adults who may want to avoid the risks associated with long-term anticoagulation therapy, valve repair and homograft replacement may offer longer durability than replacement with heterograft prostheses.



***e*FIGURE 24.1.7** Cumulative incidence of structural degeneration of porcine bioprosthetic valves (SVD) in the mitral position by age group. Data is shown for female patients. (From Grunkemeier GL, Jamieson WR, Miller DC, et al. Actuarial versus actual risk of porcine structural valve deterioration. *J Thorac Cardiovasc Surg* 1994;108:714, by permission of Mosby-Year Book, Inc.)

Gender

The use of mechanical or bioprosthetic valves in women of childbearing age has disadvantages. Pregnant women with mechanical valves require rigorous control of their anticoagulation and are at higher risk for thromboembolism and for fetal hemorrhage and embryopathy (89,90). Bioprosthetic valves may obviate the need for anticoagulation therapy (89,90 and 91), but they have the disadvantage of limited durability. Hanania and coauthors (92) found an 18% rate of structural valve failure among 74 women who had bioprosthetic valves during pregnancy. In 7 of 13 patients (54%), structural valve failure occurred before the end of the expected life span of the prosthesis (2.5 to 8.0 years; all valves were in the mitral position). In this particular study, fetal loss also occurred in 16% of pregnant women who had bioprosthetic valves. More recent studies have failed to attribute a greater risk of prosthetic valve degeneration caused by pregnancy itself, demonstrating instead that the increased risk is solely dependent on the patient's age (93). Nevertheless, a significant increase in fetal and maternal morbidity is seen with the use of either mechanical or bioprosthetic valves during pregnancy. Therefore, ideally, valve replacement should be postponed until after delivery. Women with regurgitant valves can be managed medically during pregnancy; regurgitant lesions are well tolerated because of the decreased peripheral vascular resistance that occurs during pregnancy (94). Mitral valve repair should be the procedure of choice in patients with nonrheumatic mitral regurgitation (95). Stenotic mitral valves should be treated first by percutaneous balloon dilatation, when possible (96). For patients with aortic stenosis, homografts and pulmonary allografts (97) may be good alternative choices, although their durability may be less than that of mechanical valves.

Indications and Contraindications for Long-Term Anticoagulation Therapy

Bioprosthetic valves should be used in patients at higher risk for anticoagulation-related hemorrhage. These include patients with intestinal angiodysplasia, familial polyposis, inflammatory bowel disease, liver disease, and hereditary blood dyscrasias. Patients with a history of noncompliance or severe ethanol abuse and patients whose anticoagulation therapy cannot be adequately monitored should also receive bioprostheses. Mechanical valves are also relatively contraindicated in patients who are at high risk for trauma because of their particular occupation or lifestyle.

In most patients with chronic atrial fibrillation and other conditions that require long-term anticoagulation, there are no advantages to the use of bioprosthetic valves. Therefore, mechanical prostheses are usually the preferred option in this group.

Calcium Metabolism

Accelerated calcium turnover is associated with rapid degeneration of bioprosthetic valves. This is frequently seen in patients with chronic renal failure, Paget's disease, and other chronic illnesses associated with hypercalcemia. Mechanical valves offer an advantage to those patients who have no contraindications for anticoagulation and do not have a short life expectancy. Although mechanical valve replacement traditionally has been recommended for patients who require hemodialysis, most of these patients have a limited survival, and few live long enough to develop bioprosthetic valve degeneration (98). Thus, in this patient population, the choice of valve prosthesis should be individualized according to life expectancy and the relative risk of thrombotic and hemorrhagic complications.

Prosthetic Valve Position

Structural valve failure occurs earlier in bioprosthetic valves in the mitral position than in those in the aortic position (eFig. 24.1.6) (82,99,100), probably because of the higher stress forces to which they are subjected during closure at systolic pressure. In the Veterans Affairs Cooperative Study (82), mitral valve bioprostheses required replacement because of structural degeneration twice as often as aortic bioprostheses. Because most patients who require mitral valve replacement have atrial fibrillation, left atrial enlargement, or both, chronic anticoagulation therapy often cannot be avoided. Thus, mitral valve replacement with a bioprosthetic valve should be considered mainly for patients who have contraindications to anticoagulation therapy, particularly in older age groups and among patients with sinus rhythm.

Uncommonly, congenital or acquired tricuspid valve disease requires prosthetic replacement. The tricuspid annulus is larger than the mitral annulus, usually requiring prostheses of 33 or 35 mm in diameter. Flow across these large-orifice prostheses occurs at lower velocity, increasing the risk of prosthetic valve thrombosis. The geometry of the right ventricle and the presence of dense trabeculae may also impede the normal opening of mechanical prosthetic discs. Therefore, bioprosthetic valves are preferred by most for tricuspid valve replacements. Pulmonary valve replacement is rarely needed for the management of pulmonary valve stenosis or regurgitation; often these are done as part of surgical reconstructive procedures in patients who have congenital heart disease. Pulmonary valve insufficiency can be managed conservatively in most cases. On the other hand, pulmonary stenosis responds well to balloon valvuloplasty (101). Small surgical series, however, have reported improvement in right ventricular function after valve replacement in patients with pulmonary valve stenosis or regurgitation. In most cases, bioprosthetic valves have been used. Carcinoid syndrome is a unique indication for pulmonary valve replacement in many instances. Of note, carcinoid involvement of implanted homograft valves in the pulmonary position has been reported (102).

PATHOPHYSIOLOGY AND PRINCIPLES OF THERAPY

Complications related to prosthetic heart valves can occur as early as in the immediate postoperative period. Their relative frequency and timing vary with each type of prosthesis and determine the manner in which patients with prosthetic valves should be clinically followed.

Antithrombotic Therapy in Patients with Prosthetic Valves

Thromboembolism represents one of the most important causes of morbidity and death in patients with prosthetic valves. In one of the largest follow-up series of patients with Starr-Edwards ball-and-cage valves, 44% of patients had experienced a thromboembolic episode within 10 years after implantation (103). Of these episodes, 50% resulted in permanent neurologic sequelae and 10% resulted in death. The incidence of thromboembolic events is significantly higher in patients with mechanical prosthesis who are not receiving anticoagulation therapy, ranging from 7% to 34% per year (104,105 and 106). Several mechanisms are involved in the pathogenesis of prosthetic valve–mediated thromboembolism, including platelet activation by the synthetic surfaces of the sewing ring, sutures and mechanical occluders, flow stagnation, increased shear stress, and activation of intrinsic clotting factors by the prosthetic material or the damaged endothelium (107). Patient-related contributing risk factors include older age, atrial fibrillation, and left ventricular dysfunction (108). The risk of thromboembolism is higher with both mechanical valves and bioprostheses in the early postoperative period and declines after the first 3 months for bioprosthetic valves. The risk also varies with the type, size, position, and synthetic components of the valve.

Mechanical Valves

The first generation of Starr-Edwards ball-and-cage valves demonstrated a very high incidence of thromboembolic complications in the absence of anticoagulation therapy (104,105,109). In an attempt to reduce this risk by promoting endothelialization of the prosthetic surface, cloth-covered strut models (models 2300 and 6300) were introduced in the late 1960s. However, rapid destruction of cloth fragments resulted in a much higher embolization rate (110), requiring the discontinuation of these models. Oral anticoagulation therapy with warfarin significantly reduces the risk of thromboembolism in patients who have mechanical heart valves. Improved prosthetic design and anticoagulation therapy reduced the rate of embolism to 2.5% to 4.0% per patient-year in patients receiving anticoagulation therapy who had Starr-Edwards valves that were implanted after 1970 (111). The incidence of thromboembolic complications with Björk-Shiley tilting-disc valves is approximately 4% per year for valves in the mitral position and 2.5% per year for valves in the aortic position, and an average of 1% to 3% with Medtronic-Hall valves in patients receiving anticoagulation therapy (112). Bileaflet mechanical valves have a risk of approximately 2.5% per year in the mitral position and 1% per year in the aortic position (113,114 and 115).

Whether the small difference in these rates is associated with intrinsic properties of the prostheses or merely represents differences in patient characteristics, level of anticoagulation therapy, or study design is unclear. For example, Horstkotte and associates (116) reported a lower rate of embolism with the St. Jude's Medical valve, but their study did not include transient ischemic attacks as an outcome. On the other hand, another study, which involved a large group of patients in atrial fibrillation, showed a rate of 3.9 events per 100 patient-years with the same valve (117). Regardless of the type of mechanical prosthesis, the incidence of thromboembolism is lower than 1% in patients who maintain therapeutic anticoagulation (116,117 and 118). Studies have shown that the majority of patients with mechanical valves who experience thromboembolic complications has a subtherapeutic INR (international normalized ratio) at the time of the event (103). However, chronic anticoagulation therapy increases the long-term incidence of hemorrhagic complications. Pooled data from 46 studies that observed more than 13,000 patients with mechanical heart valves for more than 50,000 patient-years have shown an incidence of major bleeding complications of approximately 1.4 per 100 patient-years (119). Cannegieter and coworkers (120) reported a risk of intracranial and spinal hemorrhage of approximately 0.6% per 100 patient-years. In their study, 72% of hemorrhagic strokes resulted in permanent neurologic damage and 44% in death, compared to 21% and 5% of ischemic strokes, respectively (Table 24.1). Other common sites of bleeding are the gastrointestinal and genitourinary tracts and the retroperitoneal, intramuscular, subcutaneous, nasopharyngeal, and joint spaces.

Event	No.	Incidence (per 100 patient-yr)[a]
Thromboembolism		
Cerebral infarction	43	0.68
Peripheral embolism	2	0.03
Valve thrombosis	0	—
Any thromboembolism	45	0.71
Fatal thromboembolism	2	0.03
Bleeding episode		
Intracranial and spinal bleeding	36	0.57
Extracranial bleeding	128	2.11
Any bleeding	64	2.68
Fatal bleeding	20	0.30
Unclassified stroke	14	0.23
First events	210	3.50

TABLE 24.1 INCIDENCE OF ADVERSE EVENTS (THROMBOEMBOLISM, MAJOR BLEEDING, AND STROKE) IN PATIENTS WITH MECHANICAL VALVES RECEIVING CHRONIC ANTICOAGULATION

In the absence of a predisposing factor, hemorrhagic complications occur significantly more frequently in patients with an INR higher than the therapeutic range (121). In the study by Cannegieter and associates (120), in which 1,608 patients with mechanical valves were observed during 6,475 patient-years, the incidence of adverse events (hemorrhagic and thromboembolic) increased from 2 per 100 patient-years among patients with INRs of 2.5 to 4.9, to 7.5 per 100 patient-years among patients with INRs of 2.0 to 2.4, and to 27 per 100 patient-years among patients with INRs of 1.0 to 1.4 (Fig. 24.2). Similarly, adverse events increased to 4.8 per 100 patient-years among patients with INRs of 5.0 to 5.5 and to 75 per 100 patient-years among patients with INRs >6.5. Predisposing conditions such as trauma or underlying illness were identified in one-half of the patients who experienced hemorrhagic events, regardless of the INR level. Both hemorrhagic and thromboembolic complications are more frequent in older patients (120). Patients younger than 50 years had an incidence of thromboembolism of 0.1 per 100 patient-years and an incidence of hemorrhage of 2.5 per 100 patient-years, compared with incidences of 1.1 and 5.6, respectively, among patients older than 70 years.

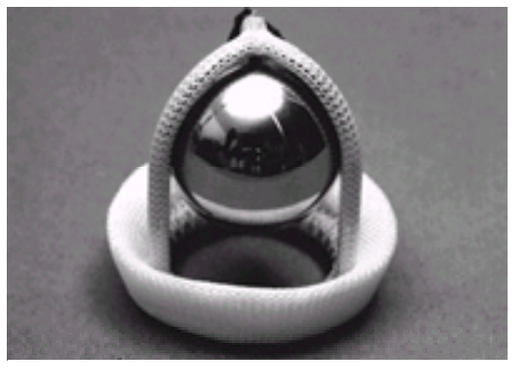

FIGURE 24.2 Cloth-covered Starr-Edwards ball-and-cage valve. This mechanical prosthesis was discontinued due to the high incidence of hemolysis and embolization of cloth fragments.

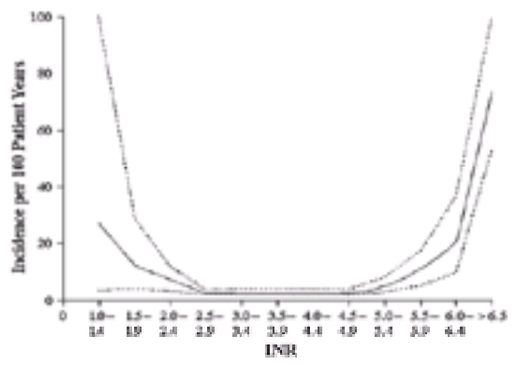
Accomplishing optimal anticoagulation requires not only achievement of a target INR but also maintenance of that level through careful patient education and rigorous monitoring. Monitoring anticoagulation by means of the INR eliminates uncertainty about the intensity of anticoagulation therapy that is caused by variability in the results of different commercial thromboplastins. The intensity of anticoagulation therapy should vary according to the type of mechanical device and to the presence of other predisposing factors (eFig. 24.1.6). In patients with ball-and-cage prostheses, the incidence of thromboembolic events is lowest when the INR is maintained between 4.0 and 4.9 (121). This higher INR also appears to reduce the rate of embolic events in patients who have multiple mechanical prostheses. An INR of 3.0 to 3.9 is associated with a very low incidence of thromboembolic events in patients with Medtronic-Hall or Björk-Shiley valves, whereas an INR of 2.0 to 2.9 appears to be sufficient in patients with St. Jude's Medical valves. Because the risk of thromboembolic events is higher for patients with any mechanical prostheses in the mitral position and for patients who have chronic atrial fibrillation, efforts should be made to maintain a higher anticoagulation level in these patients. Most hemorrhagic and thromboembolic complications can be avoided by maintaining a stable level of anticoagulation (eFig. 24.2.1).

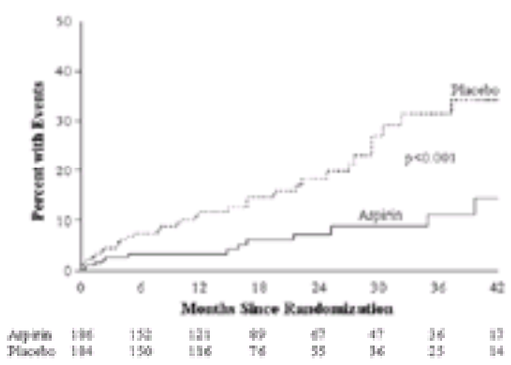


***e*FIGURE 24.2.1** Incidence of adverse events (thromboembolism, major bleeding, and stroke) in patients with mechanical heart valves according to the international normalized ratio (INR). Dotted lines represent 95% confidence limits. (From Cannegieter SC, Rosendaal FR, Wintzen AR, et al. Optimal oral anticoagulant therapy in patients with mechanical heart valves. *N Engl J Med* 1995;333:14, by permission of The Massachusetts Medical Society.)

Studies have shown that patients with prosthetic valves who receive chronic anticoagulation therapy that is monitored in a specialized clinic experienced a lower incidence of thromboembolic and hemorrhagic complications compared with patients who are followed sporadically by primary care physicians (122). Recently, studies have shown that weekly self-testing and self-dosing leads to a better control of anticoagulation therapy than standard treatment in an anticoagulation clinic (123). Whether the widespread use of home-monitoring anticoagulation kits will result in a reduction of thromboembolic complications, bleeding complications, or both remains to be determined.

Video 24.16 Thrombosis of bioprosthetic valves in the mitral and tricuspid position (arrows) in a patient with antiphospholipid syndrome in the early postoperative period demonstrated by transesophageal echocardiography. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Antiplatelet therapy may be used in combination with warfarin in patients who have mechanical heart valves. Aspirin may have a beneficial effect by reducing the platelet-mediated activation of the coagulation cascade. Turpie and colleagues (124) demonstrated that low-dose aspirin (100 mg per day) in patients with a target INR of 3.0 to 4.5 has been shown to reduce the annualized risk of death and major systemic thromboembolic events from 11.7% to 4.2% (*e*Fig. 24.2.2). Although the risk of all hemorrhage increased in the group of patients receiving aspirin in this study from 22% to 35%, the risk of major hemorrhagic events (cerebrovascular bleeding, gastrointestinal bleeding, and major bleeding requiring transfusion) appeared to be similar in both groups (13% vs. 10%; 95% confidence interval, –30% to 132%; p = .43). The additive benefit of aspirin appeared to be greater in patients who had experienced previous embolic events and were at higher risk for thromboembolism. The reduction in death rate in the group of patients receiving aspirin may also be associated with the prevention of myocardial infarction in patients with coronary artery disease, which present in at least 35% of the patients in this study. Another study has demonstrated that patients randomly assigned to receive oral anticoagulation therapy with a target INR of 2.5 to 3.5 and 200 mg per day of aspirin after mechanical mitral valve replacement had a lower risk of visualization of periprosthetic thrombi by transesophageal echocardiography 9 days after surgery (5% vs. 13%), compared with patients who received standard anticoagulation therapy without aspirin (125). The risk of thromboembolic events was also lower after 1 year of follow-up (9% vs. 25%). Nevertheless, these results have to be interpreted with caution; the incidence of thromboembolism with anticoagulation therapy alone in this study was considerably higher that previously reported. In addition, with the combination treatment, the rate of gastrointestinal hemorrhage was significantly increased (7% vs. 0%). High-dose aspirin (500 mg per day) may reduce the risk of thromboembolism in patients with a low INR (1.8 to 2.3), but it results in a higher incidence of gastrointestinal bleeding (126,127). There is no apparent benefit, but certainly a higher risk of hemorrhage, with the use of high-dose aspirin in patients who have high-intensity INR.



***e*FIGURE 24.2.2** Cumulative risk of major embolism or death in patients with mechanical valves or bioprosthetic valves with history of thromboembolism or atrial fibrillation randomized to warfarin versus warfarin plus low-dose aspirin. (From Turpie AG, Gent M, Laupacis A, et al. A comparison of aspirin with placebo in patients treated with warfarin after heart-valve replacement. *N Engl J Med* 1993;329:528, by permission of The Massachusetts Medical Society.)

The use of other antiplatelet agents alone or in combination with warfarin in patients with prosthetic valves has been studied. The value of dipyridamole in preventing thromboembolism in patients with mechanical valves is controversial (128,129). A study by Hayashi and coauthors suggested that both dipyridamole and ticlopidine have beneficial effects similar to those of low-dose aspirin in combination with warfarin therapy (130). Because of the high cost and significant side effects of these drugs, their use should be reserved for high-risk patients who are intolerant to aspirin.

Bioprosthetic Valves

Patients with heterograft bioprostheses have an increased risk of thromboembolism during the first 3 months after implantation. This risk is attributed to the thrombogenic surface of the prosthetic sewing-ring cloth, transient hypercoagulable state after surgery, platelet activation during cardiopulmonary bypass, flow stagnation due to chamber enlargement, and postoperative atrial fibrillation (129). The risk of thromboembolism appears to be higher for mitral prostheses (7%) than for aortic prostheses (3%) during this period (131), decreasing to approximately 2% per year thereafter. Anticoagulation therapy with warfarin at a target INR of 2 to 3 has been shown to significantly reduce the thromboembolic risk (131,132). Because postoperative anticoagulation increases the risk of hemorrhagic pericardial effusion and cardiac tamponade, the decision as to whether a given patient should receive anticoagulation therapy should be individualized. After 3 months, intermediate-dose aspirin (325 mg per day) may be used to further reduce the risk (133). In patients who have experienced previous embolic events, atrial fibrillation, and severe left ventricular dysfunction, long-term oral anticoagulation should be maintained. Thromboembolism occurs rarely in patients with stentless valves.

Special Situations

Anticoagulation Therapy during Pregnancy

Because pregnancy causes relative hypercoagulability (134), rigorous anticoagulation therapy is required throughout gestation (89,92) in patients with mechanical valve prostheses. Anticoagulant therapy is associated, however, with higher fetal morbidity and mortality rates, especially if the drugs are administered during the first trimester (135). Warfarin has teratogenic effects in the embryo and may result in fetal death when the embryo is exposed between the sixth and ninth week of gestation (90). Pregnant women with mechanical valves who receive warfarin during this period carry a risk of embryopathy as high as 30% (136) and a risk of spontaneous

abortion of 25% to 30% (136). Therapeutic abortion should be considered if advanced gestation is discovered accidentally while the patient is receiving this drug. Anticoagulation should be maintained during pregnancy with either continuous intravenous or subcutaneous heparin, administered twice daily starting at 17,500 to 20,000 units and adjusted to a target activated partial thromboplastin time greater than two times control 6 hours after administration (137). Subtherapeutic doses of heparin are associated with a significant risk of thromboembolism. Large doses of heparin are commonly required because of the relatively hypercoagulable state during pregnancy (138). The risk of major hemorrhagic complications in pregnant patients treated with heparin is approximately 2% (139). Substituting heparin from the sixth week until the twelfth week of gestation eliminates the risk of embryopathy in pregnant women with mechanical valves (90). Larrea and coworkers (140) also found a reduction in the risk of spontaneous abortion from 34.6% in patients receiving warfarin to 9.5% in those receiving intravenous heparin. Warfarin appears to be safe during the second trimester and the first half of the third trimester, and it reduces the risk of thromboembolism that is associated with inadequate anticoagulation with heparin. Heparin should be substituted for warfarin again after the thirty-eighth week and until delivery, because warfarin crosses the placenta and may cause fetal intracranial hemorrhage in the peripartum period (92,141). Heparin should be discontinued 24 hours before elective induction of labor. Both heparin and warfarin can be used safely by nursing mothers, because they do not appear to be secreted into breast milk (139).

Low-molecular-weight heparins have been shown to be safe and effective for the prevention and treatment of deep venous thrombosis in pregnant women (142). Because they have a longer plasma half-life, they provide steady levels of anticoagulation and a more predictable dose response than unfractionated heparin. Low-molecular-weight heparins do not cross the placenta, and they carry lower risks of heparin-induced thrombocytopenia, but they are considerably more expensive. Studies are needed, however, to determine whether low-molecular-weight heparins are safe and effective during pregnancy in patients who have mechanical valves. Low-dose aspirin has been shown to be safe when used in combination with heparin or warfarin in pregnant patients who have a high risk of thromboembolism (143).

Perioperative Management of Anticoagulation

Patients who have mechanical valves and are undergoing minor surgical procedures in which blood loss is anticipated to be minimal and easily controlled do not require discontinuation of anticoagulation therapy. Otherwise, warfarin should be discontinued 3 days before major surgical procedures during which significant bleeding is expected. This is based on the half-life of warfarin, which varies from 18 to 36 hours (122). Although the overall risk of thromboembolism when anticoagulation therapy is discontinued for less than 10 days is reported to be low (144), the risk may be significantly higher in patients with mitral prostheses, ball-and-cage valves, and atrial fibrillation. Therefore, in these cases, and in patients who have left ventricular dysfunction, who have a history of embolic events, or who are otherwise considered to be at high risk, warfarin should be substituted with intravenous heparin until 3 hours before the procedure and resumed postoperatively until adequate oral anticoagulation is resumed. In emergency situations, small parenteral doses of vitamin K or fresh-frozen plasma may be used to quickly reverse anticoagulation.

Anticoagulation after Stroke

After a nonhemorrhagic stroke, the risk of recurrent stroke is approximately 1% per day if anticoagulant therapy is discontinued (145). Maintaining anticoagulation reduces this risk to one-third, but carries an increased risk of hemorrhagic transformation (8% to 24%), particularly during the first 48 hours, if the initial stroke is large in size and involves the basal ganglia (146,147). Although few objective data exist, it is thought that hemorrhagic transformation is usually a fatal or disabling complication. Because the risk of hemorrhagic transformation with continued anticoagulation appears to be higher than the risk of recurrent embolism in patients who are not receiving anticoagulation therapy, such therapy should be discontinued for 5 to 7 days in these patients. In patients who have smaller cerebral infarcts, controlled blood pressure, and absence of hemorrhage on a cranial computed tomographic (CT) scan, anticoagulation therapy should be continued. In patients with hemorrhagic strokes, most authorities recommend discontinuing anticoagulation therapy for 1 to 2 weeks and resuming when there is resolution of mass effect and no evidence of hemorrhage extension on a repeated cranial CT scan.

Anticoagulation in Patients with Prosthetic Endocarditis

The risk of thromboembolism in patients with mechanical valve endocarditis who are not receiving anticoagulation therapy has been reported to be as high as 50% in different studies (148,149). These studies suggest that anticoagulation may reduce this risk to less than 10%, although such therapy may be associated with a 14% risk of cerebral hemorrhage. The risk of hemorrhage is particularly high in patients who have clinical or radiographic evidence of cerebral embolization. In these patients, anticoagulation therapy should be discontinued for 48 to 72 hours, until resumption is considered safe. Because patients with prosthetic valve endocarditis are hospitalized, oral anticoagulation therapy should be replaced by intravenous heparin, which can be quickly discontinued if necessary. Low-molecular-weight heparins should be used in patients developing heparin-induced thrombocytopenia.

Prosthetic Valve Thrombosis

Prosthetic valve thrombosis is a serious complication associated with both mechanical and bioprosthetic valves (Fig. 24.3). The incidence is higher, approximately 6% per year, for patients with mechanical prostheses who are receiving suboptimal anticoagulation therapy (150,151). Thrombosis occurs more frequently in patients with older models of Björk-Shiley (150,151) and Omniscience (152) single-tilting-disc valves than with Starr-Edwards ball-and-cage, Medtronic Hall single-tilting-disc, and St. Jude's Medical bileaflet valves. Patients with mechanical prostheses who are receiving adequate anticoagulation therapy, regardless of the type of valve, have a lower risk, 0.1% to 2.0% per 100 patient-years, similar to the risk among patients with bioprosthetic valves who are not receiving anticoagulation therapy (25). Valve thrombosis occurs more commonly among patients with prostheses in the mitral position than among patients with prostheses in the aortic position. The incidence of thrombosis appears to be much higher (4% per year) among patients with prostheses in the tricuspid valve position (153).

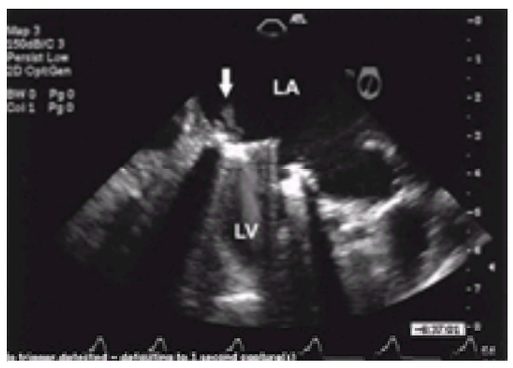

FIGURE 24.3 Thrombosis of a bileaflet mechanical valve in the mitral position. There is partial opening of one of the hemidiscs to a 45-degree angle while the other is stuck in the closed position. The arrow demonstrates the presence of a predunculated thrombus. LA, left atrium; LV, left ventricle.

The thrombus may directly obstruct the valve orifice, cause entrapment of the pivoting mechanism of tilting-disc prostheses, or interfere with the occluding mechanism, causing valvular stenosis, regurgitation, or both. Many patients who have prosthetic thrombosis also have redundant endocardial tissue growth (pannus) that partially obstructs the prosthesis. In the series by Deviri and coworkers (154), thrombus alone was seen in 54% of 106 patients undergoing reoperation for prosthetic valve obstruction. A combination of thrombus and pannus was present in 39%, and pannus alone was found in 6% of the patients. Pannus may be detected as early as 6 weeks and may cause prosthetic valve obstruction as early as 6 months after valve replacement (154). Patients with prosthetic valve thrombosis manifest systemic or pulmonary embolization and symptoms of congestive heart failure and cardiovascular collapse. The onset of symptoms may be insidious, occurring over a period of several weeks, or, more commonly, abrupt, presenting as cardiovascular collapse (155). Acute pulmonary edema appears to be more frequent with single-tilting-disc than with dual-tilting-disc thrombosed prostheses. A murmur of prosthetic stenosis, regurgitation, or both and decreased or absent opening and closing sounds are found on auscultation.

VIDEO

Video 24.19 Björk-Shiley Convexo-Concave prosthetic valve in the aortic position in a left anterior oblique view. Abnormal function is demonstrated by less than a 60-degree opening excursion and incomplete closure. The differential diagnosis includes tissue in growth versus thrombosis of valve leaflet. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 24.20 Intraoperative 90-degree transesophageal echo of a patient with a St. Jude mitral valve prosthesis with a stuck metallic leaflet due to a small clot. (The immobile leaflet is to the right of the screen; the left leaflet moves normally.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The diagnosis is easily established by two-dimensional and Doppler echocardiography; transesophageal imaging is frequently required. Single or multiple echo densities representing thrombus are often visualized within the valve. Incomplete or intermittent opening and closing of the occluder mechanism may be detected by two-dimensional or M-mode imaging (156). Thorough examination should be performed from different examining positions and angles. Thrombosis of a bileaflet mechanical valve may only affect the excursion of one of the discs. In these cases, careful identification and imaging of both discs should be performed to avoid false-negative results. M-mode images should be recorded for a reasonably long interval, because the valve mechanism may be impaired only intermittently. Continuous-wave Doppler examination is useful, demonstrating elevated transvalvular gradients, and color Doppler imaging may demonstrate abnormal regurgitant flow if there is incomplete closure of the prosthesis.

Prosthetic valve thrombosis carries a significant morbidity and mortality rate. Small thrombi of less than 5 mm in diameter often resolve with administration of intravenous heparin if they are not obstructing the occluding mechanism of the valve (157). Larger thrombi, particularly those that interfere with the mechanical function of the prostheses, are associated with a high incidence of embolization and death by cardiovascular collapse and rarely resolve with administration of intravenous heparin alone. Thrombolytic therapy or surgery is required in these patients. Successful thrombolysis has been reported with use of intravenous streptokinase, urokinase, and tissue plasminogen activator (158,159,160,161 and 162). Thrombolysis is effective and has a low complication rate in the treatment of right-heart prosthetic thrombosis. Thrombolytic therapy is effective in the treatment of aortic and mitral valve thrombosis, with an initial success rate of 70% to 80%. It appears to be more effective in patients who have thrombosed prostheses in the aortic position (160) and in patients who have had symptoms for less than 2 weeks (159). The efficacy of thrombolysis appears to be higher with the use of tissue plasminogen activator and streptokinase than with urokinase, although this difference may be caused by different patient characteristics, dosage, or both (163). Thrombolytic therapy for left-heart prosthetic valve thrombosis carries a significant morbidity and mortality rate. Pooled data from several retrospective studies (158,159,160,161,162,163,164 and 165) have shown an incidence of embolism of 5% to 22% and a 5% to 10% risk of disabling stroke or death (*e*Table 24.1.1). Incomplete resolution, recurrent thrombosis, or both occur in approximately 10% to 20% of patients. Many of these reported studies, however, are small series or a collection of reported cases (158), raising the question of whether the true incidence of complications is larger because complicated cases are most likely to be underreported. The combined risk of either death or stroke in these studies was 15%. Failure of thrombolysis occurred in an additional 11% of the cases. The highest failure and complication rates occurred in those patients presenting in New York Heart Association functional class IV. Death or stroke occurred in 7 (11%) of 65 patients presenting in New York Heart Association classes I to III versus 20 (26%) of 76 patients presenting in class IV. Transesophageal echocardiography is useful in monitoring the efficacy of thrombolysis in these patients (166). Recent studies have shown a higher success rate and a lower complication rate for thrombolytic therapy guided by transesophageal echocardiographic monitoring in treating patients with nonobstructive, small, and nonmobile thrombi (167,168). Pooled data from large surgical series (158,159,160,161,162,163,164 and 165) show a combined risk of death or stroke of 9%, although this risk also is higher in class IV patients [14 of 86 (16%) for class IV patients vs. 3 of 63 (5%) for patients in classes I to III]. On the basis of these data, surgical replacement appears to be very effective and carries a lower risk of recurrent thrombosis. However, the lower morbidity and mortality rate among surgically treated patients could be influenced by patient-selection bias. Surgery carries a low morbidity and mortality rate among patients who are hemodynamically stable and have no other significant comorbidities, and it should be the treatment of choice for patients who have large, mobile, and obstructive thrombi (158,159,160,161,162,163,164,165,166,167,168 and 169). The surgical mortality rate may be higher with emergency operations. The choice of treatment in these patients is controversial, because the morbidity and mortality associated with thrombolytic therapy in this group are also higher and the success rate is lower. The decision in this group should be based on the relative institutional availability and expertise of cardiac surgery and with respect to the age and other comorbidities of the patient.

Structural Degeneration

Mechanical Valves

Malfunction of a mechanical valve prosthesis is relatively uncommon during the first decade after implantation. Prosthetic failure of a mechanical valve resulting in stenosis, regurgitation, or both may occur as a result of ball degeneration, strut fracture, or impaired mechanical function due to thrombus, pannus formation, or infection. The Starr-Edwards ball-and-cage prosthesis has a very low incidence of mechanical failure (170). Degeneration of the silastic valve as a result of lipid infiltration or abrasion injury was common in models manufactured before 1965 (Fig. 24.4) (27). The incidence of ball degeneration, also called “ball variance,” is very low with the more recent models 1260 and 6120, but it may be a concern with valves that have been in use for 20 years or more. Auscultatory findings that suggest malfunction of a ball-and-cage valve include decreased intensity or absence of the opening or closing clicks; new diastolic murmurs, indicating incomplete closure and regurgitation with valves in the aortic position; or new diastolic rumbling murmurs or systolic regurgitant murmurs with valves in the mitral position. Two-dimensional and M-mode echocardiography may show diminished mobility of the ball. It is of paramount importance to register extended Doppler recordings, M-mode recordings, or

both of the prosthesis, because obstruction may occur intermittently. Color M-mode Doppler imaging may indicate abnormal intravalvular regurgitant jets.

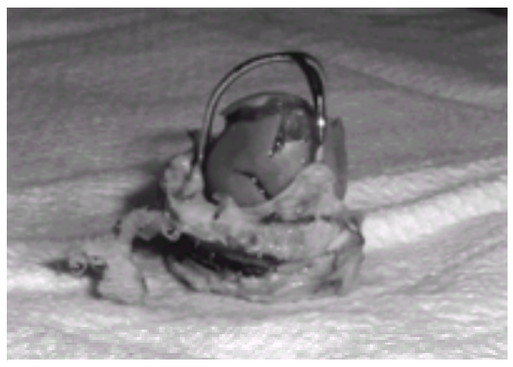

FIGURE 24.4 Structural degeneration of a Silastic ball in a Starr-Edwards valve.

Degeneration of the occluding disc of nontilting-disc valves is common. Abrasion of the edges of the disc results in incomplete occlusion and regurgitation. Entrapment of the disc by thrombus occurs also more commonly than in ball-and-cage prostheses. Tilting-disc valves may fail for a variety of reasons because of their complex structure. Immobilization of a disc can result from entrapment of the pivoting mechanism by free-floating sutures or chordae tendineae (171), resulting in valvular stenosis or regurgitation. Intermittent closure of the disc and a reduced opening angle are diagnostic features that may be found on echocardiographic and cinefluoroscopic examinations. Abnormal intravalvular regurgitation may be observed by color Doppler imaging. Although dislodgment and embolization of a disc has been reported with the Harken (172), the Duromedics (173), and the Omnicarbon (174) tilting-disc valves, most instances of disc escape due to strut fracture have been associated primarily with the Björk-Shiley convexo-concave tilting-disc valve.

Björk-Shiley Valve and Risk of Strut Fracture

In 1978, the disc used in Björk-Shiley valves underwent modifications in an attempt to reduce the risk of valve thrombosis with use of such valves and to improve their hemodynamic profile (175). These modifications included a change to a convexo-concave shape, relocation of the retaining struts 2.5 mm away from the orifice ring, and a disc opening angle of 60 degrees. Another model introduced in Europe in 1980 has an opening angle of 70 degrees. Although these modifications resulted in an improved effective orifice area, the increased stress forces led to frequent fracture of the supporting struts (176). By 1987,213 reports had been made of fracture of the valve ring strut, resulting in withdrawal of the Björk-Shiley tilting-disc valve from the market. By December 1994, 564 complete strut fractures were reported, two-thirds of which were fatal (177). Approximately 40,000 patients are carrying these valves worldwide. The risk of strut fracture appears to be greater in larger-diameter Björk-Shiley prostheses, particularly in those manufactured from 1981 through 1982 (176). Valves with a diameter between 21 and 27 mm and a 60-degree opening angle carry the lowest risk, approximately 0.02% per year (*e*Table 24.1.2). The risk is slightly higher (0.05% to 0.50%) for larger valves with a 60-degree opening angle manufactured before 1981 and after 1982. Larger valves (diameter, 29 to 33 mm) with a 60-degree opening angle manufactured between February 1, 1981, and June 30, 1982, have an intermediate risk of fracture (0.32% per year). Large valves (diameter, >29 mm) with a 70-degree opening angle carry the highest risk, approximately 2% per year. This risk is also higher in patients who are younger than 50 years at the time of implantation (177,178). Prophylactic valve replacement should be considered in patients in whom the risk of embolization exceeds the risk of reoperation.

In May 1994, the U.S. District Court in Cincinnati, Ohio, approved a settlement agreement between a worldwide class of Björk-Shiley heart valve patients and Shiley Inc. Under this agreement, a supervisory expert panel was appointed to establish guidelines for prophylactic valve replacement. Under these guidelines (last amended in June 2000), recipients of Björk-Shiley concave-convex valves qualify for monetary benefits to cover prophylactic valve replacement if their estimated risk of outlet strut fracture exceeds their life-expectancy adjusted risk of reoperation (*e*Table 24.1.3). The risk of fracture is estimated according to the size of the prosthesis, position, specific welder group and shop order fracture rates, and the patient's current age and gender. Risk factor multipliers for 60-degree models are listed in *e*Table 24.1.4. These guidelines must be applied, however, after the characteristics of the individual patient have been considered, which may determine different risk or normal life expectancy.

Strut fracture and disc embolization of an aortic prosthesis is usually fatal. Patients with strut fracture of a mitral prosthesis often survive (179). Acute pulmonary edema, syncope, shock, and acute neurological deficits are often the presenting signs and symptoms. Absence of the opening and closing clicks on auscultation, absence of the disc on radiographic or echocardiographic examination, and severe regurgitation found on color Doppler imaging help establish the diagnosis. Emergency valve replacement is required in these patients.

Incomplete fracture of the strut may be detected by high-resolution cineradiography (180) and also is an indication for valve replacement. This method appears to be very specific when specimens that have been explanted are analyzed. However, its sensitivity is unknown. Of 315 patients with mitral convexo-concave valves who were examined cineradiographically every 6 months after implantation, 11 who showed probable or definite single-leg separations underwent prophylactic explantation. In ten of these, the fracture was confirmed. The mortality rate was slightly lower than the expected mortality rate for this group, for which the fracture rate is estimated to be 0.46% per year or higher. However, two complete outlet-strut fractures occurred 3 and 7 months after radiographic examination yielded apparently normal results, which indicates that some cases were not detected or that complete outlet-strut fracture may not necessarily be preceded by incomplete fracture for a significant period of time. Thus, further studies are necessary to establish specific guidelines about the use of this method as an effective screening procedure. Acoustic analysis has been more recently proposed as a cost-effective method for detecting strut fracture (181).

Bioprosthetic Valves

Structural failure of bioprosthetic valves is common and eventually necessitates prosthetic replacement (*e*Fig. 24.4.1). After implantation of these valves, the leaflets exhibit progressive fibrosis and calcification (182,183). The thickened leaflets become less compliant and either lose their mobility, resulting in prosthetic valve stenosis, or fracture, causing valve incompetence (184). Severe intravalvular prosthetic regurgitation tends to be clinically more significant than stenosis (85). Structural valve failure can occur as early as 4 years after implantation. The incidence of structural failure requiring valve replacement for heterograft bioprostheses increases linearly thereafter, approaching approximately 30% at 10 years and reaching as high as 60% at 15 years (87,185). Approximately 10% to 20% of stentless aortic homografts degenerate and require replacement at 10 years after implantation (185,186). The bioprosthetic valve failure rate is higher among prostheses in the mitral position (187,188) and among younger patients. Approximately 50% of patients who are in the second decade of life at the time of surgery experience structural valve deterioration requiring valve replacement before 6 years (87). Recent studies suggest that structural degeneration for bioprostheses implanted in the mitral valve position may be lower for porcine supraannular bioprostheses than pericardial bioprostheses (189). Thereafter, the incidence of structural failure of heterograft bioprostheses decreases linearly with increasing age of the patient. The incidence of structural failure for stentless porcine bioprosthesis appears to be reduced, according to a few nonrandomized studies (72). However, structural degeneration leading to prosthetic stenosis has also been described with these valves (190).

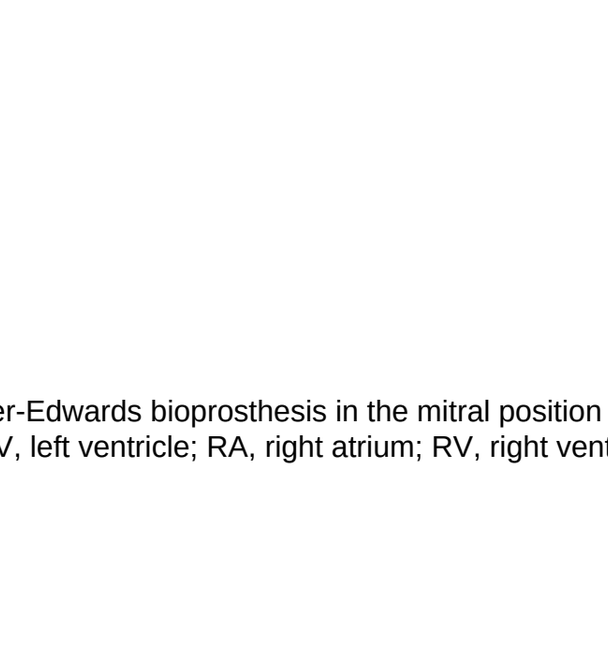
VIDEO

Video 24.21 Structural valve degeneration of a Carpentier-Edwards bioprosthesis in the mitral position demonstrated in a transesophageal echocardiogram (TEE). The arrow demonstrates a flail prosthetic leaflet. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Explanted Carpentier-Edwards mitral valve regurgitation demonstrating the left atrial side of the prosthesis. It is easy to see from this view that the markedly distorted valve leaflets would cause severe stenosis.

Bioprosthetic valve failure is usually insidious, presenting as progressive heart failure. Auscultation may reveal a stenotic or a regurgitant murmur and a soft or absent

closing sound. Leaflet thickening, calcification, and restricted motion is seen with stenotic valves by two-dimensional echocardiography. Leaflet fracture appears as excessive mobility and fluttering during opening and closing (191). Increased transvalvular gradients can be detected by continuous-wave Doppler imaging or by catheterization. Color Doppler imaging may demonstrate intravalvular regurgitation. Bending of the polypropylene stents may occur in certain models of the Hancock bioprosthesis and lead to functional stenosis (192). The incidence of this phenomenon, known as stent "creep," is unknown, but it should be suspected when transvalvular gradients are elevated in the presence of apparently normal prosthetic leaflets.

Prosthetic Valve Endocarditis

Approximately 3% to 6% of patients with prosthetic heart valves will experience prosthetic valve endocarditis during their lifetimes (193,194). Prosthetic valve endocarditis represents approximately 15% of the cases of endocarditis in developed countries (195). The incidence of prosthetic valve endocarditis peaks at 5 weeks after surgery and levels off at 9 months after surgery. This probably occurs because of different factors related to the initial perioperative period, including contamination of the surgical wound, exposure to nosocomially acquired pathogens, and depressed immune system. The different frequencies and types of causative organisms support this concept and lead to the arbitrary classification of prosthetic valve endocarditis as "early" and "late" endocarditis. The overall risk of endocarditis is similar among patients with mechanical and patients with heterograft bioprostheses (194), although some studies suggest that the early endocarditis is more frequent among patients with mechanical valves, whereas late endocarditis is more common among patients with heterograft bioprostheses (195,196). The risk of endocarditis has been reported to be much lower among patients with stentless aortic homografts.

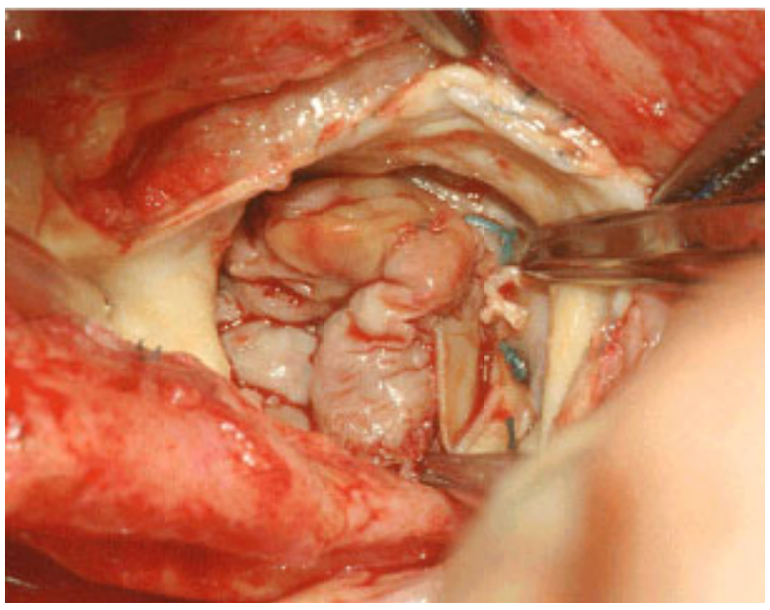
The diagnosis of prosthetic valve endocarditis is based on Duke's criteria, which require the combination of two major (evidence of endocarditis by echocardiography, positive blood cultures), one major and three minor (predisposition, fever, embolism, immunologic phenomena, suggestion of endocarditis by echocardiography, suggestive microbiology), or five minor criteria. Major echocardiographic criteria include the appearance of a new oscillating mass with independent motion attached to the prosthetic material, the detection of perivalvular tissue swelling indicative of an abscess, dehiscence of the prosthetic suture ring, or the appearance of new paravalvular or intravalvular regurgitation.

Early Prosthetic Valve Endocarditis

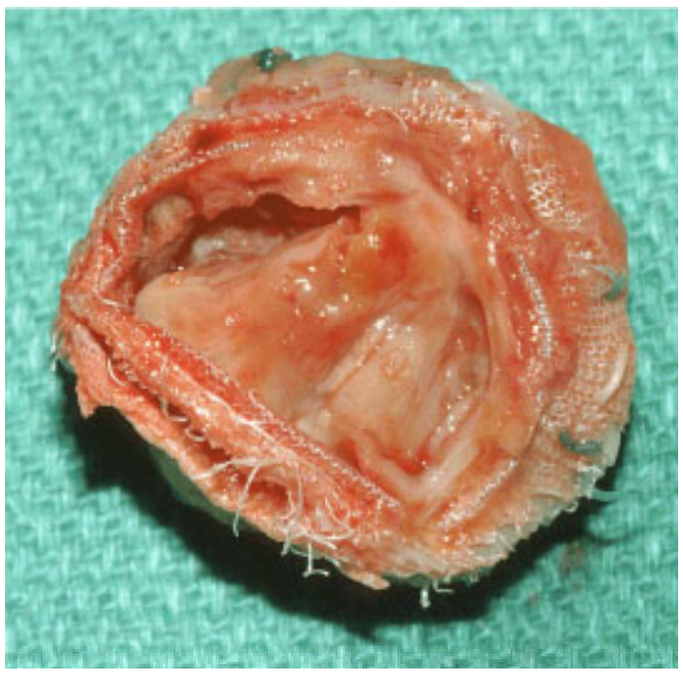
By definition, early endocarditis occurs during the first 60 days after valve implantation. It carries a higher mortality rate, ranging between 20% and 70% (195,196 and 197). The classic signs of endocarditis may be masked by the signs of extracardiac sites of infection, such as sternal osteomyelitis and indwelling catheter infections. Symptoms are usually less typical in early prosthetic valve endocarditis. Fever is the most common symptom, occurring in 97% of patients with this condition, followed by diaphoresis and back pain. Anemia is found in 74% of patients, although most of these patients are anemic because of recent blood loss during surgery. Elevated sedimentation rate is uncommonly found in early prosthetic valve endocarditis. Peripheral findings occur in approximately 10% of the cases. The clinical course tends to be more fulminant, with congestive heart failure observed in 60% and shock in 33% of patients (195). Cerebral thromboembolism is more frequent among patients with mechanical valves who are receiving inadequate anticoagulation (38% to 71%), compared to 10% among patients with therapeutic INR. The severity of neurologic deficits is higher, however, in patients receiving anticoagulant therapy, because of the increased risk of hemorrhagic complications. The differential diagnosis of early prosthetic valve endocarditis includes sternal wound, indwelling line infection, and pneumonia. Endocarditis is more frequently associated with sustained bacteremia, which is usually transient with extracardiac infections. Other features of endocarditis include (a) a longer interval between the time of surgery and the onset of symptoms (>25 days), (b) the presence of a new murmur, (c) identification of a microorganism known to be causative, and (d) the absence of an obvious extracardiac source of infection. Gram-negative organisms are not frequently associated with prosthetic valve endocarditis and most likely indicate an extracardiac source.

The incidence of early prosthetic valve endocarditis decreased steadily during the last two decades. This decrease has been attributed to the administration of prophylactic antibiotics in the perioperative period. However, no randomized study has been done to prove this belief. Studies have shown, however, that a shorter course of antibiotics (1 to 2 days) is not associated with a significant increase in risk compared to a longer course (5 to 6 days) (198). The risk of early prosthetic valve endocarditis in prostheses in the aortic position is similar to that of prostheses in the mitral position and is higher in multiple-valve recipients (193,194 and 195). Early prosthetic valve endocarditis is more common in men, perhaps as a result of skin infections related to shaving of chest hair during surgery.

Staphylococcus epidermidis is the most common causative organism of early prosthetic endocarditis, accounting for approximately 40% of the cases (199). These organisms have a particularly high affinity for implanted or indwelling synthetic surfaces. They are also the most common organisms causing infection throughout the first year after surgery. The majority of infections caused by *S. epidermidis* during the first year (80%) is resistant to methicillin. In contrast, methicillin resistance is low (20% to 30%) among these organisms after 1 year, suggesting that most infections occurring during the first year after surgery are nosocomial in origin. *Staphylococcus aureus* is the second most common causative organism of both early and late prosthetic valve endocarditis, accounting for 20% of the cases. Gram-negative organisms, diphtheroids, and fungi may also be causative organisms during the first 2 months after surgery. *Mycoplasma, Legionella* pneumonia, and atypical mycobacteria and enterococci are less frequent causative organisms during this period. Culture-negative endocarditis most commonly occurs as a result of antibiotic therapy. However, *Mycoplasma*, *Legionella*, fungi, *Coxiella burnetii*, and mycobacteria may cause prosthetic valve endocarditis with negative blood cultures.



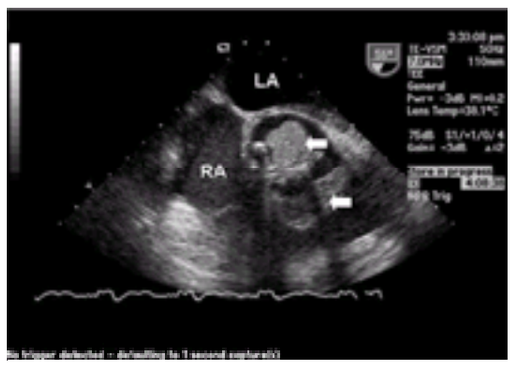
Intraoperative view of a severely damaged aortic prosthesis in a patient with coagulase positive *Staphylococcus* endocarditis. This view is through the aortotomy looking down on the aortic side of the prosthesis.



Surgical specimen of a tissue prosthesis destroyed by *Staphylococcus* endocarditis. This is the ventricular side of the aortic prosthesis. Note the thickened, scarred prosthetic leaflets causing both aortic stenosis and regurgitation.

Late Prosthetic Valve Endocarditis

Late prosthetic valve endocarditis occurs most commonly in patients who have bioprosthetic valves, valves in the aortic position, and multiple prostheses (eFig. 24.4.2). The clinical features of late prosthetic valve endocarditis resemble those of endocarditis of native valves. The incidence of late prosthetic valve endocarditis for mechanical valves is approximately 0.45% per patient-year for valves in the mitral position, 0.54% for valves in the aortic position, and 0.64% for double implants (196). The incidence for bioprosthetic valves is 0.49% for valves in the mitral position, 0.91% for valves in the aortic position, and 0.90% for double implants. The lower incidence of late endocarditis observed with mechanical valves may be explained by the resistance of the mechanical surface materials to adherence of microorganisms. Thus, infections of mechanical prostheses usually originate from the annular tissue around the sewing ring or as a complication of thrombi. A probable source of infection can be found in 25% to 80% of patients who have late prosthetic valve endocarditis (196). Dental procedures, urinary tract infections, and urologic procedures are the most common identifiable sources.



***e*FIGURE 24.4.2** Endocarditis involving a Carpentier-Edwards bioprosthesis in the aortic position demonstrated by transesophageal echocardiography. The arrows indicate a large vegetation and a paravalvular abscess, respectively. LA, left atrium; RA, right atrium.

Explanted Carpentier-Edwards mitral valve regurgitation in a patient with severe infective prosthetic valve endocarditis. The patient had severe mitral stenosis due to the large vegetations on the prosthesis.

VIDEO

Video 24.23 This is a long-axis 134-degree transesophageal view of a patient with prosthetic valve endocarditis of the aortic valve. Note the very large mobile mass or vegetation on the prosthesis accompanied by prosthetic stenosis and moderate insufficiency. The peak and mean pressure gradients across this valve were 90/27 mm Hg, and there was also a paravalvular abscess. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 24.24 The short-axis 56-degree transesophageal view demonstrating the very large vegetation attached to the Carpentier Edwards aortic valve replacement involving both aortic stenosis and aortic insufficiency. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 24.25 Transesophageal echo of a St. Jude mitral valve replacement in a patient with endocarditis. Note the large vegetation on the atrial side of the valve that prolapses across the prosthesis in systole causing prosthetic mitral stenosis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 24.26 Transesophageal 138-degree view showing the Carpentier-Edwards mitral valve replacement with thickened leaflets with multiple mobile echo densities consistent with vegetations and a clot in a patient with prosthetic valve endocarditis. The mean transesophageal gradient was 20 mm Hg on surface echo. Note the large left atrial thrombus to the right of the screen with significant spontaneous echo contrast in the left atrial cavity. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 24.27 Deep transgastric view showing the mitral valve replacement in short axis within the sewing ring. One can see the multiple mobile echo densities consistent with vegetation and/or thrombus causing the mitral stenosis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Late prosthetic endocarditis is caused by organisms similar to those that cause endocarditis in native valves. Streptococci are the most common, followed by gram-negative bacteria, enterococci, and *S. epidermidis*, organisms usually found in the dental, gastrointestinal, and skin flora. Culture-negative endocarditis, caused by fastidious gram-negative organisms, is also more frequent during the late period. Symptoms in patients with prosthetic valve endocarditis are similar to those in patients with native valve endocarditis. In patients with mechanical valves, prosthetic valve endocarditis is associated with a high rate (50% to 60%) of annular tissue invasion (195). These rates are similar to those associated with prosthetic valve endocarditis of heterograft bioprostheses during the early period (194). Interestingly, the incidence of tissue invasion seems to be lower (27%) in late endocarditis in bioprosthetic valves. These findings suggest that late endocarditis in bioprosthetic valves may be more amenable to medical management. Congestive heart failure has been reported in approximately 30% to 70% of patients with prosthetic valve endocarditis (193). Cerebrovascular embolization is common in late prosthetic valve endocarditis, occurring in 28% of patients (195). Other common complications include hemolytic anemia (200), prosthetic dehiscence, and heart block (201).

Transthoracic and transesophageal echocardiography are very useful in (a) establishing a diagnosis in patients who have culture-negative endocarditis that is caused by fastidious organisms or the use of antibiotics, (b) detecting the presence of complications such as myocardial abscess, prosthetic dehiscence, fistulae, and large vegetations that are at risk for embolization, (c) monitoring the efficacy of medical therapy, and (d) helping in the planning of surgery. The sensitivity of transthoracic echocardiography for detecting vegetations is significantly lower than its sensitivity for detecting native valve endocarditis (202). This limitation stems from the acoustic shadowing caused by the prosthetic valve components and is more significant with mechanical prostheses. For imaging infective vegetations, the sensitivity and specificity of transesophageal echocardiography are approximately 95% and 90%, respectively. Transesophageal imaging is superior in detecting small vegetations, tissue invasion, and fistula formation (203,204 and 205). Prosthetic valve endocarditis is usually associated with large vegetations, because microorganisms are particularly protected from host defense mechanisms. In patients with both mitral and aortic prostheses, transthoracic imaging may provide a better visualization of the aortic prosthesis and assist in evaluating aortic regurgitation. Transesophageal echocardiography may fail to detect vegetations in patients who present early after the onset of symptoms (206). In these patients, performing a repeated study 48 to 72 hours after presentation should be considered. Prosthetic valve endocarditis carries a very high mortality rate, reported to be between 20% to 80% in different series (205,207,208). The risk of death is higher with early prosthetic valve endocarditis and decreases over time. Congestive heart failure, cerebral embolization, extensive tissue invasion, and infection with *S. aureus* also increase the mortality rate.

Treatment of Prosthetic Valve Endocarditis

Medical treatment of prosthetic valve endocarditis requires longer courses of antibiotics than are used for treatment of native valve endocarditis. The presence of large vegetations usually requires a longer course of antibiotics to achieve sterilization. Regardless of the size of vegetation, however, medical cure is unlikely if there is extensive tissue invasion or if the organism is relatively insensitive to the antibiotic of choice (minimum bactericidal concentration, >4 µg per mL). Treatment of prosthetic valve endocarditis frequently requires surgical replacement of the prosthesis. Streptococcal prosthetic endocarditis is perhaps the only exception; this condition responds to medical treatment alone in 50% of the cases. Medical cure of prosthetic valve endocarditis caused by *Staphylococcus*, gram-negative organisms, or fungi is rare. In patients who are receiving antibiotics and are hemodynamically stable at the time of diagnosis, antibiotics should be withheld briefly to attempt the isolation of an organism from blood cultures. The duration, dosage, and choice of antibiotics is similar to those used in treatment of native valve endocarditis caused by the same organisms, with the following exceptions: (a) treatment of prosthetic valve endocarditis caused by *S. aureus* should include rifampin (300 mg three times per day) and either a semisynthetic penicillin or vancomycin and an aminoglycoside, and (b) in patients who have culture-negative endocarditis associated with a prosthetic valve, vancomycin should be added to ampicillin and gentamycin (209). In cases of penicillin allergy, vancomycin should be used as a second choice.

Surgical replacement should be promptly performed if (a) bacteremia persists after 5 days of intravenous antibiotic therapy; (b) infection recurs after discontinuation of antibiotic therapy; (c) there is evidence of tissue invasion or fistulous tracks; (d) recurrent embolization occurs on antibiotic therapy; (e) infection is caused by a fungal organism; or (f) prosthetic obstruction, dehiscence, heart block, or congestive heart failure develops (210,211). Patients with vegetations that are larger than 10 mm in diameter carry a high risk of embolization, and treatment is less likely to be successful. In these patients, early surgical replacement should be performed. Patients with prosthetic valve endocarditis who have experienced an embolic event while receiving antibiotics and who have residual vegetations carry a significant risk of recurrent

embolization and should be considered candidates for early surgical replacement. Patients in whom bacteremia persists for more than 2 days despite effective antibiotic therapy have a better prognosis with early surgical intervention (199). The overall mortality rate of patients treated with antibiotics alone is 61%, compared with 38% among patients who undergo valve replacement (212). In earlier surgical series, however, the mortality rate was high because of delayed operations in patients in whom medical therapy failed. Surgery should not be delayed in any of these circumstances, with perhaps one exception: Patients with cerebral embolization have a significant risk of intracranial hemorrhage during surgery, particularly if they have large neurologic deficits, large abnormalities on a cranial CT scan, or evidence of mycotic aneurysms on a cerebral angiogram. Aggressive removal of all infected tissue should be performed to avoid recurrence of the infection. Occasionally, the annular tissue needs to be reconstructed with autologous pericardium. The stentless aortic homograft is an excellent choice for replacement of infected aortic prostheses. The risk of recurrent endocarditis in aortic homografts is very low (213). Antibiotic treatment should be administered for 6 weeks after surgery. If the organism is methicillin-sensitive *Staphylococcus*, gentamycin should be also administered for 2 weeks. Vancomycin should be used to treat infections caused by methicillin-resistant strains.

Prosthetic valve endocarditis remains a serious complication of valve replacement, but the in-hospital mortality rate associated with reoperations for prosthetic valve endocarditis has declined. In experienced centers, most patients in whom prosthetic valve endocarditis is surgically treated have a favorable outcome. Of 146 patients reoperated for the treatment of prosthetic valve endocarditis by Lytle and colleagues (214) from 1975 through 1992, only 13% died in-hospital (eTable 24.1.5). In this study, the surgical mortality rate decreased from 20% between 1975 and 1984 to 10% between 1984 and 1992. The improvement in the prognosis of patients with prosthetic valve endocarditis during the last decade was probably caused by advancements in surgical techniques, including extensive débridement of infected tissue, use of homografts, and improved antibiotic therapy, as well as earlier surgical intervention and patient selection. Both homograft (215) and allograft (216) replacement are associated with a low risk of recurrence in aortic valve endocarditis. Recent efforts have aimed at reducing the incidence of early prosthetic valve endocarditis, such as coating the suture ring with silver (217). However, a higher than expected incidence of paravalvular regurgitation and dehiscence lead to the withdrawal of silver nitrate–impregnated mechanical valves from the market (218).

Antibiotic Prophylaxis in Patients with Prosthetic Valves

To date, no adequate controlled studies testing the effectiveness of prophylactic antibiotics in patients with prosthetic valve endocarditis have been carried out. Antibiotic prophylaxis is recommended, however, based on observations determining that (a) transient bacteremia occurs after certain invasive procedures and (b) patients with prosthetic valves in whom bacteremia is documented have a 10% risk of developing late endocarditis (219). Antibiotic prophylaxis is recommended during invasive procedures that carry a high risk of bacteremia, including dental extractions and professional cleaning and gastrointestinal, genitourinary, and oral surgery. Prophylaxis is no longer recommended before flexible endoscopy or bronchoscopy or normal vaginal delivery. For dental, oral, and respiratory tract procedures, oral antibiotics are effective and are preferred in ambulatory patients. According to the new recommendations issued by the American Medical Association (220), amoxicillin (2 g) administered 1 hour before and after the procedure is the treatment of choice. Erythromycin or clindamycin is recommended for use in patients who are allergic to penicillin. For genitourinary and gastrointestinal procedures, ampicillin (1 g intravenously) and gentamycin (80 mg intravenously) should be given 1 hour before surgery and 8 hours after the initial dose. Vancomycin (1 g intravenously) should substitute for ampicillin in patients who are allergic to penicillin.

Hemolysis

Several mechanisms may contribute to the development of hemolysis in normal and malfunctioning prosthetic valves, including shear stress, turbulence, pressure fluctuations, interaction with foreign surfaces, and intrinsic abnormalities of the erythrocyte membrane (221). With the first class of ball-and-cage prosthesis that was implanted, the observed incidence of hemolysis was between 6% and 15% in different series (222,223 and 224). The improved hemodynamic performance and surface materials of the newer mechanical and bioprosthetic valves have resulted in a significant reduction of this risk (225,226). Subclinical hemolysis (increased reticulocyte count and lactate dehydrogenase, decreased haptoglobin) is found in most patients who have mechanical valves, but it rarely results in significant anemia. However, hemolytic anemia still represents a relatively common complication among patients with malfunctioning prostheses. Hemolysis is commonly found in association with paravalvular regurgitant leaks. In a series published by Kastor and coauthors (222), 40% of patients with prosthetic valves and paravalvular regurgitation had significant hemolysis that required surgical repair or resulted in death.

VIDEO

Video 24.31 Paravalvular regurgitation demonstrated by color Doppler in a patient with severe hemolysis. LA, left atrium; LV, left ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 24.32 Intraoperative transesophageal echo (transgastric short-axis view) of a CarboMedics mitral valve replacement with both physiologic prosthetic mitral regurgitation (two jets from within the sewing ring) and an abnormal, lateral paravalvular jet (outside the sewing ring to the right of the screen). Note that the paravalvular jet is arising between the sewing ring and an area of mitral annular calcification, making it difficult for the prosthesis to be in close contact with the annulus. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Shear stress that causes morphologic alterations in the erythrocyte membrane and results in hemolysis has been well documented. By means of transesophageal echocardiography and fluid dynamic simulation, it has been demonstrated that flow acceleration, deceleration, and fragmentation may be important causes of increased shear stress associated with periprosthetic leaks (227). Patients with clinical hemolysis demonstrate patterns of flow that are associated with peak shear stresses of 4,500 to 6,000 dynes per cm^2. Direct collision with cardiac structures, such as the limbus of the left atrial appendage, that caused rapid flow deceleration was the most common flow pattern associated with hemolysis in this study. Regurgitation through several small orifices or orifices of irregular shape is associated with greater hemolysis than regurgitation through large, round orifices, perhaps because of the higher acceleration required for passage through the small orifice.

Other factors are also important in the development of hemolytic anemia with prosthetic valves. The surface area and the type of prosthetic material are important factors in the genesis of hemolysis. This phenomenon was noted with the introduction of the completely cloth-covered ball-and-cage prosthesis (Starr-Edwards, series 2300, 2310; Fig. 24.2) (110). These valves, which were developed in an attempt to decrease the incidence of thromboembolism, were associated with a 15% incidence of severe hemolytic anemia. The foreign surface effect is of greater importance when considering the probability of a patient developing hemolysis with malfunctioning prostheses. Teflon and other prosthetic materials that are used to construct the sewing ring and to partially cover the struts in some contemporary valve models become rapidly endothelialized within several weeks after implantation. However, regurgitant jets from paravalvular leaks may denude this endothelium, revealing the

prosthetic surface and increasing the propensity to develop hemolysis.

Abnormal flow through a partially thrombosed prosthetic valve may cause hemolytic anemia. Hemolytic anemia is also a common finding in patients who have prosthetic valve endocarditis (228) and in patients who have bioprosthetic valves with structural failure (229). The presence of multiple prosthetic valves or unusually small mechanical prostheses is also associated with higher incidence and severity of hemolysis (230). Mild hemolytic anemia may be treated medically with erythropoietin, iron and folic acid supplementation, and blood transfusions. Control of hypertension with beta-blockers may reduce the severity of hemolysis, probably by reducing the velocity of regurgitant flows and thus the shear stress (231). Closure of paravalvular regurgitant leaks or valve replacement is indicated in patients with severe hemolysis that requires repeated blood transfusions or in patients with congestive heart failure.

Dehiscence and Periprosthetic Regurgitation

Separation of the sewing ring from the annular tissue may occur in the early postoperative period, due to poor surgical techniques, excessive calcification and fragility of the annular tissue, or infection. Inadequate nutritional status and use of steroids may impair surgical healing and promote early dehiscence. Late dehiscence occurs commonly as the result of infective endocarditis. Polypropylene sutures increase the risk of dehiscence to approximately 10% within 4 years of operation (232). On the other hand, fractures of Dacron polyester sutures are rare. A new regurgitant murmur may herald the presence of prosthetic valve dehiscence. Abnormal rocking of the sewing ring relative to the annular tissue is the characteristic finding observed by means of two-dimensional echocardiography or cinefluoroscopy (233,234). Color Doppler echocardiography demonstrates abnormal paravalvular flow seen as a regurgitant jet distal to the prosthesis or a region of proximal flow convergence (234). Prosthetic valve dehiscence requires prosthetic replacement, although resuturing of the free portion of the sewing ring with or without a pericardial patch may have satisfactory results. In patients at high risk for reoperation percutaneous catheter, closure of the paravalvular orifice with a double-umbrella device has been successfully performed (235).

VIDEO

Video 24.33 On this cine-fluoroscopy, note the extreme motion of the Lillehei-Kaster prosthetic valve apparatus. This is consistent with a partial dehiscence of the valve. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Conduction Abnormalities

Heart block may occur after replacement of aortic valves that have become severely calcified, as a result of trauma to the bundle of His that occurs during removal of calcium from the region of the right trigone, beneath the commissure between the noncoronary and the right coronary cusp. Fortunately, complete heart block is uncommon and is usually transient and caused by postoperative edema of the periannular tissue.

Myocardial Infarction

Embolization of air through the right coronary artery is a relatively common cause of perioperative infarction of the inferior wall myocardium, but it rarely results in permanent systolic dysfunction. Myocardial infarction due to obstruction or dissection of the coronary ostia after reimplantation of the coronary trunks in stentless aortic homografts or prosthetic valve conduits may rarely occur. Intraoperative echocardiography is useful demonstrating the presence of postoperative wall motion abnormalities and the patency of flow in the coronary arteries of such patients (236). Myocardial infarction may also be caused by coronary embolization of thrombotic material or infective and aseptic vegetations of endocarditis (237). Coexisting coronary artery disease represents, however, the most common cause of myocardial infarction in patients with prosthetic heart valves.

Ventricular Pseudoaneurysm

Perforation of the posterior mitral annular region may occur after mitral valve replacement, particularly when severe calcification of the mitral annulus is present (238). The posterior pericardium may initially contain the rupture, preventing cardiac tamponade and death. The diagnosis of this infrequent complication is often incidentally made on the basis of a routine echocardiogram. Pseudoaneurysms detected early after mitral valve prosthetic implantation require prompt surgical repair.

Patient-Prosthesis Mismatch

All prosthetic valves, with the exception of the stentless aortic homograft, have effective orifices that are smaller than those of native valves of the same annular dimensions. Thus, prosthetic valves are inherently stenotic and have a residual transvalvular pressure gradient. Occasionally this gradient is significant enough to cause symptoms, particularly when small prostheses are implanted in patients of large size. Pressure gradients that are of moderate magnitude at rest may increase significantly during exercise.

Patient-prosthetic valve mismatch occurs most frequently after valve replacement for aortic stenosis. The aortic annulus is often small in these patients, and, after replacement, the effective orifice may have an area between 1.0 and 1.5 cm^2. Dobutamine or exercise echocardiography may be useful in evaluating patients whose symptoms persist after valve replacement by obtaining an estimate of the transvalvular gradients at high cardiac outputs and by evaluating the impact of these gradients in left ventricular systolic function (239). In patients with small annular size, special consideration should be given to the hemodynamic profile when the replacement valve is selected. Stented bioprosthetic valves and ball-and-cage mechanical prostheses are intrinsically more stenotic. Patients with small tilting-disc mechanical aortic prostheses often have increased resting and exercise gradients. However, recent studies have failed to demonstrate aerobic exercise impairment in these patients in comparison with age-matched healthy cohorts (240).

Surgical techniques including supraannular implantation and supraannular and annular enlargement may be performed at several institutions to permit the implantation of larger prosthetic devices and avoid patient-prosthesis mismatch (241,242). Stentless valves are probably the best choice for active patients who want to avoid anticoagulation therapy. Studies have shown better exercise hemodynamics and greater regression of left ventricular hypertrophy in patients who receive stentless valves than in patients who receive stented valve prostheses (68,69). In general, stented aortic valve prostheses smaller than 21 mm in diameter are not recommended for patients of larger size who are physically active (243,244).

Left Ventricular Outflow Obstruction

Some patients with aortic valvular stenosis have significant hypertrophy of the basal muscular septum, either as a result of long-standing pressure overload or as a separate, coexisting condition. In these patients, left ventricular outflow tract obstruction may be subtle before valve replacement because of the high afterload imposed by the stenotic valve. After replacement, the decrease in afterload may result in significant obstruction of the left ventricular outflow tract caused by systolic anterior motion of the anterior mitral valve leaflet. Intraoperative transesophageal echocardiography is useful in diagnosing this complication and should be considered in patients undergoing aortic valve replacement who have severe septal hypertrophy and a small left ventricular outflow tract. Septal myectomy is usually successful correcting this problem when the obstruction is severe. Patients with mitral stenosis and small left ventricular cavities may also develop left ventricular outflow tract obstruction that is caused by one of the supporting struts of a bioprostheses. In these patients, replacement with a mechanical valve is preferred.

ROUTINE FOLLOW-UP OF PATIENTS WITH PROSTHETIC VALVES

After replacement, a transthoracic echocardiographic examination is recommended before the patient is discharged from the hospital to exclude potential postoperative complications such as cardiac tamponade, ventricular pseudoaneurysm, prosthetic paravalvular regurgitation, and perioperative myocardial infarction. A follow-up clinical and echocardiographic evaluation 6 to 8 weeks after discharge is also recommended. At this time, careful determination of the transvalvular gradient, effective valvular orifice, and dimensionless transvalvular velocity index should be made for future comparisons. Further echocardiographic studies should not be required for several years unless there is failure of functional recovery after surgery or development of new symptoms that may indicate myocardial or valvular dysfunction. Additional information obtained from the echocardiogram, such as the left and right ventricular systolic function, chamber sizes, and the estimation of the right ventricular systolic pressure, are helpful to determine the etiology of symptoms. Failure of mechanical valves is rare, and therefore the value of routine echocardiographic follow-up of asymptomatic patients is controversial. Routine echocardiographic evaluation is most useful for patients with bioprosthetic valves because of the earlier and more gradual structural degeneration of such prostheses.

Follow-up routine echocardiographic examinations performed as early as 5 years after surgery, particularly in younger patients and patients who have valves in the mitral position, is recommended. These studies should be repeated every 2 years if the leaflets appear to be morphologically normal and every 6 to 12 months if evidence of prosthetic degeneration (e.g., leaflet thickening and calcification), intravalvular regurgitation, or stenotic flow is seen. Transesophageal echocardiography provides a more accurate assessment when regurgitation is suspected in patients with mitral prostheses or when unexplained congestive heart failure or pulmonary hypertension occurs. Anticoagulation should be monitored rigorously by specialized clinics or physicians. Maintaining adequate anticoagulation requires not only periodic monitoring of the INR but continuous patient and physician education, including knowledge of drug interactions.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Selecting a Prosthetic Valve

The choice between mechanical and bioprosthetic valves should be an early point of discussion between the cardiologist, the cardiac surgeon, and the patient. Multiple factors need to be considered in the decision-making process, including the age of the patient; the probability of future pregnancy in young women; and the patient's occupation, lifestyle, and life expectancy. The risk of a future reoperation should also be considered and may be greater after more extensive surgery such as stentless valve or allograft replacements. When feasible, valve repair should be considered. Otherwise, with very few exceptions, such as a patient who is already receiving chronic anticoagulation therapy or whose anticipated life expectancy is short, no absolute advantages are associated with a specific valve type. Mechanical valve prostheses have a longer durability but require a lifelong commitment to chronic anticoagulation therapy. They should be chosen for younger patients who do not have contraindications and are expected to be medically compliant. The relative benefit-to-risk ratio shifts earlier toward bioprosthetic valves in the aortic position. We recommend bioprosthetic valves for aortic replacement in patients older than 65 years and for mitral valve replacement in patients who are 70 to 75 years old. Middle-aged or younger patients who wish to avoid long-term anticoagulation therapy and who require aortic valve replacement are good candidates for homograft or allograft replacement, because the durability of theses valves appears to be greater than that of bioprostheses. It remains to be determined whether the durability of stentless porcine valves is comparable.

Prosthetic Valves and Pregnancy

The risk of complications to the mother and to the fetus is significant with both mechanical and bioprosthetic valves. Anticoagulation therapy carries a risk to the fetus even when heparin is substituted for warfarin in the first and third trimesters. Bioprosthetic valves undergo rapid structural degenerative changes in young patients and still carry a higher than expected fetal mortality rate. Women of childbearing age who have mild or regurgitant valvular heart disease should carry their pregnancies earlier in their childbearing years and undergo tubal ligation before prosthetic valve replacement with a mechanical valve. Valve repair should be performed whenever feasible. If valve replacement cannot be avoided, bioprosthetic valves should be used, because they carry a smaller risk of fetal and maternal complications.

Medical versus Surgical Treatment of Prosthetic Valve Complications

Most hemorrhagic and embolic complications seen in patients who have mechanical valves are managed medically, although a few patients with mechanical valves who experience recurrent embolic or hemorrhagic events may benefit from replacement with a bioprosthetic valve. With rare exceptions, other prosthetic valve complications, such as prosthetic valve degeneration, dehiscence, severe hemolysis, and most cases of endocarditis are best treated surgically. No adequate treatment for prosthetic valve degeneration is available. Balloon valvuloplasty of bioprosthetic valve stenosis has been attempted but carries an unacceptably high risk of systemic embolization, acute severe regurgitation, and early restenosis. Thrombolytic therapy of left heart prosthetic valve thrombosis carries a significant risk of stroke. In our opinion, thrombolytic therapy should be reserved for patients who have right-heart prostheses, who are otherwise at high risk for surgery, or for whom skilled surgical treatment is not readily available. Medical cure of prosthetic valve endocarditis occasionally may be accomplished, depending on the valve type and the infecting organism. *Streptococcus viridans* endocarditis in patients with bioprosthetic valves usually responds well to antibiotic therapy. In our experience, these patients should be followed closely; they frequently require valve replacement because of recurrence of infection, incomplete cure, or premature structural degeneration. Valve-induced hemolysis is frequently insidious in onset and may be managed medically, often for several years. The rate of hemolysis and thus requirements for blood transfusion tend to increase steadily over time. Often, the diagnosis of hemolysis is missed in these patients; because of chronic iron losses in urine, they present with predominant signs of iron-deficiency anemia. Because of the risks associated with repeated blood transfusions, valve replacement should be considered early in these patients.

THE FUTURE

The development and refinement of prosthetic valves during the last three decades have resulted in a remarkable improvement in survival and quality of life for millions of patients who have valvular heart disease. Replacement of a malfunctioning native valve with a prosthesis, however, substitutes one disease for another. None of the available mechanical or biologic valves has the performance and durability of the native human semilunar and atrioventricular valves. Stentless valves appear to have better hemodynamic performance than mechanical valves and stented heterografts, but their long-term durability is still unknown. Refinement of the mitral valve homograft will likely occur in the near future. Mitral homografts may become the procedure of choice for young patients and women of childbearing age who have mitral stenosis that is not amenable to commissurotomy or mitral insufficiency that is not amenable to surgical repair. Future improvements in prosthetic valve design are likely to provide less thrombogenic mechanical materials and better hemodynamic profiles. Future generations of mechanical valves may not require chronic anticoagulation therapy with warfarin. At the same time, chemical and biologic preservation techniques will continue to improve the longevity of bioprostheses. Newer advances in surgical techniques may reduce the morbidity and mortality rates associated with valve surgery. Improved surgical instruments, limited incision surgical techniques, and robotic surgery are now available in many specialized centers and likely will reduce the morbidity associated with heart valve surgery.

OVERVIEW

Despite many improvements in diagnostic and therapeutic advances, infective endocarditis (IE) remains a disease with high morbidity and mortality. Whereas formerly a younger population with rheumatic heart disease was the victim, an older population and a number of illicit drug users now present with the disease. Vegetations are usually located on the atrial surface of atrioventricular valves, the ventricular surface of semilunar valves, or in areas of the heart where jet lesions disrupt the endothelial surface. Occasionally, apparently normal valves are infected (especially in intravenous drug users). More recent diagnostic criteria have been developed that use clinical findings, pertinent laboratory data, and echocardiographic findings to diagnose endocarditis with a high degree of sensitivity and specificity. Transesophageal echocardiography (TEE) has been a major advance in diagnosing vegetations in prosthetic valve disease and in describing intracardiac complications, such as annular abscess, in all cases of IE.

Prevention of endocarditis using established criteria remains the standard of care despite lack of definitive studies. Antimicrobial therapy continues to evolve as efforts are being made to develop long-acting antibiotics that would be suitable for home therapy. Home intravenous therapy has been shown to be feasible and cost effective when the family situation allows such an approach. Advances in cardiothoracic surgery may result in earlier surgical intervention in many instances. Patients with IE often have many complicating features. The formidable challenge they often present is best met by using a team approach involving cooperation among cardiologists, cardiothoracic surgeons, and infectious disease specialists.

GLOSSARY

***Actinobacillus*:** A nonmotile, fastidious, gram-negative rod that can cause endocarditis in humans.

***Actinobacillus actinomycetemcomitans*:** A species of *Actinobacillus*.

Adenovirus: A family of double-stranded DNA viruses.

Aminoglycosides: A group of antibiotics made from species of *Streptomyces* or *Micromonosporum*. Effective against many gram-negative bacilli and *Mycobacterium tuberculosis*.

Amoxicillin: A semisynthetic penicillin with an antimicrobial spectrum similar to ampicillin.

Ampicillin: A semisynthetic penicillin that has a broader spectrum of antimicrobial activity than penicillin G.

***Bacillus*:** A genus of anaerobic, spore-forming gram positive rods found in the soil.

***Bartonella*:** A genus of bacteria that is difficult to grow in the laboratory. These bacteria cause infection in cats and can be transmitted to humans by scratches or louse bites.

Blalock-Taussig shunt: A shunt created by routing the left or right subclavian artery to the pulmonary artery.

***Brucella*:** A genus of encapsulated, gram-negative bacteria that are pathogens of humans and a variety of animals.

***Candida*:** A genus of fungi found on the skin and in feces, vaginal, pharyngeal, and gastrointestinal tracts.

Cefazolin: A broad-spectrum cephalosporin.

Ceftriaxone: A semisynthetic parenteral cephalosporin antibiotic.

Cephalosporin: One of several antibiotic substances obtained from *Cephalosporium* species of fungi. Effective against many gram-positive and gram-negative organisms.

***Chlamydia*:** A genus that includes all the agents of the psittacosis, lymphogranuloma, trachoma group.

Clindamycin: A class of antibiotics with broad activity against anaerobic bacteria and many gram-positive cocci.

***Corynebacterium*:** A genus of gram-positive rods found widely in nature; can be found in oropharynx.

***Coxiella burnetii*:** The bacteria that causes Q fever in humans.

Coxsackie B: A picornavirus responsible for a variety of diseases in humans.

***Eikenella*:** A nonmotile, gram-negative, anaerobic rod part of normal oral cavity.

Endarteritis: Inflammation of the intima of an artery.

***Enterococcus*:** A genus of gram-positive cocci that inhabits the intestinal tract of humans.

***Escherichia coli*:** A gram-negative rod widely found in nature; inhabits the intestines and causes infections of the urogenital and gastrointestinal tract.

Fibronectin: A fibrous-linking glycoprotein found in connective tissue, basement membranes, and cell surfaces; acts as an adhesive.

Gentamicin: An aminoglycoside antibiotic that inhibits growth of gram-negative and some gram-positive bacteria.

***Haemophilus*:** A gram-negative rod in the respiratory tract.

Histoplasma: A dimorphic fungus normally found in soil; it causes pulmonary infections.

Janeway lesion: Erythematous, nontender lesions on fingers, palm, or sole.

Keyhole surgery: Surgery performed through a small thoracotomy rather than large median sternotomy or large lateral thoracotomy.

Laminin: A large polypeptide glycoprotein component of basement membrane.

***Legionella*:** An aerobic gram-negative bacillus that is found in fresh water. It can cause pulmonary wound or renal infections.

***Listeria*:** A genus of motile bacteria containing small gram-positive rods; can cause meningitis, encephalitis, septicemia, endocarditis, abortion, and abscesses.

MacCallum's patch: Vegetations found along the mural surface of a cardiac chamber.

***Mycoplasma*:** A genus of gram-negative organism that lack a true cell wall; may cause pulmonary or genitourinary and postpartum infections.

Mycotic aneurysms: Aneurysmal dilatation of a vessel caused by invasion of the vascular wall from infective endocarditis.

Nafcillin: A semisynthetic penicillin resistant to penicillinase and effective against some strains of *Staphylococcus aureus*.

Osler's nodes: Small, tender, purple erythematous subcutaneous nodules visibly found on the pulp of digits.

Penicillin G: An antibiotic produced from cultures of the molds' *Penicillium* species.

***Propionibacterium*:** A genus of nonmotile, non–spore-forming gram-positive rods found on the skin and in the intestinal tract.

***Proteus*:** A genus of gram-negative bacteria that can cause genitourinary and nosocomial infections.

***Pseudomonas aeruginosa*:** A species of gram-negative, aerobic bacteria found in soil, water, and clinical specimens.

***Rickettsia*:** A genus of intracellular gram-negative bacteria that causes a variety of diseases such as spotted fever and typhus.

Roth's spots: Retinal hemorrhages with a clear center.

***Salmonella*:** A genus of gram-negative bacilli that can cause gastrointestinal and bacteremic illnesses.

***Serratia marcescens*:** Gram-negative rods that may produce infection in immunocompromised and hospitalized patients.

Splinter hemorrhage: An embolic subungual hemorrhage located proximally in the nailbed.

***Staphylococcus aureus*:** Gram-positive bacteria that may colonize the nasal mucous membranes and skin (hair follicles) and cause serious skin, soft tissue, blood, and endocardial infections.

***Streptococcus bovis*:** Gram-positive bacteria found in the gastrointestinal tract.

***Streptococcus milleri*:** A gram-positive coccus found in human throat, mouth, and nasopharynx.

***Streptococcus pneumoniae*:** A gram-positive, lancet-shaped diplococcus frequently occurring in chains; normal inhabitant of the respiratory tract.

***Streptococcus sanginosus*:** A gram-positive coccus found on oral and nasopharyngeal mucous membranes.

***Streptococcus sanguis*:** A gram-positive coccus found normally in oral and nasopharyngeal mucous membranes.

***Streptococcus viridans*:** Name applied to a group of alpha-hemolytic streptococci describing organisms isolated from the mouth and intestines.

Streptomycin: An antibiotic agent from *Streptomycesgriseus* active against *Mycobacterium tuberculosis* bacillus and a large number of gram-negative bacteria.

Type 4 collagen: A protein with a less distinct fibrillar form, characteristic of basement membranes.

Vancomycin: An antibiotic with activity against most gram-positive organisms.

Vegectomies: Surgical removal of endocarditis vegetations from a valvular surface.

Vegetations: Growth consisting of fused platelets, fibrin, and other bacteria adherent to a heart valve or other vascular structure.

HISTORICAL PERSPECTIVE

The first descriptions of infection of the heart valves in humans appeared over 300 years ago (1). Riveriere described autopsy findings associated with endocarditis in 1723, and Morgagni provided classical descriptions in 1761. In 1806, Jean Nicolause Corvisart first used the term *vegetations* to describe the characteristic macroscopic excrescences that are typically seen in patients with IE (2). During the next 75 years physicians such as Laennec, Bouillaud, Charcot, and Virchow described many of the clinical and pathologic features of IE, even though recognition of the relationship between microbes and this disease was delayed until the birth

of microbiology in the latter part of the nineteenth century. Rosenow (3) and Luschka (4), among others, thought microbes infected the valves by invading what was the network of capillaries that existed within the valves. It was not until 1937 that Gross (5) concluded that heart valves were avascular structures and the previously observed capillary network was merely a function of an inflammatory response. Subsequently, experiments by investigators such as Rosenbach, Wyssokowitsch, and Weichselbaum led to the realization that most patients with IE had preexisting damage to their heart valves and that the initiating event was the entry of microbes into the bloodstream from a site of local infection or a mucosal surface (2).

Through a series of three famous Goulstonian Lectures in 1885, William Osler was the first person to explain the clinical features of endocarditis in a clear and precise manner. He identified four cardinal manifestations of endocarditis: the presence of persistent bacteremia, the presence of active valvulitis, the occurrence of large vessel emboli, and immunologic vascular phenomena (6). These manifestations remain the cornerstones of clinical diagnosis to this day. Osler also coined the term *mycotic aneurysm* to describe the focal endarteritis that may complicate endocarditis (6). He not only noted emboli to multiple internal organs, such as the brain, spleen, kidneys, and retina, he also described “small swollen areas, some the size of a pea, others a centimeter and a half in diameter, raised, red, with a whitish spot in the center. . . . The commonest situation is near the tip of the finger.” These areas have been known as *Osler’s nodes* ever since (7).

The clinical features and morbid anatomy of endocarditis were extensively studied in the preantibiotic era of the twentieth century (6,8). Perhaps Soma Weiss reported the most famous early case. The patient was a medical student who had chronic rheumatic heart disease and then developed *Streptococcus viridans* endocarditis (9). In his diary, the budding physician noted clubbing of his fingernails followed by a host of peripheral embolic phenomenon. The diary describes his emotional reaction to the realization he has endocarditis. On discovering the cutaneous manifestations of the disease, he turned to his sister-in-law and proclaimed, “I shall be dead in 6 months.” His declaration was prophetic.

IE was invariably fatal until the discovery of penicillin and the subsequent development of other beta-lactams and antimicrobial agents. Thereafter, steady incremental advances in cardiac surgery and innumerable improvements in the technology of medical care collectively have had an enormous impact on the clinical management of this disease. During the past 15 years, new diagnostic methods such as transthoracic echocardiography and TEE have improved and simplified the diagnosis and management of endocarditis. Unfortunately, common causes of endocarditis such as enterococci and viridans streptococci have acquired resistance to standard antimicrobial agents. Clinicians who treat this potentially lethal, yet often curable, disease need to be aware of these developments and the fact that IE will remain a disease in evolution.

ANATOMIC CONSIDERATIONS

Vegetations in patients with preexisting valvular lesions are usually located on the atrial surface of incompetent atrioventricular valves or the ventricular surfaces of incompetent semilunar valves. This is likely because of the fact that these surfaces are subjected to injury from regurgitant jets. In patients with ventricular septal defects, vegetations tend to occur on the orifice of the defect, on the right ventricular side of the opening, and secondarily on the tricuspid and pulmonic valves (10). Vegetations may occasionally localize on the chordae tendineae of the anterior leaflet of the mitral valve in patients with aortic insufficiency. Patients with mitral regurgitation may also develop a vegetation (MacCallum’s patch) on the wall of the left atrium where the regurgitant jet strikes the atrial wall and results in endocardial thickening (Fig. 25.1).

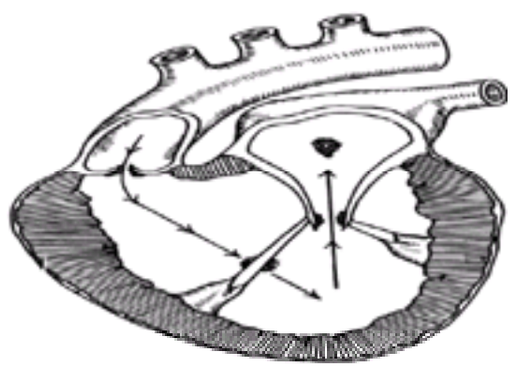

FIGURE 25.1 Sites of high-velocity streams where endocardial injury occurs in mitral and aortic insufficiency. (From Robard S. Blood velocity and endocarditis. *Circulation* 1963;27:24, with permission.)

The source of infection in some patients with endocarditis may be clinically evident (e.g., an infected vascular catheter, a dental abscess, or an infected skin lesion), but in many patients, there is no history of an antecedent localized infection. In most such instances, the source is presumed to be from minor trauma to the oropharyngeal, gastrointestinal, or genitourinary mucosa.

Endocarditis in injection drug users is dominated by one pathogen: *S. aureus*. *S. aureus* is known to have a predilection for normal as well as abnormal cardiac valves (11). This phenomenon may explain why the majority of injection drug–using patients with endocarditis has no known prior valvular disease (12). Endocarditis in injection drug users is presumed to result as a consequence of the trauma to heart valves from contaminating inorganic debris and bacteria injected along with the illicit drugs, from the paraphernalia used for drug injection, or via bacteria on the skin surface at the site of injection. Tricuspid valve involvement has been noted in 78%, mitral in 24%, and aortic in 8% of drug addicts with endocarditis (12). Simultaneous involvement of more than one valve may occur in approximately 20% of drug-abusing patients (13), and some of these infections are polymicrobial (14).

Approximately three-fourths of all patients with endocarditis have a preexisting structural cardiac abnormality at the time that endocarditis begins (15,16). During the period from 1938 to 1967, rheumatic heart disease was the underlying cardiac lesion in 39% of patients hospitalized with endocarditis at the Presbyterian Hospital in New York (17). In contrast, the authors of a large case series from Tennessee reported that only 6% of patients with endocarditis had underlying rheumatic cardiac lesions (16). Simultaneously, preexisting degenerative valvular lesions such as mitral valve prolapse (usually with coexistent mitral regurgitation) have become relatively more important as a predisposing cause for endocarditis. For example, preexisting mitral valve prolapse was the underlying cardiac lesion in 22% and 29% of cases of endocarditis in two case series (16,18). The estimated risk of endocarditis in patients with mitral valve prolapse and regurgitation has been estimated to be five to eight times higher than the normal population (19,20). However, mitral valve prolapse is a common abnormality and the overall risk of endocarditis in an individual with this lesion is quite small. Aortic valve disease (with stenosis, regurgitation, or both) is a predisposing cause for endocarditis in 12% to 30% of cases (21).

Congenital heart disease is now the underlying lesion in 10% to 20% of cases of endocarditis (10). The most common congenital heart lesions predisposing to endocarditis include bicuspid aortic valves, patent ductus arteriosus, ventricular septal defects, coarctation of the aorta, and tetralogy of Fallot. Unlike most other congenital defects, secundum atrial septal defects are not associated with an increased risk (21).

A succession of new surgical techniques for correction of congenital and acquired valvular lesions has affected the distribution of cardiac abnormalities now seen in patients with infective endocarditis (IE). The risk of endocarditis in patients with mechanical or bioprosthetic valves is similar. In a multicenter follow-up study of over 1,000 patients who were randomized to receive mechanical or bioprosthetic cardiac valves, the overall rate of prosthetic valve endocarditis was similar in both groups (0.8 cases per year of follow-up) (22). Duration of follow-up averaged 7.7 years; the cumulative percentage of patients who developed prosthetic valve endocarditis was 5.8% (22). However, other authors have suggested that mechanical prosthetic valves are more susceptible to endocarditis initially, whereas after 1 year, bioprosthetic valves are more likely to develop endocarditis (23,23a). In another study, endocarditis was more common after 11 years in patients with mechanical valves than in patients with bioprosthetic valves (23b).

A limited amount of data exists on the risk of endocarditis in patients with defined cardiac lesions. In a recent study in which 2,401 patients with congenital heart lesions were followed prospectively for a total of 40,855 days, the overall incidence of endocarditis was 135 cases per 100,000 person-years. The highest rates of endocarditis occurred in patients with aortic stenosis (4.8% of 462 cases, or 271 cases, per 100,000 person-years) and with ventricular septal defects (2.4% of 1,347 cases, or 145 cases, per 100,000 person-years). The lowest rate of endocarditis was observed in patients with pulmonic stenosis; only 1 of 592 patients developed endocarditis during the follow-up period (24). Horstkotte estimated that the risk of infective endocarditis in patients with aortic regurgitation was approximately twice as high (73 per 100,000 person-years) (25). The peak gradient across the aortic valve has been linked with the risk of infective endocarditis: The higher the gradient, the higher the risk of developing endocarditis (24).

A history of endocarditis is an additional important predisposing cause for endocarditis. Recurrent endocarditis occurred in 4.5% of patients in a follow-up study of a large cohort of patients who survived their initial episode of endocarditis (26). Other studies have reported rates of recurrence of endocarditis ranging from 2.5% to 9.0% (27). Also, not surprisingly, prosthetic valve endocarditis occurs more frequently when the original indication for the valve replacement was active endocarditis

(28).

Other uncommon but notable predisposing causes for endocarditis include pregnancy (10), arteriovenous fistulas used for hemodialysis (29), the use of central venous and pulmonary artery catheters (30), the presence of peritoneovenous (LeVeen) shunts for the control of intractable ascites (31), and the use of ventriculoatrial shunts for the management of hydrocephalus (32). In addition, patients with ulcerative lesions of the colon caused by carcinoma or inflammatory bowel disease have a poorly understood predilection to develop endocarditis caused by *S. bovis* (33,34). Infective endocarditis has also been reported in patients undergoing liver, heart, and heart–lung transplantation (35).

A number of cases of endocarditis in patients with human immunodeficiency virus (HIV) have also been reported (36). Some patients with HIV and endocarditis have had infection with unusual organisms such as *Salmonella* and *Listeria* (37,38). Although one study suggested that HIV infection was an independent risk factor for IE in injection drug abusers (39), the results of another study of a large cohort of injection drug users found no evidence that supported this concept (37). Cocaine use may be an additional risk factor for IE in injection drug users. In a study of a large number of injection drug users with fever, those who used cocaine were significantly more likely to have endocarditis (40).

PATHOPHYSIOLOGY

The endothelial lining of the heart and its valves is normally resistant to infection with bacteria and fungi. Experiments in animal models have demonstrated that a sequence of interrelated events must occur before microbes can establish an infective nidus or vegetation on the endocardium. Although a few highly virulent organisms such as *S. aureus* are capable of infecting normal human heart valves, the initial step in the establishment of a vegetation is injury to the endocardium followed by focal adherence of platelets and fibrin. This sterile platelet–fibrin nidus, in turn, becomes infected by microorganisms circulating in the bloodstream from a distant source of focal infection or as a result of a transient bacteremia from a mucosal or skin source (41,42).

Following colonization of the platelet–fibrin aggregate, microbial growth results in the secondary accumulation of more platelets and fibrin until a macroscopic excrescence or vegetation is present. The culmination of this process is mature vegetation consisting of an amorphous collection of fibrin, platelets, leukocytes, red blood cell debris, and dense clusters of bacteria. The surface of most vegetations consists of fibrin and scant numbers of leukocytes. Clumps of bacteria, histiocytes, and monocytes are usually found deep within the vegetation. Giant cells containing phagocytic bacteria may be found in some vegetations. Extremely high concentrations of bacteria (e.g., 10^9 to 10^{11} bacteria per g of tissue) may accumulate deep within vegetations. Some of these bacteria exist in a state of reduced metabolic activity. Following therapy and during the process of healing, capillaries and fibroblasts appear within vegetations, but without treatment, vegetations are avascular structures.

Infectious endocarditis of aortic valve. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Vegetations often prevent proper valvular leaflet or cusp coaptation, resulting in worsening valvular incompetence and congestive heart failure (43). Vegetation growth may result in leaflet perforation that can manifest as acute congestive heart failure (44). Patients with mitral or tricuspid valve vegetations may develop chordal rupture when infection progresses beyond the valve orifice. Extension of infection may also occur into surrounding structures such as the valve ring, the adjacent myocardium, the cardiac conduction system, or the mitral-aortic intravalvular fibrosa (45). Rarely, cavitation of periaortic abscesses may occur into the adjacent aortic wall, resulting in the formation of a diverticulum or aneurysm. Even more rarely such aneurysms may perforate into surrounding structures resulting in aortic-atrial or aortic-pericardial fistulae (44).

Endocarditis on prosthetic valve tissue differs from native valve endocarditis in that infection commonly extends outside the actual valvular apparatus, resulting in valvular dehiscence, abscess formation, and myocardial invasion (46) (Fig. 25.2). Endothelial cell proliferation overgrowing the valvular cuff of the bioprosthesis may provide a nidus that explains this propensity for valvular ring involvement (28). In addition, bioprosthetic valves are vulnerable to infection of the leaflets themselves (47).

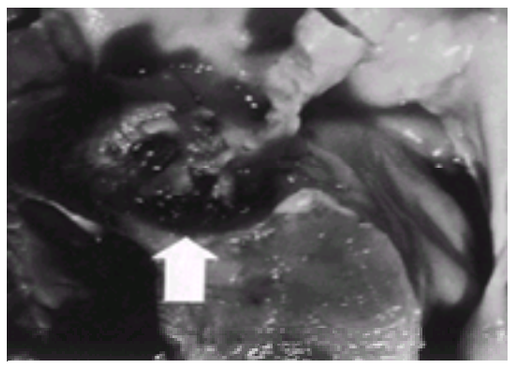

FIGURE 25.2 Pathology of a staphylococcal abscess (*arrow*) involving the annulus of the mitral valve. (From Kissane JM. Staphylococcal infections. In: Connor DH, et al., eds. *Pathology of infectious diseases.* Vol 1. Stamford, CT: Appleton & Lange, 1997:811, with permission.)

The stress placed on bioprosthetic valves is thought to be greater in the mitral position than aortic, possibly accounting for the observation that mitral bioprostheses are more prone to endocarditis than aortic bioprostheses (48). Prosthetic valvular infection may in turn result in secondary valvular thrombosis.

Microbial adherence is a crucial early event in the pathogenesis of endocarditis. The mechanism of this adherence is poorly understood and may vary among different organisms. Bacterial adherence to a platelet–fibrin nidus involves a complex interaction of components of the microbial cell wall. Bacteria such as *S. aureus*, viridans streptococci, enterococci, and *P. aeruginosa* adhere more avidly to excised canine heart valves *in vitro* than species such as *E. coli*, which rarely causes endocarditis (49).

The relative frequency with which different species of bacteria cause endocarditis in humans is directly correlated with the ability of these same organisms to cause endocarditis in an experimental rabbit model (50). One explanation for these phenomena may be related to the interaction between dextran in the cell wall of gram-positive organisms and the valvular endothelium. The amount of dextran production of streptococci grown in broth is proportional to the intrinsic ability of various species of streptococci to cause endocarditis in an experimental rabbit endocarditis model (51). A second explanation may be the intrinsic binding affinity of the organisms to fibronectin. Mutants of *S. aureus* with decreased ability to bind fibronectin have less ability to cause endocarditis in a rat endocarditis model than parent strains with higher binding affinity to fibronectin (52).

Components found in damaged endothelium, platelet–fibrin aggregates, or both that may mediate bacterial adherence include fibrinogen, laminin, and type 4 collagen. Bacterial platelet interactions also appear to be important in the pathogenesis of endocarditis, both in the induction of a vegetation and in its enlargement after colonization of a fibrin–platelet nidus has occurred.

Preexisting antibodies against certain bacteria may increase the predisposition to IE in some instances. For example, horses that are given repetitive injections of live pneumococci often spontaneously develop pneumococcal endocarditis (53). However, in some animal models of endocarditis, preexisting high antibody levels increase the median infective dose required to induce endocarditis (54).

It is virtually impossible to induce endocarditis in experimental animals unless the valvular endocardium is first traumatized with a polyethylene catheter inserted into the right or left side of the heart (41). If bacteria such as viridans streptococci, which have the inherent ability to adhere to fibrin–platelet matrices on damaged endocardium, are injected into animals with prior catheter-induced valvular lesions, vegetations predictably develop within a few days at the sites of valve injury. Similar lesions probably occur naturally in bacteremic humans with congenital or acquired cardiac lesions that induce constant endocardial trauma through regurgitant flow or high-pressure jets of blood through stenotic lesions.

Vegetations tend to occur when blood travels from an area of high pressure through a narrow orifice into an area of lower pressure. The explanation for this phenomenon can be deduced from *in vitro* experiments that demonstrate the physics of turbulent flow. If nebulized *Serratia marcescens* are injected into an air stream passing through an agar-coated Venturi tube, the highest concentration of bacteria is found in the low-pressure area immediately distal to the narrowing (55). A similar phenomenon is presumed to occur when bacteria circulate in the blood. The propensity for vegetations to form at specific sites may also relate to a decrease in lateral pressure downstream from the regurgitant flow, which causes a decrease in the perfusion of the intimal lining at these sites (49).

CLINICAL PROFILE

Classification of Infective Endocarditis

Various terms have been used to describe the many forms of endocarditis encountered by clinicians. The term *IE* should now replace the older terms *subacute* and *acute bacterial endocarditis* for several reasons. First, not all cases are caused by gram-positive and gram-negative bacteria; fungi, rickettsia, and *Chlamydia* may also cause endocarditis. Second, presentation and duration of endocarditis are not easily categorized. Although rapidly progressing (acute) endocarditis is usually due to *S. aureus*, the clinical utility of separating cases on the basis of the activity of the presentation is limited because pathogens such as *S. aureus* and streptococci can cause either fulminant or indolent disease in different patients. However, there is clinical utility in separating cases as to whether there is involvement of native or prosthetic valves; for in the latter group, the causative organisms vary if the infection occurs early (during the first 60 days after surgery) or late. In addition, right-sided endocarditis in intravenous drug users results in such a characteristic illness that it is useful to separate it from infection solely involving the left-sided structures of the heart. Although heart valves are the usual sites of infection, vegetations may also appear on pacemaker leads (56), in the mural endocardium (57), in arteriovenous shunts or fistulae (58), in vascular structures such as a patent ductus or a Blalock-Taussig shunt (59), or in coarctation of the aorta, or even in intracardiac masses such as myxomas (60).

Infective endocarditis is a highly variable disease. Its clinical course is dependent on numerous factors, including the causative pathogen, the age and underlying health of the patient, and the nature and extent of the underlying valvular disease. Decisions concerning clinical management are directly related to an accurate diagnosis. Underdiagnosis can lead to catastrophe. Overdiagnosis can lead to weeks of unnecessary therapy at great cost and risk of drug-related toxicity. Distinguishing between IE and an alternate focus of infection in a bacteremic patient with underlying heart disease can be extremely difficult. To help distinguish endocarditis from other bacteremic syndromes, consistent definitions are important. Clinical research concerning the natural history, complications, epidemiology, and treatment outcomes of endocarditis all depend on the accurate identification of patients with this disease. Definitions that are specific but not sensitive may lead to biased conclusions, as can definitions that are sensitive but not specific.

Petersdorf and Pelletier (61) developed the first diagnostic criteria for IE. Their schema classified cases as definite, possible, and probable. Surgical or autopsy confirmation was required to classify a case as definite. Designation of a case as probable or possible was based on the presence of one or more of the following criteria: predisposing valvular disease, bacteremia, the presence of emboli, and the presence of indirect evidence of an active endocardial disease process such as a new regurgitant murmur. In practice, many patients with presumed endocarditis did not meet these criteria. Thus, although this classification was reasonably specific, it lacked sensitivity.

In 1981, the Beth Israel criteria were proposed by von Reyn and colleagues (62). Four diagnostic categories were created: definite, probable, possible, and rejected. As in the Petersdorf and Pelletier schema, histologic or microbiologic confirmation either at autopsy or at surgery were required to categorize a case as definite. Other criteria included the presence of (a) persistent bacteremia, (b) predisposing valvular heart disease, (c) vascular phenomena such as emboli or splinter hemorrhages, and (d) evidence of active endocardial pathology such as a new regurgitant murmur. Echocardiography was not used as a diagnostic criterion nor was the use of illicit intravenous drugs considered to be a predisposing risk factor for endocarditis. The Beth Israel criteria were widely used during the following decade, but despite modifications by various investigators, this classification system still lacked sufficient sensitivity.

In 1994, investigators at Duke University developed a new diagnostic schema that addressed weaknesses in the Beth Israel classification: The Duke criteria used echocardiography as a major criteria for diagnosis, expanded the list of predisposing heart conditions to include intravenous drug use, and devised a system by which cases could be classified as definite using purely clinical criteria (63). The pathologic criteria used in the Duke classification were virtually identical to those proposed by Pelleteir, Petersdorf, and von Reyn. Cases were classified as definite in the Duke schema using major and minor criteria in a manner analogous to the Jones criteria for rheumatic fever (Table 25.1 and Table 25.2). In 2000, investigators from the Duke Endocarditis Service further modified the Duke criteria.

Definite
Pathologic criteria
Microorganism: demonstrated by culture, in a vegetation at surgery, from an embolized vegetation, or from an intracardiac abscess
Pathologic lesions: vegetations or intracardiac abscess present and confirmed by histology showing active endocarditis
Clinical criteria, using specific definitions listed in Table 25.2
Two major criteria, or
One major and three minor criteria, or
Five minor criteria
Possible
Findings consistent with infective endocarditis that fall short of *definite*, but not *rejected*
Rejected
Firm alternate diagnosis for manifestations of endocarditis, or
Resolution of manifestations of endocarditis, with antibiotic therapy for 4 d or less, or
No pathologic evidence of infective endocarditis at surgery or autopsy, after antibiotic therapy for 4 d or less

TABLE 25.1 DUKE CRITERIA FOR THE DIAGNOSIS OF INFECTIVE ENDOCARDITIS

TABLE 25.2 DEFINITIONS OF TERMINOLOGY USED IN THE DUKE CRITERIA FOR INFECTIVE ENDOCARDITIS

Several studies have compared the clinical utility and validity of the Duke criteria with those of von Reyn et al. (63,64,65,66 and 67). In each of these studies, a substantial number of cases that were considered as rejected when the Beth Israel criteria were applied prospectively were simultaneously classified as clinically definite by the Duke criteria (67). The negative predictive value of the Duke criteria was subsequently assessed in a follow-up study of patients considered to be rejected for a diagnosis of IE. None of 52 patients who had been considered as rejected by the Duke criteria had proven IE in follow-up (68). In another study of 100 cases of acute fever or fever of unknown origin, the specificity of the Duke criteria was found to be 99% (69).

The utility of the Duke criteria was subsequently assessed in patients with prosthetic valve endocarditis, pediatric patients, and hospitalized patients. Modifications (such as the use of serologic criteria for diagnosing endocarditis caused by *Coxiella burnetii*) have been adopted (70), and it is likely that further modifications will occur in the future (67). However, the Duke schema is currently the most sensitive and specific diagnostic criteria available and is particularly useful in diagnosing endocarditis in patients with *S. aureus* bacteremia, those with right-sided endocarditis, and those with negative blood culture results (67).

Epidemiology of Infective Endocarditis

An estimated 10,000 to 15,000 new cases of endocarditis are diagnosed in the United States each year (71). However, the precise incidence of IE is difficult to ascertain because case definitions have varied from decade to decade, among different authors, and among different medical centers. Also the incidence of predisposing conditions such as rheumatic heart disease and injection drug use has varied over time and between different areas. For example, a prospective study of the incidence of IE among patients admitted to 51 hospitals in Philadelphia and the surrounding area estimated that the incidence of endocarditis was 11.6 cases per 100,000 person-years (72). The incidence of endocarditis in Olmsted County, Minnesota, in a similar study during the period from 1950 to 1981, was 3.2 cases per 100,000 person-years (15). Other studies have reported incidence rates ranging from 0.6 to 6.0 cases per 100,000 person-years (73,74 and 75). Men predominate in most case series of endocarditis, with male to female ratios ranging from 2:1 to 9:1 (76,77). Although 50% to 70% of children less than 2 years old who develop endocarditis have no obvious underlying cardiac disease (78), most children over the age of 2 with endocarditis have coexistent congenital heart disease. Thus, the overall incidence of endocarditis in children and young adults is low (15).

Despite the discrepancies in incidence rates reported by the studies cited previously, there is general agreement that new trends in the epidemiology of endocarditis have occurred during the past 30 years. Most of these changes relate to the numbers and types of susceptible hosts rather than to shifts in the virulence of the infecting microorganisms. In addition, the age distribution of endocarditis has clearly changed. Endocarditis has increasingly become a disease of the elderly. More than one-half of all endocarditis cases in the United States now occur in persons over the age of 60, and the median age of patients has increased steadily during the past 40 years (79). The proportion of cases that present with an indolent course and the proportion caused by streptococci have declined, whereas simultaneous increases have occurred in the proportion of cases caused by *S. aureus*, fungi, and gram-negative bacilli.

The increase in the incidence of injection drug use has also had a major effect on the overall incidence of endocarditis. For example, the incidence of IE in injection drug users in Philadelphia and the surrounding areas has been estimated to be 5.3 cases per 100,000 person-years, accounting for nearly one-half of all recognized cases (72). Similar proportions of cases related to injection drug use were seen in a study from a hospital in Los Angeles (64). Other authors have estimated the incidence of IE in intravenous drug users may be 30 times higher than the general population and four times higher than the risk of endocarditis in young adults with rheumatic heart disease (80). In some areas of the United States, drug addiction is the most common predisposing cause for IE in patients less than 40 years old (81).

More than 100,000 heart valves are implanted annually in the United States (82). The presence of prosthetic valves as an important predisposing cause of endocarditis is substantial and is likely to increase in future years. Although still an uncommon disease, prosthetic valve endocarditis makes up a small but important segment of all cases of endocarditis in the United States. The overall incidence of prosthetic valve endocarditis in the Philadelphia area was estimated to be 0.9 cases per 100,000 person-years (72). Prosthetic valve endocarditis develops in 1% to 4% of prosthetic valve recipients in the first year following valve replacement and in approximately 1% of recipients annually thereafter (22,71).

Advances in medical technology have paradoxically resulted in the appearance of a new form of endocarditis (nosocomial endocarditis) that was extremely rare 25 years ago (68,83). Nosocomial endocarditis is usually a complication of bacteremia induced by an invasive procedure or a vascular device and now accounts for nearly 10% of cases of endocarditis in some areas (68,72). Nosocomial endocarditis is a particularly difficult problem to diagnose and manage in patients with prosthetic heart valves. In a multicenter study of patients with nosocomial bacteremia and underlying prosthetic heart valves, 18 of 171 (11%) developed prosthetic valve endocarditis after bacteremia occurred (84). In a review of nosocomial endocarditis in patients in intensive care units, 21 of 22 patients developed endocarditis as a consequence of bacteremia related to a medical or surgical procedure. The overall mortality was 68% (84a).

Laboratory Diagnosis

Infective endocarditis is usually a “syndrome diagnosis” based on the presence of multiple findings rather than on a single definitive test result. The diagnosis of IE is usually obvious when a patient has numerous positive blood culture results in the presence of a well-recognized predisposing cardiac lesion and the absence of infection elsewhere.

The bacteriologic diagnosis of IE is facilitated by the relative constancy of bacteremia originating from vegetations. Bacteria are discharged from vegetations at a relatively constant rate rather than haphazardly (85). A minimum of three blood cultures should be obtained. If the tempo of illness is subacute, and the patient is not critically ill, it is reasonable and often preferable to delay therapy for 1 to 3 days awaiting the results of blood cultures and other diagnostic tests. If the patient is acutely ill, three blood cultures should be obtained at least 1 hour apart before beginning empiric therapy. The constancy of bacteremia in patients with endocarditis makes it unnecessary to await the arrival of a fever spike or chills to obtain blood cultures; in addition, prior studies may have shown that venous blood culture results give approximately the same yield as arterial blood cultures.

Many patients with bacterial endocarditis have low-grade bacteremia (i.e., 1 to 10 colony-forming units per mL of blood) (86); thus, a minimum of 10 mL, and preferably 20 mL, should be obtained from adults and 0.5 to 5.0 mL from infants and children. Blood cultures inoculated with at least 5 mL of blood have a significantly higher detection rate for bacteremia than bottles inoculated with less than 5 mL of blood (92% vs. 69%; $p < .001$). The estimated yield of blood cultures in bacteremic adults increases approximately 3% per mL of blood cultured (87).

Not all microorganisms have the same propensity to cause endocarditis. For example, organisms such as viridans streptococci and *S. aureus* are more likely to cause endocarditis than are gram-negative rods such as *E. coli* and *Proteus*. This distinction has clinical importance. For instance, the Duke Criteria distinguishes among the type of organism isolated from blood cultures. The following organisms are considered to be *likely causes* of IE when isolated from two or more blood cultures: *S. aureus*, viridans streptococci, and enterococci (if the infection was acquired in the community and not nosocomially).

The setting in which bacteremia occurs also has an effect on the probability that an individual patient will have endocarditis. For example, patients who present with community-acquired enterococcal bacteremia are significantly more likely to have endocarditis than are patients who develop enterococcal bacteremia while hospitalized for another cause. The probability of endocarditis in a given patient with streptococcal infection also varies by the infecting species. For example, *S. sanguis* bacteremia is more often indicative of endocarditis than is bacteremia caused by *S. milleri* (also known as *S. anginosus*). Also, bacteremias to groups A, B, and C streptococci are seldom associated with IE, whereas bacteremia caused by group G streptococci is often indicative of the presence of endocarditis (88). The risk of endocarditis in patients with *S. aureus* bacteremia (regardless of source) is particularly high, and all such patients should be clinically evaluated for this possibility.

The interpretation of positive blood culture results in patients with suspected endocarditis is confounded by the fact that false-positive results occasionally occur despite the most exacting techniques for collection and processing. Each set of cultures should be obtained from separate venipuncture sites in order to minimize the risk of misinterpreting contaminating skin flora as pathogens.

False-positive results are likely to be present when organisms such as *Propionibacterium* species, *Corynebacterium* species, and *Bacillus* species and coagulase-negative staphylococci are recovered from a single blood culture or a minority of blood culture bottles. As all of these organisms are capable of causing endocarditis, it is important to determine if the bacteremia is persistent. Persistent bacteremia is present if (a) positive blood culture results for an organism likely to cause endocarditis are obtained from two samples collected more than 12 hours apart, or (b) if (for all other organisms) all of three or a majority of four or more separate blood culture results are positive, and if the first and last samples are collected at least 1 hour apart (63).

Culture results may remain negative in 2% to 5% of patients with IE even when the utmost care is taken in obtaining the proper number and volume of blood cultures (89). Certain organisms (e.g., *Coxiella burnetii* and *Tropheri whippelii*) with the occasional ability to cause endocarditis will not grow using cell-free media; other organisms (e.g., *Brucella*, *Mycoplasma*, *Chlamydia*, *Histoplasma*, *Legionella*, and *Bartonella*) will not grow unless special media or microbiologic methods are employed; and still other organisms (e.g., *Corynebacterium* species, *Haemophilus* species, *Actinobacillus, Cardiobacterium, Eikenella*) will not grow unless blood cultures are incubated for 7 to 21 days. The microbiology laboratory should be notified when such organisms are suspected, as most laboratories routinely discard

blood cultures when there has been no growth after 7 days of incubation.

Although unusual or fastidious organisms are an important consideration when patients with clinical findings of endocarditis are found to have negative routine blood culture results, the most common cause for negative blood culture results in patients with IE is prior antimicrobial therapy. Thus, it may be necessary to delay the institution of therapy for several days for such patients while additional blood cultures are obtained.

A total of three blood cultures is usually adequate to diagnose IE in most cases. In a study of 206 cases of endocarditis, all blood culture results were positive in 91% of the patients. In patients with streptococcal endocarditis, the first blood culture result was positive in 96% of cases and one of two culture results was positive in 98% of patients. In endocarditis, with organisms other than streptococci, the first blood culture obtained was positive in 82% of cases and one of two was positive in 100% of patients (86).

The white blood cell count is rarely helpful in making a diagnosis of endocarditis. Some patients with streptococcal endocarditis may have normal white blood cell counts when they seek medical attention. In contrast, most patients with staphylococcal endocarditis have leukocytosis (90).

The utility of other laboratory tests in the diagnosis of endocarditis is limited. An elevated erythrocyte sedimentation rate, an elevated level of C-reactive protein, or both are usually present, but these findings alone have little specific diagnostic or monitoring value. Most patients with endocarditis quickly develop a normochromic normocytic anemia, but this finding is equally nonspecific. Elevated levels of serum globulins, the presence of cryoglobulins and circulating immune complexes, hypocomplementemia, and false-positive serologic test results for syphilis may also occur in some patients with IE, but none of these findings is diagnostic or particularly helpful by itself. However, an elevated level of rheumatoid factor may occasionally be useful in diagnosis, particularly when the duration of illness is greater than 6 weeks (91). When present in individuals without a known prior rheumatologic disorder, this finding is considered to be one of the six minor criteria in the Duke Endocarditis Service diagnostic schema (63).

Most patients with endocarditis have an abnormal urinalysis result. Urinary sediment examination may disclose microscopic or gross hematuria, proteinuria, or pyuria. Microscopic hematuria and mild proteinuria occur in many cases and are often found in the absence of other renal complications (48). Like the erythrocyte sedimentation rate, all of these urinary findings lack specificity. However, the presence of red blood cell casts and a low serum complement level may be an indicator of immune-mediated glomerular disease. When present, this uncommon finding is an important minor diagnostic criterion (63).

Electrocardiography should be part of the initial evaluation of all patients with suspected endocarditis, even though this test rarely shows diagnostic findings. Besides the presence of changes suggestive of ischemia or infarction, the electrocardiogram may also reveal the presence or new appearance of heart block, an important clue to extension of infection to the valve annulus and adjacent conduction system. The presence of new prolongation of the PR interval in a patient with endocarditis, if unrelated to drug therapy or recent surgery, is virtually diagnostic of the presence of a ring abscess.

Chest radiography occasionally reveals important diagnostic clues. For example, patients with tricuspid valve endocarditis often present with radiographic evidence of septic pulmonary emboli. In such cases, there may be a few or multiple focal lung infiltrates. Some of these infiltrates may reveal central cavitation. Rarely, chest radiography discloses calcification in a *native* cardiac valve that may in turn raise the suspicion of endocarditis in a febrile patient.

Since its introduction in 1973, echocardiography has greatly simplified the process of diagnosing IE (44). Echocardiography is often of crucial importance in detecting a vegetation that is usually defined as a mass of echoes of distinct echogenicity from the adjacent valve >5 mm in its largest dimension with independent motion from the valve itself (92) (Fig. 25.3). Echocardiography should be obtained in all patients suspected of having endocarditis. Echocardiography not only may confirm the presence of vegetations in the setting of bacteremia, but it may also provide important physiologic information regarding right and left ventricular function and an estimate of valvular obstruction or regurgitation severity. Mitral valve preclosure in the setting of acute aortic insufficiency implies a marked increase in left ventricular diastolic pressure and the likely need for more urgent intervention (93) (*e*Fig. 25.3.1).

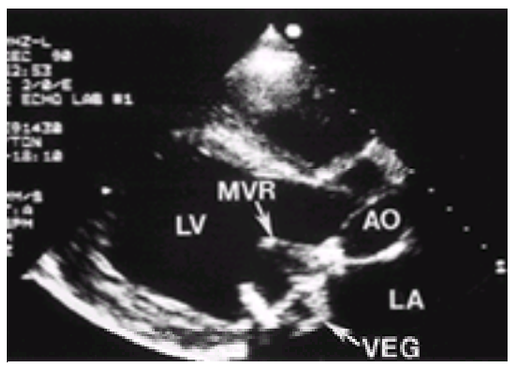

FIGURE 25.3 A vegetation (VEG) is shown on a prosthetic porcine mitral valve. The large mobile vegetation is noted to prolapse into the left atrium (LA). AO, aorta; LV, left ventricle; MVR, mitral valve replacement. (Courtesy of Dr. Thomas Ryan, Duke Medical Center.)

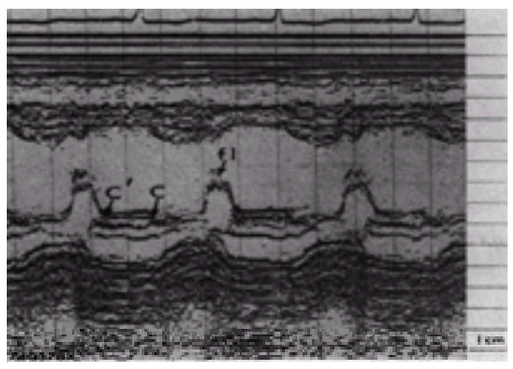
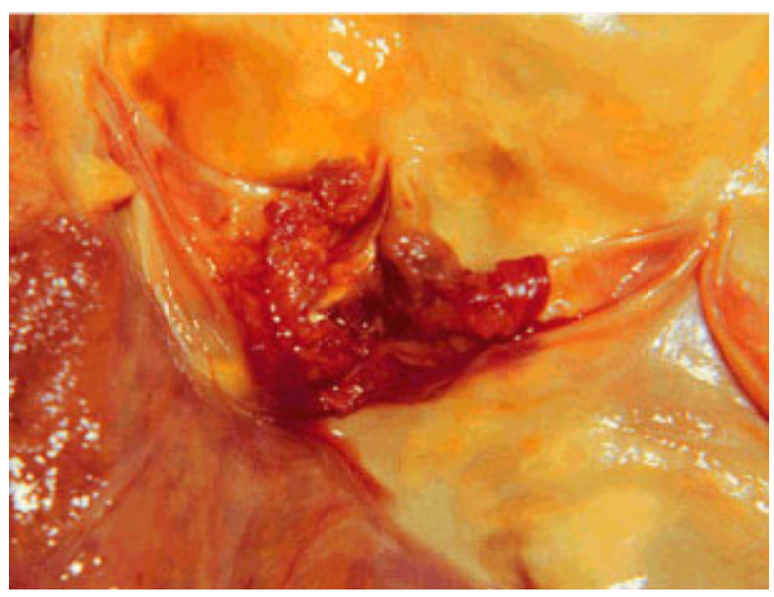
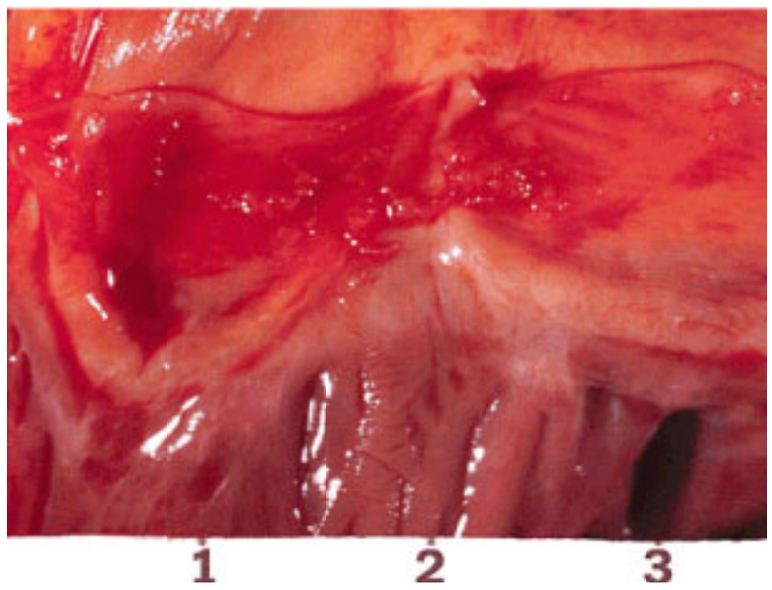


***e*FIGURE 25.3.1** Mitral valve preclosure in acute aortic insufficiency. The M-mode echocardiography allows timing of the mitral closure with the QRS. C, normal closure point; C”, early closure; fl, fluttering of the mitral valve from the aortic regurgitant jet. (From Feigenbaum H, ed. *Echocardiography*, 5th ed. Philadelphia: Lea & Febiger, 1994:289, with permission.)



Verrucal endocarditis of the aortic valve. Multiple vegetations are seen on the aortic valve cusps in this patient with subacute bacterial endocarditis.



Marantic (nonbacterial) endocarditis of the pulmonic valve. Multiple vegetations are seen on the pulmonic valve in this patient with no bacterial growth from multiple blood cultures.

Video 25.1 Intraoperative 90-degree transesophageal echo of a patient with a St. Jude mitral valve prosthesis with a stuck metallic leaflet due to a small clot. (The immobile leaflet is to the right of the screen; the left leaflet moves normally.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Three major incremental advances have occurred in echocardiographic technology in the past 25 years: (a) the advent of two-dimensional echocardiography, (b) the institution of color flow Doppler technology, and (c) the introduction of TEE. M-mode echocardiography has now largely been replaced by two-dimensional echocardiographic methods. M-mode methods detect vegetations in approximately one-half of patients with IE. Although transthoracic two-dimensional echocardiography provides a remarkable improvement in visualizing spatial anatomic relationships compared with M-mode methods, the sensitivity of transthoracic two-dimensional echocardiography is still only approximately 60% (94,95). Furthermore, two-dimensional echocardiography is often of limited utility in the detection of vegetation in patients with obesity, emphysema, and chest wall deformities.

TEE, especially when biplane probes are used, has improved the rate of detection of vegetations on native valves to 90% to 95% (95,96,97,98,99 and 100) (*e*Fig. 25.3.2). TEE is particularly useful in visualizing right-sided heart structures and masses on pacemaker leads or intravenous lines and in visualizing abnormalities on the pulmonic valve (101,102). The superiority of TEE over transthoracic imaging methods is particularly important in the detection of small vegetations. However, the sensitivity of both methods is approximately equal when vegetations are ³5 mm in size (35). In a study of 112 patients with 114 episodes of endocarditis, all of whom underwent transthoracic and TEE, Roe and colleagues reported that the findings on TEE resulted in reclassification of 22 patients from possible to definite endocarditis. Three patients were reclassified from rejected to possible (102a).

Video 25.2 Color Doppler of a myxomatous mitral valve with *Streptococcus* endocarditis (*first video*) showing a large vegetation and perforation of the anterior mitral leaflet causing severe mitral regurgitation. Notice the large proximal convergence zone on the ventricular side of the base of the anterior mitral leaflet. **Second video:** intraoperative echo of a patient with infectious endocarditis with a large vegetation on the anterior mitral leaflet with a perforation at its base causing severe mitral regurgitation. The patient had myxomatous valve disease with mitral valve prolapse predisposing her to endocarditis. *This video must be viewed with QuickTime. ***e*FIGURE 25.3.2** Transesophageal echocardiography revealing large mobile vegetation (VEG, *long arrow*) on a native mitral valve (MV, *short arrow*). AO, aorta; LA, left atrium; LV, left ventricle. (Courtesy of Dr. Carolyn Donovan, Duke Medical Center.)

Transthoracic echocardiography in patients with prosthetic valve endocarditis often produces poor images, as shadowing of the echo beam may prevent adjacent structures from being adequately visualized and the mass effect from the prosthetic valve can obscure the identification of vegetations. As a result, transthoracic echocardiography has a sensitivity of only 35% for detecting vegetations in patients with prosthetic valve endocarditis.

TEE improves the sensitivity of detecting vegetations on prosthetic valves to up to 96% (103,104). TEE is especially useful in detecting ring abscesses or intracardiac fistulae (105,106,107,108 and 109). In one study of 44 patients with endocarditis complicated by perivalvular abscesses, transthoracic echocardiography identified only 28% of the abscesses, whereas TEE detected 87% (Fig. 25.4). Most such perivalvular abscesses communicate with the intravascular space (as evidenced by color flow turbulence observable within the lesion). These may be referred to as *pseudoaneurysms* by some. This phenomenon is not always evident, however. TEE is a particularly sensitive method for the detection of mitral regurgitation in the presence of mitral annular calcification or when a prosthetic mitral valve is present (110,111) (Fig. 25.5). The presence of spontaneous echo contrast in the atria of patients with endocarditis may imply a higher risk for systemic emboli in such patients (112).

VIDEO

Video 25.5 This is a long-axis 134-degree transesophageal view of a patient with prosthetic valve endocarditis of the aortic valve. Note the very large mobile mass or vegetation on the prosthesis accompanied by prosthetic stenosis and moderate insufficiency. The peak and mean pressure gradients across this valve were 90/27 mm Hg, and there was also a paravalvular abscess. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 25.6 The short-axis 56-degree transesophageal view demonstrating the very large vegetation attached to the Carpentier-Edwards aortic valve replacement involving both aortic stenosis and aortic insufficiency. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 25.7 Transesophageal 138-degree view showing the Carpentier-Edwards mitral valve replacement with thickened leaflets with multiple mobile echo densities consistent with vegetations and a clot in a patient with prosthetic valve endocarditis. The mean transesophageal gradient was 20 mm Hg on surface echo. Note the large left atrial thrombus to the right of the screen with significant spontaneous echo contrast in the left atrial cavity. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 25.8 Transesophageal 98-degree view demonstrating the markedly thickened and distorted leaflets of a Carpentier-Edwards mitral valve replacement with multiple mobile echo densities attached in a patient with prosthetic endocarditis. Note the restricted leaflet motion with a diminished orifice causing the mitral stenosis. In addition, there is a left atrial thrombus to the right of the screen. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 25.9 Transesophageal echo of a large tricuspid valve vegetation in a patient with infectious endocarditis. This patient was an intravenous drug user, which is common in patients with right-sided endocarditis. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

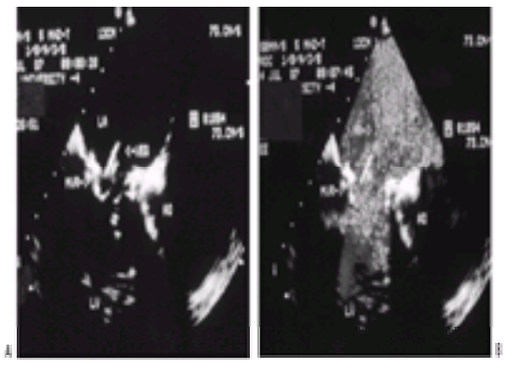

FIGURE 25.5 A: A linear vegetation (VEG) is shown on the St. Jude mitral valve. This was not visible by chest wall echocardiogram. **B:** Same view with color flow Doppler revealing marked mitral insufficiency. AO, aorta; LA, left atrium; LV, left ventricle; MVR, mitral valve replacement. (Courtesy of Dr. Joseph Kisslo, Duke Medical Center.)

Echocardiography cannot always differentiate between vegetations caused by active IE and abnormalities caused by other noninfectious valvular lesions such as those that occur in patients with malignancies or burns, or with valvular lesions associated with acute rheumatic fever, systemic lupus erythematosus, the antiphospholipid syndrome (113,114), or protein C deficiency (10,115). In addition, valvular thickening, valve aneurysms, ruptured chordae, benign leaflet nodules, suture material around a sewing ring (especially after mitral valve replacement), valvular thrombus, or pannus formation on valve structures may mimic vegetations. Although some experts believe that chronic (healed) vegetations cannot be differentiated from lesions caused by active valvular infection (92), other echocardiographers believe that active vegetations can be differentiated from chronic or healed vegetations using two-dimensional echocardiography (115a). The distinction may be subtle.

It is also important to emphasize that a negative transthoracic echocardiographic result does not eliminate the possibility that IE is present. In a study of 65 patients with clinical symptoms and signs of IE, in whom an initial TEE result was negative, an alternate diagnosis was made in 56 patients. However, 5 of the 65 patients were ultimately found to have IE by a repeat TEE in three of five, by pathologic findings, or a diagnostic clinical course (116).

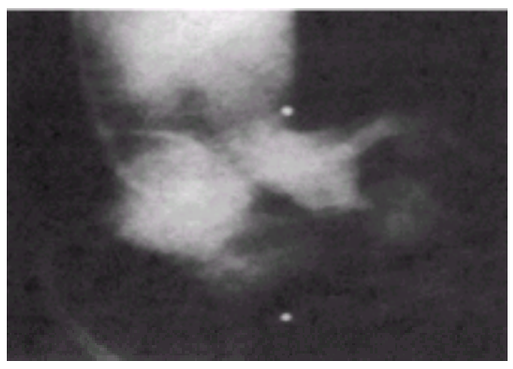
After endocardial lesions have been detected by echocardiography, their appearance during and after the completion of therapy is highly variable. The results of serial echocardiographic examinations done 3 to 16 months after the initial detection of the vegetations suggest that valvular lesions persist in approximately one-third of patients; in others, vegetations disappear during or after therapy; and rarely vegetations enlarge despite curative medical therapy (92). Thus, the presence of persistent vegetations should *not* be interpreted as indicative of persistent infection. Furthermore, neither the presence nor persistence of vegetations during or after therapy should, in itself, be a cause for clinical alarm (92,117).

It remains controversial as to whether the echocardiographic characteristics of vegetations are predictive of the risk of subsequent embolic phenomenon. A few studies have suggested that one or more of the following characteristics increase risk of emboli: size, appearance (e.g., pedunculated or sessile), and mobility (e.g., prolapsing or not) (118). Vegetations of large size (i.e., greater than 10 mm) have been associated with slower resolution during antimicrobial therapy and a greater incidence of embolism in some studies. The authors of other studies, however, have not been able to confirm the clinical value of assessing vegetation morphology in predicting such subsequent embolic events (119,120).

As a general rule, transthoracic echocardiography with Doppler flow studies should be the *initial study* performed in patients suspected of having endocarditis. However, if the clinical suspicion of endocarditis is high, a TEE may be obtained, as the initial study in selected patients. The TEE is often repeated during therapy if response to antimicrobials is inadequate, intracardiac complications are suspected, or both. Otherwise, it has been our practice to repeat the transthoracic echo Doppler (or TEE, if vegetations were not seen on the transthoracic) only at the completion of therapy.

Other imaging modalities such as gallium scanning (121,122), technetium-99m pyrophosphate scans (123), labeled antigranulocyte antibodies (124), technetium-99m labeled granulocytes (125,126), indium-111 labeled leukocytes (127), computed tomography (128), or magnetic resonance imaging (129,130) have been used to assess the presence of periaortic complications such as a ring abscess or emboli from a suspected cardiac source. Such tests are rarely clinically necessary, but they are occasionally of value in patients who cannot undergo TEE or in those whom echocardiography produces inconclusive results. Magnetic resonance imaging may be particularly useful in assessing embolic phenomenon to the central nervous system (CNS) (131).

The role of cardiac catheterization in the evaluation of patients with endocarditis remains controversial. Traditionalists have argued that intracardiac vegetations should not be crossed with intracardiac catheters; this view makes good sense, even though there are no data to confirm the danger of such maneuvers. Echocardiographic color flow Doppler methods that define the severity of regurgitation are helpful. However, it has been our experience that aortic regurgitation and mitral regurgitation often appear more severe using color flow Doppler methods than the estimates using contrast angiography. Thus, if the severity of aortic insufficiency or mitral regurgitation observed by Doppler methods is inconsistent with the clinical findings, then catheterization should be undertaken to clarify the degree of valvular competence. In addition, cardiac catheterization may occasionally be a useful tool to visual abnormal intracardiac anatomy or flow if these features are ambiguous or uncertain after use of routine clinical assessment and echocardiography (132). Aortography may reveal the presence and extent of a perivalvular abscess (eFig. 25.5.1) or fully outline fistulous channels in patients before surgical intervention.



***e*FIGURE 25.5.1** Aortography of large perivalvular ring abscess. The cavity is well seen from the contrast aortogram.

As endocarditis has progressively become a disease of the elderly, concomitant coronary artery disease is often present. It has become our practice to perform coronary angiography routinely in all patients over age 55 before surgery for endocarditis or in those at high risk for coronary artery disease based on their coronary risk factors. Coronary angiography may also be important to delineate coronary emboli from vegetations, if the clinical syndrome is suspected. In younger patients, the anatomic information provided by both transthoracic echocardiography and TEE usually provides adequate information to safely proceed to surgical repair or valve replacement without the need for invasive studies.

Explanted Carpentier-Edwards mitral valve regurgitation in a patient with severe infective prosthetic valve endocarditis. The patient had severe mitral stenosis due to the large vegetations on the prosthesis.

Clinical Manifestations

The clinical presentation of IE ranges from an illness characterized by subtle, chronic fatigue with low-grade fevers, weight loss, and malaise to one of abrupt fulminant acute pulmonary edema brought on by massive acute aortic regurgitation. The virulence of the infecting organism generally determines the acuteness of the presentation. However, the interval from onset of infection to onset of symptoms is usually short. Most patients with endocarditis develop symptoms within 2 weeks of the inciting bacteremia (133). Symptoms in staphylococcal endocarditis may even begin within a few days of the onset of infection.

A variety of nonspecific constitutional complaints may dominate the clinical presentation in individual cases (eTable 25.2.1) (133a,133b). Fever is the most common constitutional complaint. Fevers are usually low grade. Fever may be absent in the elderly and those with congestive heart failure, uremia, severe debility, and infection with coagulase-negative *Staphylococcus* (10,134). Chills, night sweats, and weight loss are also commonly present, as are a variety of neurologic and musculoskeletal complaints.

***e*TABLE 25.2.1** CLINICAL FEATURES AND COMPLICATIONS OF INFECTIVE ENDOCARDITIS

Signs and symptoms	**“Ballpark” estimates of incidence (%)**
Fever	85–97
Murmurs (acute, on presentation)	85–90
Murmurs (subacute)	90–95
Musculoskeletal symptoms	40–50
Neurologic symptoms	30–40
Weight loss	25–30
Peripheral stigmata	20–40
Splinter hemorrhages	15–20
Petechiae	10–15
Osler’s nodes	8–10
Janeway lesions	5
Clubbing	5
Roth’s spots	5
Splenomegaly	5
Complications	
Congestive heart failure; aortic insufficiency >mitral regurgitation >tricuspid regurgitation	50–60
Embolization	20–25
Glomerulonephritis	15–25
Annular abscess	10–15
Stroke	5–15
Mycotic aneurysm	15
Cerebral	5
Limbs	4–5
Mesenteric	2–3
Descending aorta	1–3
Splenic	1–2
Conduction system disturbances	5–10
Central nervous system abscess	3–4
Other rare complications	<1–2
Pericarditis	
Myocarditis	
Myocardial infarction	
Intracardiac fistula	
Metastatic abscess	

Heart murmurs are frequently noted but may be difficult to hear under certain conditions. As many as 15% or more of patients may not have a murmur at the time of initial evaluation (76,135). In acute staphylococcal endocarditis, it is even rarer to recognize a new or changing murmur in the first few days of illness (133c). Right-sided endocarditis, for instance, may be associated with inaudible tricuspid regurgitation. The diagnosis of tricuspid valve endocarditis should therefore be based on a careful clinical examination that includes analysis of the jugular venous pulse, precordium, and liver. When tricuspid regurgitation is present, the neck veins are usually distended and the venous waveforms reveal a C-V wave. The presence of a C-V wave is best detected by observing the jugular venous pulse and

simultaneously palpating the opposite carotid or auscultating the heart to define systole. The jugular venous pulse should fall during ventricular systole (the ‘x’ descent); if tricuspid regurgitation is present, right ventricular ejection into the right atrium results in systolic expansion of the jugular venous pulse (the C-V wave).

Similarly, the hemodynamics that result from acute aortic regurgitation may result in a soft or absent murmur because the rapid increase in left ventricular diastolic pressure results in minimal gradient between the aortic diastolic pressure and left ventricular end diastolic pressure. The rapid increase in left ventricular diastolic pressure in such patients also results in the softening of the first heart sound (as the mitral valve begins to close before ventricular systole begins). In patients with severe aortic insufficiency, the mitral valve may even close before the QRS of the electrocardiogram (preclosure). M-mode echocardiographic techniques may detect such preclosure. This finding may be an important indicator of the need for valve replacement in patients who are in heart failure (93).

Acute aortic insufficiency should be suspected in the presence of four clinical findings: (a) fulminant pulmonary edema, (b) a short or barely audible diastolic murmur, (c) soft or absent first heart sound, and (d) hypotension. A changing heart murmur in the setting of fever or sepsis may be an important clue to the presence of endocarditis. In such circumstances, it is important to distinguish between a new organic regurgitant murmur and an old murmur that is simply affected by a change in body temperature, hematocrit, or cardiac output.

A variety of other clinical features are seen in IE (*e*Table 25.2.1). Reports in the preantibiotic era noted that splenomegaly was almost invariably present in patients with IE (136); more recent case series report a much lower incidence, probably because the diagnosis of endocarditis is now usually made relatively soon after onset. Similarly, clubbing of the nailbeds appears to be related to chronic infection and is now also an uncommon finding in patients with endocarditis (137). Although in our experience splenomegaly and clubbing are rarely diagnostic findings in patients with IE, others have reported these findings along with a high C-reactive protein test result, and petechiae still have diagnostic utility in clinical practice (136a).

A variety of musculoskeletal complaints are common in patients with IE. In one case series, bone or joint complications occurred in 15 of 104 patients with IE; all 15 of the patients were injection drug users (138). Symptoms such as arthralgias, myalgias, and acute synovitis are common. When joint aspirates are done in patients with acute synovitis and endocarditis, the joint fluid is usually sterile, although rarely cultures reveal the same organism that is causing their endocarditis. Low back pain is common in patients with endocarditis. Such pain may be confused with the generalized arthralgias or may rarely be an indicator of concurrent vertebral osteomyelitis. Lumbar pain usually resolves without sequelae during treatment of endocarditis.

Neurologic symptoms occur in 30% to 40% of patients with endocarditis in most series. Headache is the most common of these neurologic complaints. Cerebral embolic events occur in one-fourth of patients and may be the cause of the presenting symptoms in an important number of patients (139). In a review of 218 episodes of IE from one center, 55 of 218 episodes (25%) had a neurologic complication. An embolic event was responsible for 25 of 55 (42%) of the events. In 45% of the 55 neurologic events, the neurologic manifestations were present before antimicrobial therapy had begun (139a).

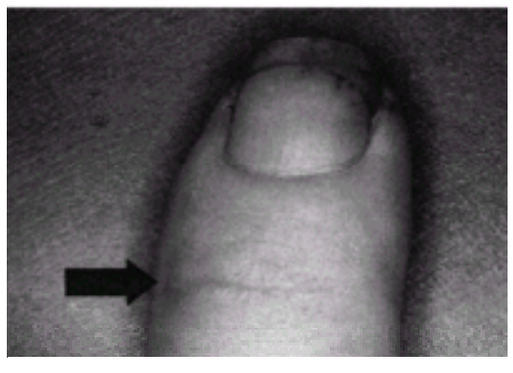
Peripheral stigmata are important in the recognition of endocarditis, but individual findings are neither diagnostic nor common. Petechiae are seen in approximately 10% to 15% of cases. Such lesions probably represent microemboli. Their presence should be sought for in the conjunctivae, on the palatal and buccal membranes, and on the extremities, especially the tops of the finger and toes in all patients. However, the presence of petechiae is not a highly specific finding. For example, petechiae may be present in many patients who undergo cardiopulmonary bypass, in some patients with staphylococcal bacteremia without coexistent endocarditis, and in patients with thrombocytopenia due to myriad causes (140).

Splinter hemorrhages—so called because they resemble a splinter being introduced into the nailbed—were first described in 1926 by Blumer (141). *e*Figure 25.5.2 depicts splinter hemorrhages caused by endocarditis. Splinter hemorrhages differ from traumatic subungual hemorrhages by being located more proximally in the nailbed. This finding is not specific, however, and splinter hemorrhages may be seen in patients with thrombocytopenia from any cause.

***e*FIGURE 25.5.2** Splinter hemorrhages. These are often seen in the middle third of nail beds and may migrate distally as the nail grows. (From Braverman IM, ed. *Skin signs of systemic disease*, 2nd ed. Philadelphia: WB Saunders, 1981:848, with permission.)

Splinter hemorrhages. Linear hemorrhages on the fingertips of a patient with infective endocarditis.

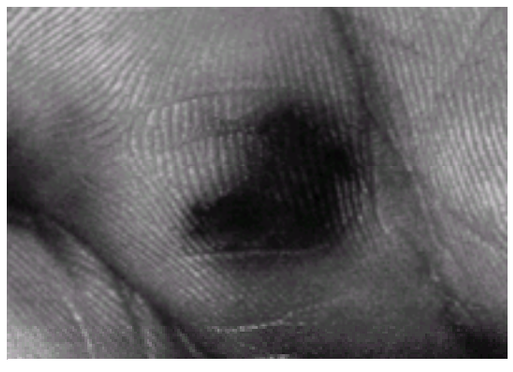
Osler’s nodes occur less commonly than petechiae and splinter hemorrhages in patients with endocarditis (*e*Fig. 25.5.3). The pathophysiology of Osler’s nodes remains controversial. Some authors believe that they result from immune complex deposition. However, other investigators have recovered bacteria from biopsies of these focal lesions (142,143). Osler’s nodes are small, tender, purple, erythematous subcutaneous nodules usually found on the pulp of the digits. Rarely, they may be seen in other areas such as the palms, soles, and ears. Even more rarely, they may become necrotic. Osler’s nodes are not pathognomonic of endocarditis; in fact, they can also be seen in other immunologic diseases (144). In some instances, their appearance is heralded by severe focal pain.



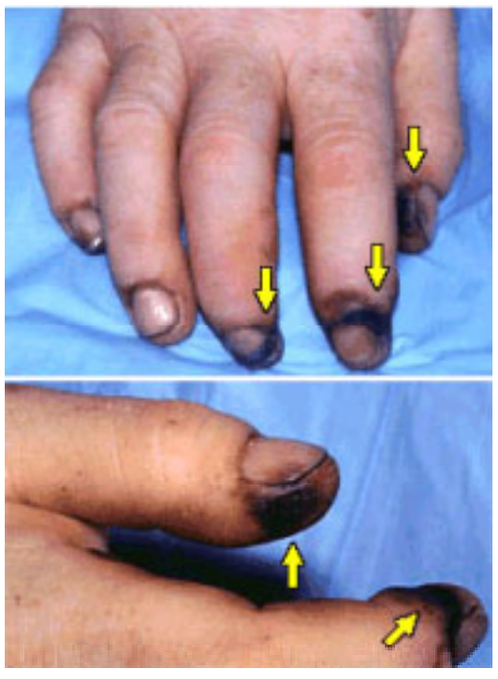
***e*FIGURE 25.5.3** Osler's node (*arrow*) and splinter hemorrhages. These are painful, wheel-like lesions in the pads of fingers and toes and may last from a few hours to days. The Osler's node is on the side of the finger with splinter hemorrhages noted in nail bed. (From Sanders CV, Nesbitt LT, eds. *The skin and infection*. Baltimore: Williams & Wilkins, 1995:45, with permission.)

Osler's nodes. There are tender nodules on the toe pads (*arrows*) secondary to infective endocarditis.

Janeway lesions were first described in 1899 (145). They are erythematous, macular, nontender lesions on the fingers, palm, or sole (eFig. 25.5.4). Similar to the controversy over the pathogenesis of Osler's nodes, some authorities believe they represent septic embolic and microabscesses (146), whereas others maintain they are caused by hypersensitivity angiitis (147,148). Regardless of their pathogenesis, both Osler's nodes and Janeway lesions are characterized histopathologically as localized vasculitis, often with central necrosis (147). The most important distinguishing difference between a Janeway lesion and Osler's node is lack of pain associated with the Janeway lesion (149).

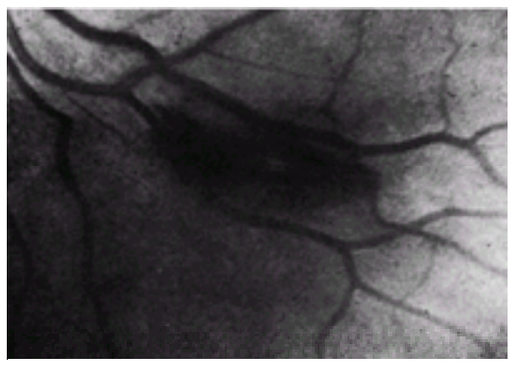


***e*FIGURE 25.5.4** Janeway lesion. These are nontender, nocular or nodular lesions on the palms or soles. (From Fitzpatrick TB, et al., eds. *Color atlas and synopsis of clinical dermatology*, 2nd ed. New York: McGraw-Hill, 1991:267, with permission.)

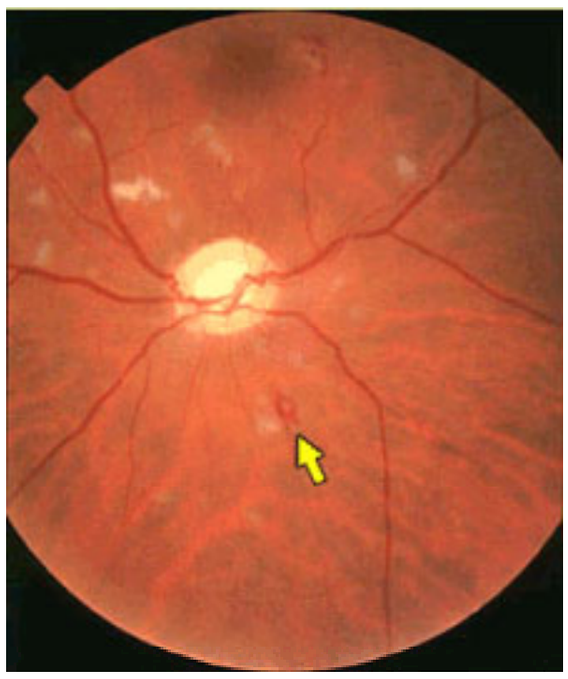


Janeway lesions of endocarditis. There are hemorrhages with nodular character at the fingertips (*arrows*).

Roth's spots, also known as *Litten's sign* (150), are retinal hemorrhages with a clear center. Roth's spots, originally described in 1872 (151), are classically associated with endocarditis (eFig. 25.5.5), but identical lesions may also occur in patients with severe anemia, a variety of other hematologic conditions, and collagen vascular disorders (147). The incidence of Roth's spots in endocarditis is low, appearing in 2% to 5% in various series. Roth's spots are presumed to occur as a result of capillary rupture, with secondary extravasation of blood and the formation of a central fibrin–platelet plug (150). Although a full ophthalmologic examination using direct ophthalmoscopy would likely improve the diagnostic yield for detecting Roth's spots, its infrequency in modern practice means the cost of ophthalmologic consultation is outweighed by the benefit.



***e*FIGURE 25.5.5** Roth's spot. Note hemorrhage with pale white center. (From Kritzinger EE, Wright BE, eds. *The eye and systemic disease*. Chicago: Yearbook Medical, 1984:27, with permission.)



Roth's spot. The yellow arrow indicates a hemorrhage with a white central spot typical of subacute bacterial endocarditis.

Clinical Complications

Surprisingly, the overall incidence of complications related to IE may not have changed significantly in the past three or four decades despite improvements in diagnostic techniques and in medical and surgical therapy (152). However, the types of complications seen in modern practice have changed substantially since the preantibiotic era. Patients now rarely die of sepsis. As a result of medical therapy, patients with IE often live longer and, thus, develop complications such as emboli, mycotic aneurysms, and heart failure more frequently. Estimates of the incidence of complications in the modern antibiotic era are presented in eTable 25.2.1.

Patients with endocarditis who undergo surgery are susceptible to a wide array of complications that were largely unknown 30 years ago (43). In a study of 287 patients treated for 300 episodes of IE in a tertiary cardiology referral center, a total of 386 complications occurred in 223 episodes. Most patients had either one (57%) or two (26%) complications, but 8% of patients had four or more complications (153). The most important and frequent cardiac complication of endocarditis is congestive heart failure. Heart failure in patients with endocarditis may be insidious or rapid in onset, but in both instances its primary cause usually is valvular insufficiency, rather than myocardial dysfunction. Patients with prosthetic valve endocarditis or endocarditis caused by fungal infection occasionally develop large bulky vegetations that may functionally occlude a valve orifice and secondarily cause heart failure. Regardless of the mechanism, the development of heart failure in patients with IE is an ominous sign. Unless valve replacement or valve repair is undertaken, most patients with this complication die, even if effective antimicrobial therapy is administered. Congestive heart failure may occur as a result of infection of any cardiac valve, but is most common in patients with aortic valve endocarditis and is least common in patients with tricuspid valve endocarditis (154).

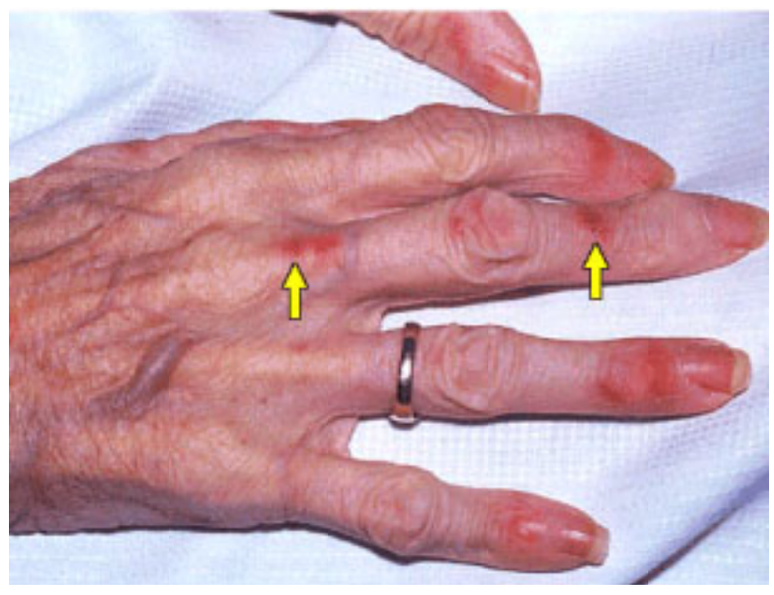
Most other cardiac complications in IE are related directly or indirectly to extension of infection from the valve leaflets or other areas of initial endocardial injury to surrounding cardiac structures such as the valve annulus, the adjacent cardiac conduction system, the sinus of Valsalva, or the mitral aortic intervalvular fibrosa. Rarely, vegetations on the aortic valve enlarge to the point that they occlude the left main coronary ostium (155).

Abscess in or adjacent to the valve annulus is often heralded by the appearance of first or second degree heart block, fever that persists despite appropriate therapy, or both. Rarely, patients with annular abscesses develop purulent pericarditis (89,156,157). Annular abscesses are more common in patients with aortic valvular infection than in those with mitral valve endocarditis (43). If infection extends beyond the valve ring, erosion may occur into the ventricular septum and secondarily into the cardiac conduction system. If the abscess extends into the lower portion of the septum, varying degrees of heart block may ensue. Extension of infection into the upper portion of the septum is less likely to produce electrocardiographic abnormalities (43). The new onset of atrioventricular or bundle branch block in a patient with endocarditis has a specificity of greater than 80% for the presence of an abscess (158). Furthermore, patients with perivalvular abscesses have higher rates of embolization and a higher risk of death than patients with endocarditis without abscess formation (116).

Uncommon cardiac complications of endocarditis include separation of the valve annulus from the surrounding myocardium with massive valvular insufficiency, myocardial infarction due to embolism to one or more coronary arteries, myocarditis, and pericarditis. Other uncommon intracardiac complications of endocarditis include fenestration of the valve leaflets, rupture of chordae tendineae, or aneurysm of the sinus of Valsalva. In the latter circumstance, aortocardiac fistulas may suddenly or gradually appear if the infective process ruptures into adjacent structures or chambers (43).

Myocarditis may occur as a result of coronary vasculitis, embolic coronary occlusion, or the effects of microbial toxins or immune complex deposition. Antisarcolemma antibodies have also been implicated in the pathogenesis of myocarditis in some cases of endocarditis (159). Pericarditis in patients with endocarditis may be either frankly purulent or follow a benign course with the formation of sterile pericardial effusions.

The most feared and most common extracardiac complication of endocarditis is embolism. Although valvular vegetations are the source of cerebral and systemic emboli in patients with endocarditis, rarely septic pulmonary arteriovenous fistulae may also provide a conduit for left-sided emboli (160). Cerebral infarction in patients with IE is usually caused by embolism that is later complicated by cerebral hemorrhage. Approximately three-fourths of all cerebral emboli involve the distribution of the middle cerebral artery. Cerebral infarction, caused by emboli or mycotic aneurysm, is the presenting sign of endocarditis in 4.5% to 14.0% of all cases of IE (161). Patients with endocarditis who develop cerebral emboli have clinically apparent evidence of systemic emboli in approximately one-half of cases; in contrast, only 2% of patients with other causes of stroke have associated systemic emboli (162).



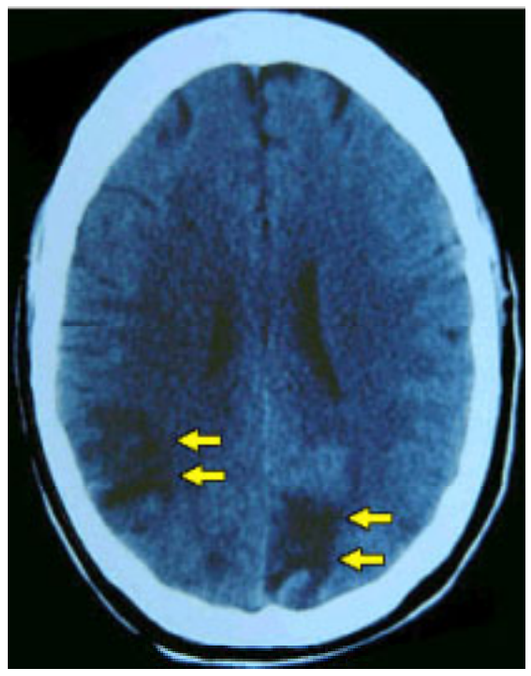
Septic emboli from infective endocarditis (*arrows*).

Septic emboli. Raised nodules from septic embolization from infective endocarditis.

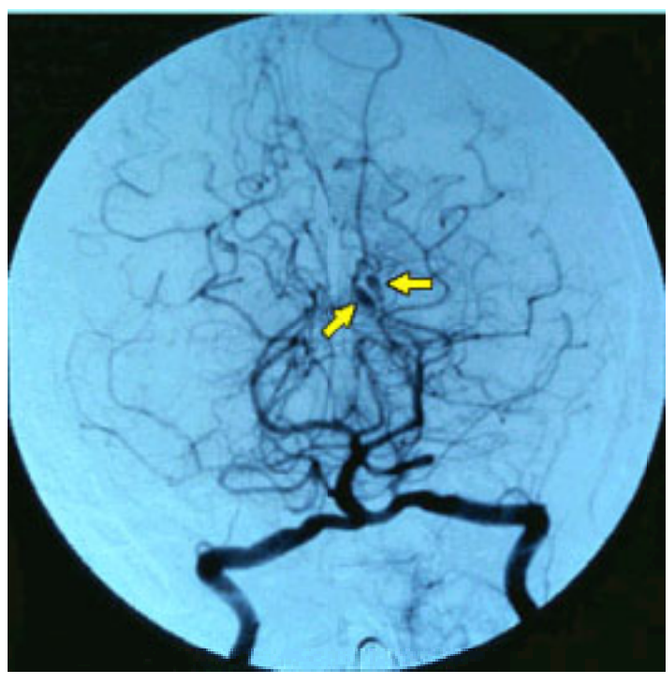
The risk of symptomatic embolism decreases rapidly after effective therapy for endocarditis is initiated. In a study that used transthoracic echocardiography to detect vegetations, the overall risk of embolism was 6.2 per 1,000 patient-days. The rate of embolism fell from 13 per 1,000 patient-days during the first week of therapy to less than 1.2 per 1,000 patient-days at the completion of therapy (163). Emboli to retina, coronary arteries, spinal cord, and the large arteries of the mesenteric circulation occasionally can produce sudden dramatic and catastrophic clinical findings such as blindness, paralysis, and signs and symptoms of an intraabdominal disaster. Peripheral large vessel embolism is uncommon in bacterial endocarditis but may be both the presenting symptom and the key to diagnosis in patients with fungal endocarditis. Microscopic examination or culture of material removed by thrombectomy may revel the fungal pathogen in some patients who simultaneously and paradoxically have negative blood cultures.

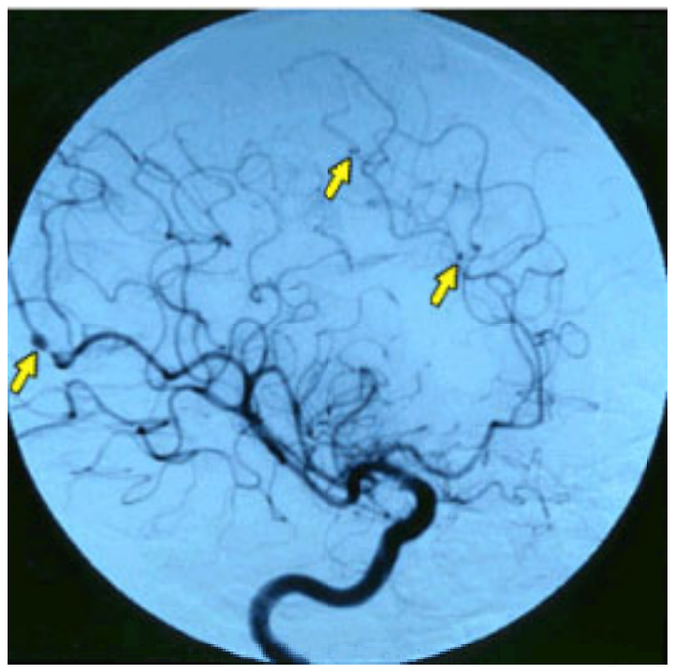
Patients with IE may also develop mycotic aneurysms in the cerebral, systemic, or both circulations, often at points of vessel branching. Mycotic aneurysms form when an arterial wall is damaged by septic emboli, which either occludes the vasa vasorum or the entire arterial lumen. Following the metastatic arrival of microbes, the vessel wall becomes secondarily infected and weakened. Thereafter, the lumen may dilate because of the combined effects of intraarterial pressure and destruction of the muscular layer. Estimates of the incidence of mycotic aneurysms vary between 1.2% and 5.4% in different studies, yet the true incidence of mycotic aneurysms is likely much higher, as many aneurysms remain asymptomatic (164). Mycotic aneurysms may decrease, increase, remain the same size, or even disappear during therapy for IE. The most significant complication of mycotic aneurysms is bleeding that may occur days, weeks, months, or rarely even years after successful therapy for the underlying endocarditis (165). When bleeding occurs, surgical intervention is often necessary, but surgery should be postponed whenever possible while antibiotic therapy is administered. Even a short period of medical therapy often makes surgical excision easier, possibly because the aneurysm wall becomes thicker from fibrosis during antibiotic treatment (164).

An array of other neurologic complications of endocarditis has been described. These include toxic metabolic encephalopathy due to sepsis, meningoencephalitis, purulent or aseptic meningitis, brain abscess, seizures, headache, and acute cranial or peripheral mononeuropathy (161). Such neurological abnormalities often are the presenting complaint. For example, a focal neurologic deficit, altered mental status, or a headache were the presenting complaint in 28% and 29%, respectively, in two large series of patients with endocarditis (166,167). Purulent meningitis is often a clue to the presence of staphylococcal endocarditis, but it may occur with any etiologic agent causing endocarditis; thus, the possibility of endocarditis should always enter the mind of clinicians when they treat patients with bacterial meningitis.



Ruptures mycotic aneurysms. Several areas of hypodensity representing ruptured mycotic aneurysms as a result of endocarditis (*arrows*).





Mycotic aneurysms from infective endocarditis. Localized aneurysmal dilatation of cerebral vessels as a result of endocarditis (*arrows*, A,B).

The renal complications of IE include focal areas of renal infarction (that often manifest as hematuria) and acute and chronic proliferative glomerulonephritis secondary to immune-mediated injury with deposition of IgG, IgM, and complement in the glomerular membrane. Chronic renal failure caused by immune complex glomerulonephritis was a common contributing cause to the death of patients with endocarditis who presented with classic subacute bacterial endocarditis in the preantibiotic era. This complication has become uncommon in modern practice. However, the presence of immune complex and secondary glomerulonephritis-mediated renal injury still occasionally occurs. Many patients with endocarditis have full or substantial return of renal function following temporary dialysis and treatment of their endocardial infection (168). As aminoglycosides are commonly used to treat staphylococcal and streptococcal endocarditis, it may be extremely difficult to separate drug-induced nephrotoxicity from renal impairment caused by the underlying disease. The development of renal insufficiency during IE is associated with a fivefold increase in the risk of a false outcome in one retrospective study of 204 consecutive episodes of IE from one medical center. Factors associated with increased risk of renal insufficiency include advanced age, the presence of *S. aureus*, severe thrombocytopenia, and prosthetic valve infection (168a).

Metastatic abscesses develop in the kidneys, spleen, or soft tissues (e.g., the psoas muscle) of some patients with IE. Surprisingly, patients with splenic abscesses often do not have marked abdominal pain or splenomegaly. Splenic abscesses usually require splenectomy for cure (43). In contrast, splenic infarcts, which are far more common than splenic abscesses in left-sided endocarditis, usually resolve spontaneously. Splenic infarct, on occasion, may be the presenting manifestation of endocarditis. Most metastatic abscesses in other locations require open or percutaneous drainage procedures.

Patients with tricuspid valve endocarditis may develop septic pulmonary emboli that later cavitate and produce hemoptysis. Such patients may also develop sterile or purulent, bloody or nonbloody pleural effusions (169). Septic pulmonary emboli may also result in the occurrence of a pneumothorax (170).

Clinical Course and Prognosis

Most patients with IE become afebrile within a few days after the institution of antimicrobial therapy. However, a small number of patients, particularly those with endocarditis caused by *S. aureus*, may remain febrile for 7 to 10 days and occasionally even longer. Drug fever, a secondary nosocomial infection, or intracardiac or extracardiac abscess formation should all be considered in such patients.

Congestive heart failure may first appear after an initial positive clinical response to medical therapy. Similarly, emboli to the CNS, coronary arterial, and systemic circulation may all occur after an initial response to antimicrobial therapy.

The prognosis in IE is related to the virulence of the infecting microorganism, the general health of the host, the valvular structures that are involved, the duration of the infection, and the presence or absence of congestive heart failure. *S. aureus* endocarditis is still fatal in 20% to 40% of cases, despite the best available medical and surgical therapies. In contrast, the prognosis of streptococcal endocarditis is substantially better. Between 90% and 95% of patients with endocarditis caused by viridans streptococci are now cured with medical or combined medical and surgical therapy. A similarly good prognosis exists for patients with endocarditis caused by other species of streptococci. Fungal endocarditis is virtually impossible to cure with medical therapy; only a small minority of such patients is currently cured with combined antifungal and surgical therapy (171). Some of these patients remain on antifungal treatment for extended periods of time on the assumption that sterilization of the infection is otherwise impossible.

The prognosis of patients with right-sided endocarditis, even those with infections caused by *S. aureus*, is remarkably good. In an analysis of 11 studies involving 362 cases of right-sided endocarditis, Chambers was able to document only two treatment failures (0.6%) and seven deaths (2.0%) in the same series (40).

Despite early surgical intervention, the prognosis of late-onset prosthetic valve endocarditis is better than for patients who acquire infection within 60 days of their replacement valve surgery. For example, in a review of 56 cases of prosthetic valve endocarditis that occurred among 3,200 recipients of bioprosthetic valves, the mortality for cases that occurred within 2 months of surgery was 75%, whereas only 25% of cases with late-onset prosthetic valve endocarditis were fatal (172).

Overall mortality for prosthetic valve endocarditis has ranged from 18% to 57% in different case series, but averages 30% to 45% in most reports (22,173,174). Although some authors have emphasized a more favorable outcome of prosthetic valve endocarditis with prompt surgical therapy (23,174,175), other authors have concluded that *long-term* outcomes of medical therapy are similar to outcomes in patients treated with combined medical and surgical therapy. It has been our experience that selected cases of prosthetic valve endocarditis can be cured medically. However, with prosthetic valve endocarditis caused by highly resistant organisms, cases complicated by congestive heart failure, or cases associated with perivalvular abscesses, surgery is usually necessary.

In a study of 49 episodes of definite prosthetic valve endocarditis (by the Duke criteria) treated at one institution, ten patients were treated with medical therapy alone and 39 patients received combined medical and surgical therapy. Long-term follow-up showed no significant differences between the two groups regarding late mortality risk of recurrent endocarditis at 5 years or the need for reoperation (175a).

PRINCIPLES OF MANAGEMENT

Prevention of Infective Endocarditis

Antimicrobial prophylaxis before selected dental and invasive surgical and diagnostic procedures has become standard and routine in most countries, despite the fact that no prospective study has been performed that proves that such therapy is clearly beneficial. Only one-half of all patients who develop endocarditis have a cardiac disorder that would have prompted endocarditis prophylaxis in the first place (176). Furthermore, follow-up incidence of endocarditis is low even if patients with predisposing valvular lesions do not receive prophylactic antibiotics: One in five untreated patients develops endocarditis after having had an invasive procedure. Thus, perhaps only one in ten endocarditis episodes can be prevented by the appropriate use of antibiotic prophylaxis before an invasive procedure.

It is our view that maintenance of meticulous dental hygiene is of equal importance to antibiotic prophylaxis in the prevention of IE. It has been our experience that some patients with valvular and congenital heart disease actually visit their dentist less often, rather than more often, when the infectious risks of dental procedures are explained to them. Vigorous brushing of teeth or even chewing gum may result in transient bacteremia in patients with periodontal disease; it is important to emphasize to the patient that maintenance of good dental hygiene is vital. In addition, it is advisable to instruct all patients to avoid gingival trauma with toothpicks and high-pressure water irrigation devices (177).

The guidelines for antimicrobial prophylaxis for endocarditis formulated by an expert committee of the American Heart Association (178) are the regimens most widely used by clinicians in the United States. Expert groups in Europe (45) have published similar guidelines. Both guidelines are based on results of *in vitro* studies, clinical experience, data from experimental animal models, and clinical assumptions concerning the bacteria most likely to produce bacteremia and cause endocarditis. These recommendations should not be assumed to be the standard of care in all clinical situations. Clinicians can reasonably deviate from these guidelines in

individual cases. For example, clinicians must often use judgment in selecting dose and duration of antimicrobial therapy in elderly or obese patients or in those with underlying renal disease. Furthermore, there are sometimes instances in which the risk of prophylactic therapy may actually outweigh the risk of postprocedure endocarditis. Patients in such circumstances often have cardiac lesions of questionable or little hemodynamic consequence, have a documented or possible drug allergy, or are undergoing procedures in which the risk of bacteremia is extremely low.

The primary justification for prophylactic therapy to prevent endocarditis is based on the results of animal experiments. If bacteria with a known ability to cause endocarditis are injected into animals after their heart valves have been abraded using vascular catheters, the animals predictably develop endocarditis (179). If antimicrobial therapy is given immediately before or for up to 30 minutes after this experimental bacteremia has been induced, endocarditis does not ensue (180). However, if therapy is delayed for several hours after a bacteremia has been produced in an animal rendered susceptible by cardiac valvular damage, endocarditis is likely to occur. These data suggest that antimicrobial therapy can prevent endocarditis by either killing bacteria before they establish a nidus of infection in a susceptible heart, or by killing organisms shortly after they adhere to a localized area of damaged endothelium (180).

No studies have conclusively demonstrated that prophylactic antibiotics are effective in preventing endocarditis in humans after dental procedures. Furthermore, currently recommended antibiotic regimens might fail to prevent endocarditis, even if such therapy is given immediately before an invasive procedure. For example, in a study of 52 cases of endocarditis that occurred despite prophylactic antimicrobial therapy, two-thirds of the cases had pathogens that were susceptible *in vitro* to the agents the patients had received prophylactically (23).

Three studies have been published in an attempt to measure the efficacy of prophylactic antibiotic therapy in the prevention of endocarditis. Two of these studies (8,181) produced results that suggested a benefit of prophylactic antibiotics; the third (182) found no benefit of such therapy. However, all three studies had serious limitations in their design or lacked appropriate numbers of patients to achieve necessary statistical power (180).

*e*Table 25.2.2 outlines the current clinical situations wherein antibiotic prophylaxis is recommended based on the risk involved. The precise risk of endocarditis following invasive dental or surgical procedures in patients with any of the listed conditions cannot be precisely measured; in fact, differences in opinions continue to exist as to whether even patients with each of the listed predisposing conditions should receive antibiotic therapy before an invasive procedure. There is general agreement, however, that those patients with a prior history of endocarditis and those with prosthetic heart valves are at higher risk than patients with acquired congenital and valvular lesions.

***e*TABLE 25.2.2** CARDIAC CONDITIONS AND THE NEED FOR ENDOCARDITIS PROPHYLAXIS[a]

Endocarditis prophylaxis recommended
Prosthetic cardiac valves, including bioprosthetic and homograft valves
Previous bacterial endocarditis, even in the absence of heart disease
Most congenital malformations
Rheumatic and other acquired valvular dysfunction, even after valvular surgery
Hypertrophic cardiomyopathy
Mitral valve prolapse with valvular regurgitation
Endocarditis prophylaxis not recommended
Isolated secundum atrial septal defect
Surgical repair without residua beyond 6 mo of secundum atrial septal defect, ventricular septal defect, and patent ductus arteriosus
Previous coronary artery bypass graft surgery
Mitral valve prolapse without valvular regurgitation[b]
Physiologic, functional, or innocent heart murmurs
Previous Kawasaki's disease without valvular dysfunction
Previous rheumatic fever without valvular dysfunction
Cardiac pacemakers and implanted defibrillators

[a]This table lists selected conditions but is not meant to be all inclusive.
[b]Individuals who have mitral valve prolapse associated with thickening, redundancy, or both of the valve leaflets may be at increased risk for bacterial endocarditis, particularly men who are 45 years of age or older.

In general, risk of IE is considered to be highest for oral or dental procedures in which the oral mucosa is penetrated and in which gingival or mucosal bleeding is likely to occur. Invasive dental procedures in which the risk of transient bacteremia is above 50% include tooth extractions, periodontal surgery, and cleaning of teeth with removal of tartar. The risk of bacteremia is substantially lower for invasive genitourinary procedures such as dilation of strictures, insertion of endoscopes and catheters, and prostatectomy. The risk of bacteremia following invasive gastrointestinal procedures such as colonoscopy with biopsy and endoscopic retrograde cholangiopancreatography is generally less than 5% to 10%. The American Heart Association has listed those invasive procedures in which endocarditis prophylaxis is and is not recommended (*e*Table 25.2.2). Clinicians may choose to use antimicrobial prophylaxis in some patients with a high risk for endocarditis who undergo a procedure with a low or intermediate risk of bacteremia, yet reasonably forego antimicrobial prophylaxis in patients with a very low risk of endocarditis (e.g., those with a history of drug allergy) who undergo a procedure with an intermediate or high risk of bacteremia (*e*Table 25.2.3).

***e*TABLE 25.2.3** DENTAL OR SURGICAL PROCEDURES AND ENDOCARDITIS PROPHYLAXIS

Endocarditis prophylaxis recommended
Dental procedures known to induce gingival or mucosal bleeding, including professional cleaning
Tonsillectomy, adenoidectomy, or both
Surgical operations that involve intestinal or respiratory mucosa
Bronchoscopy with a rigid bronchoscope
Sclerotherapy for esophageal varices
Esophageal dilatation
Gallbladder surgery
Cystoscopy
Urethral dilatation
Urethral catheterization if urinary tract infection is present
Prostatic surgery
Incision and drainage of infected tissue
Vaginal hysterectomy
Vaginal delivery in the presence of infection
Endocarditis prophylaxis not recommended
Dental procedures not likely to induce gingival bleeding, such as simple adjustment of orthodontic appliances or fillings above the gum line
Injection of local intraoral anesthetic (except intraligamentary injections)
Shedding of primary teeth
Tympanostomy tube insertion
Endotracheal intubation
Bronchoscopy with a flexible bronchoscope, with or without biopsy
Cardiac catheterization
Endoscopy with or without gastrointestinal biopsy
Cesarean section
In the absence of infection for urethral catheterization, dilatation and curettage, uncomplicated vaginal delivery, therapeutic abortion, sterilization procedures, or insertion or removal of intrauterine devices

The antimicrobial regimens suggested by the American Heart Association for endocarditis prophylaxis are listed in Table 25.3. Although the evidence supporting the routine use of antibiotic prophylaxis is spotty, failure to adhere to these guidelines in the current medicolegal climate may invite litigation. Other expert groups such as the British Society for Antimicrobial Chemotherapy proposed guidelines that differ only slightly. For example, the American Heart Association guidelines recommend that the primary antibiotic regimen for patients undergoing dental, oral, or upper respiratory procedures should be amoxicillin, 2 g orally, 1 hour before the procedure, whereas the British Society for Antimicrobial Chemotherapy recommends a single 3-g oral dose of amoxicillin (183). Some authors (184) have suggested that prophylaxis in patients with prosthetic heart valves should always be parenteral (184), but such recommendations are certainly not a consensus opinion, and we do not routinely use parenteral therapy in such patients.

- Standard regimen for dental/oral/upper respiratory tract procedures
  - Standard regimen in patients at risk (includes those with prosthetic heart valves and other high-risk patients): amoxicillin, 2.0 g, orally 1 h before procedure
  - For amoxicillin/penicillin-allergic patients: clindamycin (600 mg orally), cephalexin or cefadroxil (2 g orally), or azithromycin (500 mg orally) taken 1 h before procedure
- Alternate standard regimens for dental/oral/upper respiratory tract procedures
  - For patients unable to take oral medications: ampicillin, 2.0 g i.v. (or i.m.) 30 minutes before procedure; then ampicillin, 1.0 g i.v. (or i.m.) 6 h after initial dose
  - For ampicillin/amoxicillin/penicillin-allergic patients unable to take oral medications: clindamycin, 600 mg i.v., or cefazolin, 1 g i.v., 30 min before procedure
- Standard regimen for genitourinary/gastrointestinal procedures
  - Standard regimen in patients at high risk: ampicillin, 2.0 g i.v. (or i.m.), plus gentamicin, 1.5 mg/kg i.v. (or i.m.) (not to exceed 120 mg) 30 min before procedure; then amoxicillin, 1 g orally, i.m. or i.v. 6 h after initial dose
  - For amoxicillin/ampicillin/penicillin allergic patients: vancomycin, 1.0 g i.v. administered over 1 h, plus gentamicin, 1.5 mg/kg i.v. (or i.m.) (not to exceed 120 mg) 1 h before procedure
  - Alternate oral regimen for genitourinary/gastrointestinal patients at moderate risk: amoxicillin, 3.0 g orally; ampicillin, 2 g i.v.; or vancomycin, 1 g i.v. to be completed 30 min before the procedure

TABLE 25.3 RECOMMENDED BACTERIAL ENDOCARDITIS PROPHYLAXIS REGIMENS

Medical Therapy during the Course of Infective Endocarditis

General Principles

Individuals with IE often present with unique issues that must be addressed while treating the disease. For that reason, cases of endocarditis caused by the same organism may not be treated in precisely the same manner. On the other hand, common medical and social issues often arise while treating individuals with endocarditis caused by dissimilar pathogens. Table 25.4 outlines a typical approach that might be used for the patient without complications.

- Initial evaluation
  - Establish diagnosis (including history, physical, blood cultures, echocardiogram, supportive laboratory studies)
  - Initiate appropriate antibiotic therapy using minimum inhibitory concentration levels as guide
  - Obtain other baseline studies (electrocardiography, sedimentation rate, complete blood cell counts, electrolytes, chest roentgenography)
  - Continue chronic medications except warfarin
  - If on warfarin, discontinue and let international normalized ratio drift down to 2.0, then begin therapeutic heparin
  - Begin search for source of valvular infection
  - If significant valvular regurgitation present, begin angiotensin converting enzyme inhibitor
  - Cardiovascular surgical consult in most instances, particularly if resistant organism, prosthetic valve endocarditis, evidence of hemodynamic instability, or perivalvular abscess is present
  - Evaluate home situation and lifestyle regarding potential for home therapy
- Once therapy has begun
  - Daily vital signs, physical examination; telemetry at least the first week
  - Insert percutaneous indwelling central venous catheter line (or Hickman's) for intravenous antibiotic use
  - Continue search for source of valvular infection if appropriate
  - Repeat blood cultures after 72 h of therapy and repeat if fever persists
  - Obtain trough and peak antibiotic drug levels initially, and if dosage altered
  - Ongoing laboratory studies: Every 3 d, complete blood cell counts, electrolytes. Weekly, electrocardiography, chest roentgenography.
  - Continue i.v. antibiotic therapy 5 to 14 d in hospital, then arrange for completion of course (usually 4 wk) as outpatient
  - If patient on chronic warfarin, may resume after first week of therapy if surgery not apparently required
  - As outpatient on therapy, continue daily vital signs and weekly complete blood cell counts and electrolytes
  - Once therapy complete, follow-up echocardiography

TABLE 25.4 REPRESENTATIVE THERAPEUTIC APPROACH FOR UNCOMPLICATED NATIVE VALVE INFECTIVE ENDOCARDITIS

After establishing the initial diagnosis, as previously described, a search should be undertaken for the source of the valvular infection. This extent and nature of this search is dependent on the infecting organism. For instance, a dental abnormality is often associated with *S. viridans* endocarditis; a skin infection, deep abscess, or infected vascular catheter may be the origin if the organism is *Staphylococcus*, whereas a gastrointestinal source, such as colon cancer, may be the source of *S. bovis* endocarditis. If a source for the endocarditis can be found, then its treatment or eradication should be undertaken before cardiac valve repair or replacement is undertaken. For example, if an infected catheter or foreign body is the source of *S. aureus* endocarditis, this source should be removed before proceeding to valve replacement.

In the 1990s, it became acceptable and often necessary to reduce the length of hospitalization by use of a home health agency to administer home intravenous therapy. The patient's home situation should to be evaluated and the suitability for home intravenous therapy should be assessed soon after the diagnosis of IE is established. For most native valve endocarditis, at least 5 to 7 days of in-hospital intravenous therapy is given, followed typically by several more weeks of intravenous antibiotics that, in selected patients, may be completed at home. Criteria for outpatient treatment of endocarditis include the following: (a) unequivocal clinical response to initial therapy, (b) stable hemodynamic status, (c) absence of metastatic or intracardiac complications, and (d) ability to comply with the mechanics and scheduling of outpatient antibiotic therapy. For some patients home therapy is simply not an option because of their social situations. In patients with those home environments, completing the entire antibiotic course as an inpatient or in a convalescent care facility is preferred. Six weeks of therapy is used for most prosthetic valve endocarditis or when a relatively resistant organism causes native valve endocarditis. At times, more than 6 weeks of therapy may be needed, especially when a virulent or relatively resistant organism such as a gentamicin-resistant enterococcus is present.

Once the diagnosis of endocarditis is established, a baseline electrocardiogram, complete blood count with differential, sedimentation rate, electrolytes, and chest roentgenography should be obtained. A chest wall echocardiogram should be obtained in all patients. TEE should be employed in accordance with the guidelines noted previously. After the initial blood cultures, repeat blood cultures should be obtained in most patients after 3 days of treatment to ensure that bacteremia has resolved. Persistent bacteremia on surveillance cultures should raise concern that the antibiotic therapy is less than adequate. After that, blood cultures are usually only obtained again if fever resumes or if other signs of active infection, such as recurrent leukocytosis, occur.

Persistent fevers in the face of seemingly appropriate therapy are an occasional clinical dilemma. When fever is accompanied by mental confusion or congestive heart failure, therapy with antipyretics such as acetaminophen is warranted, but in general it is preferable to avoid antipyretics in order to monitor the clinical response to therapy. The blood counts and electrolytes are repeated every 3 days until the results are stable or normal. Patients are usually monitored with telemetry for the first week of therapy; electrocardiography and chest roentgenography are repeated weekly. Prolongation of the PR interval on electrocardiography (unrelated to drug usage) or radiographic or clinical signs of congestive heart failure may in turn lead to other studies and more careful clinical assessment. When aminoglycosides or vancomycin are used as therapy, antibiotic drug levels should be monitored at least once during therapy. Specialized microbiologic testing of the etiologic agent should be assessed with certain organisms such as viridans staphylococci and enterococci. Repeat echocardiography may be necessary if there is confusion regarding the clinical status of the patient, but, in most instances, serial echocardiograms are not necessary while therapy is ongoing.

Early surgical consultation should be obtained in most cases. Such consultation may be helpful regarding timing of future surgical intervention and the risks involved. Surgical consultation is mandatory when a virulent organism is the causative pathogen, in all cases of prosthetic valve endocarditis, or if there are extenuating circumstances, such as significant comorbid illnesses that could significantly increase surgical morbidity and mortality. Surgical consultants should also be involved in decisions concerning the need for cardiac catheterization. If a surgical indication arises early in the treatment of endocarditis, there is no advantage in waiting for "sterilization" of the valve before proceeding to surgery.

Few medications are contraindicated in the treatment of endocarditis; however, one frequent exception is warfarin (Coumadin). After the diagnosis of endocarditis is established, warfarin is usually discontinued and when the international normalized ratio drops to 2.0, heparin (either unfractionated or low-molecular-weight) is started in its place. Should cardiovascular or other surgery (e.g., placement of a Hickman's catheter) be needed, heparin anticoagulation can be quickly reversed by its discontinuation or the use of protamine. Warfarin is then restarted in patients with metallic prosthetic valves once the clinical course stabilizes, surgery appears unlikely

to be needed, or the patient is being readied for home antibiotic therapy.

An indwelling central line is usually placed soon after a diagnosis of endocarditis is established. In general, a peripheral indwelling central catheter is used for vascular access, although a Hickman's catheter or other devices [e.g., peripheral venous reservoirs such as the Passport (Wilson-Cook Medical, Inc., Winston-Salem, NC)] may be used in selected patients.

Most patients are monitored during home antimicrobial therapy with the assistance of personnel in home health organizations. However, it may also be appropriate to manage selected patients using a local infusion center or in a convalescent care facility. Patients receiving outpatient therapy typically should be seen weekly in the outpatient clinic during the course of their home therapy, and as necessary after the completion of treatment. A repeat chest wall echocardiogram following completion of the antimicrobial therapy should be obtained to assess the magnitude of residual valvular and ventricular dysfunction and to provide a baseline for subsequent follow-up evaluations.

The previously mentioned strategy is a broad overview of how uncomplicated patients with native valve IE caused by a susceptible organism should be managed. This approach is frequently modified as the clinical situation warrants. Other issues frequently arise during the course of treatment for IE and may require an alternative approach.

Antimicrobial Therapy

Before the availability of antimicrobial therapy, IE was invariably fatal. Even today a substantial percentage of patients with IE die because of highly virulent organisms such as *S. aureus*, despite having received appropriate antimicrobial therapy in a timely manner and despite the skillful use of modern diagnostic techniques, surgical methods, and supportive care. However, the majority of patients with endocarditis now survives infections.

Following the establishment of a diagnosis using clinical deduction and microbiologic and echocardiographic methods, antimicrobial therapy should be administered in a dose designed to give sustained bactericidal serum concentrations throughout much of or the entire dosing interval. The duration of this therapy has to be long enough to eradicate microorganisms growing in the valvular vegetations.

Soon after the discovery of sulfonamides and penicillins, it was apparent that bactericidal therapy was more effective than bacteriostatic therapy in treating endocarditis. Although early clinical trials showed that a few patients with streptococcal endocarditis could be cured with low doses of penicillin administered for as short a period as 6 days, longer therapy was necessary to ensure cure in all patients. For example, the results of two early landmark treatment trials performed in the 1940s and early 1950s revealed that approximately 20% of patients with viridans streptococcal endocarditis relapsed when penicillin was administered for only 14 days (185,186). In contrast, in a later study of patients with viridans streptococcal endocarditis, none of 66 consecutive patients who survived a 4-week course of penicillin G relapsed, and only 1 of 77 patients treated with this regimen died of active infection. Similarly, 4 to 6 weeks of bactericidal therapy with a single drug is highly effective as treatment for endocarditis caused by other streptococcal species and staphylococci. Such prolonged therapy is presumed to be necessary because bacterial concentrations within vegetations may be as high as 10^9 to 10^{10} colony-forming units per g of tissue, and because organisms deep within vegetations are not accessible to phagocytic cells and often are in a state of reduced metabolic activity (187).

The need for prolonged therapy in treating endocarditis and the problem of reduced *in vitro* sensitivity to commonly used antimicrobial agents has stimulated interest in using combination therapy to treat endocarditis. Combination therapy using a beta-lactam agent such as penicillin with an aminoglycoside has been shown to be highly effective in streptococcal endocarditis and somewhat effective in a small subset of patients with staphylococcal endocarditis. Combination therapy with penicillin or ceftriaxone and an aminoglycoside for 2 weeks is highly effective in viridans streptococcal endocarditis (188,189 and 190).

Combination therapy with nafcillin and an aminoglycoside for 2 weeks has been shown to be effective in patients with right-sided endocarditis caused by *S. aureus* (191). One study suggests that aminoglycoside therapy is not critical to the success of these short-course regimens. In a randomized trial, cloxacillin therapy alone for 2 weeks was as effective as the combination of cloxacillin and gentamicin (192). However, combined therapy with vancomycin and an aminoglycoside administered for 2 weeks does not appear to be effective. Also, combined therapy with nafcillin and an aminoglycoside is not effective in left-sided endocarditis if treatment is given for only 2 weeks.

Several reports have described the successful use of oral regimens for selected patients with IE (193). Despite reports of success with such regimens, oral regimens should not be used as initial therapy for endocarditis. Nonconventional regimens should only be used in highly selected cases in which the causative organism is known, in which the antimicrobial susceptibility has been carefully studied, and in which *in vitro* studies show high levels of susceptibility. Generally, there should be a compelling reason to use oral therapy over conventional intravenous therapy now that home health agencies allow for home antibiotic infusions. We do not believe there are adequate data to support a preference for oral antibiotic usage.

Until more recently, most patients with endocarditis received the entire duration of their antimicrobial therapy while in the hospital. However, the development of systems and equipment that allows for prolonged and safe administration of intravenous therapy to outpatients has made it acceptable and appropriate to treat selected patients with endocarditis as outpatients during much or even all of their therapy (190). Patients selected for outpatient therapy should have responded clinically to inpatient therapy and without evidence of metastatic or intracardiac complications. In addition, they should be hemodynamically stable, compliant, and capable of managing the technical aspects of intravenous therapy (188). Such patients still require careful and regular monitoring and must have ready access to full medical care should complications such as drug allergy, emboli, or cardiac failure occur.

Endocarditis Caused by Streptococcus Viridans and Streptococcus bovis

The various species of streptococci that make up the viridans group and *S. bovis* account for approximately 40% to 50% of all cases of native valve endocarditis in community practice. Endocarditis caused by these organisms can usually be microbiologically cured if one of four different regimens is used (eTable 25.4.1). Most of these organisms are highly penicillin-susceptible [i.e., have a minimum inhibitory concentration (MIC) £0.1 µg per mL].

***e*TABLE 25.4.1** SUGGESTED REGIMENS FOR THERAPY OF NATIVE VALVE ENDOCARDITIS CAUSED BY PENICILLIN-SUSCEPTIBLE VIRIDANS STREPTOCOCCI AND *STREPTOCOCCUS BOVIS* (MINIMUM INHIBITORY CONCENTRATION £0.1 µG PER ML)

Antibiotic	Dosage and route	Duration (wk)	Comments
Aqueous crystalline penicillin G sodium or	12–18 million U/24 h i.v. either continuously or in six equally divided doses	4	Preferred in most patients older than 65 yr and in those with impairment of the eighth nerve or renal function
Ceftriaxone sodium	2 g once daily or i.m.	4	
Aqueous crystalline sodium	12–18 million U/24 h i.v. either continuously or in six equally divided doses	2	When obtained 1 h after a 2- to 30-min i.v. infusion or i.m. injection, serum penicillin concentration of gentamicin of approximately 3 µg/mL is desirable; trough concentration should be <1 µg/mL
With gentamicin sulfate	1 mg/kg i.m. or i.v. every 8 h	2	
Vancomycin hydrochloride	30 mg/kg per 24 h i.v. in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored	4	Vancomycin therapy is recommended for patients allergic to beta-lactams (see text); peak serum concentrations of vancomycin should be obtained 1 h after completion of the infusion and should be in the range of 30–45 µg/mL for twice-daily dosing

Endocarditis caused by highly penicillin-susceptible streptococci can be reliably cured using aqueous crystalline penicillin G at a dose of 12 to 18 million units daily for 4 weeks. This regimen or an equally effective regimen consisting of ceftriaxone, given as a 2-g daily dose for 1 month, remains the preferred treatment for elderly patients or in other patients in whom aminoglycoside therapy is considered risky or contraindicated.

Selected patients with native valve endocarditis without evidence of intracardiac or extracardiac complications or preexisting renal or otic disease can be treated with shorter courses of combination therapy consisting of either aqueous crystalline penicillin G or ceftriaxone with gentamicin. The latter agent should be given at a dose (usually 1 mg per kg) designed to give a peak gentamicin serum level of 3 µg per mL. Although streptomycin can also be used with either of the previously mentioned beta-lactam antibiotics to achieve the same effect, gentamicin is currently more widely used in clinical practice. Furthermore, determinations of gentamicin serum levels are more widely available and dosing regimens are more familiar to clinicians than streptomycin.

Patients with histories of penicillin allergy can usually be treated with other beta-lactam antibiotics, such as cefazolin, if their prior history of penicillin allergy consists of skin rash without other signs of immediate-type hypersensitivity. Patients with histories of immediate-type hypersensitivity may be treated either with vancomycin for 4

weeks or desensitized to penicillin and treated with a standard regimen.

Patients with endocarditis caused by viridans streptococci and MICs >0.1 µg per mL and patients with endocarditis caused by streptococci with nutritional deficiencies that hinder their growth in routine laboratory culture media should receive aqueous penicillin G for a total of 4 weeks. Gentamicin should be added to this regimen for the first 2 weeks. As for other patients with streptococcal endocarditis with immediate-type hypersensitivity reactions to beta-lactams, vancomycin is an acceptable alternative (eTable 25.4.2).

***e*TABLE 25.4.2** THERAPY FOR NATIVE VALVE ENDOCARDITIS CAUSED BY STRAINS OF VIRIDANS STREPTOCOCCI AND *STREPTOCOCCUS BOVIS* RELATIVELY RESISTANT TO PENICILLIN G (MINIMUM INHIBITORY CONCENTRATION >0.1 µG PER ML AND <0.5 µG PER ML)

Antibiotic	Dosage and route	Duration (wk)	Comments
Aqueous crystalline penicillin G sodium	18 million U/24 h i.v. either continuously or in six equally divided doses	4	Cefazolin or other first-generation cephalosporins may be substituted for penicillin in patients whose penicillin hypersensitivity is not of the immediate type
With gentamicin sulfate	1 mg/kg i.m. or i.v. every 8 h	2	
Vancomycin hydrochloride	30 mg/kg per 24 h i.v. in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored	4	Vancomycin therapy is recommended for patients allergic to beta-lactams

Other streptococcal species (e.g., groups A, B, C, and G and *Streptococcus pneumoniae*) are occasional causes of endocarditis. Therapy should always be based on the results of susceptibility tests. As most such organisms are highly sensitive to penicillin, regimens used to treat endocarditis caused by viridans streptococci are usually effective. However, increasing numbers of isolates of *S. pneumoniae* have become relatively or highly penicillin resistant. Such organisms may be simultaneously resistant to other beta-lactams as well as to other antimicrobial agents. Therapy in such cases usually requires the input of an infectious disease specialist or a microbiologist. A few strains of *S. pneumoniae* only respond to vancomycin therapy.

Endocarditis Caused by Enterococci

Unlike streptococci, members of the genus *Enterococcus* are uniformly resistant to low concentrations of penicillin. Enterococci are also relatively resistant to expanded spectrum penicillins and vancomycin. Furthermore, they are uniformly highly resistant to all cephalosporins and typically resistant to aminoglycosides at concentrations achieved after standard dosing regimens. However, if penicillin, ampicillin, or vancomycin is given in synergistic combination with aminoglycosides such as gentamicin, most strains of enterococci are killed both *in vitro* and *in vivo* (eTable 25.4.3).

***e*TABLE 25.4.3** STANDARD THERAPY FOR ENDOCARDITIS CAUSED BY ENTEROCOCCI

Antibiotic	Dosage and route	Duration (wk)	Comments
Aqueous crystalline penicillin G sodium	18–30 million U/24 h i.v. either continuously or in six equally divided doses	4–6	
With gentamicin sulfate	1 mg/kg i.m. or i.v. every 8 h	4–6	4-wk therapy recommended for patients with symptoms <3 mo in duration; 6-wk therapy recommended for patients with symptoms >3 mo in duration
Ampicillin sodium	12 g/24 h i.v. either continuously or in six equally divided doses	4–6	
With gentamicin sulfate	1 mg/kg i.m. or i.v. every 8 h	4–6	
Vancomycin hydrochloride	30 mg/kg per 24 h i.v. in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored	4–6	Vancomycin therapy is recommended for patients allergic to beta-lactams; cephalosporins are not acceptable alternatives for patients allergic to penicillin
With gentamicin sulfate	1 mg/kg i.m. or i.v. every 8 h	4–6	

During the past 10 to 15 years, a number of new trends in the resistance pattern of enterococci have appeared. Some strains (particularly strains of *Enterococcus faecalis*) have acquired genetic material that allows them to produce beta-lactamase. Other strains, particularly strains of *E. faecium*, have acquired high-level resistance to streptomycin, gentamicin, or both. In addition, intrinsic high-level resistance to penicillin and ampicillin has appeared in some strains of enterococci. Finally, increasing numbers of enterococci have acquired high-level resistance to vancomycin. Some, but not all, of these highly resistant strains are also resistant to the investigational glycopeptide antibiotic, teicoplanin.

The previously mentioned microbiologic characteristics have a direct effect on the guidelines for treatment of enterococcal endocarditis. Standard therapy for enterococci with “typical” low-level penicillin resistance consists of a combination of intravenous aqueous penicillin G or ampicillin combined with gentamicin for 4 to 6 weeks. Patients with symptoms for less than 3 months can usually be treated successfully with 4 weeks of therapy. Patients with symptoms of more than 3 months’ duration before the initiation of treatment, those with a relapsed infections, and those patients with prosthetic valve infection should receive a 6-week course of therapy. Gentamicin therapy should be given at doses designed to achieve peak serum levels of approximately 3 µg per mL and trough serum concentrations <1 µg per mL. Patients with a history of penicillin allergy should be treated with a combination of vancomycin and gentamicin for 4 to 6 weeks.

Enterococcal endocarditis caused by strains with intrinsic high-level penicillin resistance (MIC >16 µg per mL) should be treated with a combination of vancomycin and gentamicin. Organisms that are resistant to penicillin via the production of beta-lactamase can be treated with either ampicillin-sulbactam, gentamicin, or vancomycin and gentamicin (188).

Endocarditis caused by enterococci with high-level aminoglycoside resistance, vancomycin resistance, or both may require special evaluation by microbiologists or infectious disease specialists. Some strains of enterococci that are streptomycin-resistant are gentamicin-susceptible and vice versa. When endocarditis is caused by enterococci that are highly resistant to both streptomycin and gentamicin, the addition of an aminoglycoside is not beneficial. Such patients may be treated with high doses of penicillin or ampicillin for 8 to 12 weeks and surgical resection of the involved valve may be necessary for cure. Other patients with vancomycin-resistant enterococcal endocarditis have been successfully treated with the oxazolidinone antibiotic linezolid (188a).

Staphylococcal Endocarditis

The success of therapy for staphylococcal endocarditis is dependent on numerous factors. These include whether the right-or left-sided valvular structures are involved, whether the staphylococcus is coagulase-negative or -positive, whether the infection occurs on a native or prosthetic valve, and whether there is favorable antimicrobial susceptibility to the staphylococcal isolate (eTable 25.4.4 and eTable 25.4.5).

***e*TABLE 25.4.4** THERAPY FOR ENDOCARDITIS CAUSED BY STAPHYLOCOCCUS IN THE ABSENCE OF PROSTHETIC MATERIAL

Antibiotic	Dosage and route	Duration	Comments
Methicillin-susceptible staphylococci			
Regimens for non–beta-lactam-allergic patients			
Nafcillin sodium or oxacillin sodium	2 g i.v. every 4 h, 4–6 wk		Benefit of additional aminoglycosides has not been established
With optional addition of gentamicin sulfate	1 mg/kg i.m. or i.v. every 8 h	3–5 d	
Regimens for beta-lactam–allergic patients			
Cefazolin (or other first-generation cephalosporins in equivalent dosages)	2 g i.v. every 8 h	4–6 wk	Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin
With optional addition of gentamicin	1 mg/kg i.m. or i.v. every 8 h	3–5 d	

Vancomycin hydrochloride	30 mg/kg per 24 h i.v. in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored	4–6 wk	Recommended for patients allergic to penicillin
Methicillin-resistant staphylococci			
Vancomycin hydrochloride	30 mg/kg per 24 h i.v. in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored	4–6 wk	

***e*TABLE 25.4.5** TREATMENT OF STAPHYLOCOCCAL ENDOCARDITIS IN THE PRESENCE OF A PROSTHETIC VALVE OR OTHER PROSTHETIC MATERIAL

Antibiotic	Dosage and route	Duration (wk)	Comments
Regimen for methicillin-resistant staphylococci			
Vancomycin hydrochloride	30 mg/kg per 24 h i.v. in two or four equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored	>6	
With rifampin	300 mg orally every 8 h	>6	Rifampin increases the amount of warfarin sodium required for antithrombotic therapy
And gentamicin sulfates	1.0 mg/kg i.m. or i.v.	2	
Regimen for methicillin-susceptible staphylococci			
Nafcillin sodium or oxacillin sodium	2 g i.v. every 4 h	>6	First-generation cephalosporins or vancomycin should be used in patients allergic to beta-lactam
With rifampin	300 mg orally every 8 h		Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin or with gentamicin methicillin-resistant staphylococci
And with gentamicin sulfate	1.0 mg/kg i.m. or i.v. every 9 h		

Native valve endocarditis caused by *S. aureus* is best treated with a semisynthetic penicillin such as nafcillin or oxacillin for 4 to 6 weeks. As methicillin-susceptible strains of *S. aureus* are more rapidly killed both *in vitro* and *in vivo* in a rabbit experimental model of endocarditis, many authorities recommend the addition of gentamicin for the first 3 to 5 days of therapy.

The combination of nafcillin and gentamicin given for the first 2 weeks of therapy in a multicenter collaborative study of native valve endocarditis caused by methicillin-susceptible strains of staphylococcal endocarditis was associated with more rapid clearing of the bacteremia than in patients randomized to receive monotherapy with nafcillin, but such combination therapy did not improve cure rates. Furthermore, combination nafcillin and gentamicin therapy was associated with a higher incidence of renal dysfunction.

Patients with native valve endocarditis caused by *S. aureus* who have histories of penicillin allergy can be treated with either first-generation cephalosporins such as cefazolin (if there is history of penicillin reaction that is not typical of an immediate-type allergy) or vancomycin. Vancomycin should not be used on the basis of convenience related to its pharmacokinetics in patients without a history of penicillin allergy, as clinical experience and *in vitro* studies have suggested that vancomycin is a less effective antistaphylococcal antibiotic than either nafcillin or oxacillin (188,194).

Selected patients with native valve endocarditis caused by *S. aureus* that involves the right-sided heart valves can be successfully treated with a 2-week treatment regimen using the combination therapy of nafcillin and gentamicin (191). Regimens that substitute vancomycin or cefazolin for nafcillin are not considered to be reliably effective in such patients if only 2 weeks of therapy are given (195). It is important to realize that short-course regimens using combination therapy are not suitable for patients with simultaneous infection of both left-sided heart valves, in patients with isolates that demonstrate high-level gentamicin resistance (MIC >500 µg per mL), or in patients with metastatic infection outside of the lungs.

Patients with prosthetic valve endocarditis caused by methicillin-susceptible *S. aureus* should be treated with nafcillin or an equivalent beta-lactamase–resistant beta-lactam antibiotic for at least 6 weeks. Because such infections are notoriously difficult to cure with medical therapy, most authorities recommend simultaneously treating with oral rifampin. In addition, many experts advise the addition of gentamicin for the first 2 weeks of therapy. A first-generation cephalosporin or vancomycin can be substituted for nafcillin in patients with a history of penicillin allergy.

The only effective therapy for patients with endocarditis caused by methicillin-resistant staphylococci is vancomycin. Monotherapy with vancomycin for 4 to 6 weeks is usually adequate for therapy with endocarditis caused by methicillin-resistant native valve endocarditis caused by either *S. aureus* or coagulase-negative staphylococci. However, when methicillin-resistant staphylococci cause infection in patients with prosthetic valves or other prosthetic material, combination therapy is generally used. Such patients can be treated with intravenous vancomycin and oral rifampin therapy for 6 to 8 weeks. The addition of gentamicin is recommended for the first 2 weeks of this therapeutic regimen. The appearance of strains of *S. aureus* that have intermediate- or high-level resistance to vancomycin has raised the possibility that such organisms could cause endocarditis for which all currently available therapy is ineffective. At present, there is little *in vivo* information available on the optimal treatment of human infection with such organisms.

Endocarditis Caused by HACEK Organisms

A number of fastidious gram-negative bacilli, collectively grouped by the acronym *HACEK*, accounts for 5% to 10% of all cases of native valve endocarditis in individuals who do not use illicit intravenous drugs. Organisms in this category include the following: *Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*. All of these organisms grow slowly in blood culture media, and incubation for 7 to 14 days may be required to detect their growth. This delayed growth makes standard antibiotic susceptibility testing difficult. Although in the past most HACEK organisms were ampicillin-sensitive, this is no longer true, as many species in this group have acquired the ability to produce beta-lactamase. However, virtually all of these organisms are highly susceptible to third-generation cephalosporins such as ceftriaxone and cefotaxime (Table 25.5). Either agent is usually effective when given for 3 to 4 weeks to patients with native valve endocarditis; patients with prosthetic valve endocarditis should be treated for 6 weeks (188).

Antibiotic	Dosage and route	Duration (wk)	Comments
Ceftriaxone sodium	2 g once daily i.v. or i.m.	4	Cefotaxime sodium or other third-generation cephalosporins may be substituted
Ampicillin sodium	12 g/24 h i.v. either continuously or in six equally divided doses	4	
With gentamicin sulfate	1 mg/kg i.m. or i.v. every 8 h		

TABLE 25.5 THERAPY FOR ENDOCARDITIS CAUSED BY HACEK MICROORGANISMS (*HAEMOPHILUS PARAINFLUENZAE*, *HAEMOPHILUS APHROPHILUS*, *ACTINOBACILLUS ACTINOMYCETEMCOMITANS*, *CARDIOBACTERIUM HOMINIS*, *EIKENELLA CORRODENS*, AND *KINGELLA KINGAE*)

Serum Bactericidal Levels

A commonly asked question in clinical practice relates to serum bactericidal levels. In general, serum bactericidal levels are of little clinical benefit since there is a relatively poor correlation between bactericidal levels and outcome and because results obtained when performing serum bactericidal levels may vary depending on

laboratory technique.

Surgical Therapy

Surgery was not an option in the management of endocarditis until 1964 when Yeh and colleagues first reported their success in surgical correction of an aortic valve perforation caused by endocarditis (196). The following year, Wallace and colleagues reported their success with valve excision and replacement in a patient with active endocarditis (197). In the ensuing 30 years, valve replacement has become routine in the management for patients with endocarditis who develop congestive heart failure, perivalvular abscesses, or intracardiac fistulae. In addition, surgery is now often used to manage extracardiac complications such as mycotic aneurysms and metastatic abscess formation.

The classic indications for cardiac surgery in patients with IE have remained relatively constant for the past two decades. Surgery is recommended for patients who develop congestive heart failure, who exhibit recurrent emboli during the course of therapy, and who fail to achieve an adequate bactericidal response to therapy. Most clinicians, including the authors, believe that abscess formation or the presence of a fungal endocarditis is a relative indication for surgical intervention. There is now a general consensus that the indication for surgery in active endocarditis differs little between native valve (Table 25.6) and prosthetic valve infection (Table 25.7). Large bulky vegetations—especially if they represent infections with organisms with a propensity to embolize, such as HACEK—may be an indication for surgical intervention, although no adequately controlled prospective study has examined this question. Congestive heart failure is the most common indication for surgery in patients with left-sided endocarditis, whereas refractory infection is the most frequent indication for surgery in right-sided endocarditis. There is widespread consensus that surgical intervention has been shown to improve patient survival in virtually every instance in which congestive heart failure complicates endocarditis. Before the routine use of surgery in patients with complicated endocarditis, congestive heart failure caused over 90% of all deaths. At times, congestive heart failure may be subtle, clinically evident only by a persistent tachycardia for no other reason. Thus, careful daily assessment by experienced clinicians is necessary for patients with hemodynamic instability or unexplained tachycardia or dyspnea.

Major indications
Congestive heart failure (New York Heart Association Functional Classification III or IV) caused by valve dysfunction
Persistent sepsis while receiving antimicrobial therapy
Recurrent embolism
Minor indications
Intracardiac abscess or fistula formation
Rupture of sinus of Valsalva aneurysm
Pathogen not susceptible to antimicrobial therapy
Fungal endocarditis
Acute *Staphylococcus aureus* endocarditis on left-sided heart valves with congestive failure
Relapse after an adequate course of antimicrobial therapy
Culture-negative endocarditis with persistent (>10 d) fever

TABLE 25.6 INDICATIONS FOR CARDIAC SURGERY IN NATIVE VALVE ENDOCARDITIS

Major indications
Congestive heart failure caused by unstable prosthesis
Fungal endocarditis
Significant perivalvular dehiscence
Recurrent septic emboli
Evidence for intracardiac abscess or fistula formation
Persistent sepsis (>3 d on antimicrobial therapy)
Interference with valve function caused by vegetation
Pathogen not susceptible to antimicrobial therapy
Minor indications
Nonstreptococcal pathogen
Relapse after adequate course of antibiotic therapy
Culture-negative endocarditis with persistent (>10 d) fever

TABLE 25.7 INDICATIONS FOR CARDIAC SURGERY IN PROSTHETIC VALVE ENDOCARDITIS

It is important to realize that the severity of cardiac and extracardiac manifestations of heart failure and the degree of hemodynamic stability of the individual patient are the major determinants of the optimal timing for surgery (198). In most case series, congestive heart failure caused by endocarditis-induced aortic insufficiency has a worse prognosis than endocarditis-induced mitral insufficiency. However, regardless of the valve involved, valve replacement should be undertaken in most patients as soon as signs and symptoms of congestive heart failure appear. It has been our experience that clinical signs of heart failure are more important than the echocardiographic assessment of left ventricular function. However, when aortic insufficiency is severe enough to result in preclosure of the mitral valve as detected by echocardiography, then operative intervention is likely to be required (137).

Recurrent emboli are a difficult criterion on which to base the need for surgical intervention. Some patients who experience episodes of peripheral embolism after the institution of antimicrobial therapy can be successfully managed without surgery. Furthermore, there is no precise threshold for the number of embolic events that mandate surgery. However, the authors share the opinion of Weinstein that surgery is usually indicated when a second episode of embolization occurs, especially in patients with endocarditis caused by *S. aureus*, any fungal pathogen, or *Haemophilus* species (43). The optimal timing of surgery for recurrent cerebral embolism is often problematic, because full heparinization during bypass surgery may exacerbate the clinical course of a recent cerebral infarct regardless of whether it is hemorrhagic or ischemic. However, it is our experience, and that of others, that surgery can usually be safely undertaken in such patients (199).

Despite the availability of an array of antimicrobial agents, failure to control infection is still a problem in the treatment of endocarditis. Such failure remains an indication for surgical intervention as one is removing the source of the bacteremia. The definition of bacteriological failure though is not clear-cut. Some organisms, such as *S. aureus*, may persist in the bloodstream for up to 5 days after initiation of therapy that will ultimately be curative. However, in general, persistently positive blood culture results after 5 to 7 days of therapy are an indication of the need for surgical intervention. Fungal endocarditis is notoriously difficult to cure with medical therapy alone. A few cases of endocarditis caused by *Candida* species have been cured without surgery (200,201 and 202), but most patients with *Candida* endocarditis, and virtually all patients with endocarditis caused by *Aspergillus*, require surgery to control their infections. Even combined surgical and medical therapy often leads to a poor outcome in patients with fungal endocarditis. For example, in a review of the outcome of 108 cases of fungal endocarditis, 97 of 108 (90%) died (35).

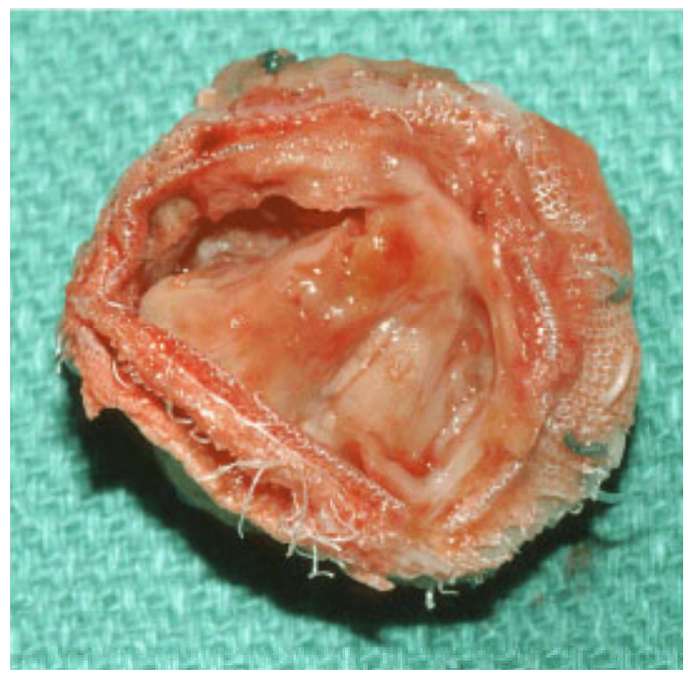
Bacteriological cure may be particularly difficult to achieve in patients with prosthetic valve endocarditis. The authors agree with others that prosthetic valve endocarditis caused by organisms other than viridans streptococci and that the HACEK group is difficult to cure with medical therapy. Most such patients eventually require surgery to achieve cure (203). In addition, when prosthetic valve endocarditis relapses after a course of medical therapy, a perivalvular infection is usually present. Such patients almost always require surgery. Certain organisms such as vancomycin-resistant enterococci cannot be effectively treated with any currently available agent. Patients with endocarditis caused by this organism should undergo early surgery whenever this is feasible.

The principal goals of surgery in patients with endocarditis are as follows: (a) valve repair or replacement, (b) drainage or repair of intracardiac abscesses, (c) excision of necrotic tissue, and (d) closure of intracardiac fistulae (204). The operative mortality for surgery in patients with endocarditis has varied widely from decade to decade and between different authors and medical centers. Some authors of more recent reports have reported operative mortality as low as 4.0% to 5.7% (198,205,206), whereas other authors have reported mortality of 20% to 30% (173,207,208). However, it is important to note that some case series included many patients who underwent emergency surgery, whereas other series included patients who underwent valvular replacement or repair for mild to moderate symptoms of congestive heart failure after lengthy periods of antimicrobial therapy (203). In general, surgery is of the highest risk and poorest outcome in patients with acute endocarditis caused by *S. aureus* complicated by the acute onset of congestive heart failure or perivalvular or aortic root abscess formation. In fact, abscess formation itself, regardless of causative organism, has been found to be an independent predictor of operative mortality by multivariate analysis in one study (204).

Most patients who undergo surgery for endocarditis require valve replacement. However, selected patients, particularly those with mitral valve endocarditis, can be effectively treated with mitral valve repair or vegectomy (209,210). Patients who have extensive damage to the aortic root and aortic valve may require placement of a homograft of the aortic root and ascending aorta (211). A variety of surgical procedures have been devised to deal with the problem of perivalvular abscess, aneurysm,

or fistula formation. These procedures include translocation of the aorta (212), valve conduit replacement of ascending aorta (213), and patch closure of annular mycotic aneurysms (214). Although some authors have found higher rates of recurrent endocarditis in patients receiving bioprostheses for infected heart valves than in those who receive mechanical valves (215), others have found the exact opposite (173). The authors agree with Mullany and colleagues who believe that the decision to place a bioprosthetic or a mechanical prosthesis should be dictated by the usual criteria (e.g., age, annular size, and ability to take anticoagulants) rather than by theoretical concerns about the risk of reinfection (204).

Patients with endocarditis who undergo valve replacement and survive through the early operative period have a reasonably good long-term prognosis. In a study of 151 patients who underwent valve replacement for endocarditis, the 5-year survival was 53% and the 10-year survival was 44%. Predictors of poor long-term survival in this group of patients using multivariate analysis included renal impairment, aortic valve involvement, and congestive heart failure at the time of surgery and surgery for an infected prosthetic valve (204). Others have also found that long-term outcome after valve replacement for endocarditis is heavily dependent on left ventricular function (203).



Surgical specimen of a tissue prosthesis destroyed by *Staphylococcus* endocarditis. This is the ventricular side of the aortic prosthesis. Note the thickened, scarred prosthetic leaflets causing both aortic stenosis and regurgitation.

FUTURE DIRECTIONS

Despite advances in echocardiography and surgery, IE remains a serious and often fatal disease. In one surgical study of 65 patients with aortic valve endocarditis complicated by periannular abscesses who underwent aortic valve replacement, the 30-day mortality was 24% in those who received aortic allografts and 8.5% in those patients who received prosthetic valves only. The 11-year survival rate was 82% in the allograft recipients and 65% in those receiving prosthetic valves (204a). Our basic understanding of the disease process thus remains incomplete, and our therapy is imperfect. Although there is a basic understanding of the nature of the vegetations, there is a great need to better understand exactly how vegetations propagate and result in valvular and perivalvular invasion. As noted in this chapter, it is generally accepted that vegetations begin on damaged heart valve tissue, often in an area where a jet effect from a high- to low-pressure system is present. A sterile platelet–fibrin thrombus forms and in the presence of bacteremia and circulating agglutinating antibodies specific for the invading organism, the thrombus then becomes infected as the organism adheres to the platelet aggregation (216). Studies suggest that *in vitro* resistance to thrombin-induced platelet microbicidal protein has an effect on the ability to cause endocarditis (216a). Moreover patients with endocarditis caused by infected intravascular devices are more likely to become infected with strains of *S. aureus* resistant to platelet microbicidal protein (216b). More research is needed in this area.

Nonbacterial thrombotic endocarditis lesions are seen in other conditions unrelated to IE, such as terminal cancers, congestive heart failure, pyelonephritis, or pneumonia (217). In addition, active collagen vascular diseases such as systemic lupus erythematous can result in vegetations (Libman-Sacks disease) that are similar to those seen in IE (113). Clearly, our understanding of the pathophysiology of vegetation remains incomplete.

More research is needed to learn whether agents such as anticoagulants that directly affect the vegetation might reduce their size or growth or prevent their occurrence all together. As vegetations also occur on apparently normal heart valves (218), our current understanding of the local hemodynamic and immunologic factors that lead to vegetations needs expanding. Similarly, it is not fully understood why some patients with endocarditis exhibit little or no immunologic response to their intravascular infection, whereas others demonstrate an array of immunologic complications that affect the kidney, skin, and joints. The precise mechanism and pathophysiology of this immunologic response in individual patients need further explanation.

More research is also needed to develop better therapies for the treatment of IE. Better drugs than are currently available are needed with less toxicity, especially renal, to treat enterococcal and staphylococcal endocarditis. There is a need for agents that can be given orally at infrequent intervals to facilitate use on an outpatient basis. As the age of the population with endocarditis grows older, the effects of antibiotics on this geriatric population also need to be clarified.

The value of prophylactic antimicrobial therapy in the prevention of endocarditis is still an unresolved issue. Successful medical malpractice claims continue to be litigated despite an absence of valid scientific data that prophylactic antimicrobial therapy is effective and of more benefit than risk. Indeed, every study on the value of prevention, even following dental work, has been underpowered. A true definitive study on the benefits of prophylaxis is needed.

Additional agents that are now responsible for culture-negative endocarditis will likely be recognized in the future. The role of viruses as causes for endocarditis has been debated for years (11). Viruses, such as HIV, can result in nonbacterial thrombotic endocarditis lesions (219), and endocarditis in mice has been produced by coxsackie B and adenoviruses (220). It is probable that new causes of endocarditis will be recognized as advances in diagnostic microbiology occur.

The surgical approach to IE will also likely evolve as advances in valvular and cardiovascular surgery occur. Given the high incidence of emboli from mitral valve endocarditis, surgery may become an early treatment option in more patients. Advances in less invasive cardiothoracic surgical techniques (221) and renewed interest in valvular preservation with improvements in valve repair and vegectomies (222) will likely continue, and these advances may alter the current surgical approach to endocarditis. Robotics may evolve to the point that the procedure of repair could be performed with less trauma to the patient. Prosthetic valve endocarditis often occurs in the prosthetic sewing ring, yet there are no studies to date examining whether improvements in prosthetic materials could reduce the risk of the endocarditis and the valve ring extension of infection.

Because endocarditis is an uncommon heterogenous disease there is a need for national and international registries or databases that prospectively collect data to answer important questions about management and outcome of frequent and uncommon pathogens that cause endocarditis, as well as frequent and uncommon complications such as cerebral embolism, mycotic aneurysms, and congestive heart failure.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Controversies revolving around the diagnosis and treatment of IE include the duration of therapy needed, the use of outpatient therapy, the use of expensive diagnostic tests such as TEE, the risks and benefits and indications for prophylactic antibiotic therapy (especially in the mitral valve prolapse syndrome), the timing of surgical intervention (including when surgical colleagues should be consulted), and the ethical issues that arise when ecurrent endocarditis results from destructive or erratic patient behavior such as often seen among illicit drug users.

All but the ethical issues have been addressed in detail in this chapter. It is our belief that endocarditis requires intravenous therapy. Until conclusive data showing efficacy of oral therapy are published or presented, we do not advocate therapy with any currently available oral antibiotic agent. We also advocate inpatient therapy for at least 5 to 7 days before considering outpatient intravenous therapy. The use of once-a-day administration of drugs with a long half-life, such as ceftriaxone, greatly assists in the administration of outpatient therapy. If there is any question regarding the suitability of the patient and family regarding home therapy though, we favor completing the entire antibiotic course as an inpatient or in a convalescent facility or infusion center.

We believe that TEE provides a substantial and clinically important identification of vegetations on leaflets and involvement of contiguous structures so that its routine

use makes some sense even though the chest wall echo may be adequate for diagnosis alone. This is particularly true for aortic valve endocarditis in which annular abscess may be discovered. The presence of abscess by TEE has prompted us to recommend surgery when other indications may not have been present.

Despite few data supporting prophylactic antibiotic usage to prevent endocarditis, our practice is to be quite liberal in its use. As prevention potentially protects from a serious disease that is seemingly much easier to potentially prevent than treat, the risk-benefit ratio of antibiotic usage, especially with dental procedures, seems in favor of antibiotic usage. Antimicrobial prophylaxis for mitral valve prolapse often presents a true therapeutic dilemma given the high prevalence in the population. Because the presence of mitral regurgitation in this disease is dependent on the relationship between the valve apparatus and left ventricular volume, mitral regurgitation may be audible at one time but not another. Given the reduction in emphasis on the physical examination in the majority of training programs in this country, the ability to properly auscultate also is troublesome if the criteria for use of antibiotic prophylaxis in patients with mitral valve prolapse require careful auscultation for murmur detection. For that reason, we are quite liberal in the use of antibiotic prophylaxis in patients with mitral valve prolapse.

We also believe that a close relationship with cardiovascular surgery is mandatory to ensure proper care of these often complex patients. We have formed an endocarditis team that includes cardiologists with an interest in valvular and congenital heart disease, specialists in infectious disease and bacteriology, and cardiovascular surgeons. We believe that consultation with cardiovascular surgeons should be done in almost all patients, regardless of their current clinical status. As mentioned in this chapter, this is particularly important in prosthetic valve endocarditis or when a potential complication, such as ring abscess, fungal valvular infection, or mycotic aneurysm, is present. Issues surrounding the surgical options can be complex, especially if there has been CNS bleeding or significant comorbid disease.

Finally, the debate on the treatment of recurrent endocarditis in patients who chronically use illicit intravenous drugs should be openly discussed and resolved. Ethical dilemmas and controversies often arise in patients with endocarditis who clearly indicate that their illicit drug use will continue. Our current policy is to replace or repair the infected heart valve in intravenous drug abusers only once; the ethical and financial issues that such an approach raise need to be resolved. We believe that every effort should be made to provide medical care for all intravenous drug abusers with special emphasis on efforts at rehabilitation. However, in an era of managed care and reduced resources, it is critical that personal responsibility for health become the accepted norm. Our policy at this time is to involve the ethics committee to provide a forum to understand the specifics for each individual who abused intravenous drugs and also has recurrent infective endocarditis.

THE FUTURE

Despite advances in echocardiography and surgery, IE remains a serious and fatal disease. Our basic understanding of the disease process remains incomplete. More research is needed to better understand vegetation propagation and the role of anticoagulant therapy. Refinements in antibiotic prophylaxis and treatment as well as surgical techniques are also important areas of research currently being pursued.

OVERVIEW

Diseases of the pericardium and restrictive cardiomyopathies cause impairment of diastolic function of the heart. Myriad underlying etiologies, via several mechanisms, result in final common clinical presentations, making specific diagnosis difficult. Historically, in the realm of invasive cardiac investigation (1,2), these disorders have become illuminated by several evolving noninvasive techniques including echocardiography (3,4) and magnetic resonance imaging (MRI) (5). This chapter discusses the general principles of diastolic heart failure including the biology and physiology, clinical presentation, epidemiology, investigation, and treatment. Specific diseases of the myocardium and pericardium that may cause diastolic dysfunction are reviewed.

GENERAL PRINCIPLES OF DIASTOLIC HEART DISEASE

Historical Perspective

Since the heart was determined to be a pump, physicians and biologists of the last century focused on systolic cardiac function. In an early reference to cardiac chamber filling by Wiggers in 1949, the term *inherent elasticity* was proposed to describe the passive elastic properties of the heart (6). In the 1970s, physiologists assessed the properties of active ventricular relaxation and passive filling using invasive quantification of intracavity pressure and volume (7). In the following decade, clinicians recognized that diastolic heart failure was an important cause of congestive heart failure (8,9 and 10), and Doppler echocardiography emerged as an important noninvasive method to assess diastolic function and the filling properties of the left and right ventricle (11,12,13 and 14). The term *diastology* was coined in the 1990s, and imaging modalities such as tissue Doppler echocardiography (TDE), color M-mode Doppler, and MRI were advancing our understanding of diastolic function (4,15,16) (*e*Table 26.0.1). Currently, new techniques and indices for assessing diastolic function continue to evolve (17,18,19,20 and 21), and there has been a shift toward evidence-based medicine with larger scale clinical trials to determine targeted treatment for diastolic heart failure.

***e*TABLE 26.0.1** HISTORICAL DEVELOPMENTS IN THE IDENTIFICATION, INVESTIGATION, AND TREATMENT OF DISORDERS OF DIASTOLIC FUNCTION

100 BCE	Galen suggested that the heart filled by active dilatation of the right ventricle.
1628	Harvey speculated that most ventricular filling occurred during atrial contraction.
1877	François-Franck concluded that most of left ventricular filling occurred in early diastole.
1906	Henderson described the three phases of diastole.
1921	Wiggers and Katz proposed that the atrial contribution to left ventricular filling varied.
1927	Meek proposed that the "contraction remainder" extended into diastole, thus suggesting active relaxation.
1949	Wiggers coined the term *inherent elasticity* to describe the passive diastolic properties of the myocardium.
1970s	*In vivo* and *in vitro* studies were performed on left ventricular relaxation and passive properties in health and disease.
1980s	Diastolic dysfunction was recognized as a common cause of heart failure in the presence of intact systolic function. Doppler echocardiography emerged as an important noninvasive method to assess diastolic function.
1990s	The *diastology* term was coined. Newer imaging modalities, including tissue Doppler echocardiography, color M-mode Doppler, and magnetic resonance imaging, emerged.

Modified from Shah PM, Pai RG. Diastolic heart failure. *Curr Prob Cardiol* 1992;17:783–868, with permission.

Definition of Diastolic Dysfunction

Clinical congestive heart failure is most often secondary to impairment of left ventricular (LV) systolic function (22). Diastolic impairment, although less common, is associated with significant morbidity and mortality (23). Clinically, it is important to distinguish isolated diastolic heart failure (normal ejection fraction) from systolic heart failure; although combined, systolic and diastolic heart failure will be more commonly observed (24,25). Several pathophysiologic definitions of diastolic heart failure have been proposed: (a) impaired capacity of the ventricles to fill without a compensatory increase in left atrial pressure (26); (b) abnormal ventricular filling that would produce inadequate cardiac output with a mean pulmonary venous pressure of less than 12 mm Hg (27); and (c) resistance to filling of one or both ventricles with an inappropriate upward shift of the pressure-volume loop, especially with exercise (28). These definitions have in common an abnormal resistance to filling causing elevated left-sided filling pressures and congestion. Diastolic dysfunction impairs filling of the ventricle by impairing relaxation (early diastole), reducing compliance (early to late diastole), or by external constraint from the pericardium (28,29). Numerous pathologic processes and disease states may produce the clinical constellation of diastolic dysfunction (Table 26.1).

Condition	Mechanism of diastolic dysfunction
Restrictive cardiomyopathy (idiopathic, restrictive cardiomyopathy, cardiac amyloidosis)	Increased resistance to ventricular inflow
Constrictive pericarditis	Increased resistance to ventricular inflow, with decreased ventricular diastolic capacity
Ischemic heart disease	
Flash pulmonary edema, dyspnea during angina	Impaired myocardial relaxation Diastolic calcium overload
Postinfarction scarring and hypertrophy (remodeling)	Increased resistance to ventricular inflow
Hypertrophic heart disease (hypertrophic cardiomyopathy, chronic hypertension, aortic stenosis)	Impaired myocardial relaxation Diastolic calcium overload Increased resistance to ventricular inflow due to thick chamber walls, altered collagen matrix Activation of renin-angiotensin system
Volume overload (aortic or mitral regurgitation, arteriovenous fistula)	Increased diastolic volume relative to ventricular capacity Myocardial hypertrophy, fibrosis
Dilated cardiomyopathy	Impaired myocardial relaxation Diastolic calcium overload Myocardial fibrosis or scar
Mitral or tricuspid stenosis	Increased resistance to atrial emptying

TABLE 26.1 CONDITIONS INVOLVING DIASTOLIC HEART FAILURE

As a framework to design and implement treatment trials, diagnostic criteria for patients with diastolic heart failure have been proposed. The 1998 European Study Group on Diastolic Heart Failure required (a) clinical evidence of congestive heart failure, (b) normal or mild LV dysfunction, and (c) the presence of impaired relaxation, filling, or compliance to diagnose diastolic heart failure (30) (*e*Table 26.1.1). All three components as assessed by noninvasive testing or cardiac catheterization were necessary for a diagnosis. Vasan and Levy subsequently proposed a less rigid criteria using similar inclusions but defining diastolic heart failure as definite, probable, or possible depending on the number of elements present (31). It has been suggested that the incorporation of exclusionary criteria will be required before using these standards for selection of patients for drug therapies to understand the specific effects on various pathologic conditions (32).

***e*TABLE 26.1.1** DIAGNOSTIC CRITERIA FOR DIASTOLIC HEART FAILURE

Signs or symptoms of congestive heart failure:

Exertional dyspnea [eventually objective evidence by reduced peak exercise oxygen consumption (<25 mL kg^{-1}•min^{-1})], orthopnea, gallop sounds, lung crepitations, pulmonary edema

and

Normal or mildly reduced left ventricular systolic function:

LVEF = 45% and LVEDIDI <3.2 cm•m^{-2} or LVEDVI <102 mL•m^{-2}

and

Evidence of abnormal left ventricular relaxation, filling, diastolic distensibility, and diastolic stiffness:

Slow isovolumic left ventricular relaxation:

LV dP/dt_{min} <1,100 mm Hg•s^{-1}

and/or $IVRT_{<30\ yr}$ >92 ms, $IVRT_{30–50\ yr}$ >100 ms, $IVRT_{>50\ yr}$ >105 ms

and/or t >48 ms

and/or slow early left ventricular filling:

PFR <160 ml•s^{-1}•m^{-2}

and/or $PFR_{<30\ yr}$ <2.0 EDV•s^{-1}, $PFR_{30–50\ yr}$ <1.8 EDV•s^{-1}, $PFR_{>50\ yr}$ <1.6 EDV•s^{-1}

and/or $E/A_{<50\ yr}$ <1.0 and $DT_{<50\ yr}$ >220 ms, $E/A_{>50\ yr}$ <0.5 and $DT_{>50\ yr}$ >280 ms

and/or $S/D_{<50\ yr}$ >1.5, $S/D_{>50\ yr}$ >2.5

and/or reduced left ventricular diastolic distensibility:

LVEDP >16 mm Hg or mean PCW >12 mm Hg

and/or PV A flow >35 cm•s^{-1}

and/or PV A t >MV A t + 30 ms

and/or A/H >0.20

and/or increased left ventricular chamber or muscle stiffness:

b >0.27

and/or b” >16

A/H, ratio of atrial wave to total signal excursion on the apexcardiogram; b, constant of left ventricular (LV) chamber stiffness; b”, constant of muscle stiffness; E/A, ratio of peak early to peak atrial Doppler flow velocity indexed for age groups; EDV, end diastolic volume; IVRT, isovolumic relaxation time indexed for age groups; LV dP/dt_{min}, peak negative left ventricular dP/dt; LVEDIDI, left ventricular end diastolic internal dimension index; LVEDP, left ventricular end diastolic pressure; LVEDVI, left ventricular end diastolic volume index; LVEF, left ventricular ejection fraction; MV A t, mitral atrial flow velocity duration; PCW, pulmonary capillary wedge pressure; PFR, peak LV filling rate indexed for age groups; PV A flow, pulmonary venous atrial flow velocity; PV A t, pulmonary venous atrial flow velocity duration; S/D, ratio of pulmonary vein systolic and diastolic flow velocities indexed for age groups; t, time constant of LV pressure decay.

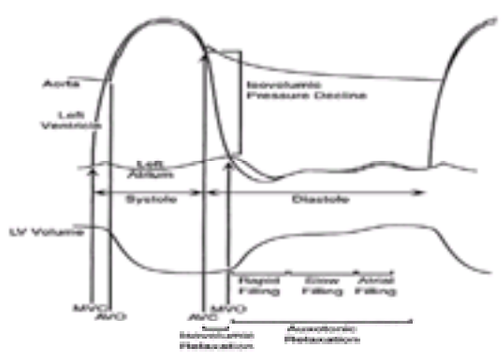
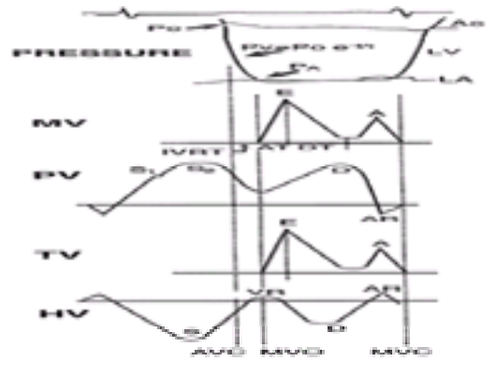
Pathophysiology of Diastolic Function

Phases of Diastole

The exact onset of diastole has been a matter of controversy over the years. Early definitions were provided by Wiggers (including isovolumic relaxation time in systole) (33) and Brutsaert et al. (including rapid filling phase in systole according to the triple control of relaxation) (34,35). A more contemporary clinical definition proposes that diastole is the period from the closure of the aortic valve to the end of mitral inflow and divided into two periods; an isovolumic relaxation period, and an auxotonic period that includes rapid filling, diastasis (slow filling), and atrial systole (36) (*e*Fig. 26.0.1). These phases are shown relating LV and left atrial pressure tracings and mitral, tricuspid, pulmonary, and hepatic venous Doppler echocardiography profiles (*e*Fig. 26.0.2). Each phase may be influenced by multiple factors including the effects of myocardial relaxation (37,38), the passive filling characteristics of the left ventricle (7,39), dynamics of the left atrium (40,41 and 42), pulmonary veins (43), mitral valve (44), and heart rate (45). The influence of the determinants of LV diastolic function on the phases of diastole are shown in *e*Figure 26.0.3.

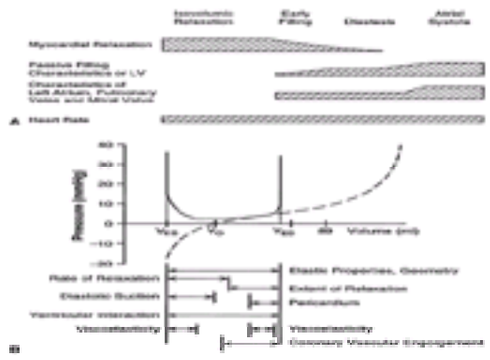


***e*FIGURE 26.0.1** Schematic drawing of the cardiac cycle in systole and diastole with left ventricular (LV) and left atrial pressures and LV volumes. Diastole is divided into two phases: an isovolumic relaxation period from aortic valve closure (AVC) to mitral valve opening (MVO) when the LV pressure falls with no change in volume; and an auxotonic period from MVO to mitral valve closure (MVC) when the LV volume increases with a variable increase in pressure and includes a rapid filling phase, slow filling, and atrial filling. AVO, aortic valve opening. (From Zile MR. Diastolic dysfunction: detection, consequences, and treatment. Part 1: definition and determinants of diastolic function. *Mod Con Cardiovasc Dis* 1989;58:68, with permission.)



***e*FIGURE 26.0.2** Diastole using Doppler echocardiography: combined schematic displaying left atrial (LA), left ventricular (LV), and aortic (Ao) pressure during diastole. Instantaneous LV pressure (Pv) falls exponentially through the isovolumic relaxation period (IVRT), from the Po [LV pressure at aortic valve closure (AVC)] to P_A [LV

pressure at mitral valve opening (MVO)] via the equation shown. Transmitral (MV) Doppler demonstrates an early rapid filling wave (E) broken into an acceleration time (AT) and a deceleration time (DT); a diastasis period with little inflow; and an atrial contraction wave (A) associated with an elevation of LA pressure above LV pressure until mitral valve closure (MVC) is induced by the onset of ventricular systole. Pulmonary vein (PV) demonstrates a systolic wave (S_1) related to atrial relaxation and a second systolic wave (S_2) related to mitral annular descent, a diastolic wave (D) associated with atrial emptying through an open mitral valve, and an atrial reversal wave (AR) associated with atrial systole causing regurgitation of flow back up the pulmonary veins. Transtricuspid (TV) inflow has a similar pattern velocity to transmitral. Hepatic vein (HV) flow is similar to pulmonary vein flow, with a more prominent reversal of flow between the S and D waves associated with ventricular systole (VR).



***e*FIGURE 26.0.3 A:** Influence of the determinants of diastolic function on the different phases of diastole (clinical definition). Note that the effect of myocardial relaxation extends into the early or rapid filling phase. LV, left ventricle. (From Little WC, Downes TR. Clinical evaluation of left ventricular diastolic performance. *Prog Cardiovasc Dis* 1990;32:276, with permission.) **B:** Effect of the different factors that influence LV diastolic pressure during diastole, using the pressure-volume loop format. The wavy lines refer to the time period when each factor is important (i.e., the elastic properties and geometry of the ventricle are important for all of diastole). Note: During early diastole, the combination of active relaxation and the elastic recoil from the elastic energy stored in the muscle from the previous systole (diastolic suction) determine the atrioventricular pressure gradient and ventricular filling. The dashed line refers to the purely elastic pressure-volume curve of the myocardium in the absence of relaxation. Note that there are negative pressures resulting from the stored elastic energy. V_{ED}, end diastolic volume; V_{ES}, end systolic volume; V_O, equilibrium volume. (From Gilbert JC, Glantz SA. Determinants of left ventricular filling and of the diastolic pressure-volume relation. *Circ Res* 1989;64:827, with permission.)

Isovolumic Relaxation

The isovolumic relaxation time period occurs from the time of aortic valve closure to mitral valve opening with no change in LV volume (46). During this period, active, energy-dependent myocyte relaxation occurs until mid-diastole. Ventricular pressure (P_v) decay during the isovolumic period follows an approximately exponential curve that can be characterized by its starting pressure (P_o) and its time constant (tau, t) (47). This curve may be fitted with the assumption of either a zero asymptote $P_v = (P_o\, e^{-t/t})$ (47), where P_o is the LV pressure at the time of aortic closure or peak negative dP/dT, *t* is the time after the onset of relaxation, and t is the time constant of relaxation. A more physiologic description with a nonzero value asymptote (to account for subatmospheric pressure and the effects of pericardial pressure) is shown in equation 1 (27,48).

$$P_v = (P_o\, e^{-t/\tau}) + P_b$$

A low value of tau is indicative of fast relaxation, whereas a high value represents slow relaxation. Isovolumic relaxation duration can be obtained invasively and by several noninvasive modalities including phonocardiography, M-mode, and Doppler echocardiography (49,50 and 51). Manipulation of the nonzero equation ($P_o\, e^{-t/t} + P_b$) has allowed the calculation of tau from the Doppler-derived isovolumic relaxation time (IVRT), systolic blood pressure, and left atrial pressure (P_{LA}) via tau = IVRT/[ln(systolic blood pressure) – ln(P_{LA})] (52). This estimate of relaxation may be useful in patients in the intensive care unit with hemodynamic monitoring. The time constant seems to be less preload dependent than the IVRT (46,47). Other noninvasive methods for determining LV relaxation have used the aortic and mitral regurgitant velocity profiles (53). Newer modalities including the color M-mode slope (Vp) (54) and TDE annular early velocity have been shown to relate closely to the time constant of relaxation (16). Isovolumic relaxation ends when the LV pressure falls below the left atrial pressure, resulting in mitral valve opening and the start of rapid filling phase (27).

Rapid Filling

The auxotonic period occurs from mitral valve opening until mitral valve closure (36). The rapid filling phase begins at mitral valve opening, when the LV pressure falls below left atrial pressure. LV pressure continues to fall because of ongoing relaxation and elastic recoil, with blood accelerating because of the development of a left atrial to LV pressure gradient (27). This gradient is influenced by the level of left atrial pressure at mitral valve opening and the rate of decline of LV pressure (55,56). Blood rapidly enters the left ventricle from the left atrium during the early filling period, with approximately 70% of the stroke volume received by the left ventricle during the first third of diastole (3). Active ventricular suction (pulling of blood) may play an important role in the rapid filling phase (57,58) (*e*Fig. 26.0.3B). It has been shown that if mitral flow is prevented, the LV pressure decreases to a subatmospheric asymptote (59). Ventricular suction may occur because of the recoil of the compressed elastic elements during contraction (39). Rapid filling ends as atrial and ventricular pressures equilibrate (27).

Diastasis (Slow Filling)

Diastasis, or the slow filling period, occurs between the rapid filling phase and atrial contraction and accounts for less than 5% of filling. After rapid filling, left atrial and ventricular pressure are almost equal, yielding no immediate forward driving gradient (27).

Atrial Filling (Contraction)

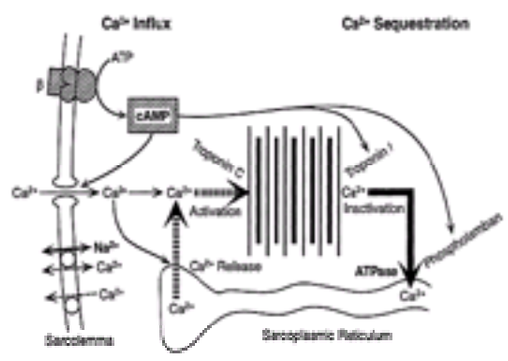
The atrial filling phase of diastole occurs when the left atrial pressure rises above ventricular pressure, forcing or pushing blood across the mitral valve and a small amount of regurgitation into the pulmonary veins. This late diastolic transmitral flow increases ventricular end diastolic volume by 25% in healthy subjects with only a small rise in mean pulmonary venous pressure. Diastole ends with onset of ventricular systole when the rapid increase in ventricular pressure closes the mitral valve (27).

Determinants of Diastolic Function

Diastolic function is dependent on four major factors: (a) active myocardial relaxation; (b) passive pressure-volume relationships (i.e., LV compliance); (c) left atrium (including atrial function), pulmonary vein, and mitral valve characteristics; and (d) heart rate (27) (*e*Fig. 26.0.3). Each variable can be in turn affected by different physiologic states and organic heart diseases. The physiology of ventricular diastolic function is exceedingly complex, involving interactions at the subcellular, myocyte, myocardial tissue, and whole chamber levels (29,60). Pericardial contributions to diastolic physiology are discussed in the section Pericardial Disease.

Myocardial relaxation is mediated by intracellular adenosine triphosphate (ATP) and calcium (61,62). Contraction is initiated by calcium release in large quantities from the sarcoplasmic reticulum (*e*Fig. 26.0.4). This free ionized calcium ion binds to the troponin-tropomyosin complex, removing the inhibitory effect of that complex on the actin-myosin myofilaments (37). Active cross-bridges form between actin and myosin with consequent contraction of the myofilaments. This rapid increase of intracellular calcium is countered by calcium sequestration into the sarcoplasmic reticulum by the calcium-ATPase pump (63), which is tonically inhibited by the phospholamban. Abnormal relaxation and diastolic tone may result from either elevated cytosolic levels of calcium in diastole or inadequate intracellular ATP levels to dissociate actin from myosin (62). Enhanced relaxation of the LV myocytes results in a reduction of an intracavitary pressure gradient within the left ventricle during

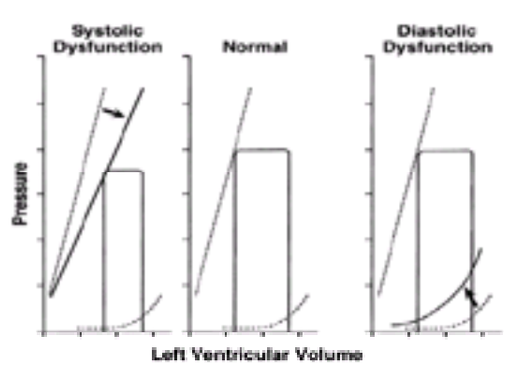
early diastole, and a pressure gradient is generated across the mitral valve pulling in blood from the left atrium (64). It has been demonstrated that relaxation is asynchronous, occurring earliest in apical segments and resulting in the intracavitary suction of blood from middle and basal regions toward the apex (64). Because relaxation is an energy-dependent process, it is influenced by many factors including ischemia and LV mass (65,66 and 67).



***e*FIGURE 26.0.4** Role of calcium ions in activation and inactivation of contractile proteins in myocytes. Calcium influx across the sarcolemma and release of calcium contained in the sarcoplasmic reticulum allow cross-linking of actin and myosin, causing active contraction. Calcium is then rapidly resequestered into the sarcoplasmic reticulum by calcium adenosine triphosphatase (ATPase), allowing active relaxation. Beta-adrenergic receptor stimulation increases intracellular cyclic adenosine monophosphate (cAMP) and further enhances the action of the calcium ATPase via the protein phospholamban. ATP, adenosine triphosphate. (From Bonow RO, Udelson JE, et al. Left ventricular diastolic dysfunction as a cause of congestive heart failure. *Ann Intern Med* 1992;117:505, with permission.)

The passive filling characteristics of the ventricle describe the late diastolic volume-pressure relationship of the chamber. This is determined by the viscoelastic nature of the myocardium; chamber size, shape, and wall thickness; right ventricular (RV) and LV pressure-volume interaction; intrathoracic pressure and pericardial constraint; and any active myocardial relaxation that remains incomplete (7). *Compliance*, the ratio of change in volume per change in pressure, quantifies the net result of all the previously mentioned factors. Intrinsic myocardial stiffness relates to the amount of collagen within the myocardium. Collagen plays an essential role in converting the contractile force of the myocytes into intraventricular pressure, as well as determining overall ventricular size and shape (68,69). Collagen fibrils coil around myofibrils. Little force is needed initially to stretch the coil, whereas large forces are required at full stretch, yielding an exponential stress-strain relationship (70). Pressure-induced hypertrophy is associated with increased collagen content and secondarily increased overall stiffness. Local collagen scarring following myocardial infarction is threefold stiffer than the surrounding myocardium (71).

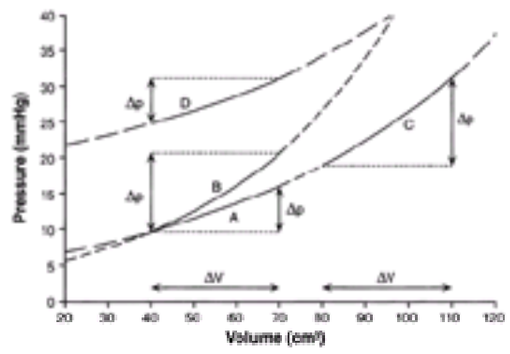
Diastolic properties of the ventricle have been studied and quantified extensively using pressure-volume loops (eFig. 26.0.5) (72,73 and 74). Simultaneous recording of ventricular pressures and volumes (contrast angiography, radionuclide imaging, or echocardiography) yield the loops that have traditionally been the benchmarks for quantifying systolic and diastolic function of the heart.



***e*FIGURE 26.0.5** Schematic representation of ventricular pressure-volume loops. The center panel demonstrates the normal situation. Note the exponential nature of the curve through late diastole. In systolic dysfunction (*left*), the end systolic pressure line is displayed downward and is manifest by a decreased ability of the left ventricle to generate high pressures for a given volume. Diastolic dysfunction involves an upward and leftward shift of the exponential curve—a result of elevated filling pressures for a given volume. (From Katz AM. Influence of altered inotropy and lusitropy on ventricular pressure volume loops. *J Am Coll Cardiol* 1988;11:438, with permission.)

There is a curvilinear relationship between the volume and pressure in the ventricle that is determined by the stress-strain relationship. As the volume increases in the left ventricle during diastole, there is an increase in LV pressure (70). The slope of the pressure-volume curve during diastole (dP/dV) is the chamber *stiffness*, and the inverse of this relation is the chamber *compliance* (14).

If we represent the ventricle as a thin-walled sphere with wall thickness *h* made up of tissue with a linear stress-strain relationship (constant stiffness, E), chamber stiffness (dP/dV) is approximately equal to the product of wall thickness multiplied by wall stiffness, *hE*, demonstrating that both myocardial stiffness and wall thickness influence chamber stiffness (29,75). The slope (dP/dV), or stiffness of the left ventricle, is not constant, but rather follows an exponential curve upward as volume increases (eFig. 26.0.6). Thus, when end diastolic volume increases without intrinsic change in the mural stress-strain relationship, stiffness increases along this exponential curve (eFig. 26.0.6). Conversely, an increased stiffness constant *E* moves the loop to a steeper curve with no change in volume (eFig. 26.0.6). Finally, it can be seen that increasing loading pressure without changing volume moves the loop directly upward, with no change in dP/dV or stiffness (eFig. 26.0.6).



***e*FIGURE 26.0.6** Relationship between chamber stiffness and the diastolic pressure-volume curve. Stiffness is the local slope of the curve, given by dP/dV (Dp, DV) (A). Stiffness increases (along the same exponential curve) with increased volume loading, without any innate change in the chamber properties (C). Intrinsic chamber changes may change the underlying exponential curve, increasing stiffness at normal loading volumes (B). Finally, increasing pressure, without changing volume or the intrinsic characteristics of the chamber, moves the entire curve upward, without any change in stiffness (D). (From Thomas JD. Assessment of diastolic heart failure by echocardiography. *Heart Failure* 1991;7:195, with permission.)

Pulmonary vein, left atrium, and mitral valve characteristics determine the volume of blood that enters the left ventricle (27). Early rapid filling is largely dependent on the pressure gradient between the pulmonary veins and left atrium and the left ventricle and the rate of myocardial relaxation and ventricular suction (55,57,58,76).

Diseases of the mitral valve such as mitral stenosis delay LV filling and prevent early rapid filling (27).

The left atrium acts as a reservoir of blood, as a passive conduit during early LV filling and as an active pump at end diastole (77). Atrial systolic function (active phase) may be essential to maintain cardiac output in disease states (78,79). Atrial function relates to its compliance (80), preload, afterload, and intrinsic contractility. Atrial preload, the volume and pressure at the time of atrial activation, has been shown in animals to influence the strength of atrial contraction in a manner analogous to Starling's law in the ventricle (81). Thus, a high left atrial pressure at the time of atrial contraction (e.g., due to delayed ventricular relaxation, elevated heart rate, or first-degree atrioventricular block) leads to a more forceful contraction and a larger mitral A wave. A strong relationship between left atrial (+) dP/dT, an invasive measure of left atrial contractility, and a combination of mitral inflow A wave and pulmonary venous atrial reversed flow has been demonstrated (82). The left atrial peak + dP/dT showed a linear relationship with left atrial pressure before atrial contraction, suggesting the presence of the Frank-Starling mechanism of the left atrium. Atrial afterload, in effect ventricular stiffness, impedes transmitral flow (83). Atrial contractile performance varies considerably in health and disease (78,79). In young and healthy normal individuals, the atrial contribution is less than 20% of the total volume, whereas in older healthy subjects, the atrial "kick" accounts for a greater proportion of the total LV filling (84). Atrial contractile function has delayed recovery following electrical cardioversion (42). Decreased atrial systolic function due to infiltration plays a role in the reduction in forward transmitral atrial contraction wave by Doppler echocardiography seen in advanced cardiac amyloidosis (85).

Heart rate bears directly on cardiac output in cases of diastolic dysfunction (45,86,87). As heart rate increases, the diastolic filling period preferentially decreases with respect to the systolic ejection period. As ventricular filling is functionally delayed, adequacy of inflow deteriorates and cardiac output paradoxically falls.

Neurohormonal activation, conduction abnormalities, and pericardial constraint may also influence diastolic function. Catecholamines may enhance relaxation and increase heart rate, thus decreasing the diastolic period (88). Conduction abnormalities may also influence diastole (89). LV relaxation may be impaired by conduction abnormalities by causing segmental asynchrony (90,91), which may contribute to decreased exercise tolerance in patients with left bundle branch block or RV paced rhythms. The pericardium (see below) considerably affects diastolic function, notably in constrictive pericarditis (13).

Diagnostic Approach to Diastolic Function

Clinical heart failure with normal systolic function (usually by echocardiography or nuclear techniques) would suggest diastolic dysfunction. The goals of investigation should include identification and quantification of diastolic dysfunction using the LV filling patterns (92,93 and 94) and newer Doppler techniques (16); semiquantitation of mean left atrial and end diastolic filling pressures (17,95,96,97 and 98); determination of underlying pathophysiologic mechanisms (constriction vs. restriction) (99,100,101 and 102); and stratification and prognostication and monitoring and guidance of therapy (103,104). Cardiac catheterization, echocardiography, radionuclide angiography techniques, and MRI are discussed in the following sections (24,105).

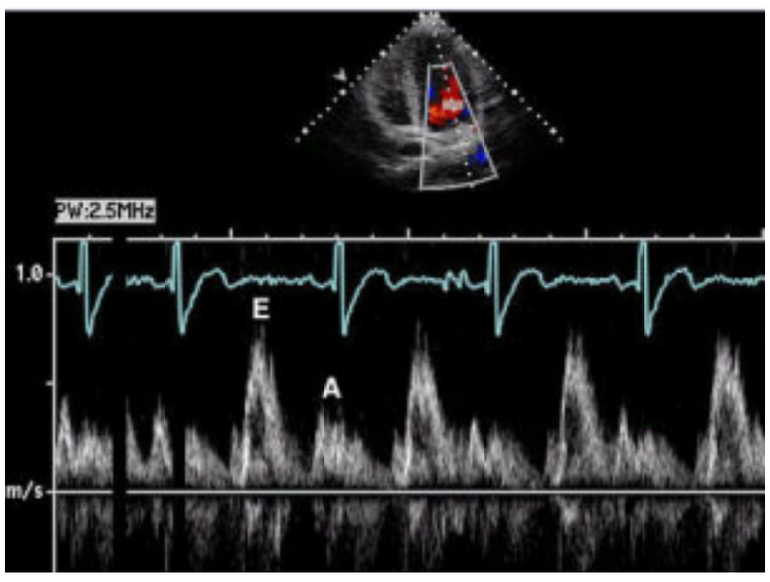
Echocardiography

Echocardiography has emerged as the main technique in the evaluation of patients with diastolic dysfunction and can be used as an alternative to cardiac catheterization (4,15). This modality encompasses M-mode, two-dimensional echocardiography, and Doppler echocardiography. This noninvasive modality quickly and safely assesses systolic ventricular function, atrial size, and function and valvular function; indirectly infers filling pressures and inflow patterns; and offers information to identify specific pathologies such as constrictive pericarditis, pericardial effusion, cardiac amyloidosis, and sarcoidosis (15,51).

With its enhanced spatial and temporal resolution, M-mode echocardiography has been used to time cardiac events such as the period of LV contraction and relaxation and the timing of valve opening and closing. Digitized M-mode echocardiography of the endocardium has been used to characterize diastolic filling in various diseases (106,107 and 108). M-mode echocardiography has been used to demonstrate abnormal RV diastolic collapse in cardiac tamponade (109), the abnormal septal bounce in constrictive pericarditis (110), and decreased annular motion in coronary artery disease (111). Ultrasound systems with high frame rate imaging now have the ability to generate anatomic M-mode tracings in any plane from digitally acquired two-dimensional images (112).

A complete two-dimensional echocardiogram is part of the diastolic function evaluation. It allows for assessment of global and regional systolic evaluation, LV mass and volumes, atrial dimensions, and pericardial thickness. Two-dimensional echocardiography helps exclude other causes of heart failure such as valvular heart disease (15,16). Diastolic dysfunction is unlikely with no organic heart disease, as documented by echocardiography. Similarly, there is a significant relationship with increasing left atrial size and stage of diastolic dysfunction (113). Inferior vena cava (IVC) plethora by echocardiography is closely associated with elevated right atrial (RA) pressure (114).

An integrated approach to the Doppler evaluation of diastolic function includes an evaluation of filling of both the left and right ventricles. The phase of respiration can be assessed simultaneously with Doppler flow velocities using a nasal thermistor to measure the change in temperature between inspiration, expiration, and apnea. Respiratory variations are crucial in differentiating constrictive pericarditis from restrictive cardiomyopathy (4). Transmitral flow is assessed in the apical four-chamber view with the pulsed Doppler sample volume (1 to 2 mm) at the leaflet tips along a laminar flow stream into the LV cavity. Optimal recordings depend on many technical features including sample volume placement, transducer alignment, and machine settings (115). Peak velocities of E and A, E/A ratio, and deceleration times are obtained and can be compared with age- and gender-matched subjects (84). Isovolumic relaxation time can be measured by placing a continuous wave Doppler beam between the LV outflow tract and the LV inflow to measure the time from the aortic valve closure to mitral valve opening. An alternative approach to measuring isovolumic relaxation time is to use pulsed wave Doppler (116).



Pulsed wave Doppler signal from the mitral valve inflow. Note the E (early) and A (atria) waves.

Pulmonary venous flow can be assessed by transthoracic echocardiography by placing the sample volume (3 to 4 mm) into the right upper pulmonary vein from the apical four-chamber view. Adequate recordings can be achieved in up to 80% to 90% of patients, especially with the use of contrast echocardiography (15,117,118). Failure to obtain this information, critical to some cases, is an indication to proceed to transesophageal echocardiography (119).

RV inflow is assessed by placing the sample volume (1 to 2 mm) at the leaflet tips of the tricuspid inflow from the apical four-chamber view or the RV inflow view (120). The inferior vena cava diameter can be measured from the subcostal view and its respiratory variation calculated using M-mode echocardiography. Also from the subcostal position, hepatic venous flow sample volume (3 to 4 mm) can be recorded by placing the sample volume 1 to 2 cm into the right superior hepatic vein. The patient may have to control his or her depth of respiration to maintain the sample volume in a stable position. Finally, superior vena cava flow can be measured by placing the sample volume (3 to 4 mm) at a depth of 5 to 7 cm into the vein from the supraclavicular position (4). The diastolic filling variables that are typically measured are shown in Table 26.2.

Left ventricular filling	Right ventricular filling
Left ventricular inflow	Right ventricular inflow
E-wave velocity (cm/sec)	E-wave velocity (cm/sec)

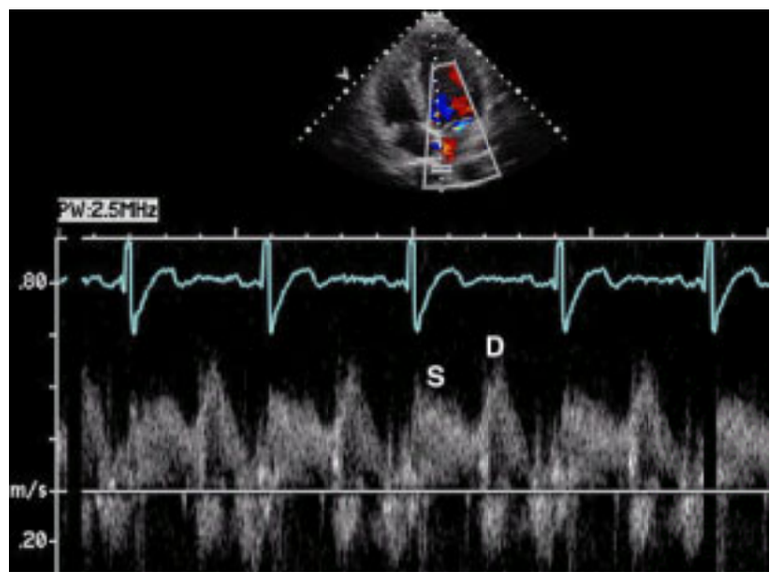
TABLE 26.2 DIASTOLIC FILLING VARIABLES



Pulmonary vein pulsed wave Doppler flow. Note the S (systolic) wave and the D (diastolic) wave.

Color M-mode Doppler is increasingly performed as a routine component of the diastolic function assessment. Pulsed wave Doppler records flow at a single spatial location in time. In contrast, color M-mode Doppler provides a map of LV filling velocities across a scan line with enhanced spatial and temporal resolution. In the apical four-chamber view with a standard depth, the M-mode cursor is aligned with the mitral inflow color Doppler flow, with the color Doppler sector size covering only the left ventricle and mitral valve. The positioning of the image should be adjusted to align the scan line parallel to the direction of flow. The color Doppler Nyquist limit is set below the mitral E wave peak velocity to allow for color Doppler aliasing of flow. The scan line from the mitral leaflet tips to the LV apex is obtained. LV filling is measured from the slope of the early propagation velocity (Vp) at the mitral valve plane to 4 cm into the LV cavity. Measurements are made at a sweep speed of 100 mm per second using the slope of the first aliasing velocity (17,121). Care must be taken to avoid measuring intracavitary flow starting before the onset of the mitral inflow. This may be prominent in some patients with hypertrophic cardiomyopathy or restrictive cardiomyopathy. It may be difficult to obtain accurate recordings in patients with sinus tachycardia as well as first-degree heart block because of fusion of the E and A waves (similar to mitral inflow).

TDE allows for evaluation of myocardial performance by evaluating myocardial rather than blood flow velocities. By means of a filter and amplification method, low-velocity and high-amplitude signals of tissue are preferentially displayed. A pulsed wave or color-encoded M-mode or two-dimensional map can be displayed and is superimposed over the two-dimensional image (122). TDE is able to provide myocardial velocities at different locations of the myocardium from different acoustic windows. Both systolic and diastolic patterns are displayed. For the assessment of diastolic function, Doppler velocities are obtained from the apical four-chamber view where the myocardium is near parallel with the transducer. The sample volume is approximately of 10-mm length, and the filter is set at 100 Hz or lower with a sweep speed of 100 mm per second. Sampling can be done at the lateral and septal annulus as well as the anterior and inferior annulus in the two-chamber view (16,123). TDE has the same limitations as the standard Doppler techniques. There are several limitations of TDE, including the effect of translation motion, Doppler angle of incidence, sample volume size, and inability to interrogate the apical segment (16,21).

Transesophageal echocardiography can complement transthoracic echocardiography in the comprehensive assessment of diastolic filling, providing both a physiologic assessment using Doppler echocardiography and excellent anatomic delineation. Optimal pulmonary venous flow recordings can be obtained by pulsed Doppler in virtually all patients from both the left and right upper veins from multiple planes. Isovolumic relaxation time, using continuous wave Doppler, is difficult to record using the transesophageal approach, but sometimes can be recorded from the apical five-chamber view from the deep transgastric approach. The pericardium can be visualized and measured when it is thickened by constrictive pericarditis (124). This is especially obvious over the RA and ventricular free walls, which are often seen to be “tethered” (101,119).

Acoustic Quantification and Color Kinesis

Acoustic quantification and color kinesis are automated boundary techniques that can provide complementary information about global and regional diastolic function (125). Acoustic quantification uses ultrasonic backscatter to allow instantaneous calculation of LV cavity areas during the cardiac cycle (126). Early studies showed good correlation between change of total area that occurred during rapid filling and atrial filling phases obtained by acoustic quantification and the mitral inflow patterns (127). Acoustic quantification evaluation of diastolic function has been also used in patients undergoing cardiac transplantation (126,128). Color kinesis is another echocardiographic technique (based on acoustic quantification) that encodes endocardial motion and is able to evaluate regional and global diastolic function (129,130).

TEI Index

The Doppler-derived index of combined systolic and diastolic myocardial performance is a relatively new index based on an old concept (ejection time intervals) (131). This index is the sum of isovolumic contraction time and isovolumic relaxation time divided by ejection time [(ICT + IRT)/ET]. It is easily measured from the LV outflow and mitral inflow using Doppler echocardiography. The TEI index has been shown to correlate with invasive measures of diastolic performance (18) and has been shown to be a useful predictor of survival in patients with cardiac amyloidosis (132) and dilated cardiomyopathy (133).

Exercise Capacity and Diastolic Function

Dyspnea on exertion is often the only symptom in patients with diastolic dysfunction and, accordingly, evidence of diastolic dysfunction may only be discernible by exercise. The normal hemodynamic response to exercise is an increase in ejection fraction and cardiac output with a decrease in the diastolic filling period. LV pressure in early diastole falls, allowing increased diastolic filling without increased left atrial pressure. However, in the presence of diastolic dysfunction, ventricular pressure fails to fall and an abnormal rise in left atrial pressure is required to maintain adequate inflow in the shortened filling period. Exercise testing with invasive hemodynamic monitoring (134) showed patients with diastolic dysfunction to have a significantly lower stroke volume index and end diastolic volume index than controls, whereas the end systolic volume index was not different. Patients, but not controls, had a markedly increased capillary wedge pressure with peak exercise. Exercise echocardiography may enable the examination of patterns of ventricular filling during or immediately after exercise and may prove to be a useful tool in detecting latent ventricular dysfunction, which may not be evident at rest.

Several studies have shown that baseline diastolic function is an important determinant of exercise capacity in various diseases (135,136,137,138 and 139). Other studies have focused on the role of medications, including angiotensin receptor blockers, on exercise tolerance and quality of life in patients with hypertensive response on a treadmill exercise test (140). Regional diastolic function has been evaluated with TDE in patients to detect LV ischemia during dobutamine stress testing (141). There has been recent interest in using TDE ratio E/Em during exercise to assess LV filling pressure (141a).

The difficulty with performing diastolic function measurements during exercise stress testing is the effect of tachycardia on the filling parameters (causing fusion of the

E and A waves), and the lusitropic effects of dobutamine as a stressor.

Cardiac Catheterization

The hemodynamic diagnosis of diastolic dysfunction requires measurement of LV volumes and pressures using high-fidelity micromanometer-tipped catheters (142). An elevated pulmonary capillary wedge pressure (PCWP) or mean left atrial pressure suggests diastolic dysfunction. Invasive measures can determine the passive elastic properties of the left ventricle from the pressure-volume relationship and the rate of myocardial relaxation from the time course of the fall of LV pressure during isovolumic relaxation (7).

The net passive diastolic properties of the left ventricle can be assessed by constructing pressure-volume loops and calculation of the LV chamber stiffness (dP/dV) and the modulus of chamber stiffness (K) (143). The passive diastolic properties of the myocardium can be assessed by calculation of the myocardial stiffness and the constant of myocardial stiffness (k) using the myocardial stress-strain relationship. Isovolumic relaxation can be assessed by the time course of isovolumic pressure decline by the negative dP/dT and the time constant of relaxation (14,144). Quantitative analysis of filling can be performed by using frame by frame analysis of the contrast angiogram or using volumes derived from conductance catheters (27,145). LV filling rates can be derived from the first derivative of LV volume with respect to time (dV/dT) (146). Several technical and theoretical problems have limited the usefulness of invasive measures in the clinical assessment of diastolic function.

Radionuclide Angiography

Radionuclide angiography can be used to document a normal ejection fraction and evaluate LV diastolic function using analysis of the LV time-activity curve (147). First-pass and gated equilibrium radionuclide imaging techniques have been used to noninvasively measure LV volume. The count activity over the left ventricle minus the background counts can be used to derive the relative LV volume and the time-activity curve. The parameters that can be generated from the time-activity curves include the peak rate of rapid diastolic filling and time to peak filling rate and an estimate of filling in early and late diastole to total stroke volume (147). Peak filling rates are usually normalized to end diastolic counts. Regions of interest in different sectors can be used to delineate regional time-activity curves and the spatial and temporal heterogeneity of diastolic function (147,148). Diastolic filling by radionuclide angiography relates generally to the diastolic filling parameters by Doppler echocardiography, especially the timing of events and the relative contributions of the early and late filling phases to total stroke volume (149). Extensive literature has been published showing the utility of clinical evaluation of LV diastolic filling by radionuclide angiography in coronary artery disease at rest and with exercise (150,151 and 152), in hypertrophic cardiomyopathy (153,154 and 155), hypertension (156,157), and dilated cardiomyopathy (158). Limitations include technical factors such as variations in the heart rate, smoothing, and effect of loading conditions. Also an increase in the peak filling rate may not necessarily suggest improvement of diastolic function (159), but rather an increase in left atrial pressure (160).

Magnetic Resonance Imaging

MRI has an increasingly valuable role in the assessment of diastolic function in restrictive cardiomyopathy and pericardial diseases. In particular, it can define the anatomic and functional abnormalities of diastolic function, especially in pericardial (pericardial effusions, constriction) and myocardial diseases (cardiac amyloidosis, hemochromatosis). It has been useful in differentiating constrictive pericarditis from restrictive cardiomyopathy (161,162).

In restrictive cardiomyopathy, the absence of increased pericardial thickening in the presence of abnormal filling is suggestive of restrictive cardiomyopathy (5,163,164). MRI provides excellent visualization of the pericardium and thus can define the presence and extent of pericardial effusions and increased pericardial thickness in constrictive pericarditis (161,165,166). Ancillary evidence includes conical or tubular narrowing of the ventricles from the constricting pericardium (5). Velocity-encoded cine MRI can be used to demonstrate diastolic flow patterns similar to Doppler echocardiography (167).

Diastolic Filling Patterns

Extensive literature exists regarding the empirically observed patterns of transmitral flow observed in normal individuals and patients with diastolic dysfunction. These patterns are the end result of the complex events only briefly described previously and are nonspecific for any particular physiologic perturbation. Diastolic filling patterns may be influenced by technical (sample volume placement) and hemodynamic factors (heart rate, volume status, conduction disorders) and not always be concordant with diastolic function (115).

Most simply, investigators have measured the peak velocity of the E wave and A wave by transmitral pulsed wave Doppler and their relationship, the *E/A ratio* (168). These basic parameters vary with age and within the spectrum of diastolic filling (Fig. 26.1) (84,92). Taken alone, the normal situation (E/A ratio greater than 1) passes through a delay relaxation phase (E/A ratio less than 1), then through a “pseudonormal” pattern (E/A ratio greater than 1) to the most abnormal “restrictive” pattern (E/A ratio greater than or equal to 1). Thus, the E/A ratio demonstrates a U-shaped curve, making it impossible to tell from this single parameter where in the spectrum a given patient lies (16). The pulmonary venous pattern is an important source of added information (43) that may overcome the limitations of the E/A ratio for determining diastolic function in many patients. An increased pulmonary atrial reversal (AR) flow, reversal velocity, or width, as well as Valsalva maneuver, may aid to differentiate “pseudonormal” from normal diastolic function, corresponding to elevation of mean left atrial or LV diastolic pressures, respectively (113,169,170).

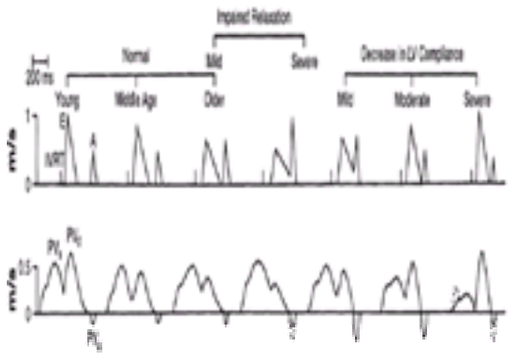


FIGURE 26.1 Natural history of left ventricular (LV) filling. Schematic representation of transmitral and pulmonary venous Doppler profiles, demonstrating the progression of the patterns with the normal aging process, and with diseases of diastolic function showing impaired relaxation and decrease in LV compliance. Isovolumic relaxation time (IVRT), E wave (E), A-wave (A) filling, pulmonary venous systolic (PV_s), diastolic (PV_d), and atrial reversal (PV_a) waves are shown. *Left*: In young healthy subjects, the E/A is greater than 1, the deceleration time and IVRT are short, and there is mild blunting of pulmonary venous systolic flow. With age, ventricular relaxation becomes impaired and the E/A ratio reverses, the A wave increases, the mitral deceleration time and IVRT lengthen, and the pulmonary venous systolic flow increases. *Middle*: With diseases showing impaired relaxation, there may be similar findings with a further decrease in E/A ratio. *Right*: With more severe derangements of diastolic function, as chamber compliance decreases, left-atrial pressure rises, the deceleration time decreases, the E/A ratio increases, and IVRT becomes shorter (restrictive physiology). PV_s flow becomes progressively blunted as mean left atrial pressure and the PV_a increases, helping to differentiate the “pseudonormal” pattern from normal. (From Appleton CP, Hatle LK. The natural history of left ventricular filling abnormalities: assessment by 2-D and Doppler echocardiography. *Echocardiography* 1992;9:453, with permission.)

Still, exceptions and limitations to the utility of pulmonary venous flow diminish the capability of distinguishing diastolic flow patterns in all individuals. Some patients may not have adequate pulmonary venous flow profiles, particularly the AR wave may not be well delineated. Blunting of pulmonary venous systolic waves may be present in young individuals due to rapid diastolic “suction,” and AR may be absent in advanced diastolic dysfunction due to the loss of atrial function with amyloid infiltration (169,171). Therefore, newer modalities for assessment of diastolic function including color M-mode Doppler and TDE have evolved that provide important adjunct information to determine diastolic function and LV filling pressures (16) (Fig. 26.2).

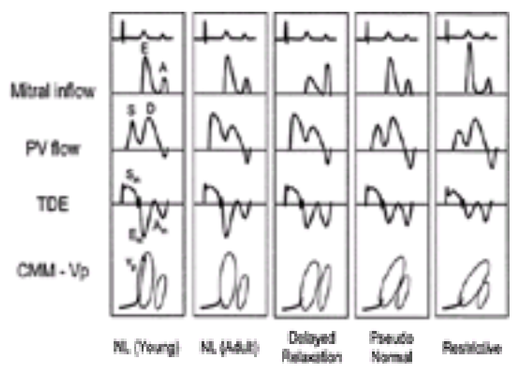

FIGURE 26.2 Stages of diastolic function. Schematic representation of the typical patterns seen with mitral inflow, pulmonary venous flow, tissue Doppler echocardiography (TDE), and color M-mode (CMM) – propagation velocity (Vp) for normal (NL, young and adult), impaired relaxation, pseudonormal, and restrictive diastolic function. Using an integrated approach with these four different modalities for assessment of diastolic flow pattern the stages of diastolic dysfunction can be determined. A, late mitral filling; A_m, diastolic filling during atrial contraction; D, diastolic filling; E, early mitral filling; E_m, early diastolic; S, systolic filling; S_m, systolic. (Adapted from Garcia MJ, Thomas JD, Klein AL. New Doppler echocardiographic applications for the study of diastolic function. *J Am Coll Cardiol* 1998;32:865–875.)

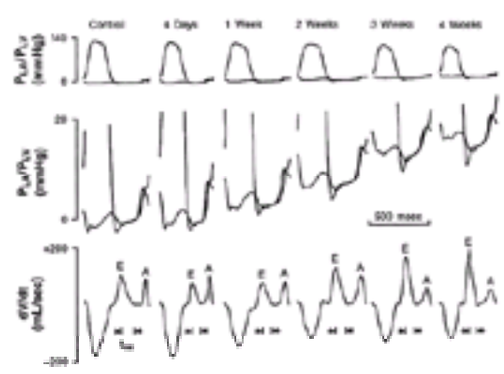
Transmitral Flow Assessment in Health and Diastolic Dysfunction

Determination of pulsed Doppler mitral inflow pattern is a standard component of most echocardiographic studies. The components are an E wave, which represents the early diastolic filling velocity, and an A wave, which represents atrial contraction. As the ventricular myocardium relaxes during early diastole, the LV pressure (P_v) falls below left atrial pressure (P_a). The atrioventricular pressure gradient ($P_a – P_v$) is influenced by the degree of relaxation and left atrial pressure and ventricular suction (see the section Phases of Diastole). Slow relaxation (long tau) generates a high LV minimal pressure gradient, thus decreasing the pressure gradient. In contrast, an elevated left atrial pressure, which can be seen in patients with volume overload, shows an increased pressure gradient.

Thus, the E wave results from the acceleration of blood across the mitral valve due to the atrioventricular pressure gradient in early diastole and myocardial relaxation (55,75). As the volume of blood enters the left ventricle, the LV pressure increases and the left atrial pressure decreases until the pressure gradient equalizes and the blood column decelerates. The deceleration time (DT) of the E wave can be measured as the time from the peak velocity to return to the baseline and is related to the operating LV stiffness in clinical studies (169).

In vitro studies have demonstrated that the rate of early transmitral flow deceleration through a restrictive orifice is proportional to the net atrioventricular stiffness (S_{NET}) (40,172). More recent studies in a dog model of dilated cardiomyopathy have validated that LV stiffness is related to 1/DT in nonrestrictive orifices (146,173). eFigure 26.2.1 shows a shortening of the deceleration time in an animal model with progressive heart failure because of increasing LV stiffness.



***e*FIGURE 26.2.1** Recording over a 4-week period in a canine model of pacing-induced heart failure of the left atrial (P_{LA}) and left ventricular (P_{LV}) pressures and the time derivative of left ventricular volume (dV/dt). The dV/dt indicates the filling pattern (similar to Doppler), with peak filling rate in early diastole (E) and during atrial contraction (A) and the deceleration time (DT) of the E wave. Note that at 4 days, there is a slowing of relaxation, which results in a decreased left atrial–left ventricular (LA-LV) driving pressure and a decreased E wave. With progressive heart failure over the 4-week period, there is an increase in left atrial pressure, which increases the LA-LV driving pressure and the peak E wave, and a shortening of the deceleration time, which reflects increasing stiffness of the left ventricle. (From Ohno M, Cheng CP, Little WC. Mechanism of left ventricular filling during the development of congestive heart failure. *Circulation* 1994;89:2245, with permission.)

Following diastasis, the left atrium contracts, increasing left atrial pressure and the gradient ($P_a – P_v$) across the mitral valve (A wave). This atrial contraction is proportional to the atrial preload and atrial function and is inversely related to LV end diastolic stiffness (see the section Phases of Diastole) (75).

Physics of Mitral Inflow

Transmitral flow by pulsed Doppler relates to pressure gradients as determined by the Bernoulli flow equation:

$$P_A - P_V = [1/2\rho \times (v_V^2 - v_A^2)] + \left(\rho \int_A^V \frac{d\vec{v}}{dt \times d\vec{s}}\right) + [R \times \vec{(v)}]$$

This equation has three basic components: a convective, inertial, and resistive component. Of these, the convective component [$1/2p \times (V_V^2 – V_A^2)$] is important for spectral Doppler. When evaluating flow across stenotic valves, the convective component is much larger than the inertial component:

$$\left(\rho \int_A^V \frac{d\vec{v}}{dt \times d\vec{s}}\right)$$

thus allowing a quantitative assessment of pressure gradients (174). In contrast to nonstenotic valves, the inertial component has been shown to represent greater than 50% of the actual pressure gradient (175). Thus, spectral Doppler cannot be used to obtain a quantitative assessment of pressure gradients across a nonstenotic orifice; however, there still remains a qualititative relationship between the convective and the total pressure gradients across the mitral valve. This indirect qualitative relationship underlies the basis for using transmitral flow in the assessment of diastolic function (75).

Pulmonary Venous Velocity Patterns in Health and Diastolic Dysfunction

The pulmonary venous velocity pattern provides important adjunctive information to the transmitral pattern, particularly in distinguishing the normal transmitral pattern from the “pseudonormal” pattern (43) and evaluation of LV end diastolic pressures (96).

Pulmonary venous flow can be recorded by transthoracic echocardiography in 80% to 90% of cases (118,176) and by transesophageal echocardiography (119,177).

The pulmonary venous velocity profile typically has three distinct waves (Fig. 26.2).

The S wave has two components that are temporally separated: early systolic (S_1) and late systolic (S_2) waves. This wave occurs during ventricular systole and is an antegrade wave reflecting the fall in left atrial pressure due to atrial relaxation (S_1) and descent of the mitral annulus during ventricular contraction ('x' descent) and RV stroke volume (S_2) (178,178a). The D wave occurs during ventricular diastole shortly following the peak of the forward E wave through the mitral valve, reflecting the fall in atrial pressure with atrial emptying into the left ventricle ('y' descent). The height of pulmonary venous D wave is proportional to the height of the transmitral E wave (15). During this phase, the left atrium functions largely as a conduit between the pulmonary veins and the left ventricle (43,178) (*e*Table 26.2.1).

***e*TABLE 26.2.1** HEMODYNAMIC FACTORS INFLUENCING PULMONARY VENOUS FLOW

	Atrial factors	**Ventricular factors**
Systolic phase	LA contractility	LV contractility (mitral annular motion)
	LA relaxation	Right ventricular stroke volume
	LA pressure	
	LA compliance	
	Compliance of pulmonary veins	
	Rhythm	
Diastolic phase	LA pressure	LV compliance
	LA compliance	LV relaxation
Atrial reversal phase	LA pressure	LV compliance
	LA contractility	
	LA relaxation	
	LA compliance	
	PR interval, rhythm	

LA, left atrial; LV, left ventricular.
Modified from Klein AL, Tajik AJ. Doppler assessment of pulmonary venous flow in healthy subjects and in patients with heart disease. *J Am Soc Echocardiogr* 1991;4:381, with permission.

The AR wave represents retrograde flow into the pulmonary veins during atrial contraction. The degree of retrograde flow is proportional to the relative impedance to flow presented by the left ventricle versus the pulmonary veins. If pulmonary venous impedance is considered relatively constant, then the ratio of forward to reversed A wave should relate to the operating compliance of the ventricle at the time of atrial contraction. Furthermore, the sum of the forward and reversed blood velocity should relate to the total stroke volume of atrial contraction and thus reflect, to some degree, atrial systolic function.

Pulmonary venous flow is dictated physically by Newton's second law, force = mass × acceleration, where force is the pressure difference between the central pulmonary veins and the left atrium, and the mass relates to the inertance of blood within the distal pulmonary veins. Pulmonary venous inertance is approximately equal to the length of the distal pulmonary veins (179). Furthermore, pulmonary venous flow demonstrates a significant phase lag behind its driving pressure gradient.

Right-Sided Doppler Flows

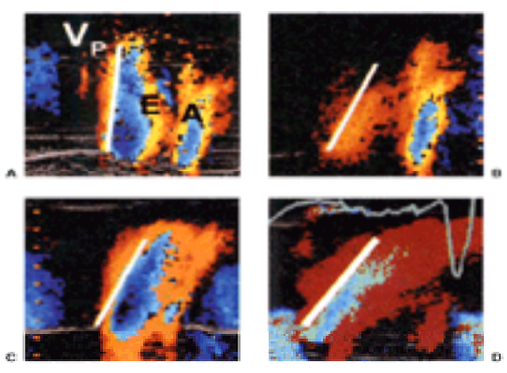
Diastolic function of the right-sided heart can be evaluated by the interrogation of the tricuspid inflow, hepatic vein flow, and superior vena cava (120,180). The Doppler flow patterns in the hepatic veins and superior vena cava are somewhat similar to the pulmonary venous flow patterns (4,15). In addition to the S, D, and AR waves, a second reversed flow is often seen between the S and the D wave at the end of ventricular contraction (VR) (120). Right-sided flow velocities normally increase during inspiration and decrease with Valsalva manuever (120,181).

As with the pulmonary venous flow, the S wave is related to RA relaxation and tricuspid annular descent, and the D is related to early RV filling velocity (E). The magnitude of AR and VR varies according to RV stiffness, RA contractility, and central venous pressure (182). The effect of respiration of the right-sided flows is useful in differentiating constriction from restriction and estimating right-sided filling pressures (4,15).

Color M-Mode Doppler

In more recent years, a number of investigators have studied the use of the color Doppler M-mode to characterize the spatiotemporal distribution of blood velocity throughout the ventricular inflow region in diastole (16,54,183,184,185 and 186).

A typical color Doppler M-mode echocardiogram has a temporal resolution of 5 ms, a spatial resolution of 300 µm, and a velocity resolution of approximately 4 cm per second. In normal sinus rhythm from the apical four-chamber view, the color Doppler M-mode demonstrates a characteristic pattern consisting of two filling waves, propagating from the left atrium to the left ventricle, corresponding to the E and A waves. The Vp changes with the different stages of diastolic dysfunction (*e*Fig. 26.2.2). The velocities are highest above the mitral valve and lowest as they approach the apex as shown by the change in color. The onset of flow occurs earlier at the mitral valve level than at the apex (16). The flow does not propagate instantaneously, but rather propagates with a velocity (Vp) given by the slope of the leading edge of the blood wave.



***e*FIGURE 26.2.2** Color Doppler M-mode transthoracic echocardiography in normals **(A)** and patients with delayed relaxation **(B)**, pseudonormalization **(C)**, and restrictive physiology **(D)**. Vp, propagation velocity (*white line*). Color M-mode display shows the column of blood flow over time and space from the mitral valve into the left ventricular cavity. There is a delay in time for blood to reach the apex and thus a slower propagation velocity with stages of decreasing relaxation and advanced diastolic impairment. (From Garcia MJ. Diastolic dysfunction and heart failure: causes and treatment options. *Cleve Clin J Med* 2000;67:727–738, with permission.)

Using digital processing of the color M-mode Doppler display, numerical values can be obtained to quantify pressure gradients using the Bernoulli's equation (187,188 and 189) or the simplified Euler equation:

$$-\frac{\partial p}{\partial s} = \rho\left[\frac{\partial v}{\partial t} + v\frac{\partial v}{\partial s}\right]$$

Previous clinical studies have shown that there is a poor relationship between the flow propagation velocity (Vp) and the peak E wave by pulsed Doppler (17,185). Vortex formation in the left ventricle may partly explain why the velocities of blood particles moving in a circular motion (E wave) may exceed the velocity of flow propagation (Vp) (16). Contrast echocardiographic studies in dilated left ventricles and apical dysfunction have also shown increased vortex formation (190).

Several qualitative and quantitative parameters have been proposed to characterize transmitral filling by color Doppler M-mode echocardiography. These studies have been used to characterize ventricular relaxation compared with cardiac catheterization (54,191). Brun et al. identified the leading edge of the E wave as representing the propagation velocity (54). This parameter is measured by identifying the boundary of the leading edge of color as it propagates into the ventricle, drawing a tangent to this line and measuring its slope on the M-mode. A negative correlation was demonstrated between this propagation velocity and the time constant of relaxation (tau)

in patients with coronary disease and cardiomyopathy. This propagation velocity parameter has been reported to be altered in conditions of delayed relaxation and ischemia, with a more rapid decrease in ventricular pressure allowing a greater propagation of flow into the left ventricle (54,191).

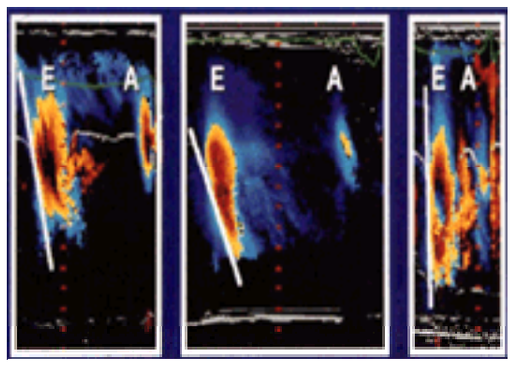
Another approach quantifying the propagation velocity (183) measured the delay required for the point of maximum velocity to traverse from the mitral valve to the apex. These investigators demonstrated that the time for flow to propagate from the mitral annulus to the ventricular apex was delayed significantly during ischemia associated with angioplasty, reverting to normal when the angioplasty balloon was deflated. They postulated that ischemia eliminated the physiologic early diastolic intraventricular pressure gradient pulling blood into the ventricle and thus there is a slower propagation of flow into the ventricle.

In contrast to the standard mitral inflow velocities, color M-mode propagation velocity has been determined to be relatively preload independent, validated by hemodynamic measurements in humans and animals (185,192).

In the study by Takatsuji et al., color M-mode flow propagation (Vp) was compared with the standard pulsed Doppler parameters for patients with abnormal relaxation and elevated filling pressures (diastolic dysfunction) and a control group with normal diastolic function. Color M-mode Doppler (Vp) was significantly lower in the patients with diastolic dysfunction than in the control group, whereas the mitral inflow velocities were similar (185).

When coupled with the ratio of the mitral inflow E wave over the color M-mode propagation velocity in patients in the intensive care unit, it provided a good estimate of PCWP (17). A more recent study showed that an E/Vp ³1.5 to be the single best predictor of in-hospital clinical heart failure in patients with their first myocardial infarction (186).

It appears that the propagation velocity may also be a discriminating feature between restrictive and constrictive diseases. Constrictive pericarditis is characterized by relatively normal early diastolic relaxation (and thus early diastolic filling) with an abrupt mid-diastolic cessation of inflow. Restrictive diseases have abnormal relaxation and impaired inflow from the opening of the mitral valve. These pathophysiologies seem to be reflected in the propagation velocity profile. Constrictive pericarditis is associated with extremely rapid flow propagation (a slope of greater than 100 cm per second), whereas restrictive cardiomyopathy shows markedly slowed propagation of the E wave (15,121) (eFig. 26.2.3).

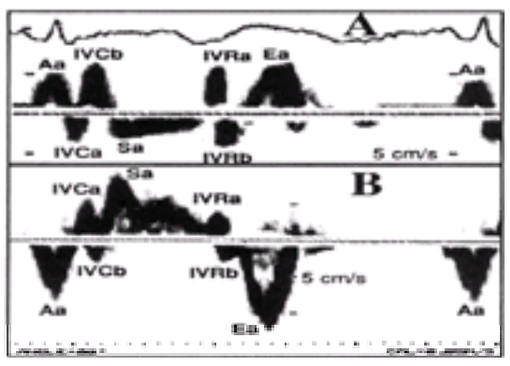


***e*FIGURE 26.2.3** Color Doppler M-mode transesophageal echocardiography of diastolic flow from the left atrium (*top*, left atrium) toward the ventricular apex (*bottom*, left ventricular apex) is imaged in a four-chamber view. Flow propagation is seen during early (E) and late (A) filling with normal filling (*left*), restriction (*center*), and constriction (*right*). Scale markers indicate 1 cm. (From Cohen GI, Pietrolungo JF, Thomas JD, et al. A practical guide to assessment of ventricular diastolic function using Doppler echocardiography. *J Am Coll Cardiol* 1996;27:1753–1760, with permission.)

Tissue Doppler Echocardiography

TDE quantifies the low velocity and high amplitude of tissue such as the ventricular myocardium or the motion of the mitral annulus (21,123,193). It provides a detailed spatial map of velocity in the myocardium, which can be further temporally enhanced with the color M-mode Doppler and pulsed wave Doppler.

The TDE myocardial velocities are composed of several waves (eFig. 26.2.4). Following the electrocardiographic QRS, a short-amplitude multiphasic signal coincides with the closure of the mitral and tricuspid valve (194) and is caused by translational motion and geometric LV changes assuming a more spherical shape during isovolumic contraction. Following this signal, a larger positive wave represents ventricular systole (S_M). A second multiphasic signal during isovolumic relaxation coincides with aortic valve closure and tricuspid valve opening. In sinus rhythm, two waves corresponding to early filling (E_M) and atrial contraction (A_M) appear as a mirror image of the mitral inflow early (E) and atrial (A) filling velocities. In healthy subjects, the peak of the E_m occurs earlier than the peak mitral inflow E wave (20 ms), suggesting that fast relaxation of the myocardium generates suction that pulls blood into the ventricle (E wave). However, in patients with diastolic dysfunction, the mitral inflow E wave coincides with or precedes the E_m, suggesting more passive filling (16).



***e*FIGURE 26.2.4** Doppler tissue imaging velocity spectrum recorded from parasternal short-axis view at mid-ventricular level from **(A)** anteroseptal and **(B)** posterior left ventricular wall. (From Garcia M, Rodriguez L, Ares M, et al. Myocardial wall velocity assessment by pulsed Doppler tissue imaging; characteristic findings in normal subjects. *Am Heart J* 1996;132:648–656, with permission.)

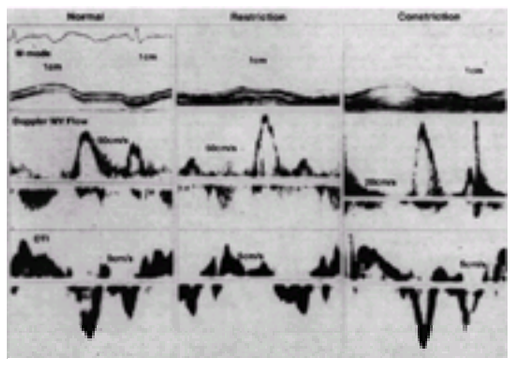
A major limitation of TDE is the effect of translation and rotation of the heart, in particular from the parasternal long-axis view. Thus, motion of the LV myocardium and annulus in the longitudinal plane can be measured from the apical four-chamber view. Because the apex is relatively fixed throughout the cardiac cycle and the axial plane of motion of the LV myocardium is parallel with the axis of the transducer, the velocities obtained from this acoustic window represent motion secondary to contraction and relaxation and do not require angle correction (16).

Color Doppler TDE provides a color map with high spatial resolution that is able to provide velocity data simultaneously from multiple segments of the myocardium. To decode the data, digital storage and off-line analysis are necessary. In contrast, pulsed wave TDE is much simpler, providing high temporal and velocity resolution with the data being stored using digital or video format. A limitation is that it measures only one point in time compared with the multiple information obtained from color TDE (195).

Our preference has been to use pulsed wave TDE from the mitral annulus medial and lateral walls for the assessment of diastolic function. In healthy subjects, the tissue Doppler echocardiographic velocities are a mirror image of the mitral inflow velocities. With the aging process, there is an inverse effect on the E_m/A_m ratio similar to that reported for the mitral inflow (194); however, there are significant differences in patients with organic disease, distinct from transmitral flow velocities (196). In patients with impaired relaxation, the E_m velocity decreases with E_m/A_m ratio less than 1. In patients with advanced diastolic dysfunction (see following discussion) the E_m remains low, even in the presence of elevated filling pressures (194).

Tissue Doppler E_m is less affected by preload than standard Doppler LV filling indices. Similar to color M-mode Doppler, tissue Doppler E_m has been shown to correlate with the time constant of relaxation in both patients with normal or increased preload (197,198 and 199). In hemodynamic studies performed by Oki et al., the time constant of relaxation correlated well with E_m in all patients independent of filling pressures (197). Sohn et al. demonstrated the relative preload insensitivity of E_m by infusing volume in patients with abnormal relaxation patterns and nitroglycerin in patients with normal or pseudonormal patterns. While mitral inflow E/A ratio and deceleration time were affected by volume changes, there was no significant change in E_m, demonstrating the utility of this parameter to differentiate normal from pseudonormal patterns. Patients with abnormal diastolic function (elevated preload and t greater than or equal to 50 ms) could be discriminated from those with normal filling (normal preload and t less than 50 ms) by a lower E_m (less than 8.5 cm per second) with a sensitivity of 88% and specificity of 67% despite having similar mitral inflow Doppler patterns (198). In an animal experiment, Garcia et al. showed that both peak mitral E-wave and E_m changes decreased with preload reduction (IVC occlusion); however, the effect of preload was less with more prolonged relaxation. When tau was less than 50 ms, the changes in E_m with preload reduction were significantly greater (DE_m = 2.83 ± 0.62 cm per second) than when tau ranged from 50 to 65 ms (DE_m = 1.21 ± 0.25 cm per second) or was greater than 65 ms (DE_m = 0.49 ± 0.09 cm per second, p <.05). Therefore, it appears that although E_m may be affected by alterations in preload, the effect is minimal in ventricles with impaired relaxation (192,200). In patients with various degrees of diastolic function, the tissue Doppler E_m was the best discriminator between healthy subjects (16 cm per second) and patients with abnormal diastolic function (7.5 cm per second) compared with the standard mitral inflow or pulmonary vein flow (201). Other groups have confirmed that a TDE E_m of 8 cm per second was a useful cutoff between normal and abnormal filling pressures (202).

We have used TDE myocardial velocities to differentiate constrictive pericarditis from restriction. In patients with restriction, both relaxation and compliance are abnormal, whereas relaxation is normal in constriction. We showed that patients with restriction had slow early diastolic motion of the annulus, whereas patients with constriction had normal or rapid early diastolic annular velocity (greater than 8 cm per second), suggesting preserved relaxation (121,123) (eFig. 26.2.5). Recently, another study showed that annular motion may not always distinguish constriction from restriction, especially if the annulus is involved with the pericardial process (202a).



***e*FIGURE 26.2.5** Samples of mitral annular M-mode tracings, Doppler tissue imaging (DTI) velocities in the longitudinal axis, and transmitral Doppler flow velocities in a normal volunteer, a patient with restrictive cardiomyopathy, and a patient with constrictive pericarditis. There is a marked difference in early diastolic longitudinal axis velocities, despite similar early transmitral flow velocities. MV, mitral valve. (From Garcia MJ, Rodriguez L, Ares M, et al. Differentiation of constrictive pericarditis from restrictive cardiomyopathy: assessment of left ventricular diastolic velocities in longitudinal axis by Doppler tissue imaging. *J Am Coll Cardiol* 1996;27:108–114, with permission.)

Preliminary studies suggest that TDE of the myocardial velocities may be used in detecting rejection in cardiac transplantation (203). Because of the effects of translation and rotation on TDE, the myocardial velocity gradient has been developed as a measure of regional myocardial diastolic function, which is independent of translational motion. It is the velocity gradient between the endocardium and epicardium across the myocardial wall and is measured as the slope of the regression line for the transmural velocity profile across the myocardium (204,205 and 206). It is given by the follwoing equation: MVG = $(V_{end} - V_{epi})/L$.

The peak negative myocardial velocity gradient is a good noninvasive measure of diastolic function that is less preload dependent than mitral inflow (205). It has been used to differentiate myocardial hypertrophy in athletic hearts from patients with hypertrophic cardiomyopathy with an accuracy of greater than 0.9 (20), as well as patients with hypertension and dilated cardiomyopathy (205), and to differentiate patients with constriction from restriction (206). It has also been used to differentiate transmural from nontransmural acute myocardial infarction after reperfusion therapy (207).

Strain imaging is another newer modality that measures the deformation properties of a myocardial segment independent of translation or rotation. It is given by the equation $S = (L_0 - L_1)/L_0$, where L_0 is initial length and L_1 is compressed length (21,208). The strain rate measures the velocity in a certain direction dV/dX (sec^{-1}) of the longitudinal or circumferential fibers of the myocardium from parasternal or apical views. This technique has been used in patients with hypertrophic cardiomyopathy (209) and patients with coronary artery disease (21,210,211).

Interpretation of Diastolic Filling Patterns

Using information from mitral inflow, pulmonary vein flow, color M-mode, and tissue Doppler imaging, four patterns of diastolic function can be determined (Fig. 26.2). These patterns are dependent on age and hemodynamic conditions and represent stages of relaxation and compliance abnormalities and filling pressures. A classification was proposed that diastolic dysfunction be graded in four stages that correlate with diastolic impairment and symptom class (212) (Fig. 26.3).

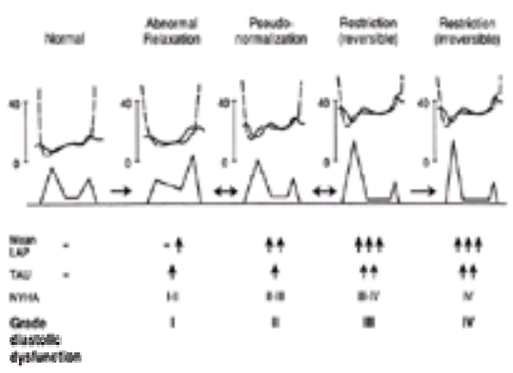


FIGURE 26.3 Proposed grading system for diastolic dysfunction based on progression of clinical disease patterns. Top row shows the high-fidelity left atrial and left ventricular pressure curves for the four grades of diastolic dysfunction, graded on a scale of I to IV, representing a progression from abnormal relaxation, pseudonormalization, restrictive (reversible), and restrictive (irreversible) disease. Below are the corresponding mitral flow velocity profiles; below these are the mean left atrial pressure (LAP), time constant of relaxation (TAU), and New York Heart Association (NYHA) class. Measurements are given in mm Hg. (From Nishimura RA, Tajik AJ. Evaluation of diastolic filling of the left ventricle in health and disease: Doppler echocardiography is the clinician's Rosetta stone. *J Am Coll Cardiol* 1997;30:8–18, with permission.)

Normal Pattern

The normal filling pattern is seen in healthy subjects with normal relaxation, compliance, and filling pressures. Healthy individuals demonstrate a briskly accelerating E wave, relatively rapid deceleration, and an A wave significantly smaller in magnitude than the E wave. The E/A ratio is greater than 1, the mitral deceleration time is typically between 150 and 220 ms, and the IVRT less than 100 ms. The S/D ratio is generally greater than 1, and the AR wave should be less than 35 cm per second. The color M-mode propagation is relatively fast (greater than 45 cm per second), and the tissue Doppler E_m is greater than 8 cm per second consistent with normal

ventricular relaxation (16).

In young healthy subjects, there is a greater predominance of early diastolic filling due to the rapid “suction” effect of the ventricle (more enhanced relaxation with Vp greater than 55 cm per second and E_m greater than 10 cm per second) and little additional filling during atrial contraction. This results in an even greater E/A ratio with further shortening of the deceleration time. Because atrial contribution is minimal, the mitral inflow A wave and pulmonary vein AR are small. The S/D ratio may be less than 1, representing the large contribution of early filling.

Normal left-sided values with 95% confidence intervals with age are graphically shown in eFigure 26.3.1 and eFigure 26.3.2, and right- and left-sided normal values are listed in eTable 26.2.2 (4,84,92,120). eFigure 26.3.3 shows the left- and right-sided Doppler tracings in healthy subjects.

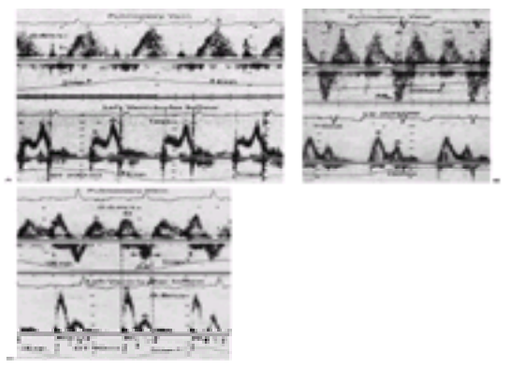
Delayed Relaxation Pattern (Stage I)

The delayed relaxation pattern is seen in patients with delayed LV relaxation but with relatively normal compliance and filling pressures (213). With normal aging and various pathologic states, the time constant of relaxation is lengthened, the E wave shows a slower acceleration and a lower peak velocity, a prolonged deceleration time (greater than 220 ms), and isovolumic relaxation time (greater than 100 ms). To the extent that emptying may not be complete by the end of diastasis, an increased left atrial volume is present at the time of atrial contraction, leading to a larger A wave, compensating in large part for the smaller E wave. Thus, the E/A ratio is less than 1 and concomitantly the S/D ratio is greater than 1, because if E is small, the corresponding D is small. Because relaxation is impaired, the color M-mode Vp is prolonged (less than 45 cm per second) and E_m is decreased (less than 8 cm per second).

Impaired relaxation may occur with normal or elevated filling pressures. If LV end diastolic pressure is normal, pulmonary vein AR is less than 35 cm per second; although if it is elevated, the AR is greater than 35 cm per second or the duration of AR is greater than the duration of the mitral inflow A duration (96).

This pattern is seen in normal aging (4,84), ischemia (214), hypertrophic cardiomyopathy (215,216), and secondary hypertrophy (217) and is usually seen in patients who typically have only mild symptoms or are asymptomatic (113) (*e*Fig. 26.3.4). It can also be seen with hypovolemia because of a decreased left atrial to LV pressure gradient with greater filling during atrial systole (15,218).



***e*FIGURE 26.3.4** Transmitral filling and pulmonary venous flow patterns. **A:** Abnormal relaxation, with the transmitral flow showing an early (E) filling wave less than the late filling (A) wave with a prolonged deceleration time (DT, 300 ms); pulmonary venous flow shows greater systolic than diastolic flow. **B:** Pseudonormal pattern with E wave greater than A wave, resembling a normal pattern; pulmonary venous flow shows a normal systolic (S) flow with an increased and prolonged atrial reversal (AR). **C:** Restrictive pattern with E wave markedly increased with a small A wave with shortened DT (90 ms); pulmonary venous flow shows a blunted pulmonary venous flow with an increased and prolonged AR. Exp., expiration; Insp., inspiration; LV, left ventricular.

Pseudonormal Pattern (Stage II)

The pseudonormal pattern is difficult to recognize because it is similar to the normal pattern. As left atrial pressure increases further to compensate for deteriorating diastolic function, the peak E-wave velocity increases. Therefore, abnormalities of relaxation and compliance and elevated filling pressures are present. This is associated with a normal appearance of the transmitral inflow with an E/A ratio between 1 and 2, a deceleration time between 150 and 220 ms, and an isovolumic relaxation time between 60 and 100 ms (15,92,113) (*e*Fig. 26.3.4). One important feature to distinguish this pattern from normal is the pulmonary venous AR wave, which in pseudonormal filling displays a prolonged and increased AR greater than 35 cm per second (84), whereas the pulmonary vein S/D ratio could be normal or less than 1. The AR wave prominence may not be present if atrial systolic failure occurs, although the duration of AR greater than the mitral A wave may still occur. In addition, the Valsalva maneuver may be useful in differentiating normal from pseudonormal by reducing the preload, causing the normal-appearing E/A ratio to be greater than or equal to 0.5, and thus exposing a delayed relaxation pattern (4,92,170,219). Color M-mode propagation velocities and tissue Doppler imaging are particularly helpful to detect pseudonormal filling with a Vp less than 45 cm per second and E_m less than 8 cm per second (201).

Usually in patients with pseudonormal patterns, the left atrial size is increased, the LV function may be impaired or wall thickness increased, and the patient may have dyspnea (97,113). This pattern may represent an intermediate stage between impaired relaxation and restrictive filling as a result of disease progression, ischemia, or a change in loading conditions (15,100,113).

Restrictive Filling Pattern (Stage III)

The restrictive filling pattern is seen in the presence of severely reduced LV compliance and elevated filling pressures and ongoing delayed relaxation. It is characterized by a very elevated peak E-wave velocity with extremely rapid deceleration indicative of increased LV operating stiffness and diminutive (often absent) A wave (*e*Fig. 26.3.4). The E/A ratio is usually greater than 2, with a deceleration time less than 150 ms, and isovolumic relaxation time less than 60 ms (15). Pulmonary venous flow usually shows markedly blunted systolic flows with large and prolonged ARs (except in conditions of atrial systolic failure) (4). A pulmonary venous systolic fraction 0.40 to 0.55 of the of the sum of the systolic plus diastolic fraction is consistent with significant elevation of PCWP (96,220). Similar to pseudonormal patterns, the color M-mode propagation velocity and E_m are reduced.

Reduced filling due to increased ventricular stiffness may be counteracted by increases in heart rate, inotropic state, or most commonly left atrial pressure. This preload compensation dramatically changes the morphology of the E wave from a pattern consistent with delayed relaxation to one consistent with the restrictive pattern (221). Diastolic mitral and tricuspid regurgitation may occur as a result of ventricular pressure rising rapidly in a stiff ventricle and exceeding atrial pressure in mid- or late diastole (15).

The restrictive filling pattern is equivalent to the “square-root sign” or “dip and plateau” pattern seen in the ventricular pressure tracing at cardiac catheterization (92). The association between the restrictive filling pattern and the need for elevated filling pressures perhaps explains the poor prognosis connoted by the restrictive pattern (103). This pattern can be seen in patients with advanced stages of diastolic dysfunction due to restrictive, dilated, or ischemic cardiomyopathy, and usually the patients have dyspnea at rest and high New York Heart Association functional class (113). Severe enlargement and hypocontractility of the left atrium may be seen, and this pattern carries a poor prognosis in ischemic (222), dilated (223,224), and restrictive cardiomyopathies (103). In hypertrophic cardiomyopathy, there is a less clear prognostic potential of the filling patterns because of the complex interplay between systolic outflow tract obstruction, mitral regurgitation, and diastolic dysfunction (225).

Restrictive Filling Pattern (Stage IV)

As noted previously, restrictive filling patterns are associated with a poor prognosis for patients with various types of cardiac diseases. Additional prognostic information can be obtained in patients with restrictive filling patterns evaluated under different hemodynamic conditions. Failure to convert a restrictive mitral inflow filling pattern to a nonrestrictive pattern substantially increased the risk of death greater than twofold in a study of patients with chronic heart failure (226,227).

Estimating Left Atrial and Left Ventricular Filling Pressures

Transmitral inflow and pulmonary venous flow by Doppler echocardiography have been used to noninvasively estimate left heart filling pressures, including mean pulmonary capillary wedge and left atrial pressure and LV end diastolic pressure, primarily in patients with cardiac disease (96,97,220,228,229 and 230). A notable exception in the use of Doppler flow patterns to predict filling pressure is patients with hypertrophic cardiomyopathy in whom Doppler mitral flow patterns do not correlate well with LV filling pressures due mainly to the exaggerated relaxation abnormalities and other variables affecting diastolic function in this disease (225).

An increased E/A ratio, a shortened deceleration and isovolumic relaxation time, a decreased atrial filling fraction, a decreased pulmonary venous systolic fraction, an elevated and prolonged AR flow velocity, and increased left atrial volume may suggest an elevated mean left atrial pressure. Because these parameters are influenced by left atrial pressure and ventricular relaxation, these correlations work best for patients with abnormalities of LV relaxation in which left atrial pressure is the only variable. This includes mostly patients with structural heart disease. In the setting of isolated diastolic dysfunction with normal systolic function, mitral inflow and pulmonary venous inflow parameters are poorly related to LV filling pressures. By combining the mitral E wave, a variable that correlates modestly with left atrial

pressure and one that is associated with ventricular relaxation (color M-mode propagation velocity or TDE early filling velocity), closer approximations of left atrial pressure can be obtained.

Garcia and colleagues studied patients in intensive care units with a variety of medical or cardiac diseases and a mean LV ejection fraction of 40%. Using the regression equation, PCWP could be estimated by the equation, PCWP = 5.27 × (E/Vp) + 4.6, with an r = 0.80, *p* <.001 (17). Similar studies have confirmed these findings and included patients with atrial fibrillation (231,232). In a more recent study of 100 patients undergoing cardiac catheterization, Ommen et al. compared various mitral inflow and pulmonary venous flow measurements to the ratio of E/E_m to assess mean LV filling pressure (a surrogate for left atrial pressure). Ratios of E/E_m greater than 15 were associated with increased LV filling pressure, whereas E/E_m less than 8 correlated with normal pressures. These associations were best for patients with LV dysfunction (202).

LV filling pressures can be estimated even in patients with atrial fibrillation. One study showed a correlation between PCWP and mitral deceleration time for patients with LV dysfunction and atrial fibrillation (231). A subsequent study showed an even better correlation with the initial deceleration slope of the pulmonary venous diastolic wave (233).

End diastolic LV pressure has been estimated by echocardiography independent of left atrial pressure. Several studies have shown that the difference between the duration of the pulmonary venous AR and transmitral inflow A-wave duration can be used as an estimate of elevated LV end diastolic pressure (96,97 and 98) (*e*Fig. 26.3.5). When the duration of the pulmonary venous reversal wave is prolonged with respect to that of the forward mitral A-wave duration (greater than 20 to 30 ms), then the LV end diastolic pressure is usually elevated (greater than 15 mm Hg) (96). This variable has been shown to be relatively age independent (234) and not affected by mitral regurgitation (234a). Studies have demonstrated that the difference in duration between the pulmonary venous AR and mitral A wave of greater than or equal to 30 ms is a predictor of severity of disease in cardiac amyloidosis (235) and cardiac mortality in patients with coronary artery disease (236).

Pulmonary venous flow velocities recorded by transthoracic Doppler ultrasound: relation to left ventricular diastolic pressures. *J Am Coll Cardiol* 1993;21:1687–1696, with permission.)

Clinical Presentation and Significance

Patients with impaired diastolic function present with the typical syndromes of congestive heart failure including dependent edema, limited exercise tolerance, ascites and effusions, orthopnea, and flash pulmonary edema. In general, the clinical examination is unreliable in differentiating systolic from diastolic dysfunction. The jugular veins are distended, and dependent pitting edema may be severe. Rales may be present on chest auscultation. Cardiac auscultation may demonstrate an S_3, S_4, or a pericardial knock (15,26). The typical clinical characteristic of patients with diastolic heart failure include the elderly, women, and those with hypertension, diabetes, and renal dysfunction (237). One study in Olmsted County, MN, of patients with diastolic heart failure found that nearly 50% of patients were 80 years of age or older (238). The presentation of heart failure may be with flash pulmonary edema and hypertensive heart disease (239,240), advanced ischemic heart disease, or hypertensive hypertrophic cardiomyopathy (241). Those patients who do not respond to treatment for heart failure include patients with diseases such as aortic stenosis or hypertrophic cardiomyopathy, infiltrative cardiomyopathy, and constrictive pericarditis (242) (Table 26.1). Patients with diastolic heart failure may present with new onset of atrial fibrillation or flutter, especially with more advanced diastolic dysfunction (238,242a).

More specific signs of individual disease states are discussed in the following sections.

Management of Diastolic Heart Failure

The general goal of treatment is twofold: to reduce the variables responsible for the underlying diastolic dysfunction and to reduce the clinical manifestations of the process. Treatment consists of reducing elevated filling pressures, maintaining atrial contraction, decreasing heart rate, preventing ischemia, improving relaxation, and causing the regression of ventricular hypertrophy (28,62,243,244). Therapy must be targeted to the specific pathologic process as some medications may be inappropriate for certain conditions. For instance, a beta-blocker or calcium channel blocker would be preferable to an angiotensin-receptor blocker in patients with hypertrophic cardiomyopathy since the latter medication may contribute to LV outflow obstruction.

Diuretics produce symptomatic relief but should be used judiciously, as noncompliant ventricles, by definition, require higher pressures to achieve adequate filling. Nitrates may be beneficial secondary to their effects on reducing preload and ischemia (22). Beta-blocking agents slow heart rate, decrease myocardial oxygen demand, control blood pressure, and produce regression of LV hypertrophy. Calcium channel blockers have multiple benefits as negative chronotropic agents, controlling blood pressure, decreasing myocardial oxygen demand, dilating the coronary arteries, and regressing hypertrophy (26). Angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers have direct and indirect effects. These include blood pressure control and substantial ventricular mass regression. The degree of myocardial mass regression of these agents appears more potent than any other antihypertensive agents for similar blood pressure reduction (245). Data have demonstrated improvement in diastolic function with lisinopril by reduction in myocardial fibrosis (including decreased collagen volume) independent of LV regression (246). Preliminary data support further investigation of nitric oxide donors, which produce improved myocardial relaxation (244,247).

Doppler flow patterns may be useful in guiding therapy (15) (*e*Table 26.2.3). Patients with abnormal relaxation with fusion of the E and A wave may need a calcium channel or beta-blocker to slow the heart rate, whereas patients with pseudonormal or restrictive filling may need diuretics or angiotensin-converting enzyme inhibitors to lower the elevated filling pressures. If there is a prolonged PR interval in the setting of dilated cardiomyopathy, dual-chamber pacing may be beneficial (248). There may be some additional benefit of the use in Doppler flow patterns in the evaluation of biventricular pacing (249).

***e*TABLE 26.2.3** POTENTIAL TREATMENT STRATEGIES OF DIASTOLIC FUNCTION ACCORDING TO DOPPLER FILLING PATTERN AND CLINICAL AND TWO-DIMENSIONAL ECHOCARDIOGRAPHIC CONTEXT

Doppler finding	Clinical/echocardiographic context	Treatment
Impaired relaxation	Hypovolemia	Fluids
	Excessive afterload	Antihypertensive drugs to regress hypertrophy; relieve outflow
	Coronary artery disease	Antianginal drugs; revascularization
	Infiltrative cardiomyopathy	Nitrates; diuresis; treat metabolic or immunologic derangement
(E-, A-wave fusion)	Inadequate filling time	Slow heart rate (beta-blockers, verapamil, diltiazem)
Pseudonormal filling or restriction	Volume overload	Nitrates; diuresis; dialysis; correct valvular regurgitation
	Coronary artery disease	Antianginal drugs; revascularization; transplantation
	Infiltrative cardiomyopathy	Nitrates; diuresis; treat metabolic or immunologic derangement; transplantation
	Dilated cardiomyopathy	Reduce afterload; angiotensin-converting enzyme inhibitors; correct outflow obstruction; optimize preload; treat coronary artery disease; inotropes for systolic dysfunction; transplantation

(End diastolic mitral regurgitation)	Prolonged PR interval	Dual-chamber pacing to reduce PR interval
Constriction	Thickened pericardium; chamber compression	Medical treatment of cause, especially if acute (antibiotics, antiinflammatory agents; hormonal therapy, chemotherapy, radiotherapy); pericardial stripping, if chronic
Tamponade	Pericardial effusion; chamber compression	Pericardiocentesis; pericardial window if recurrence likely; medical treatment of cause, evacuate hematoma after heart surgery or rupture; achieve hemostasis

Prognosis

Patients with congestive heart failure secondary to diastolic dysfunction generally have a better prognosis than patients with systolic dysfunction (250); however, they may have recurrent congestive heart failure and recurrent chest pain despite coronary revascularization (23,240). eTable 26.2.4 summarizes the mortality in a number of studies in patients with diastolic dysfunction. The prognosis of diastolic heart failure varies, depending on the population studied with an annual mortality varying from 1.3% to 17.5%, which is lower than patients with systolic dysfunction (19%) (22). The lower mortality with diastolic function has been shown in a large number of population-based studies including the Veterans Administration Cooperative Study and Coronary Artery Surgery Study (22,251). The addition of coronary artery disease in patients with congestive heart failure adds considerable risk to diastolic dysfunction; however, it does not approach the risk of patients with low ejection fractions (250). A study by Senni et al. showed similar mortality in older patients with diastolic and systolic dysfunction (238).

From Vasan RS, Benjamin EJ, Levy D. Prevalence, clinical features and prognosis of diastolic heart failure: an epidemiologic perspective. *J Am Coll Cardiol* 1995;26:1565–1574, with permission.

Large prospective epidemiologic studies have provided significant insight into the clinical outcomes of patients with diastolic heart failure. One study group of 2,498 patients with functional class II to IV symptoms and LV ejection fractions greater than or equal to 40% were analyzed from the Duke University Cardiovascular database. A 5-year mortality of 28% was observed with predictors of mortality in a multivariable model including advanced age, minority status, coronary artery disease, severe heart failure or lower ejection fraction, diabetes, and peripheral vascular disease (252). An ongoing study (Candesartan in Heart Failure, Assessment of Reduction in Mortality and Morbidity) will address the effect of an angiotensin II type I receptor blocker in patients with systolic and diastolic dysfunction (253).

SPECIFIC DISEASE STATES

Restrictive Cardiomyopathy

Classification

The definition and classification of restrictive cardiomyopathy and other cardiomyopathies has evolved over time (254). Restrictive cardiomyopathy was originally classified as a group of primary muscle diseases of unknown etiology (255,256,257 and 258). According to the 1980 World Health Organization (WHO)/International Society and Federation of Cardiology (ISFC) task force on the definition and classification of cardiomyopathies (255), restrictive cardiomyopathy could exist either with or without obliteration and included endomyocardial fibrosis and Löffler's cardiomyopathy. This classification, which excluded "specific heart muscle diseases" of known cause or associated with other forms of myocardial disease, was becoming more blurred by more recent advances in imaging techniques such as Doppler echocardiography and radionuclide imaging (259). Indeed, the presence of restrictive physiology was by no means diagnostic of restrictive cardiomyopathy and restrictive cardiomyopathy may be diagnosed in the absence of demonstrable restrictive physiology. Thus, the WHO/ISFC classification of cardiomyopathy was not universally accepted and the number of cases with overlapping and unusual features was not insignificant (259,260).

Based on the problems outlined previously and increased knowledge, the 1995 WHO/ISFC Task Force found that the distinction between cardiomyopathy and specific heart muscle disease was not well delineated as previously thought; therefore, the current classification of cardiomyopathies now includes mention of the predominant pathophysiology, etiology, and provision for specific cardiomyopathies (254).

Restrictive cardiomyopathy is defined as a disease of the myocardium, which is characterized by "restrictive filling and reduced diastolic volume of either or both ventricles with normal or near-normal systolic function" (254). Systolic function may be normal in the early stage of disease, while wall thickness may be normal or increased depending on the etiology of the disease (254,261,262). The disease may be "idiopathic or associated with other disease" such as amyloidosis (254,261).

Despite this controversy of classification, in clinical practice, *cardiomyopathy* is a more loosely applied term. Dilated, hypertrophic, restrictive, and RV cardiomyopathies encompass the major categories of disease, although unclassified and specific cardiomyopathies (such as valvular, ischemic, hypertensive, and so forth) are also included (254). Restrictive cardiomyopathies are recognized as primary and secondary where the secondary forms include the specific heart muscle diseases in which the heart is affected as part of a multisystem disorder (e.g., infiltrative, storage, and noninfiltrative disease) (263).

A "working classification" of restrictive cardiomyopathy is shown in Figure 26.4 (261,263). Infiltrative cardiomyopathies can be further divided into interstitial and storage disorders. In interstitial diseases, the infiltrates localize to the interstitium (between myocardial cells), as with cardiac amyloidosis and sarcoidosis, whereas in storage disorders, the deposits are within cells, as with hemochromatosis and glycogen storage diseases (51). These secondary forms of restrictive cardiomyopathies are probably more common than the primary form (264) and display the classic restrictive hemodynamics only in their advanced form. The prototypical secondary

restrictive cardiomyopathy is cardiac amyloidosis (51).

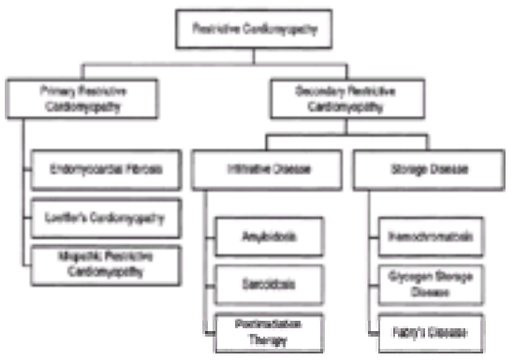

FIGURE 26.4 Working classification of restrictive cardiomyopathy. (From Leung DY, Klein AL. Restrictive cardiomyopathy; diagnosis and prognostic implications. In: Otto CM, ed. *Practice of clinical echocardiography*. Philadelphia: WB Saunders, 1997:474, with permission.)

Anatomic Considerations

In idiopathic restrictive cardiomyopathy, pathologic studies have shown mild to moderate degrees of hypertrophy and fibrosis (259) with the hemodynamic findings unrelated to the histopathologic abnormalities detected (259). In cardiac amyloidosis (see the section Cardiac Amyloidosis), there is interstitial infiltration of amyloid fibrils in the ventricles and atria causing a firm, rubbery consistency of the heart (265,266), whereas in the endomyocardial diseases there is an endocardial fibrotic shell with extension into the myocardium (267).

Pathophysiology

The characteristic feature of restrictive cardiomyopathy is a marked increased stiffness of the myocardium or endocardium that causes the ventricular pressure to rise dramatically with only small changes in volume causing an upward shift of the LV pressure-volume relationship and a dip and plateau or square-root hemodynamic pattern (268,269). As mentioned, there is a controversy about whether this restrictive hemodynamic pattern is necessary (270,271) to be included as a restrictive cardiomyopathy; however, the 1995 WHO/ISFC classification does include restrictive hemodynamics as an absolute criterion for the diagnosis. Both ventricles are affected with the restrictive process, but usually the pressures are higher on the left than the right (272), which may reflect the relatively decreased compliance of the left ventricle compared with the right ventricle. An exception may be tropical endomyocardial fibrosis in which the right ventricle may be predominantly involved (273).

Clinical Profile

The clinical signs and symptoms of restrictive cardiac diseases relate closely to the degree of left atrial hypertension required to compensate for poor ventricular filling (274). This gives rise to the typical clinical features of exercise intolerance in early cases and dyspnea at rest and symptoms of low cardiac output state such as fatigue in advanced cases (263). Left atrial dilatation, pulmonary congestion, distention of central veins, hepatic distention, ascites, peripheral edema, and anasarca are seen in advanced cases. Exertional chest pain is usually absent. Atrial fibrillation is common because of the atrial enlargement. Ventricular arrhythmias or heart block are not uncommonly present in advanced cases and are often the cause of death in these patients. Symptoms of the underlying multisystem disorder, if present, may also be evident (263). Examination may reveal jugular venous distention, S_4, or S_3 depending on the filling characteristics (275). Kussmaul's sign (272) can be detected, whereas apical retraction (as in constrictive pericarditis) is not seen (276).

In our experience, the main laboratory test to diagnose restrictive cardiomyopathy is echocardiography (4). Transthoracic or transesophageal echocardiography with respirometry has successfully been used to differentiate restriction from constriction (101,119). In patients with restriction, there is no significant respiratory variation as there is in constriction (13,101). Newer imaging modalities, including TDE and color M-mode Doppler (15,16,121,123), appear promising to further distinguish these disorders. MRI and computed tomography (CT) scanning may also be useful to exclude pericardial thickness (124,277,278). Cine MRI may show abnormal patterns of filling in early and advanced stages of restrictive cardiomyopathy similar to echocardiography (279). MRI may also be capable of distinguishing tissue characteristics of infiltrative processes, such as amyloid, differentiating it from other forms of cardiomyopathy (163).

Management

The prognosis of restrictive cardiomyopathy depends on whether there is early or advanced stage of the disease as shown with cardiac amyloidosis (103). The prognosis is variable, but usually progressive (280). Diuresis may help with symptomatic relief, while angiotensin-converting enzyme inhibitors may be of benefit with LV dysfunction. Vasodilators should be used cautiously because they may cause hypotension. Reversible underlying conditions such as hemochromatosis should be addressed. Transplantation can be considered; however, often the restrictive cardiomyopathy is part of a systemic illness (281). Signs or symptoms of ischemia in children with restrictive cardiomyopathy predict sudden death and should be managed aggressively with beta-blockers, an implantable defibrillator, or consideration for transplantation (282).

Primary Restrictive Cardiomyopathy

Idiopathic Restrictive Cardiomyopathy

Idiopathic restrictive cardiomyopathy is a disease in patients with diastolic heart failure that is often characterized by familial transmission and the association with skeletal myopathies (259,283,284). It was first described by Benotti et al. (285), who described nine patients with heart failure, with elevated RV and LV filling pressures with normal systolic function and dip and plateau hemodynamic tracing.

Other investigators have described similar findings using strict hemodynamic criteria (270,286,287,288 and 289). Some series have excluded patients with hypertrophy, and others have not shown the dip and plateau pattern in all patients (271,284). Thus, there is a lack of consensus on the type of diastolic filling pattern and the degree of LV hypertrophy in this disease (259).

Anatomic Considerations

The diagnosis of this disease is confirmed by the lack of any specific pathology on endomyocardial biopsies or autopsy specimens. The atria are disproportionately large with normal or near-normal ventricular cavity size (eFig. 26.4.1A). The left ventricle shows normal systolic function and there may be hypertrophy of the left or right ventricles (259). Thrombi may be present in the atrial appendages (261). Histologic examination is unremarkable or shows nonspecific degenerative changes seen in other cardiomyopathies, including myocyte hypertrophy, interstitial fibrosis, and nuclear changes (259) (eFig. 26.4.1B). Some series have reported myofibrillar disarray, increased fibrosis, and some hypertrophy of myocytes (270,286,287,288 and 289). Fibrosis may occur in the sinoatrial and atrioventricular nodes (283).

Assignment of patients into classification of cardiomyopathies. *Circulation* 1992;86:1626, with permission.) **B:** Scanning electron micrographs of the myocytes (*left*) and the interstitial collagen fibrils (*right*) in a patient with idiopathic restrictive cardiomyopathy. Note that there is a thick collagen fiber network, which results in the hemodynamics of restriction. (From Hirota Y. Restrictive cardiomyopathy, cardiac amyloidosis and hypereosinophilic heart disease. In: Abelman WH, Braunwald E, eds. *Cardiomyopathies, myocarditis and pericardial disease. Atlas of heart diseases*. Vol 2. Philadelphia: Current Medicine, 1995, with permission.)

Pathophysiology

The classic hemodynamic filling pattern is the dip and plateau pattern (285). The pathogenesis of the stiff ventricle may be secondary to myocyte abnormalities including abnormal calcium handling, accumulation of desmin, which is a cytoskeletal component, and myofiber disarray, as well as abnormalities of the extracellular matrix including proliferation of collagen fibers and elastic elements (273). As mentioned, it is believed that a restrictive filling pattern should not be an absolute requirement for the diagnosis. However, there must be abnormalities of diastolic filling, whether restrictive or abnormal relaxation on Doppler echocardiography or abnormal filling pressures on cardiac catheterization (259,290).

Clinical Presentation

Idiopathic restrictive cardiomyopathy is usually a sporadic disease, but it can occur in families with autosomal dominant transmission. There may be a family history, the presence of a distal skeletal myopathy, and heart block in this condition, which has been reported in five generations of an Italian family (261,283,284). Another restrictive cardiomyopathy with autosomal dominance with variable penetrance is associated with Noonan's syndrome (291).

There may be differences in idiopathic restrictive cardiomyopathy in children compared with adults. In children, the disease may be more common in girls (292,293), and children may have a worse prognosis with the disease than adults (292,293).

Diagnosis

Cardiac catheterization, echocardiography, or both, and endomyocardial biopsy should be done to make the diagnosis. Atrial enlargement with nondilated ventricles with near-normal systolic function is uniformly present on echocardiography. In one series, the ejection fraction ranged from 40% to 55% in patients with advanced disease needing heart transplantation (294). Variable degrees of hypertrophy may be present (259,286,288,289). Cardiac catheterization and Doppler echocardiography may show restrictive hemodynamics; however, other patterns may be present as well (259). Biopsy is important to exclude other diseases and to assess myocyte hypertrophy and interstitial fibrosis (259).

Differentiation between Restrictive Cardiomyopathy and Constrictive Pericarditis

It is important to differentiate idiopathic restrictive cardiomyopathy from secondary forms such as cardiac amyloidosis, as well as constrictive pericarditis, because of different treatment regimens and prognosis (259). As a result of the rapid early ventricular filling, a prominent 'y' descent is often seen in the jugular venous pulse and the RA pressure tracing. Left atrial pressure is usually greater than 15 mm Hg, right atrial pressure is greater than 7 mm Hg, and the pulmonary wedge pressure is greater than 12 mm Hg (295,296 and 297). LV end diastolic pressure is usually 5 mm Hg higher than the right-sided pressures (259), although the absence of this difference does not suggest constriction (298). Moderate pulmonary hypertension is usually present in advanced restrictive disease (274,299). In restrictive cardiomyopathy, the RV end diastolic pressure is often less than one-third of the peak RV systolic pressure (274,299). In early stage restrictive disease or with marked diuresis, these characteristic changes may only be unmasked by intravenous fluid challenge, exercise, or pharmacologic interventions (297,300). A comparison of hemodynamic abnormalities in restrictive and constrictive disease is shown in Table 26.3. The hemodynamic findings show much overlap in distinguishing these two similar conditions (13,301).

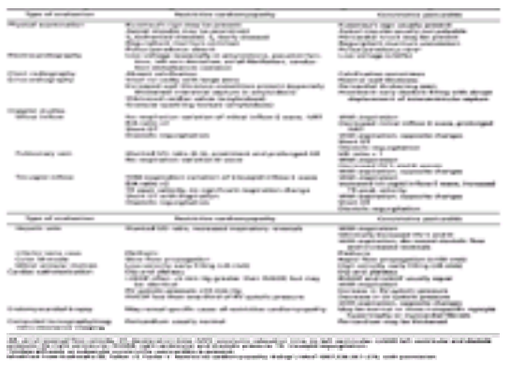

TABLE 26.3 DIFFERENTIAL DIAGNOSIS OF RESTRICTIVE CARDIOMYOPATHY AND CONSTRICTIVE PERICARDITIS

Management

Most small series show a protracted clinical course in adults, with a mean survival of 4 to 14 years (mean, 9 years) (285,288). Patients have symptoms of congestive heart failure, elevated jugular veins, and mitral and tricuspid regurgitation (288). Progressive heart failure that responds poorly to medical management and complete heart block requiring a pacemaker may occur (283,288). In one series, the mean follow-up time to transplantation or death was 117 months compared with 44 months for cardiac amyloidosis (284). In a large series of 94 patients with echocardiographically defined idiopathic restrictive cardiomyopathy, predictors of poor prognosis included advanced age, male gender, left atrial enlargement, and advanced functional class (302). The 5-year survival rate for this group was 64%. Heart transplantation can be considered in patients with idiopathic restrictive cardiomyopathy (284).

Endomyocardial Disease

There are two forms of the hypereosinophilic syndrome: endomyocardial fibrosis and Löffler's endocarditis (303). Endomyocardial fibrosis (Davies' disease) is a disease endemic to equatorial countries (Uganda, Nigeria, and Brazil) with rare appearance in nontropical countries (274,304). In contrast, Löffler's endocarditis is a disease of temperate countries, but occurs sporadically across the world (305). The common theme to this disease is an abnormal eosinophilia in the blood and the endocardium causing a restrictive (obliterative) cardiomyopathy, with endocardial fibrotic thickening at the apex and subvalvular regions causing impairment of ventricular inflow (303,306).

It has generally been thought that the two conditions are different forms of the same disease that result from tissue damage from the toxic effect of eosinophils and result in identical pathologic findings in advanced disease (303,307). However, despite the similarities of the two conditions, there are important differences. Eosinophilia is present in Löffler's endocarditis (308). In contrast, endomyocardial fibrosis affects younger patients without regard for gender and has no significant eosinophilia (303,308).

The eosinophil in these disorders is an abnormal cell, with fewer granules than normal (309). The abnormal eosinophil is thought to be cardiotoxic with the release of toxic substances from the granules (310) producing the necrotic reaction, followed by thrombosis and then fibrosis (303).

Löffler's Endocarditis

Löffler's endocarditis is considered to be part of the idiopathic hypereosinophilic syndrome that is characterized by a persistently elevated blood eosinophil count

without recognizable cause, despite a careful workup with signs and symptoms of organ involvement, especially in the heart, nervous system, and bone marrow (274,311,312). Cardiac involvement occurs in more than 75% of the cases of the syndrome (303).

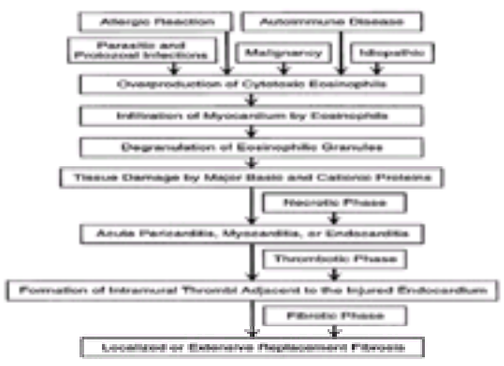
A case of Löffler's syndrome demonstrating extensive infiltration of the myocardium by eosinophils (A,B). (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

The etiology of the eosinophilia is unknown, but may be related to parasitic and protozoal infections, malignancy (leukemia), or allergic or autoimmune reactions (313,314). For example, the eosinophilia-myalgia syndrome is associated with eosinophilia and restrictive cardiomyopathy, supporting the role of the eosinophil in the pathogenesis of this disorder (315). The pathogenesis resulting from the toxic eosinophil is shown in eFigure 26.4.2.



***e*FIGURE 26.4.2** Pathogenesis of Löffler's syndrome showing the effect of tissue damage from the cytotoxic eosinophil resulting in a necrotic, thrombotic, and fibrotic phase. (From Hirota Y. Restrictive cardiomyopathy, cardiac amyloidosis and hypereosinophilic heart disease. In: Abelman WH, Braunwald E, eds. *Cardiomyopathies, myocarditis and pericardial disease. Atlas of heart diseases.* Vol 2. Philadelphia: Current Medicine, 1995;5.3–5.15, with permission.)

Pathology

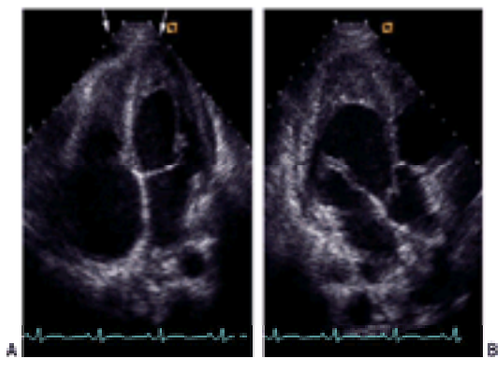
Cardiac involvement includes biventricular endocardial thickening of the inflow portion and the apex of both ventricles (316). The stages of the disease include necrotic, thrombotic, and fibrotic phases (273,316): (a) acute eosinophilic myocarditis involving the myocardium and endocardium with necrosis; (b) thrombosis overlying the endocardium, which is infiltrated with eosinophils; and (c) endocardial thickening with collagen fibrils and chronic inflammation and fibrosis of several millimeters (312) (eFig. 26.4.2).

Clinical Manifestations

The typical presentation is a man less than 50 years of age who lives in a temperate climate and has the hypereosinophilic syndrome (274,305). Right- and left-sided congestive heart failure, mitral regurgitation, systemic embolism, cardiac enlargement on the chest radiography, and T-wave inversions on the electrocardiogram are the main clinical manifestations of this disorder, which depends on the stage of disease (264,317).

Echocardiography commonly demonstrates mural thrombosis (eFig. 26.4.3). There may be obliteration of the apex and immobility of the posterior leaflet of the mitral

valve with entrapment against the thickened posterobasal endocardium, thus resulting in mitral regurgitation (264,318). These findings were described in a review of 29 patients with classic echocardiographic features of the hypereosinophilic syndrome (319). LV systolic function is often preserved, and restrictive physiology may be demonstrated by Doppler echocardiography, usually in the fibrotic phase (320).



***e*FIGURE 26.4.3** Transthoracic echocardiogram in a patient with endomyocardial fibrosis. **A:** Apical four-chamber view. **B:** Apical long-axis view. There is obliteration of the left and right ventricular apices with thrombosis and fibrosis (*arrows*), which is typical of endomyocardial fibrosis. Note also the marked right atrial enlargement. [From Thamilarasan M, Klein AL. Restrictive cardiomyopathy: diagnosis and prognostic implications. In: Otto CM, ed. *The practice of clinical echocardiography: transthoracic and transesophageal imaging*, 2nd ed. Philadelphia: WB Saunders (in press), with permission.]

Cardiac catheterization typically shows the dip and plateau physiology with reduced LV compliance because of the dense scarring of the ventricle, and mitral and tricuspid regurgitation may be present as well (303,312). Endomyocardial biopsy may be necessary to confirm the diagnosis; however, it may be difficult to obtain an adequate tissue sample (312).

Management

The treatment options depend on the stage of the disease; early Löffler's disease is treated medically with corticosteroids, whereas surgery is reserved for the fibrotic stages. Corticosteroids and hydroxyurea may be used to treat the myocarditis when associated with the hypereosinophilia (312,313,321). Also, interferon has been used in a limited number of patients with promising results (314,322). Standard supportive medical therapy should include digoxin, diuretics, afterload reducers, and anticoagulants (303,312). Surgical treatment involves debriding the fibrous plaque from the endocardial surface and replacement of the valves and pacemaker insertion (305,312,313).

Endomyocardial Fibrosis

Endomyocardial fibrosis is endemic to tropical and subtropical Africa and occurs less frequently in South America and Asia (300,323,324). It is a common cause of congestive heart failure and death in equatorial Africa, accounting for 15% to 25% of the deaths secondary to heart disease (274,305). Endomyocardial fibrosis involves both ventricles in 50% of the cases, followed by involvement of the left ventricle in 40% and right ventricle in 10% of the cases (274,307).

Endomyocardial fibrosis occurs in three distinct areas: the LV apex, subvalvular apparatus, and the RV apex (274,325). The fibrosis at the ventricular apex extends to the lower ventricular septum and to the posteromedial papillary muscle. The fibrosis also extends in the area behind the posterior mitral valve, causing tethering of the chordae tendineae and resulting in mitral regurgitation. The anterior leaflet of the mitral valve and the outflow tract is often spared. It also may involve the RV apex, causing impairment of filling of the tricuspid inflow and encasement of the papillary muscles of the tricuspid valve and resulting in tricuspid regurgitation (307,319).

A classification scheme according to the location of fibrosis was proposed by Shaper et al. (326). Usually, the right ventricle is obliterated more than the left ventricle (307). Microscopically, there is a thick layer of collagen tissue over a layer of connective tissue in the endocardium, with granulation tissue extending into the myocardium (327).

Clinical Profile

The clinical presentation in the endomyocardial fibrosis depends on whether the left, right, or both ventricles are involved. The disease affects both male and female subjects, usually children and young adults (308). Left-sided disease results in pulmonary congestion, whereas right-sided disease results in right-sided heart failure simulating constrictive pericarditis. Often, mitral and tricuspid regurgitation is present because of the involvement of the valves. Atrial fibrillation is not uncommon, occurring in one-fourth of patients with endomyocardial fibrosis, especially when there is RV involvement. Embolism is a frequent finding with endomyocardial fibrosis. A pericardial and pleural effusion may also be present (274,305,324).

Two-dimensional echocardiography shows the obliteration of the apices of the ventricles and dilated atria, whereas Doppler echocardiography shows evidence of mitral and tricuspid regurgitation. The posterior leaflet shows decreased mobility in left-sided disease (274,305). The basal ventricle may be hypercontractile due to the obliterated apex (328). Cardiac catheterization and Doppler echocardiography may show the restrictive hemodynamics of the disease.

Management

The prognosis is poor in endomyocardial fibrosis, with progressive disease and death caused by heart failure, or sudden death (274,305,326). The 2-year mortality is between 35% and 50% in patients with advanced disease (308,329). Surgery may improve symptoms in the fibrotic stage with excision of the fibrous endocardium and repair or replacement of the mitral and tricuspid valves (314,330,331); operative mortality has been reported in the range of 15% to 25% (332,333). However, one study of 11 patients undergoing surgery with endocardial resection and valve replacement reported a 10-year survival of near 70% (334).

Secondary Restrictive Myocardial Diseases

Infiltrative Conditions

Interstitial Diseases

Cardiac Amyloidosis. Cardiac amyloidosis is the prototype of restrictive myocardial diseases and the most frequently encountered in clinical practice (51).

Etiology and Classification of Amyloidosis. Amyloidosis is a multisystem disease in which linear, nonbranching, aggregated fibrils with a cross-beta pleated configuration are deposited in various organs of the body including the heart (335,336). The fibrils deposit between cells (interstitial) with a replacement of the normal tissue structures. Amyloidosis can be classified by the type of protein deposited. The primary type is the most common one, occurring in 85% of cases with amyloid, with fibrils composed of kappa or lambda immunoglobulin light chains (AL type), often associated with multiple myeloma. Recent work has suggested that circulating light chains from patients with amyloidosis (AL type) may directly cause diastolic dysfunction independent of extracellular fibril deposition (336a). There may be extracellular deposition of amyloid protein in the kidney, heart, liver, nerve, skin, and tongue resulting in tissue damage and organ malfunction (337). The most common manifestations include nephrotic syndrome or renal failure, congestive heart failure, sensorimotor peripheral neuropathy, and orthostatic hypotension. Most of the following discussion focuses on cardiac amyloidosis (AL type).

Secondary amyloidosis (AA type) is rare, with the fibrils consisting of protein A, a nonimmunoglobulin (336,338). Familial amyloidosis results from the production of a mutant prealbumin protein (transthyretin; TTR) (339), and there are six different types that present with a cardiomyopathy, neuropathy, or nephropathy. More than 50 mutations of this TTR protein have been described (340,341). This type of amyloid is important to recognize because liver transplantation may be life-saving. Senile systemic amyloidosis results in the elderly from the production of a normal TTR protein or atrial natriuretic-like protein and has become increasingly common as the population ages (335).

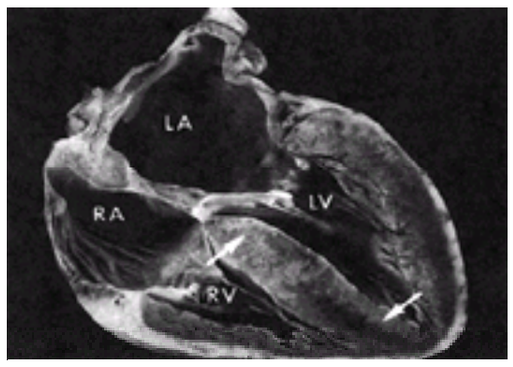
The heart is commonly involved in primary amyloidosis (AL type) (335). One-third of patients manifest cardiac involvement and one-fourth have congestive heart

failure; however, the heart is involved in most patients by pathologic examination (342). Death from cardiac involvement secondary to congestive heart failure or arrhythmia occurs in greater than 50% of patients with systemic amyloidosis (335). Cardiac involvement is unusual in secondary amyloidosis, with the renal manifestations being more predominant (338).

In familial amyloidosis, cardiac involvement occurs in 28% of patients at the time of diagnosis; however, it usually presents late in the course of the disease (339). Peripheral neuropathy and renal failure are the usual presenting features; however, cardiac features may predominate (343). It was reported over 30 years ago from a Danish family (344) but has been described in a family from Appalachia (345) and, more recently, in an Italian family (343). Cardiac failure or cardiac arrhythmia is responsible for the deaths in over 50% of patients (339). Familial amyloidosis has been reported in elderly blacks in the United States as a cause of heart failure secondary to a mutation in TTR isoleucine (122,346,347).

Senile cardiac amyloidosis may have extensive deposits in the heart producing congestive heart failure or may have minor deposits in the atria with no symptoms (335). It is important to differentiate senile cardiac amyloidosis from nonsecretory immunoglobulin-derived amyloidosis (AL type) and familial amyloidosis because of different treatment regimens (335,348).

Pathology. Pathologic examination shows focal and diffuse deposits, microscopic and macroscopic interstitial deposits of amyloid in the myocardium, endocardium, and pericardium (51,265,266) (eFig. 26.4.4). The amyloid protein can be seen histologically between myocytes, particularly in the papillary muscles (349). Endocardial involvement occurs frequently in the ventricles and the atria (171), and the valves may also show focal thickening. The coronary arteries and veins may have interstitial deposits of amyloid protein in the media and adventitia, which may occlude the lumen of these vessels (343,350). Macroscopically, in advanced cases, the heart has a firm, rubbery consistency and is mildly to moderately enlarged with enlarged atria and thickened myocardium, interatrial septum, and valves (51).



***e*FIGURE 26.4.4** Gross necropsy specimen showing diffuse amyloid infiltration in a four-chamber view of 67-year-old woman's heart with diffuse amyloid infiltration. Note the pale transmural and subendocardial areas (*arrows*) indicating amyloid infiltration in the ventricular septum, left ventricular (LV) free wall, and apex. Note enlarged atria. LA, left atrium, RA, right atrium; RV, right ventricle. (From Click RL, Olson LJ, Edwards WD, et al. Echocardiography and systemic diseases. *J Am Soc Echocardiogr* 1994;7:201–216, with permission.)

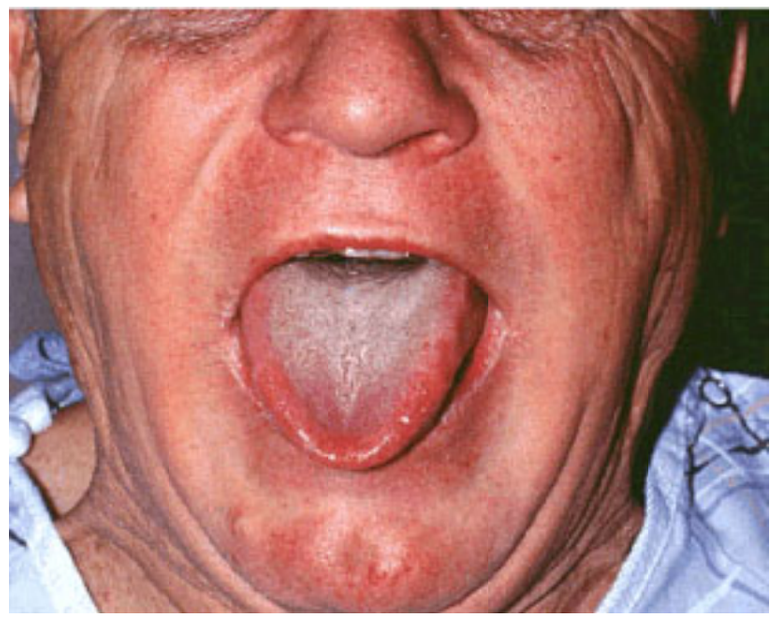
Amyloid deposition. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

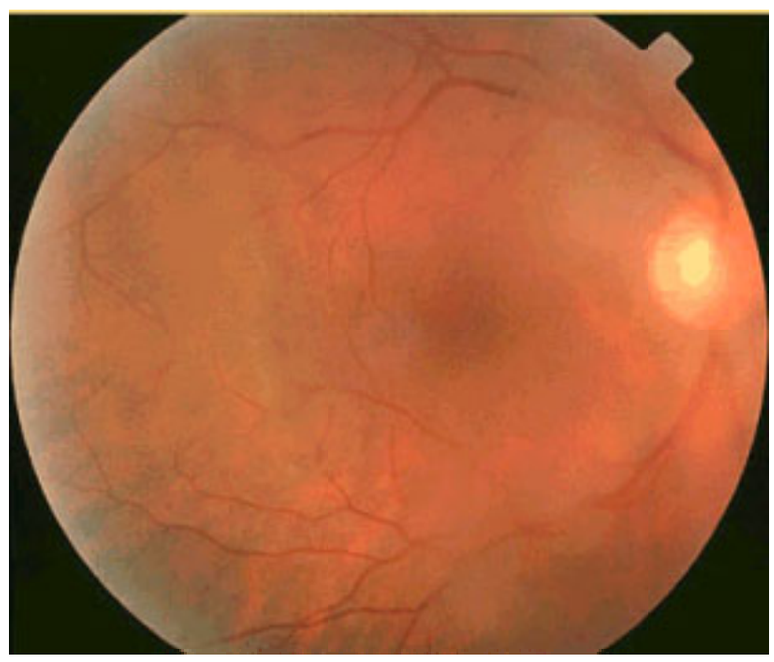
Clinical Presentation. Cardiac amyloidosis usually presents in men over 30 years of age (336,342) and occurs in older patients in the familial form (339). Patients with cardiac amyloidosis present with diastolic heart failure and the "stiff heart syndrome" resulting from amyloid infiltration. Patients may present with various degrees of progressive biventricular heart failure depending on the stage of disease as shown by two-dimensional and Doppler echocardiography (275). In early cardiac amyloidosis, patients may be asymptomatic, whereas patients with advanced disease have the typical evidence of restrictive cardiomyopathy with severe right-sided heart failure, ascites, and peripheral edema (305). During cardiac catheterization a square-root sign is present, and restrictive hemodynamics by Doppler echocardiography are detected only in the advanced stages of the disease (275). In addition, there may be an intermediate stage in which patients have more symptoms as left atrial pressure increases. Individual patients may actually evolve through the different stages of involvement (100). Often, it may be difficult to differentiate advanced cardiac amyloidosis from constrictive pericarditis (101,123). As the disease progresses, there are both systolic and diastolic heart failure (351). Chest pain resembling angina pectoris may also be present despite normal epicardial coronary arteries during cardiac catheterization (350), or there may be partial obliteration of the distal coronary arteries by amyloid infiltration (266,343,352). Involvement of the intramyocardial vessels may be an another explanation for this presentation (325,353). In 10% to 15% of cases, orthostatic hypotension is detected in patients with cardiac amyloidosis. This is secondary to amyloid infiltration of the autonomic nervous system with symptoms of syncope, diarrhea, lack of sweating, and impotence (337). Kidney, adrenal, and cardiac involvement with amyloid deposition may aggravate the postural hypotension. Refractory supraventricular and ventricular arrhythmias or conduction defects may also be another mode of presentation (354). Sudden death secondary to arrhythmias may also be the cause of death, especially in familial amyloidosis (339).



Amyloidosis. Infiltration of the tongue occasionally leads to macroglossia. Cardiac manifestations include cardiomegaly, congestive heart failure, and arrhythmias.

Amyloidosis. Infiltration of the skin results in raised waxy papules or plaques that are usually in clusters.

Physical examination may reveal an S_4 (early disease) or S_3 (advanced disease) on auscultation, depending on the stage of the illness (275). Mitral and tricuspid valvular regurgitation may also be present (51). There is evidence of biventricular heart failure with often predominant right-sided heart failure (305), an elevated jugular venous pulse with a prominent 'y' descent, hepatosplenomegaly, ascites, and peripheral edema, especially in advanced disease. The blood pressure may also be decreased.



Vitreous opacities in association with amyloidosis.

The cardiac silhouette on chest radiography is usually enlarged in patients with advanced disease with evidence of pulmonary congestion (297). Electrocardiography typically is of low voltage and shows a pseudoinfarction pattern with Q waves simulating a myocardial infarction in the precordial leads (325,355). Arrhythmias especially atrial fibrillation are common (30% of patients) and a sick sinus syndrome may be present (325).

Atrioventricular conduction defects may be present, especially in familial amyloidosis associated with polyneuropathy (339). Also, ventricular arrhythmias consisting of ventricular tachycardia may be present in advanced disease and may be a forewarning of death (343).

A 68-year-old male patient with amyloidosis.

Investigations: Echocardiography. Two-dimensional and Doppler echocardiography is the procedure of choice in the noninvasive diagnosis, serial follow-up, and prognosis of patients with cardiac amyloidosis (51,100,103,180,275,351,356). Cardiac amyloidosis gives a distinctive appearance on two-dimensional echocardiography and is associated with abnormal LV and RV diastolic function. The findings of a normal or small LV cavity size with markedly thickened myocardium

associated with a highly abnormal texture that is often described as “granular sparkling” in appearance is the classic presentation (51) (Fig. 26.5).

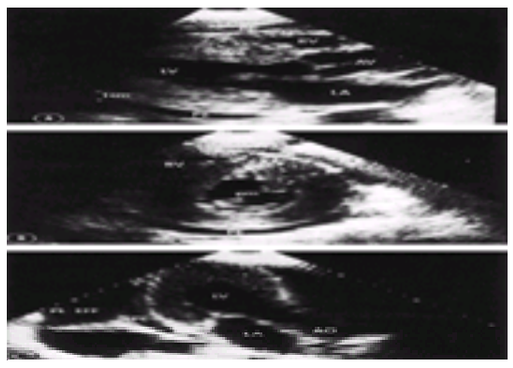


FIGURE 26.5 Parasternal long-axis **(A)**, short-axis **(B)**, and apical long-axis **(C)** views show typical echocardiographic features of advanced cardiac amyloidosis. Note left ventricle (LV) size is normal with markedly thickened ventricular walls [ventricular septum, 22 mm; posterior wall, 18 mm; and right ventricular (RV) free wall, 15 mm] and its characteristic granular sparkling appearance. Small pericardial effusion (PE) and left pleural effusion (PL EFF) are also present. AO, aorta; AV, aortic valve; LA, left atrium; pm, papillary muscle; VS, ventricular septum. (From Klein AL, Oh JK, Miller FA, et al. Two-dimensional and Doppler echocardiographic assessment of infiltrative cardiomyopathy. *J Am Soc Echocardiogr* 1988;1:48–59, with permission.)

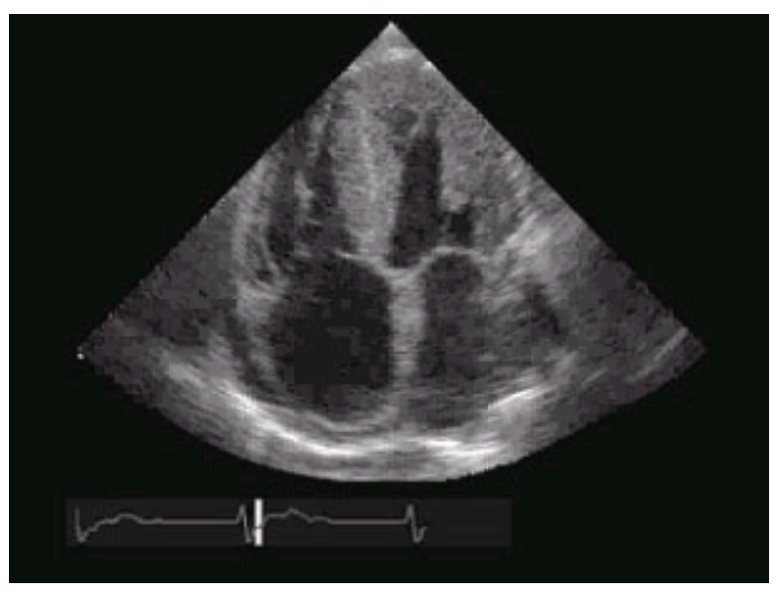
VIDEO

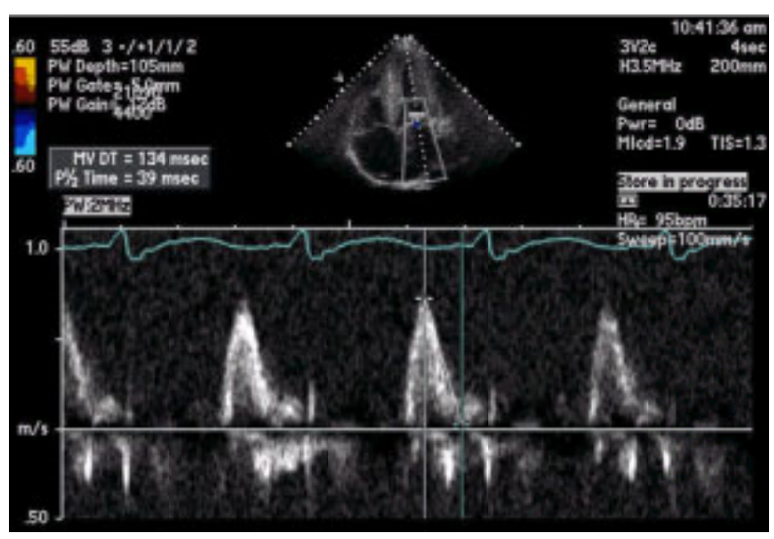
Video 26.1 Transthoracic apical four-chamber view of a patient with amyloidosis. Note the thickened “sparkling” walls of the right and left ventricles. Both the mitral and tricuspid valves are mildly thickened, and there is biatrial enlargement and a trivial pericardial effusion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 26.2 Transthoracic subcostal view of a patient with amyloidosis showing markedly thickened right and left ventricular walls, showing the characteristic “sparkle.” The right ventricle is towards the top of the screen, and the right ventricle free wall is 1.5 cm thick. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Apical four-chamber view of amyloid heart disease. Note the significant thickening of the left ventricle and right ventricle walls due to infiltration. There is also characteristic thickening of the valves and biatrial enlargement. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)



Pulsed wave Doppler of the mitral valve inflow in a patient with amyloidosis demonstrating a short deceleration time (134 ms) consistent with restrictive physiology.

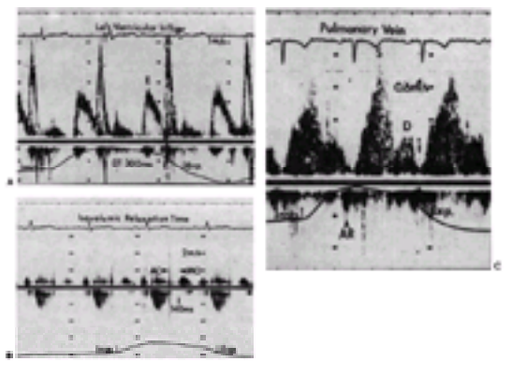
The sparkling granular appearance is thought to be caused by the acoustic mismatch between the highly reflective amyloid deposits in the endocardium, myocardium, and pericardium and the normal tissue (357). Moreover, autopsy and clinical biopsy series have demonstrated the presence of amyloid fibrils in the myocardium at the site of the granular sparkling echoes. Ultrasonic tissue characterization has been used to identify patients with cardiac amyloidosis (358).

Global LV systolic function is usually preserved in early disease, whereas systolic function is usually impaired in advanced disease. The interatrial septum and valve leaflets are also thickened. Both atria are enlarged, and small to moderate pericardial effusions are usually present (351,356).

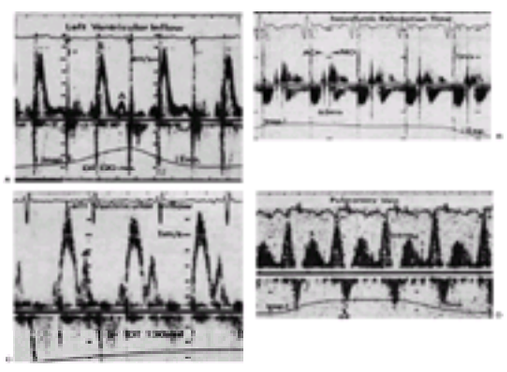
Patients with cardiac amyloidosis have a low ratio of electrocardiographic voltage to LV wall thickness ratio, which is thought to be specific to cardiac amyloidosis and suggested to be predictive of clinical symptoms and prognosis (359,360). However, the usefulness of this ratio is limited by the presence of coexisting diseases that may result in decreased electrocardiographic voltage.

Left Ventricular Diastolic Dysfunction. Cardiac amyloidosis has traditionally been considered to be associated with a restrictive pattern of ventricular filling (361); however, a spectrum of LV filling abnormalities using pulsed wave Doppler echocardiography is detected in patients with cardiac amyloidosis (51,275,361). In a study of

53 patients with the classic echocardiographic features of cardiac amyloidosis (275), patients with a mean LV wall thickness between 12 and 15 mm showed a transmitral flow pattern consistent with abnormal relaxation. The peak E-wave velocity was decreased while the A-wave velocity increased, giving rise to a lower E/A ratio. The isovolumic relaxation time (greater than 86 ms) and deceleration time (greater than 240 ms) were also prolonged. The pulmonary vein flow velocity profile also showed increased peak systolic and decreased diastolic forward filling (275) (eFig. 26.5.1). In contrast, in patients with advanced disease (i.e., a mean LV wall thickness of greater than 15 mm) a “restrictive” physiology pattern of LV filling was observed (275). The mitral E-wave velocity was increased while the A wave decreased with a shortened deceleration time (less than 150 ms) and isovolumic relaxation time (eFig. 26.5.2). The pulmonary vein systolic forward flow velocity was markedly decreased with an increase in the diastolic forward flow velocity. Furthermore, in serial studies of individual patients, patients with the “impaired relaxation” pattern gradually evolved into a restrictive pattern through a pseudonormal or intermediate phase with the progression of the disease (100). The mechanism for this serial change in LV filling pattern is thought to be due to a gradual decrease in the compliance of the left ventricle with progressive deposition of amyloid fibril in the myocardium leading to subsequent loss of myocardial cells from pressure necrosis (362). As compliance decreases, LV end diastolic and left atrial pressure increase. When the duration of the pulmonary venous AR wave is longer than the mitral A-wave duration, filling pressures are elevated and the disease is advanced with restrictive physiology (235).



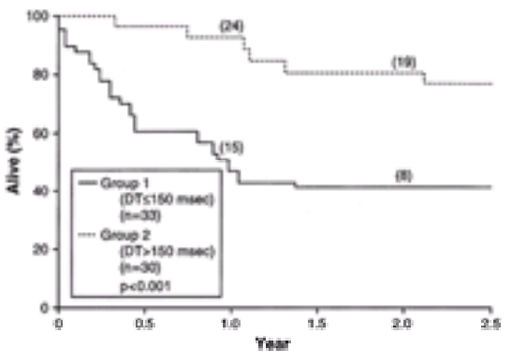
***e*FIGURE 26.5.1 A:** Early case of cardiac amyloidosis associated with impaired relaxation pattern of mitral inflow with a decreased E/A ratio and prolonged deceleration time (DT) of 300 ms. **B:** Continuous wave Doppler recording of the aortic valve and mitral valve flows. The isovolumic relaxation time is markedly prolonged (140 ms). **C:** A relatively normal pulmonary venous Doppler flow pattern with a small atrial reversal wave (AR). AC, aortic valve closure; Exp., expiration; Insp., inspiration; MO, mitral valve opening. (From Klein AL, Hatle LK, Burstow DJ, et al. Doppler characterization of left ventricular diastolic function in cardiac amyloidosis. *J Am Coll Cardiol* 1989;13:1017–1026, with permission.)



***e*FIGURE 26.5.2 A:** Advanced case of amyloidosis associated with a restrictive pattern of mitral inflow with an increased E/A ratio and a shortened deceleration time (DT) of 120 ms. **B:** Shortened isovolumic relaxation time. **C:** An example of an advanced case of amyloidosis with a normal E/A, but a shortened deceleration time. **D:** Note the blunted pulmonary venous systolic (S) flow and increased atrial reversal (AR). AC, aortic valve closure; Exp., expiration; Insp., inspiration; MO, mitral valve opening. (From Klein AL, Hatle LK, Burstow DJ, et al. Doppler characterization of left ventricular diastolic function in cardiac amyloidosis. *J Am Coll Cardiol* 1989;13:1017–1026, with permission.)

Right Ventricular Diastolic Function. Patients with cardiac amyloidosis also have been shown to have abnormalities of RV diastolic function (180). The RV filling pattern is often similar to that of the left ventricle or may be less advanced. In early cases (i.e., patients with RV free wall thickness of less than 7 mm), there is abnormal relaxation. In advanced cases, when the RV wall is greater than or equal to 7 mm in thickness, restrictive physiology is present. The systolic forward flows in the superior vena cava and hepatic vein were also decreased, and the diastolic flow increased compatible with restrictive physiology. Flow reversals were increased compared with normal values and showed further increase with inspiration (180).

Prognostic Stratification. The mean LV wall thickness has been suggested as a useful variable in assessing the degree of cardiac involvement and prognosis (363). In a study of 132 patients with biopsy-proven amyloidosis, patients with a mean wall thickness of 15 mm had a median survival of 0.4 years compared with a median survival of 2.4 years for those with a mean wall thickness of 12 mm. Doppler echocardiography has also been shown to be useful in prognostic stratification of patients with cardiac amyloidosis (103). Patients with a deceleration time of the mitral early filling wave at baseline study of less than or equal to 150 ms had a significantly reduced survival compared with those whose deceleration time was greater than 150 ms (1-year probability of survival 49% vs. 92%, p <.001) (eFig. 26.5.3).



***e*FIGURE 26.5.3** Survival in 63 patients with cardiac amyloidosis subdivided on the basis of the deceleration time (DT) of 150 ms. Patients with a shortened DT of less than or equal to 150 ms (*bold line*) had a significantly reduced survival compared with the patient subgroup having a DT greater than 150 ms. (From Klein AL, Hatle LK, Taliercio CP, et al. Prognostic significance of Doppler measures of diastolic function in cardiac amyloidosis. A Doppler echocardiographic study. *Circulation* 1991;83:808–816, with permission.)

Bivariate analysis showed that the combination of shortened deceleration time of less than or equal to 150 ms and an increased mitral E/A ratio were stronger predictors of cardiac death than two-dimensional variables of mean LV wall thickness and fractional shortening. The prognostic significance of a shortened deceleration time can most likely be explained by its association with elevated left atrial and LV diastolic pressures (296).

A new Doppler index (isovolumetric contraction time plus isovolumetric relaxation time/ejection time) combining systolic and diastolic performance for predicting outcome has been described in cardiac amyloidosis (364). RV enlargement has also been identified as an independent predictor of poor outcomes among patients with

primary amyloidosis (365).

Differentiation from Hypertrophic Cardiomyopathy. LV hypertrophy and hypertrophic cardiomyopathy are also associated with an increased myocardial all thickness, and differentiation from cardiac amyloidosis may be important as treatment and prognosis of these conditions are different (366). The presence of low voltage on the electrocardiogram favors a diagnosis of amyloidosis rather than hypertrophic cardiomyopathy; however, endomyocardial biopsy may be necessary in some cases to give a definitive diagnosis because of the grim prognostic implications of a diagnosis of cardiac amyloidosis (366). Consideration should be given to screen patients with serum and urine protein electrophoresis if they have increased wall thickness on echocardiography and unexplained congestive heart failure (336).

Nuclear medicine techniques may also be useful in the diagnosis of cardiac amyloidosis, and these include radionuclide angiography and technetium-99m pyrophosphate scintigraphy and indium-labeled antimyosin antibodies (163,367,368 and 369).

Cardiac amyloidosis can be diagnosed noninvasively antemortem in most cases from the classic appearance on two-dimensional echocardiography, electrocardiography, and an abdominal fat aspirate showing systemic amyloidosis (51,342). However, there has been a report of endomyocardial biopsy-proven AL type amyloid without echocardiographic features (370). Other sites of biopsy can include the rectum, gingiva, bone marrow, kidney, and liver (342). Fat aspirate and bone marrow biopsy may detect amyloidosis in most patients (371). If the echocardiogram is not diagnostic or the fat pad aspirate is negative and cardiac amyloidosis is still suspected, then an endomyocardial biopsy can be performed to make the diagnosis.

Serum and urine protein electrophoresis is recommended to assess for the secretion of a monoclonal protein (335). In 10% of cases, there is no monoclonal protein secreted (nonsecretory primary amyloidosis). For accurate classification of the different type of amyloid, antisera against TTR, the kappa and lambda light chains, and protein A in the biopsy should be performed (335,336).

Magnetic Resonance Imaging. MRI can be used to identify the increased myocardial thickness and small LV cavity in cardiac amyloidosis. It can be used to demonstrate the lack of increased pericardial thickening with the ancillary findings of biatrial enlargement and inferior cava dilatation, similar to echocardiography (372). Usually, the myocardial image has normal MRI properties (T2-weighted images) (373). Myocardial wall thickening due to hypertrophy or amyloid infiltration may be distinguishable (163).

Management. The prognosis of cardiac amyloidosis is uniformly poor but does depend on the type of disease, with AL amyloidosis having the worse prognosis (335,336,338,339,342). In a series of over 800 patents with primary amyloidosis over a 10-year period, the median survival was 2.1 years (374). The treatment for cardiac amyloidosis (AL type) includes alkylating agents, such as melphalan and prednisone (374).

There have been two randomized trials of chemotherapy showing benefit in AL amyloid (341,375,376). A trial of 100 patients with primary amyloidosis using melphalan, prednisone, and colchicine showed improvement of systemic disease when the major features were not cardiac or renal (377). Colchicine has also been used to prevent amyloidosis associated with familial Mediterranean fever (374); however, there is no evidence that it halts the progression of amyloid deposition in primary amyloidosis. Dose-intensive melphalan with blood stem cell support is currently being evaluated (378).

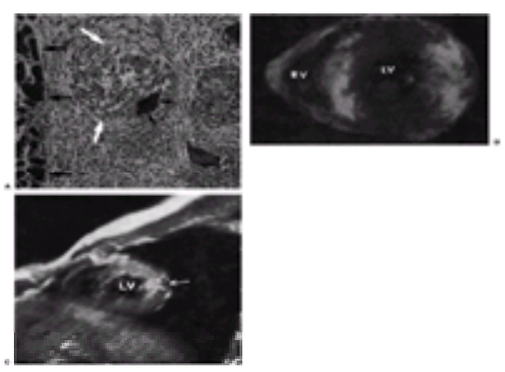
Cardiac transplantation is generally not performed for patients with AL type amyloidosis, because this is a systemic illness with progressive amyloidosis in other organs (281). However, it has been considered in select patients without extracardiac disease (379,380). Liver transplantation has been suggested for the familial type (TTR variant) since the circulating TTR is produced in the liver. Thus, the new liver replaces the variant TTR with a normal TTR. There is no specific treatment for the senile type (381,382).

Avoidance of digoxin is recommended since digoxin-induced arrhythmias may occur because the digoxin may bind to the amyloid fibrils (305,383). However, it has been used to control heart rate in patients with atrial fibrillation with careful monitoring (336). Also, patients with cardiac amyloidosis may be sensitive to the negative inotropic effects of calcium channel blockers either because of their abnormal binding to amyloid fibrils or the vasodilator effects (305,384). Vasodilator agents and diuretics should be used judiciously because of the risk of postural hypotension. Pacemakers may be useful to treat symptomatic high atrioventricular block (385), and anticoagulation should be considered because of the risk of thrombus formation with atrial amyloid involvement and atrial standstill (171,386).

Cardiac Sarcoidosis. Sarcoidosis is a noncaseating granulomatous disorder of unknown etiology that may involve the lung, lymph nodes, skin, liver, spleen, parotid glands, and heart (387,388). Pulmonary manifestations are the predominant finding, with pulmonary hypertension and pulmonary fibrosis resulting in right-sided heart failure (389). Sarcoid granulomata are found in the myocardium at autopsy in up to 25% of the patients with sarcoidosis and are often clinically silent (390,391,392 and 393).

Sarcoidosis. Skin plaques with purple, raised lesions seen in sarcoidosis (*arrows*).

Pathology. Characteristically, the noncaseating granulomata infiltrate the ventricular walls and become fibrotic (393). They are typically found in the LV free wall and the superior interventricular septum, although other areas—including the papillary muscles, atria, conduction system, and pericardium—can also be affected (394,395 and 396). Clinical evidence of heart disease is only seen in approximately 5% of patients with sarcoidosis, whereas 25% have microscopic evidence (390). There may be transmural involvement with portions of the myocardium replaced by scar tissue and secondary aneurysm formation (396) (*e*Fig. 26.5.4A and *e*Fig. 26.5.4B). The interstitial inflammation of the granulomata in the heart may cause initially abnormal diastolic function with preserved systolic function (397). Systolic function becomes impaired with the injury and fibrosis of advanced disease.



***e*FIGURE 26.5.4 A:** Sarcoidosis: histologic section of cardiac biopsy showing noncaseating granuloma (*white arrows*), multinucleated giant cells (*small black arrows*), and normal myocardial border (*large black arrows*). **B:** Sarcoidosis: gross pathologic specimen. Clinical Manifestations. The clinical presentation of cardiac sarcoidosis is variable and may depend on the amount of myocardium replaced with granulomata and the amount and the location of scar tissue (264,394,396,398,399). Most patients are asymptomatic; however, rhythm abnormalities and conduction disorders may predominate (264,394). The most common arrhythmia is ventricular tachycardia (396,400,401), while complete heart block is the most common conduction disorder (393). Sudden death is the most feared complication (395,402) and occurs in 17% of patients when there is extensive myocardial involvement. Valvular dysfunction and pericardial effusions are less common manifestations in this disease (394,396,398,399).

Patients with congestive heart failure may show clinical features of restrictive cardiomyopathy, dilated cardiomyopathy, or both (393). Patients with marked disease may develop aneurysm formation and papillary dysfunction and mitral regurgitation (393,403). The electrocardiogram may show T-wave abnormalities, atrioventricular (AV) block, or Q waves mimicking myocardial infarction (393,404).

The echocardiographic findings consist of systolic and diastolic ventricular dysfunction, LV aneurysm formation, small to moderate pericardial effusions, and abnormal ventricular wall thickness (51,405,406,407 and 408). Regional wall motion abnormalities (suggestive of coronary artery disease) may be detected in the basal septum with sparing of the apex (409). There may be RV dilatation and increased wall thickness consistent with cor pulmonale (389). LV diastolic function abnormalities may be present in 14% of patients with pulmonary sarcoidosis without evidence of cardiac disease, suggesting subclinical sarcoid cardiomyopathy (410).

Thallium-201 or gallium-67 scanning may show segmental defects suggestive of sarcoid infiltration (411,412,413 and 414). The gallium-67 uptake in the myocardium may be able to predict the efficacy of corticosteroids. MRI may also be useful to identify areas of high intensity in the LV septum and the free wall of the ventricle in the inflammatory phase, while detecting thinning and aneurysm formation in the chronic phase (415). The findings on MRI may be useful in guiding endomyocardial biopsy (416). Endomyocardial biopsy may be useful although the sensitivity is reported to be in the range of 20% to 30% and thus does not exclude the diagnosis if negative (393,404).

Management. The finding of pulmonary involvement with bilateral hilar adenopathy and evidence of myocardial disease may suggest sarcoidosis involving the heart in a young person (393). Echocardiography shows LV dilatation, regional wall motion abnormalities, or aneurysm formation (264,408). Treatment of sarcoidosis may include the use of corticosteroids, especially with myocardial involvement; conduction abnormalities and ventricular arrhythmias are present, however, this remains controversial (404,417,418 and 419). Permanent pacemakers may be needed to treat the conduction abnormalities (392,393). Implantable defibrillators may be needed to prevent sudden death (420,421), whereas heart transplantation is reserved for intractable heart failure (392,420).

Gaucher's Disease Gaucher's disease is a rare disease of ceramide metabolism with a deficiency of the beta-glucosidase enzyme, which causes deposition of the cerebrosides in the myocardium, liver, spleen, bone marrow, lymph nodes, and brain (422). Deposition of the cerebrosides in the myocardium may cause diastolic impairment. The cardiac manifestations may include LV dysfunction, increased LV wall mass, restrictive cardiomyopathy, pericardial effusions, constrictive pericarditis, thickening or calcification of the left-sided valves, and pulmonary hypertension (which may also be due to treatment) (274,423,424 and 425) (*e*Fig. 26.5.5). There has been progress in treating this disorder with aglucerase or the recombinant form of glucocerebrosidase imiglucerase (426).

***e*FIGURE 26.5.5** Patient with Gaucher's disease. An 18-year-old man with a family history of Gaucher's disease who presented with congestive heart failure. Cardiac magnetic resonance imaging revealed severe mitral stenosis and insufficiency, severe aortic stenosis, and relative hypoplasia of the entire thoracic aorta with wall thickening and calcification. (From Cho L, Lytle BW, Moodie DS. Type IIIC Gaucher's Disease. *Circulation* online 2000;102:e69–e70, with permission.)

Hurler's Syndrome Hurler's syndrome is an autosomal recessive disorder of mucopolysaccharide metabolism caused by a deficiency of the enzyme alpha-iduronidase in the lysosomes of the cell. Thus, Hurler cells filled with mucopolysaccharides infiltrate interstitial tissues and cause a rubbery consistency, decreased compliance, and restrictive physiology (274). Clinical manifestations may include coarse facial features, short stature, clouding of the cornea, and cardiac involvement, and survival into adulthood is rare. Cardiac manifestations may include premature coronary disease, mitral and aortic regurgitation and stenosis (427,428), decreased systolic function, and low voltage on the electrocardiogram. Echocardiography reveals thickened right and LV walls, mitral valve leaflets, and decreased systolic function (274,429,430).

Metastatic Malignancies. Metastatic malignant involvement of the myocardium causing an impairment of diastolic filling and a restrictive cardiomyopathy with interstitial deposition is rare. The more common metastatic tumors are leukemia, malignant melanoma, lymphoma, and lung and breast carcinomas (274,431). More commonly, pericardial involvement is seen as a by-product of radiation. Metastatic involvement can be documented with echocardiography, CT scan, and MRI (432).

Storage Diseases

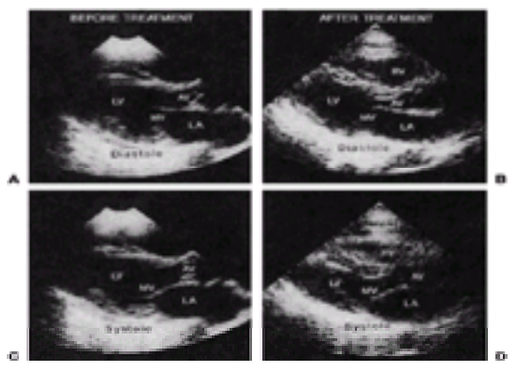
Hemochromatosis. Hemochromatosis is an iron storage disease that affects the heart, pancreas, liver, gonads, and skin (433). Primary idiopathic hemochromatosis is an autosomal recessive disorder related to the human leukocyte antigen on chromosome 6, whereas secondary hemochromatosis results from hemoglobin synthesis abnormalities leading to ineffective erythropoiesis, chronic liver disease, excessive intake of iron, or multiple blood transfusions (433,434).

Pathology. Iron is deposited within the sarcoplasmic reticulum in myocardial cells, especially in the subepicardium, subendocardium, papillary muscles, conduction system, and less commonly in the myocardium and the atria (435) (*e*Fig. 26.5.6). On gross examination, the "iron heart" is usually dilated, with normal or

increased wall thickness (435,436). The severity of myocardial involvement is related to the rate of iron deposition in the heart (436).

Clinical Presentation. Manifestations of cardiac involvement occur when there is a large amount of iron deposited over a long time period. One-third of patients manifest cardiac symptoms with evidence of congestive heart failure, supraventricular or ventricular arrhythmias, and conduction defects (433). One-third of patients die from cardiac involvement. A dilated or restrictive cardiomyopathy may be present with evidence of systolic and diastolic dysfunction. Cardiomegaly may be seen on chest radiography. Electrocardiographic findings have included arrhythmias, conduction disorders, and low voltages (51,433).

Echocardiography is a useful noninvasive technique in the assessment of cardiac involvement in primary hemochromatosis, detecting clinically occult heart involvement, following patients serially, and assessing LV function after phlebotomy (437,438 and 439) (eFig. 26.5.6).



***e*FIGURE 26.5.6** Hemochromatosis: Parasternal long-axis echocardiographic images of hemochromatosis before **(A,C)** and after **(B,D)** treatment (5-year period between studies). AV, aortic valve; LA, left atrium; LV, left ventricle; MV, mitral valve; RV, right ventricle. (From Click RL, Olson LJ, Edwards WD, et al. Echocardiography and systemic diseases. *J Am Soc Echocardiogr* 1994;7:201–216, with permission.)

Olson et al. described 19 patients with primary hemochromatosis and demonstrated that 7 (37%) had chamber dilatation and systolic dysfunction secondary to the hemochromatosis, whereas 12 patients did not (440). Increased ventricular wall thickness and mass may also be observed, although Olson and coworkers suggested that increased ventricular wall thickness is not always present with cardiac hemochromatosis (440). Patterns consistent with dilated or restrictive cardiomyopathy have also been described in patients with primary hemochromatosis (441). Ventricular dysfunction and increased ventricular mass may normalize after successful venesection (441). The presence of systolic dysfunction usually signifies poor prognosis (439). Secondary hemochromatosis manifestations in the heart include increased LV wall thickness and mass, cavity dimension, and left atrial enlargement. Most patients have normal systolic function, and those with the depressed systolic function have the worst prognosis (442).

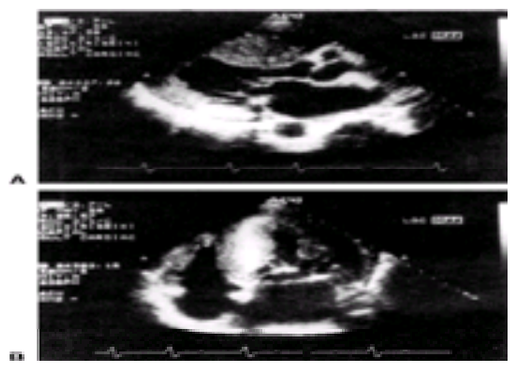
Other noninvasive tests, including CT scan or MRI, may be useful in demonstrating subclinical involvement of hemochromatosis (443). The MRI may show a low myocardial signal on the cine gradient-echo consistent with myocardial iron deposition. Endomyocardial biopsy may be useful to exclude the diagnosis, especially when the echocardiographic or clinical features are not evident (444,445). Laboratory tests show an elevated serum ferritin and increased ratio of plasma iron level to total iron-binding capacity, urinary iron, liver iron, and saturation of transferrin (445).

Management. Treatment by repeat phlebotomies in primary hemochromatosis or the use of chelating agents (desferrioxamine) in secondary hemochromatosis may result in improvement of the cardiac involvement, thus making early diagnosis important (433,446,447). Heart transplantation may be considered when the heart involvement is life-threatening (447) or combined heart and liver transplantation may be useful in patients with heart and liver failure (448).

Glycogen Storage Disease Glycogen storage diseases are autosomal recessive disorders of carbohydrate metabolism in which there is deposition of glycogen in the heart and the skeletal muscle (449). Cardiac involvement can occur in type II glycogenosis (Pompe's disease), but also can occur in type III glycogenosis (Cori's disease) with glycogen debranching enzyme deficiency (450). Detection of the debranching enzyme activity in muscle can be used to predict whether patients will develop cardiac involvement (451). The echocardiogram shows thickened walls and papillary muscles resembling hypertrophic cardiomyopathy, whereas the electrocardiogram demonstrates LV hypertrophy (425,450,452).

Fabry's Disease. Fabry's disease is a rare X-linked recessive disorder of glycolipid metabolism, secondary to a deficiency of the lysosomal enzyme alpha-galactosidase A. This disease severely affects homozygous male subjects with milder symptoms occurring in female subjects (453). Abnormal deposition of glycolipid occurs in the heart, skin, and kidney (454). Histologic examination shows diffuse involvement of the myocardium, conduction system, vascular endothelium, and the mitral valve secondary to deposition in the lysosomes of the affected tissue.

Patients may develop angina and myocardial infarction with normal epicardial coronary vessels, mitral regurgitation, and congestive heart failure and increased wall thickness on echocardiography, mimicking hypertrophic cardiomyopathy and cardiac amyloidosis (eFig. 26.5.7) (454,455 and 456). The electrocardiogram may show atrioventricular block and a short PR interval (457). Studies in adult patients have shown a correlation between age, the degree of alpha-galactosidase activity, and the degree of LV hypertrophy (458). Similarities in the structure of the glycolipid, ceramide trihexoside, and the amyloid fibril may account for their similar appearance (455). MRI may show mildly increased signal intensity in the myocardium (459). Endomyocardial biopsy may show low alpha-galactosidase A levels (274,460,461).



***e*FIGURE 26.5.7** Echocardiographic example of Fabry's disease. A 57-year-old man with exertional dyspnea and renal failure. Parasternal long-axis view **(A)** and apical four-chamber view **(B)** of patient with Fabry's disease. Both views show severe asymmetric increased wall thickness of the interventricular septum due to infiltration of glycosphingolipid. This feature may be indistinguishable from hypertrophic cardiomyopathy by echocardiography. (From Nakayama Y, Tsumura K, Yoshimaru K. Images in cardiology: echocardiographic features of cardiac involvement in Fabry's disease. *Heart* 2000;83:695, with permission.)

Noninfiltrative Diseases

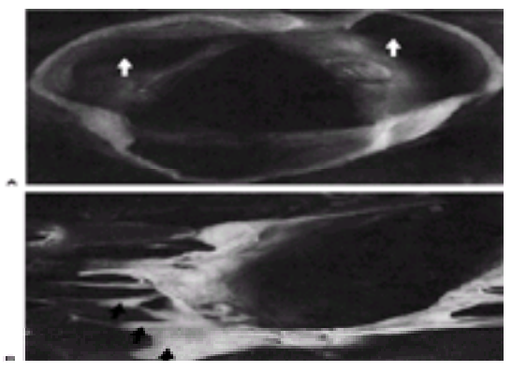
Carcinoid Heart Disease

Carcinoid heart disease is a rare cause of restrictive cardiomyopathy (462,463). Carcinoid syndrome results from metastatic carcinoid tumors that cause cutaneous flushing, diarrhea, bronchoconstriction, and fibrous endocardial plaques in the heart (464,465). Cardiac disease is detected by echocardiography in over 50% of patients with carcinoid syndrome, whereas clinically apparent heart disease with right-sided heart failure is detected in 25% of patients (464,466).

The carcinoid tumors most commonly originate in the small bowel and appendix in over 60% of cases, but they also may arise in the bronchus, biliary tract, pancreas, testis, and ovary (463,464). Carcinoid tumors from the ileum are the ones that metastasize to the liver and lymph nodes. These tumors contain cytoplasmic

granules that take up and reduce silver salts (463). Carcinoid heart disease results from hepatic metastases that produce large amounts of humoral substances that can reach the right side of the heart and are not inactivated by the liver but by the lungs (464). The humoral substances may include 5-hydroxytryptamine, serotonin, bradykinin, and other substances. Rarely, left-sided disease may occur when the humoral substances can cross right to left through a patent foramen ovale or when produced by carcinoid tumor of the bronchus or when there is extensive right-sided involvement (465,467,468,468a).

Pathology. Pathognomonic lesions in carcinoid heart disease are usually right-sided and are composed microscopically of fibrous plaques superimposed on mural and valvular endocardium (*e*Fig. 26.5.8). Histologically, the fibrous plaques are composed of smooth muscle cells that are mixed with mucopolysaccharide and collagen material (469). The fibrous plaques may be related to increased expression of transforming growth factor-b causing stimulation of fibroblasts and their matrix production (470). These white-yellow deposits affect the surface of the tricuspid and pulmonic valves, causing regurgitation and stenosis (471), with resultant RV overload and failure (464). Infiltration into the underlying mural endocardium and myocardium of the right atrium and right ventricle has also been demonstrated. Extensive involvement of the myocardium may result in restrictive physiology (462,463 and 464), whereas involvement of the mitral valve may also cause regurgitation and stenosis (463).



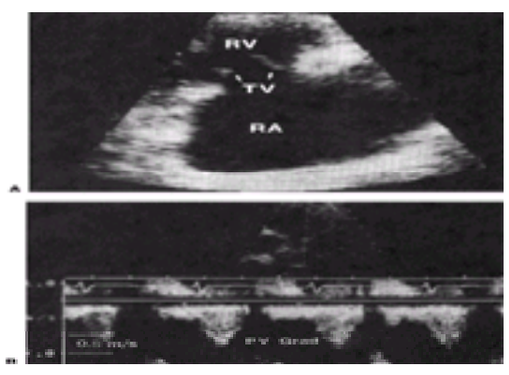
***e*FIGURE 26.5.8** Carcinoid. **A:** Gross pathologic specimen of carcinoid heart disease. Pulmonic valve leaflets are thickened, retracted, and shortened (*arrows*), with a fixed opening. **B:** Tricuspid valve leaflets and chordae are thickened and retracted. (From Click RL, Olson LJ, Edwards WD, et al. Echocardiography and systemic diseases. *J Am Soc Echocardiogr* 1994;7:201–216, with permission.)

Clinical Presentation. Carcinoid heart disease is difficult to diagnose until there is evidence of right-sided heart failure with an elevated jugular venous pulse with a prominent 'v' wave and tricuspid regurgitation (463). A systolic murmur along the left sternal border that shows inspiratory augmentation (tricuspid regurgitation) followed by an early diastolic sound and a diastolic rumble (tricuspid stenosis) may be detected. Also, there may be murmurs of pulmonic stenosis and regurgitation (464). Chest radiography may show cardiac enlargement, pleural effusions, and nodules. The pulmonary trunk is normal in size. The electrocardiogram is nonspecific with evidence of RA enlargement, nonspecific ST- and T-wave abnormalities, and sinus tachycardia (464). The hemodynamic findings are that of significant tricuspid regurgitation with a large RA 'v' wave and diastolic gradient (464).

Echocardiography is a sensitive technique to document the combined tricuspid and pulmonic abnormalities and RV overload, as well as to follow the progression and detect subclinical involvement (464,472).

Using echocardiography in one series, right-sided disease was detected in 66% of patients with carcinoid syndrome, and the patients with more severe valvular disease were more associated with higher levels of bradykinins and serotonin (466,473). In another series of 132 patients with carcinoid syndrome, Pellikka et al. found that 56% of patients had cardiac involvement, which was associated with higher levels of 5-hydroxy-indoleacetic acid. The 3-year survival of patients with echocardiographic evidence of carcinoid heart disease was reduced compared with those without cardiac involvement (464). Other studies have shown a correlation between posttreatment 5-hydroxy-indoleacetic acid levels and progression of disease assessed by an echocardiographic score of valvular involvement (474).

The echocardiographic features of cardiac involvement are remarkable (475). The tricuspid valve leaflets are thickened, shortened, and retracted and show incomplete coaptation and decreased excursion, resulting in stenosis and regurgitation. The pulmonic valve also shows thickening, retraction, and commissural fusion and stays open in a partly fixed position, resulting in both stenosis and regurgitation. The predominant lesions seen are tricuspid regurgitation and pulmonary stenosis (476) (*e*Fig. 26.5.9). Carcinoid plaques causing these lesions are usually seen on the ventricular surface of the tricuspid valve and the pulmonary artery surface of the pulmonary valve (476) (*e*Fig. 26.5.10). The Doppler findings show severe tricuspid regurgitation with a distinctive dagger-shaped Doppler spectral profile with an early peak pressure and rapid decline. In addition, the pressure half-time is prolonged, which is consistent with associated tricuspid stenosis (464). Also, there is evidence of RV volume overload from the associated tricuspid regurgitation (264). Transesophageal echocardiography may be useful in assessing the thickness of the valvular leaflets and the superficial wall layers on the cavity side of both atria (472,477).



***e*FIGURE 26.5.9** Carcinoid. **A:** Two-dimensional echocardiogram of right ventricular (RV) inflow tract view. The carcinoid syndrome: comparison of 21 necropsy subjects with carcinoid heart disease to 15 necropsy subjects without carcinoid heart disease. *Am J Med* 1985;79:339–354, with permission.)

Management. Carcinoid heart disease can be diagnosed in the presence of the right-sided heart findings with the classic systemic features. There may be urinary excretion of 5-hydroxy-indoleacetic acid, the principal metabolite of serotonin (463,476).

The long-term prognosis is poor, regardless of treatment modality (478). Chemotherapy may be partially effective in treating the hepatic metastasis, while removal of the primary tumor is rarely indicated. Occasionally, the liver metastasis is removed; more commonly, hepatic arterial embolization is performed (463,479). Medical therapy often includes digitalis and diuretics for mild congestive heart failure. The effects of the carcinoid syndrome can be treated with the use of somatostatin analogs, serotonin antagonists, and alpha-adrenergic blockers (463,480,481 and 482).

Interventional and surgical therapy has also been performed for patients with carcinoid valvular heart disease. Balloon valvuloplasty of the tricuspid stenosis and pulmonic stenosis can also be performed (483,484,485 and 486). Tricuspid valve replacement and pulmonary valvotomy is recommended with advanced disease (487,488). Implantation of a biologic valve or allograft is not recommended because of carcinoid developing on the new valve (463,476,489). Surgical mortality for symptomatic patients with severe valve disease is high (490); however, there can be marked improvement in symptoms in survivors (478).

Radiation Heart Disease

Therapeutic radiation for malignancies such as Hodgkin's and non-Hodgkin's lymphoma can cause damage to the pericardium, myocardium, endocardium, and coronary arteries (491,492). Specific risk factors for cardiac involvement include prior chemotherapy, left-sided chest radiation field, and greater than 4,000 rad of exposition (492). Myocardial involvement with interstitial fibrosis, especially in the right ventricle (493), may cause a restrictive cardiomyopathy (494,495) or a mixed picture of pericardial and myocardial disease, which can be documented by echocardiography (119) and MRI (274).

Anthracycline Cardiomyopathy

Anthracyclines, which are used to treat acute leukemias and lymphomas, can cause myocardial toxicity, which is dose related and can be detected by endomyocardial biopsy. Myocardial toxicity usually results in a dilated cardiomyopathy, restrictive cardiomyopathy, or both. Restrictive physiology can be confirmed with echocardiography or cardiac catheterization (496). Fibrous thickening of the endocardium and interstitial fibrosis, loss of myofibrils, and vacuolation of the cytoplasm are the histologic basis for restrictive cardiomyopathy (274,497). Diastolic abnormalities often precede the abnormalities of systolic function in this disease and are unrelated to the dose (496,498). Dobutamine echocardiography, radionuclide angiography, and heart-rate variability analysis have been used to detect subclinical disease in children (499,500,501 and 502). Some data exist that show that antioxidants such as probucol may reduce the toxicity of anthracyclines on the myocardium (503,504).

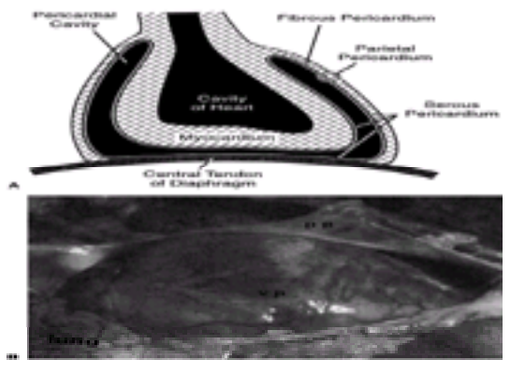
Scleroderma

Scleroderma is a rare cause of restrictive cardiomyopathy resulting from myocardial fibrosis (505). Pericardial involvement and atrioventricular conduction defects are more frequent (see the section Pericardial Disease) (274).

Pericardial Disease

Anatomic Considerations

The pericardium is a closed fibroserous membrane sac in the middle mediastinum, posterior to the sternum and the second to sixth costal cartilages and anterior to the fifth to eighth vertebrae (506). During embryologic development, the heart invaginates the sac, based on a pedicle of the great vessels, cavae, and pulmonary veins. A layer of the serous sac becomes densely adherent to the myocardium, forming the visceral pericardium or epicardium. This layer envelopes the entire heart apart from a bare area on the posterior aspect of the left atrium (eFig. 26.5.11), between the pulmonary veins, the oblique sinus. The visceral layer reflects back on itself and is continuous with the parietal pericardium. This reflection forms a second cleft between the great vessels and the left atrium, the transverse sinus (507).



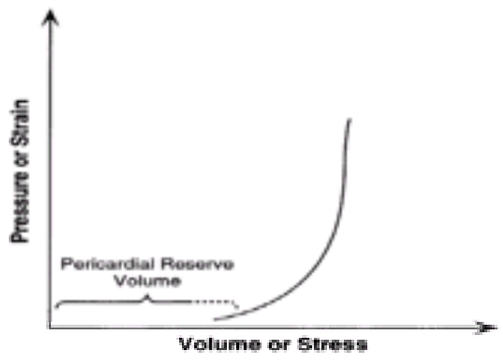
***e*FIGURE 26.5.11 A:** Anatomic structure of the pericardium, a double-walled fibroserous sac that encloses the heart and the great vessels (pulmonary artery and aorta). The pericardium is composed of two layers: an outer layer called *fibrous pericardium* and a double-layered sac called *serous pericardium*. (From Moore KL. *Clinically orientated anatomy*. Baltimore: Williams & Wilkins, 1980, with permission.) **B:** Anatomy of the normal pericardium *in situ* with the sternum and ribs removed. The parietal pericardium (pp) is made of fibrosa lined by mesothelial serosa, which is continuous with the serosa of the visceral pericardium (vp), which lines the pericardial sac. Note the transparent serosa of the visceral pericardium. (From Spodick DH. *The pericardium: a comprehensive textbook*. New York: Marcel Dekker, 1997:8, with permission.)

The parietal pericardium consists of an outer fibrous layer composed of multiple layers of collagen, aligned in different directions, and interspersed with elastin fibrils. This fibrous layer has ligamentous attachments with the central tendon of the diaphragm inferiorly, the sternum anteriorly by the superior and inferior sternopericardial ligaments, and the pleural membranes laterally. The inner layer of the parietal pericardium is a serous mesothelial membrane, with microvilli, to aid fluid secretion (508). The normal pericardium contains approximately 50 mL of pale serous fluid to minimize friction and restrict excessive cardiac motion. The fluid is low in protein, with a relatively high proportion of albumin, consistent with a ransudate.

The pericardium is innervated by branches of C4-5 via the phrenic nerve. This may explain the conscious perception of pericardial pain in the left shoulder tip. Arterial supply to the pericardium is via the internal (thoracic) mammary arteries and multiple branches of the bronchial, esophageal, and phrenic arteries. Venous drainage is via the azygous system.

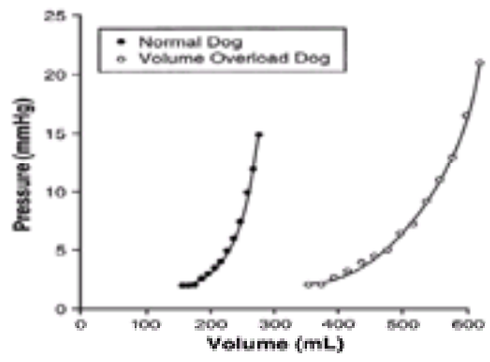
Normal Physiology of Pericardium

The normal pericardium consists of a mesothelial fluid-secreting layer, inside of several layers of collagen fibers, aligned in different directions (509). The mesothelium may secrete large amounts of prostacyclin and other substances that may have a regulatory role in sympathetic neural regulation, cardiac contractility, and coronary vasodilatation (510,511). This directionality of the collagen fibers imparts the interesting physical property called *anisotropia*: differential stress-strain relationships for different directions of applied load (512). For the pericardium as a whole, there is an exponential stress-strain relationship. At normal cardiac volumes, the pericardium is on the flat portion of the curve, and physiologic changes in volume are associated with minimal changes in intrapericardial pressure. However, with abrupt large increases in volume (such as in acute overhydration or valve rupture), the pericardium quickly reaches the exponential portion of the curve and significantly restricts further cardiac dilatation. In this way, it can be argued that the pericardium plays a small role in limiting cardiac filling at normal physiologic volumes and only exerts a constraining effect on filling when abrupt changes in volume occur (eFig. 26.5.12). The pericardial pressure usually approximates pleural pressure and varies with the respiratory cycle being approximately –6 mm Hg at end inspiration and –3 mm Hg at end expiration. The lowering of pericardial pressure more than atrial pressure and transmural pressures in inspiration allows increased filling of the right side of the heart while there is increased aortic transmural pressures and pooling of the RV output and consequently decreased left-sided heart filling (513,514).



***e*FIGURE 26.5.12** Schema of stress-strain and pressure-volume curves of the normal pericardium. After the relatively small pericardial reserve volume is exhausted by filling of the pericardial sinuses and recesses, the curve at first rises gently; with continued filling at some point more acutely, the time scale and exact proportions are variable depending on the rate of filling of the intact pericardial sac. (From Spodick DH. *The pericardium: a comprehensive textbook*. New York: Marcel Dekker 1997:19, with permission.)

As the heart slowly enlarges in the face of a chronic process such as cardiomyopathy or chronic valvular insufficiency, so too the pericardium increases in volume and mass (515). Thus, even in cardiomegalic states, the pericardial stress-strain curve shifts to the right, and during normal daily living, exerts very little constraining effect to filling. Similarly, abrupt changes in cardiac volume superimposed on a chronically dilated heart move the pericardium into the steep portion of the pressure-volume curve, and a constrictive effect on cardiac filling is observed (*e*Fig. 26.5.13).



***e*FIGURE 26.5.13** The pressure-volume relation of the pericardium in dogs under normal conditions (*left curve*) and after a period of cardiac dilatation resulting from a chronic abdominal aortic arteriovenous fistula (*right curve*). (From Freeman GL, LeWinter MM. Pericardial adaptations during chronic cardiac dilation in dogs. *Circ Res* 1984;54:294–300, with permission.)

When the cardiac volume causes the pericardium to reach the steep portion of its pressure-volume curve, a phenomenon of ventricular interdependence is observed (516). Put simply, the ventricles, with their common interventricular septum, are forced to exist in a finite volume cavity. Therefore, increased filling of one chamber (e.g., right ventricle during inspiration) shifts the septum into the left ventricle, impeding its filling and therefore output. A similar effect is seen in cardiac tamponade and constrictive pericarditis and is the pathophysiologic mechanism underlying pulsus paradoxus and “flow paradoxus” (13,517,518 and 519).

Clinical Presentations of Pericardial Disease

Acute Pericarditis

Inflammation of the layers of the pericardium, from any of myriad causes, yields a common clinical syndrome termed *acute pericarditis*. The causes of acute pericarditis are listed in Table 26.4. The classic symptom complex represents an important differential diagnosis in the assessment of chest pain presentations. However, the relatively common finding of pericardial inflammation at autopsy suggests that the majority of cases is subclinical.

Malignant tumor
Idiopathic pericarditis
Uremia
Bacteria infection
Anticoagulant therapy
Dissecting aortic aneurysm
Diagnostic procedures
Connective tissue disease
Postpericardiotomy syndrome
Trauma
Tuberculosis
Other
Radiation
Drugs inducing lupus-like syndrome
Chylopericardium
Postmyocardial infarction syndrome (Dressler's)
Fungal infections
Acquired immunodeficiency syndrome–related pericarditis

From Kowlgi NG. Pericardial disease. Heart Dis Stroke 1994;3:83–94, with permission.

TABLE 26.4 CAUSES OF ACUTE PERICARDITIS

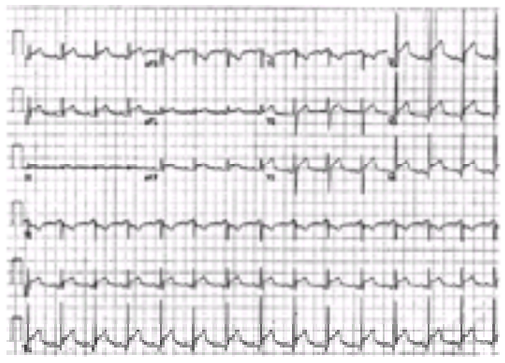
Pathology. The histopathology of pericarditis is dependent on the underlying etiology. The majority of cases is manifested by hyperemia and increased microvascularity, polymorpholeukocyte accumulation, and fibrin deposition. Adhesions can form between the layers of the pericardium and between pericardium and adjacent structures such as pleura and mediastinum.

Clinical Presentation. Acute pericarditis classically presents with progressive, often severe, chest pain over hours. This mechanical pain is typically postural, being worse on lying supine and relieved by sitting forward. It is often pleuritic and aggravated by coughing, motion, and swallowing. It is described as sharp, “stabbing,” or “knife-like” in character. The pain my radiate to the neck and less frequently to the arms and back and even left shoulder, making differentiation from coronary ischemic pain more difficult. There is often a low-grade fever associated with viral and idiopathic pericarditis, while purulent pericarditis is associated with high fevers and systemic sepsis.

The presence of a pericardial rub is pathognomonic for pericarditis, although its absence does not exclude the syndrome. This “to and fro” rasping sound has a timing consistent with the cardiac cycle. It is best appreciated with the diaphragm of the stethoscope applied to the lower left sternal edge and is creaking in nature, like leather on leather. It is heard best with the patient leaning forward in end expiration. The sound classically has a triple cadence (520) with components related to (a) atrial systole, (b) ventricular systole, and (c) ventricular diastole. In 33% of the cases, the rub is biphasic, whereas in 10% it is monophasic. The intensity of the sound can be attenuated by subcutaneous tissue thickness and hyperinflated lung volume. Furthermore, the development of a pericardial effusion as part of the inflammatory syndrome can lead to waxing and waning of the rub over days, although a loud pericardial rub can be still be heard occasionally in the presence of a significant effusion. The sound should be differentiated from a pleural rub, which, although similar in character, is timed with the respiratory cycle; subcutaneous emphysema, which may be an associate in postsurgical or traumatic cases; and loud intracardiac murmurs such as ventricular septal defect.

Investigations. Electrocardiography represents the most useful diagnostic test in acute pericarditis (*e*Fig. 26.5.14). Inflammation of the subepicardial myocardium is thought to be the mechanism producing ST- and T-wave changes, while inflammation of the atrium is thought to cause the PR-segment changes (521). The

PR-segment deviations may precede the ST changes (522). In contrast to the regional ST changes of myocardial ischemia, pericarditis produces widespread electrocardiographic changes in limb and precordial leads. Four phases of electrocardiographic abnormalities have been recognized (Table 26.5) (521,523): Stage I, with ST elevation and upright T waves, is present in 90% cases. Over days, the ST changes resolve and the electrocardiogram may look normal (stage II). There may be further evolution to T-wave inversion (stage III) and finally to normal (stage IV).



***e*FIGURE 26.5.14** Electrocardiographic recording of a 50-year-old man in sinus tachycardia with T-wave abnormality and findings of stage I pericarditis.

Sequence stage	Leads of "epicardial" derivation: at least I, II, aV_F, aV_L, V_3–V_6			Leads reflecting "endocardial" potential: aV_R often V_1, sometimes V_2		
	J-ST	T waves	PR segment	ST segment	T waves	PR segment
I	Elevated	Upright	Depressed or isoelectric	Depressed	Inverted	Elevated or isoelectric
II early	Isoelectric	Upright	Isoelectric or depressed	Isoelectric	Inverted	Isoelectric or elevated
II late	Isoelectric	Low to flat to inverted	Isoelectric or depressed	Isoelectric	Shallow to flat to upright	Isoelectric or elevated
III	Isoelectric	Inverted	Isoelectric	Isoelectric	Upright	Isoelectric
IV	Isoelectric	Upright	Isoelectric	Isoelectric	Inverted	Isoelectric

TABLE 26.5 FOUR-STAGE (“TYPICAL”) ELECTROCARDIOGRAPHIC EVOLUTION OF ACUTE PERICARDITIS

The electrocardiographic abnormalities should be differentiated most importantly from acute myocardial ischemia. The ST changes are more widespread in pericarditis and have a typical saddle-shaped or upward concave appearance. Unlike myocardial infarction, there are no Q waves or loss of R-wave progression. The other important differential diagnosis of these electrocardiographic changes is the early repolarization pattern. Although it is difficult without clinical correlation, differentiation can be made by the presence of PR-segment elevation (especially aV_R) and ST elevation in V_6, which is uncommon in the early repolarization syndrome (524). Most patients with acute pericarditis remain in sinus rhythm (525) (Fig. 26.6).

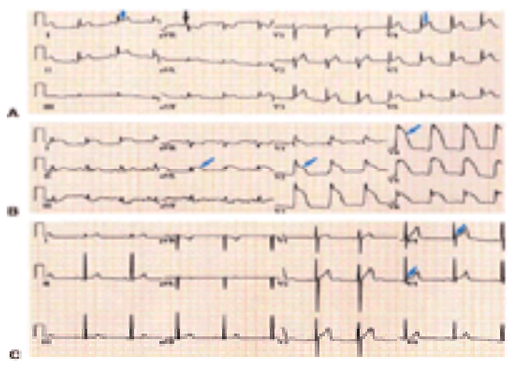

FIGURE 26.6 Differential diagnosis of acute pericarditis. **A:** Acute pericarditis. Note the upward concavity ST elevations in limb leads I, II, aVF, and aVL and in precordial leads V_3–V_6. (*blue left and right arrows*) and the PR segment elevation in aVR (*green middle arrow*). **B:** Acute myocardial infarction. Note the convex ST elevation in leads I, aVL, V_1–V_6 (*blue left, right, middle arrows*), indicating a large anterior myocardial infarction. **C:** Early repolarization. Note the elevation of the J point (*blue right arrows*) with pseudonormalization of the ST segment in V_4–V_6. (From Aikat S, Ghaffari S. A review of pericardial diseases: clinical, ECG and hemodynamic features and management. *Cleve Clin J Med* 2000;67:903–914, with permission.)

Chest radiography contributes relatively little to the diagnosis of acute pericarditis. The presence of cardiomegaly may be seen in the minority of cases in which a significant pericardial effusion has accumulated. Laboratory analysis of blood often shows a modest leukocytosis and raised C-reactive protein and sedimentation rate.

Radionuclide scanning with In-111 (526) and Ga-67 (527,528) has been reported to be useful in identifying the pericardium as the source of an inflammatory syndrome of unknown diagnosis in some patients. Serum troponin I has been reported to be elevated in patients with ST elevation and acute pericarditis, reflecting a degree of myocardial injury (529). MRI, with gadolinium-diethylenetriaminepentaacetic acid enhancement, has identified specific regions of the pericardium involved in the inflammatory process (530).

Diagnostic Algorithm. The following sequence has been proposed (531). All patients should have a complete history and physical examination, electrocardiography, and chest radiography. Diagnosis-specific testing may include tuberculin skin testing, rheumatoid factor and antinuclear antibody, and viral studies from pharyngeal and fecal swabs. In more complex cases (i.e., symptoms and signs lasting longer than 1 week, clinical evidence of tamponade, or purulent pericarditis), echocardiography, sputum and gastric aspirate for tubercle bacillus examination, and blood cultures *should be considered*. Pericardiocentesis (either percutaneous or surgical) is indicated for clinical tamponade, evidence for purulent pericarditis, high suspicion of tumor, or illness lasting longer than 1 week.

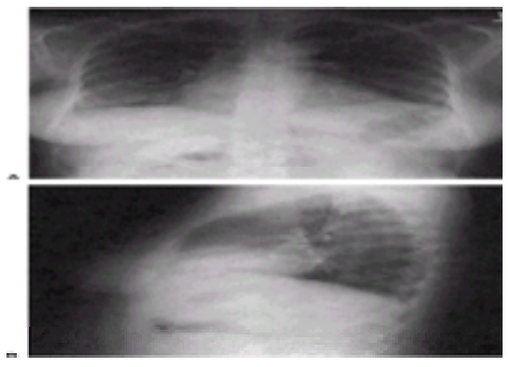
Pericardial Effusion

Pericardial effusion is diagnosed in routine echocardiographic practice in almost one in ten patients (532,533 and 534). Large pericardial effusions that develop slowly can be remarkably asymptomatic, while rapidly accumulating smaller effusions can present with tamponade.

Massive chronic pericardial effusion is a diagnosis ascribed to a syndrome consisting of a large pericardial effusion present for at least 3 months, not attributable to any systemic cause (535). This is an uncommon presentation of pericardial disease, accounting for 2.0% to 3.5% of all cases of large effusion (535). These effusions can be present for many years and were well tolerated in one series, with tamponade a rarity (536). However, in two series of patients, cardiac tamponade occurred in nearly 33% of the patients (535,537). In the larger study, 28 patients with large idiopathic chronic pericardial effusions were followed for a median of 7 years. Unexpected tamponade occurred in eight patients (29%) and pericardectomy was performed in 20 patients. Chronic nonspecific pericarditis was found in all patients evaluated by histology (537).

Clinical Presentation. Pericardial effusions that are not causing hemodynamic embarrassment to the heart are usually asymptomatic. Patients may describe dyspnea or dysphagia due to space-occupying effects in the chest. Physical compression may cause hoarseness (recurrent laryngeal nerve), hiccups (phrenic nerve), or nausea

(diaphragm). Physical examination of patients with large effusions demonstrates muffled heart sounds. Ewart's sign—dullness on auscultation under the left scapula—is a result of compression of the base of the left lung. This may be associated with coarse crepitations due to local atelectasis. Chest radiographic findings include cardiomegaly, which may be massive, often with a characteristic globular shape to the heart silhouette (eFig. 26.6.1). The cardiac margins are unusually sharp, as the pericardium is free of the cardiac motion that usually blurs the silhouette radiographically. Electrocardiography demonstrates diminished QRS and T-wave voltages. Electrical alternans is a marker of massive pericardial effusion.



***e*FIGURE 26.6.1** Pericardial effusion [posterior-anterior **(A)** and lateral **(B)** chest radiographs]. Globular enlargement of the cardiac silhouette without evidence of pulmonary venous hypertension suggests pericardial effusion. (Courtesy of R. D. White, MD, The Cleveland Clinic Foundation.)

Echocardiography is the diagnostic tool of choice for pericardial effusion. Initially, M-mode was the standard, with a high sensitivity for posterior pericardial fluid (533). The advent of two-dimensional echocardiography has shown the various presentations of effusion, including circumferential, posterior, and loculated (Fig. 26.7). Loculated effusions are more common when scarring has supervened (e.g., postsurgical, posttrauma, postpurulent pericarditis). The size of effusions can be graded as small (less than 10 mm of echo-free space in systole and diastole), moderate (greater than or equal to 10 mm at least posteriorly), large (greater than or equal to 20 mm), or very large (compression of the heart) (538). Furthermore, two-dimensional echocardiography can give information about the nature of the fluid, suggesting the presence of fibrin, clot, tumor, air, and calcium. Care must be taken to differentiate pericardial fluid from pleural fluid and ascites. Left pleural effusions can be difficult to differentiate from pericardial fluid. By transthoracic echocardiography in the parasternal long-axis view, pericardial fluid can be seen to reflect at the posterior atrioventricular groove, while pleural fluid continues under the left atrium, posterior to the descending aorta. Spin-echo and cine MRI can also be used to assess the size and extent of simple and complex pericardial effusions similar to echocardiography (161). The effusions by MRI may tend to be larger than by echocardiography (539).

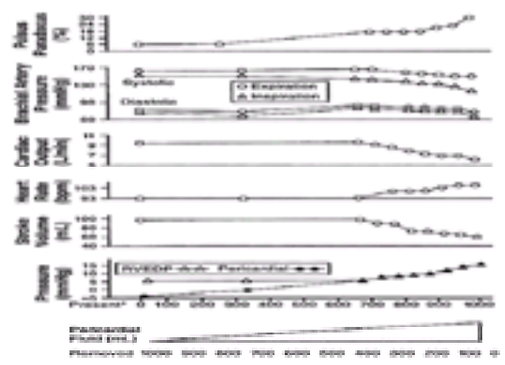
Comparison of Doppler and two-dimensional echocardiography for assessment of pericardial effusion. *Am J Cardiol* 1992;70:1353–1357, with permission.)

Management. The action taken after finding a significant pericardial fluid collection depends on the underlying etiology, the presence of hemodynamic compromise, and the volume of fluid. Pericardiocentesis may not be necessary in all cases, particularly when the diagnosis can be made based on other systemic features. Where doubt remains, particularly in cases in which malignancy or purulent pericarditis is suspected, pericardiocentesis is indicated. Hemodynamic compromise is an absolute indication for drainage (see following discussion).

Pericardial Tamponade

Fluid accumulation in the finite pericardial space causes an increase in pressure with subsequent cardiac compression. Tamponade is not a binary phenomenon, with a spectrum existing from mild cardiac compression and embarrassment to cardiovascular collapse.

Pathophysiology. Information regarding the cardiovascular response to pericardial tamponade is mostly derived from animal data (540). As fluid is infused into the pericardium, intrapericardial pressure rises and cardiac output falls (540). Systemic pressure is preserved by alpha-adrenergic–mediated peripheral vasoconstriction until eventually systolic pressure drops as a premortal event. As noted previously, the pericardial pressure-volume curve has a flat and a steep portion (515). Once intrapericardial volume passes this critical transition point, small increments in volume result in large increases in pressure. The actual volume at which this transition occurs depends on the current finite volume for the pericardium, itself a function of its degree or lack of chronic distention (*e*Fig. 26.7.1). The rise in extracardiac intrapericardial pressure results in decreased transmural distending pressures and thence poor diastolic ventricular filling (541). Because of the finite volume available in the pericardial space, there is an equalization of filling pressures of the four cardiac chambers and the pericardium.



***e*FIGURE 26.7.1** Hemodynamic changes during serial fluid withdrawals in a patient with cardiac tamponade. Pulsus paradoxus is expressed as a percentage decrease in the systolic arterial pressure with inspiration. Note that there is significant pulsus paradoxus and changes in the cardiac output, heart rate, and stroke volume when there is equalization of right ventricular diastolic pressures (RVEDP) and pericardial pressure. (From Fowler N. Pericardial disease. In: Abelman WH, ed. *Cardiomyopathies, myocarditis, and pericardial disease*. *Atlas of heart diseases*. Philadelphia: Current Medicine, 1995, with permission. Adapted from Reddy PS. Hemodynamics of cardiac tamponade in man. In: Reddy PS, Leon DF, Shaver JA, eds. *Pericardial disease*. New York: Raven Press, 1982:161;177.)

Systemic venous flow occurs in two phases: *systolic*, related to filling of the atrium with a closed tricuspid valve ('x' descent on central venous pressure trace, S wave on hepatic venous Doppler), and *diastolic*, related to filling of the right atrium as it empties through the open tricuspid valve ('y' descent on central venous pressure trace, D wave on hepatic venous Doppler). In tamponade, the heart is compressed and remains in a finite volume. Ventricular ejection decreases the relative proportion of the pericardial space occupied by the heart, allowing a fall in intrapericardial and atrial pressure and a rapid inflow of blood (large 'x' descent and S wave). During diastole, the pericardium contains filled ventricles that increase its pressure and thus forward flow from the systemic veins decreases (blunted 'y' descent and D waves) (519,542). The systemic venous flow in cardiac tamponade should be distinguished from constrictive pericarditis with prominent 'x' and 'y' descents (S and D on hepatic venous Doppler) (4,15).

Pulsus paradoxus, defined as an inspiratory drop of systolic blood pressure of greater than 10 mm Hg, is a hallmark of cardiac tamponade (*e*Fig. 26.7.1). With inspiration, intrathoracic pressure becomes subatmospheric. Intrapericardial pressure, pathologically high in this syndrome, is reduced during inspiration (as it is physiologically reduced in the normal state), allowing increased RV filling. Systemic venous diastolic flow ('y' descent, hepatic vein D wave) increases, and RV size and stroke volume increase. Again, because of the finite volume of the pericardium, the left ventricle is partially compressed by the enlarging right ventricle (due to leftward displacement of the intraventricular septum) causing an inspiratory decrease in systemic stroke volume (543). An alternative mechanism is that the pulmonary venous to left atrial pressure gradient is decreased because the changes in intrathoracic pressure are not transmitted to the left ventricle due to shielding by the pericardial fluid and because of the increased pulmonary vascular compliance. There is reciprocally increased flow on the right side of the heart because of interventricular interdependence (544,545). Pulsus paradoxus is also seen in severe lung disease, in which intrathoracic pressure swings are supraphysiologic, and in pulmonary embolus, in which RV filling pressures are disproportionately higher than left (543,546).

Clinical Presentation. The spectrum of presentation of patients with cardiac tamponade ranges from dyspnea and edema to frank circulatory collapse. The classic triad of cardiac tamponade was described by Beck including hypotension, elevated jugular venous pressure, and distant heart sounds (547). Early tamponade is manifest by tachycardia, tachypnea and dyspnea, edema and elevated venous pressure, and quiet cardiomegaly. Examination of the central venous waveform shows a prominent 'x' descent and absence of the 'y' descent.

Pulsus paradoxus is examined using the stethoscope over the brachial pulse and measuring the pressure gap between the appearance of the Korotkoff's sounds during expiration only and their continuous presence. It is defined by a fall in systolic blood pressure of 10 mm Hg with inspiration, an exaggeration of the normal situation. False-positive pulsus paradoxus without cardiac tamponade may occur with obstructive lung disease, RV infarction, and pulmonary embolism, and a false-negative finding may occur with high LV pressures as with LV dysfunction or hypertrophy, severe hypotension, severe aortic regurgitation, or in the case of an atrial septal defect (548).

Profound circulatory collapse or shock is more common in patients with acute tamponade related to cardiac or pericardial trauma. In the most extreme cases, such as acute aortic dissection into the pericardium, patients may present with electromechanical dissociation. Patients who develop the syndrome subacutely tend to present in a less dire status and manifest signs of right-sided heart failure with edema, hepatomegaly, ascites, and pleural effusion. Rarely, low-pressure cardiac tamponade, without the typical signs, can develop in the presence of dehydration and hypovolemia (549). Other variant forms of tamponade may include hypertensive cardiac tamponade (with high blood pressure), tamponade with ventricular dysfunction (RV or LV dysfunction), regional cardiac tamponade (localized effusions), or effusive constriction (538).

With an increase in invasive cardiac procedures in the electrophysiology and cardiac catheterization laboratories, the complication of cardiac tamponade is more frequent. A report of near 7,000 patients undergoing percutaneous coronary intervention found an incidence of 0.2% with cardiac tamponade developing 2 to 36 hours after the procedure (550).

Investigations. Electrocardiography and chest radiography do not differentiate tamponade from noncompressive pericardial effusion. Large pericardial effusions allow "swinging" of the heart on its vascular pedicle, causing in some cases electrical alternans.

Echocardiography is a fast and noninvasive modality to accurately diagnose tamponade (519) (*e*Fig. 26.7.2, Table 26.6). The presence of pericardial fluid should be documented and its location defined. The classic signs of cardiac tamponade are RA and RV collapse (109,551,552). Postsurgical effusions may be loculated (e.g., behind the left atrium) and sometimes difficult to visualize from the transthoracic window. Indeed, if the diagnosis of tamponade is suspected in this scenario, transesophageal echocardiography is indicated (4). Two-dimensional echocardiography can also exclude pericardial masses and ventricular and valvular dysfunction as the cause of hemodynamic compromise. Doppler echocardiography allows direct quantitation of mitral and tricuspid inflows, pulmonary venous and systemic venous flows; and with the use of a nasal thermistor, variation with respiration can be assessed (553). Respiratory variation of transmitral E waves is minimal in healthy subjects, and greater than 25% variation (increasing on the first beat of expiration and conversely on inspiration) is highly suggestive of significant tamponade (*e*Fig. 26.7.2). Tricuspid E waves often exhibit some degree of respiratory variation in healthy subjects. Cardiac tamponade is present when there is greater than 40% variation (opposite pattern to the left side) and increased hepatic venous flow reversals in expiration (519) (Table 26.6).

TABLE 26.6 ECHOCARDIOGRAPHIC FINDINGS IN PATIENTS WITH CARDIAC TAMPONADE

MRI may also be used to detect the signs of tamponade from hemopericardium and compression of the cardiac chambers by hematoma (165,554).

Cardiac catheterization has historically been the diagnostic standard for tamponade and remains useful, particularly in cases in which noninvasive modalities are not conclusive. Right-sided heart catheterization is often performed simultaneously with pericardiocentesis, allowing monitoring of improvement as the effusion is drained. Typically, patients demonstrate an elevated RA pressure, with a prominent 'x' descent and diminished or absent 'y' descent (542). The PCWP is also elevated and often equal to intrapericardial and RA pressure. As pericardial fluid is drained, intrapericardial pressure falls below biatrial pressure. If this does not occur, the diagnosis of effusive constrictive disease should be considered (see below).

Pericardiocentesis. While preparing the equipment for pericardiocentesis, the patient in tamponade may be supported with cautious fluid loading and inotropes (such as norepinephrine or isoproterenol). Percutaneous pericardiocentesis should be performed in an environment in which advanced cardiac life support equipment and personnel are immediately available. Historically, these procedures have been performed in the cardiac catheterization laboratory, with arterial and right-sided heart catheters in situ. More recently, the procedure has tended to be performed in the procedure room of the cardiac or intensive care unit, or even at the bedside, using echocardiographic guidance (555,556 and 557). Surgical drainage of the pericardium (either by a subxyphoid approach or using a complete pericardectomy) is indicated for loculated effusions, patients at risk of excessive bleeding, and in situations in which fluid has recurred after previous drainage procedures (558).

Echocardiography can demonstrate the most accessible window for passage of the needle (555,556,559). Historically, the subxyphoid approach has been used most commonly, with a long needle passed under the xiphoid and directed toward the left shoulder at a 30-degree angle to the skin. Echocardiography performed at the cardiac apex can often identify a window where the pericardium can be entered (usually in the sixth or seventh rib space in the anterior axillary line) without risk of cardiac puncture. A short needle is passed through the rib space under constant negative pressure until fluid is aspirated. It is important to confirm that the fluid aspirated is intrapericardial (i.e., the blood should not clot).

By either approach, once the pericardial space is reached a soft-tipped guidewire is passed and the needle removed. A multiholed catheter is then introduced and the pericardial fluid suctioned out. It is prudent to drain the fluid in steps of less than 1 L at a time to allow cardiovascular equilibrium to be restored at each stage and to avoid the rare complication of acute RV dilatation (560,561). Clinical improvement usually occurs after the aspiration of only 100 to 200 mL of fluid. The fluid should be drained completely, and specimens sent for chemistry, cytology, culture, and acid-fast bacilli staining. It is common practice to leave the catheter in for some hours, connected to a free drainage bag, to allow further drainage as the patient assumes different postures. It is important to avoid allowing air into the pericardium because this is most uncomfortable for the patient.

Percutaneous pericardiocentesis is a rapid and safe procedure when performed by trained personnel (559). In a study of patients undergoing urgent pericardiocentesis following cardiac perforation, tamponade was relieved in 99% of patients. A major complication rate of 3% occurred and included pneumothorax and RV laceration. No deaths resulted directly from pericardiocentesis (562). A similar review of 245 pericardiocenteses performed in patients with postoperative effusions showed that anticoagulant therapy was the most common contributing factor to early pericardial effusions (less than 7 days), and postpericardiotomy syndrome contributed most often to late effusions (563). The rate of major complications from pericardiocentesis was 2% in this study.

Surgical Procedures. A median sternotomy or anterolateral thoracotomy approach provides good visualization for pericardial surgery including pericardiectomy for constrictive and effusive disease (564). However, less invasive procedures are available for drainage of pericardial effusions when pericardiocentesis is not feasible or recurrent fluid accumulates.

Subxyphoid pericardiectomy is a safe and efficacious method of draining large pericardial effusions. A small vertical incision is made in the upper epigastrium and the pericardium approached by posterior retraction of the diaphragm from the sternum. A pleuropericardial window is often created to allow ongoing drainage (565).

Alternative nonthoracotomy techniques for formation of a pericardial window include percutaneous pericardiotomy using an inflatable balloon from a subxyphoid approach (566,567,568,569,570,571,572 and 573) and a video-assisted thoracic surgical pericardiectomy. These procedures are effective for the management of malignant and other large pericardial effusions.

Constrictive Pericarditis

Dense fibrosis and adhesion of the parietal and visceral layers of the pericardium create a rigid "case" around the heart, limiting its filling and causing profound disturbances of cardiac function (eFig. 26.7.3). This final common pathway may be the end result of one (or more) of many etiologic agents including infections, postcardiac surgery, or radiation. The constrictive process can follow the etiology acutely, subacutely (months), or chronically (years) (538). The clinical presentation is well recognizable, with debilitating right-sided heart failure and a poor prognosis. Voluminous literature exists about the many methods of differentiating this constellation from that of restrictive cardiomyopathy, which presents with similar clinical signs and symptoms (Table 26.3).

***e*FIGURE 26.7.3** Postmortem excised specimen of constrictive pericarditis demonstrating unusually thickened pericardium (Pm). (From Spodick DH. *The pericardium: a comprehensive textbook*. New York: Marcel Dekker, 1997, with permission.)

Pathophysiology. The fundamental abnormality in constrictive pericarditis is limited filling and enhanced interventricular dependence of the heart because of the rigid encasement of the heart by thickened pericardium, effectively isolating it from the normal respiratory swings in pressure and allowing a finite filling volume for the ventricles (13). Within the pericardium, the myocardium is intrinsically normal (unless there is a combined abnormality such as in radiation myocarditis), with no specific abnormality of systolic or diastolic function. In constriction, the ventricle fills abruptly on valve opening (often more abruptly than normal due to elevated atrial filling pressures). However, in mid-diastole, the chambers reach the maximum volume that the constraining pericardium will allow, and filling abruptly ceases. This can be appreciated visually on two-dimensional echocardiography as wall motion ceases with a shudder in mid-diastole. In contrast, restrictive myocardial diseases involve abnormal ventricular filling from the onset of diastole, as the chamber relaxes slowly and stiffness increases with a compensatory increase in left atrial pressure (272).

However, it is the effect of respiration on cardiac flows that is the major hallmark for differentiating constrictive from restrictive cardiac diseases. As the heart is effectively isolated from the thorax by its rigid encasement, it does not experience marked respiratory swings in pressure. Thus, on inspiration, intrathoracic (and therefore pulmonary vein) pressure decreases, but left atrial pressure does not. Thus, the pulmonary vein to left atrial pressure gradient that drives left atrial inflow diminishes, as does mitral inflow. The resultant decreased LV filling during diastole allows more room for RV filling because of a septal shift and enhanced ventricular interdependence and thus right-sided inflows increase. The exact opposite sequence occurs in expiration (4,13,101,102,166).

Filling pressures rise to compensate for the decrease in cardiac output via renal retention of salt and water. The finite space of the pericardium causes the filling pressure of the four chambers (and the pulmonary wedge pressure) to equalize. Intraventricular pressure recordings demonstrate the classical dip and plateau or square-root sign morphologies. The dip represents the abrupt early filling at atrioventricular valve opening related to high filling pressures and corresponds to a deep ‘y’ descent on the central venous tracing. The plateau phase represents a period of unchanging pressure and volume related to the finite volume of the pericardial encasement. The ‘x’ descent on the venous trace may also be prominent, as systolic emptying of the ventricles allows filling of the atria. The ‘x’ and ‘y’ descents are sometimes referred to as the *W pattern* (574) (Fig. 26.8).

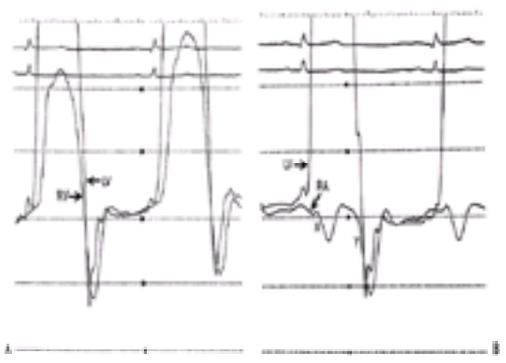

FIGURE 26.8 A,B: Simultaneous right ventricular (RV) and left ventricular (LV) pressure recordings demonstrating equalization of diastolic pressures and dip and plateau physiology. Simultaneous right atrial (RA) and LV pressure recordings demonstrating equalization during diastole and prominent ‘x’ and ‘y’ descents in the RA tracing. (From Vaitkus PT, Cooper KA, Shuman WP, et al. Images in cardiovascular medicine. Constrictive pericarditis. *Circulation* 1996;93:834–835, with permission.)

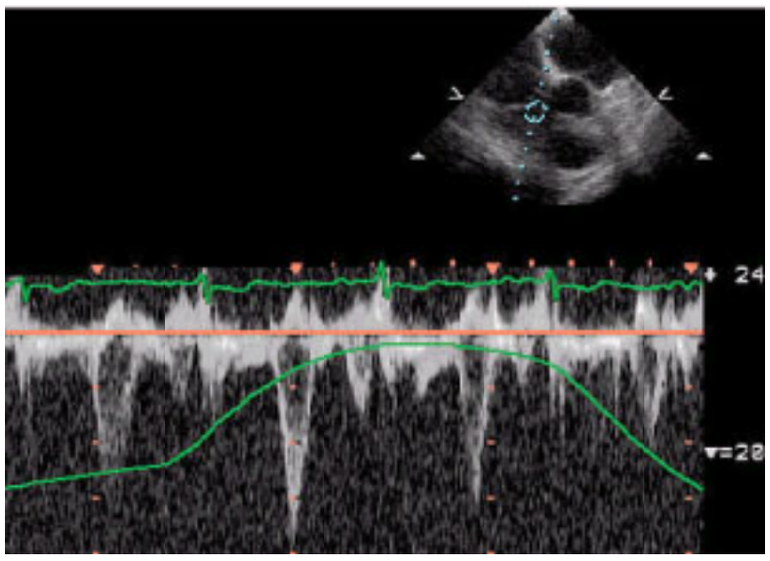
Differentiating Restriction from Constrictive Pericarditis.

Hemodynamics. Cardiac catheterization has been traditionally the gold standard in distinguishing between these two similar diseases; however, there can be overlap of the hemodynamics (13). These hemodynamic findings have been shown in Table 26.3. Simultaneous recordings of the right and left heart pressures have revealed elevation and equalization of pressures (within 5 mm Hg) of the RA, right ventricle diastolic, PCWP, and pre–‘a’ wave LV diastolic pressure. The RA pressure contour typically shows an M or W configuration with a preserved systolic ‘x’ descent and a prominent ‘y’ descent with small ‘a’ and ‘v’ waves. The RV and LV pressure tracings show a dip and plateau contour. The RV and pulmonary artery systolic pressures are mildly elevated, with a pressure of less than 50 mm Hg compared with a pressure greater than 50 mm Hg in restriction. Administration of saline over 6 to 8 minutes can enhance the classic findings of constriction in a patient with occult constriction (542). The respiratory changes in cardiac flows have been shown to be useful in the hemodynamic diagnosis of pericardial constriction. One study demonstrated that, although conventional hemodynamic variables failed to accurately diagnose constriction, differences between left and RV pressures on inspiration, a marker of ventricular interdependence, were highly specific and sensitive for the syndrome (301).

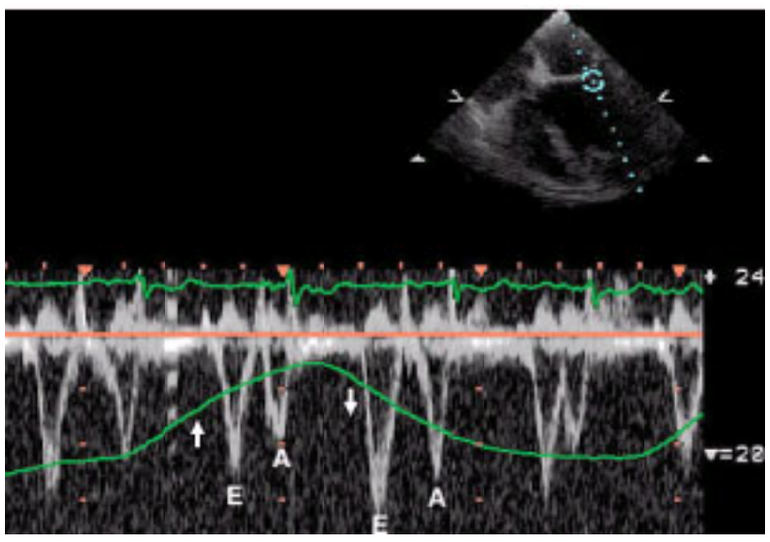
Echocardiography. There have been many M-mode and two-dimensional signs that have been used to differentiate these two conditions; however, these signs have proven to be nonspecific and insensitive (575,576,577 and 578). The important two-dimensional echocardiographic features of constriction that may provide clues to the diagnosis include pericardial thickening, myocardial tethering, a septal bounce with respiration, and inferior vena cava plethora (272,579).

Video 26.7 Transesophageal echo (four-chamber view) demonstrating constrictive pericarditis. Note the abnormal septal bounce and the tethering of the right atrium and right ventricle by the thickened pericardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Pulsed wave Doppler through the tricuspid valve of a patient with constrictive pericarditis. Note the decrease of the E wave with inspiration due to interventricular dependence.

Doppler Echocardiography. As described earlier, Doppler echocardiography with respirometry has emerged as a useful tool in these conditions (13,101,580). Limited ventricular filling and enhanced ventricular interaction account for the Doppler findings in constrictive pericarditis, whereas decreased distensibility of the ventricles accounts for the Doppler findings in restriction (13).



Pulsed wave Doppler of the mitral valve inflows of a patient with constrictive pericarditis. Note the decrease of the E wave during inspiration (*upward arrow*) due to interventricular dependence, and the increase in the E wave during expiration (*downward arrow*) for the same reason.

The classic Doppler echocardiographic findings are shown in Figure 26.9 and Figure 26.10. The similarities with restriction by Doppler echocardiography include a short deceleration time indicative of the dip and plateau hemodynamic pattern and limited filling. The main differences include enhanced respiratory variation in mitral inflow and pulmonary venous flow (greater than or equal to 25% at the onset of inspiration and expiration) in constriction, but not with restriction (unless a concomitant pericardial effusion accounting for respiratory variation is present). In restriction, there is a markedly blunted pulmonary venous systolic flow with greater diastolic forward flow indicative of a prominent ‘y’ descent and elevated left atrial pressures, whereas in constriction, there are usually both systolic and diastolic flows present (4) (Fig. 26.11). Because of enhanced ventricular interdependence, there is a decreased transtricuspid flow in expiration and enhanced expiratory flow reversals in the hepatic vein with constriction, while there are increased inspiratory flow reversals in restriction. Respiratory variation in the tricuspid regurgitation peak velocity and velocity duration has been noted in constriction but not in restriction (581). Superior vena cava Doppler can help distinguish respiratory variation of mitral inflow in patients with chronic obstructive lung disease and constrictive pericarditis (582). The systolic forward component of superior vena cava flow varies significantly with chronic obstructive lung disease, whereas there is little change with constrictive pericarditis. The newer modalities of color M-mode Doppler and TDE have provided complementary information in the evaluation of patients with constrictive pericarditis (see the section Phases of Diastole) (121,123,206,583,583a) (*e*Fig. 26.11.1). Recently, in patients with constrictive pericarditis, the mitral inflow E/Em was shown to be inversely correlated with PCWP (annulus paradoxus).

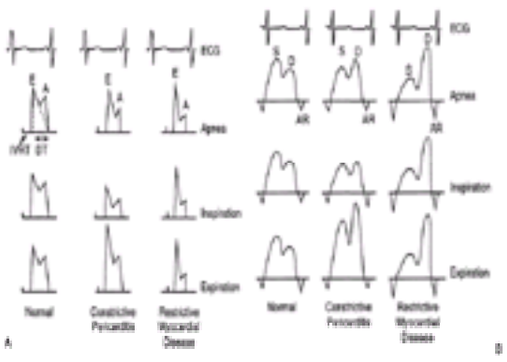


FIGURE 26.9 A,B: Left ventricular inflow velocities and pulmonary venous flow during different phases of respiration. (From Klein AL, Cohen GI. Doppler echocardiographic assessment of constrictive pericarditis, cardiac amyloidosis, and cardiac tamponade. *Cleve Clin J Med* 1992;59:278–290, with permission.)

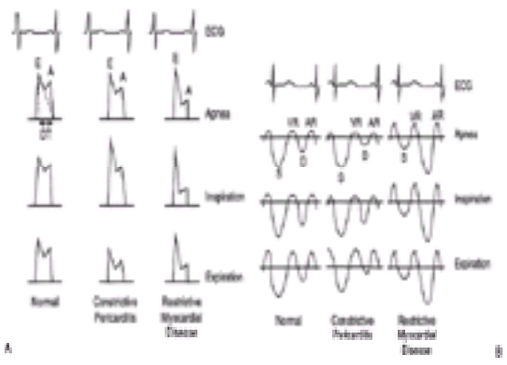

FIGURE 26.10 A,B: Right ventricular inflow velocities and hepatic venous flow during different phases of respiration. (From Klein AL, Cohen GI. Doppler echocardiographic assessment of constrictive pericarditis, cardiac amyloidosis, and cardiac tamponade. *Cleve Clin J Med* 1992;59:278–290, with permission.)

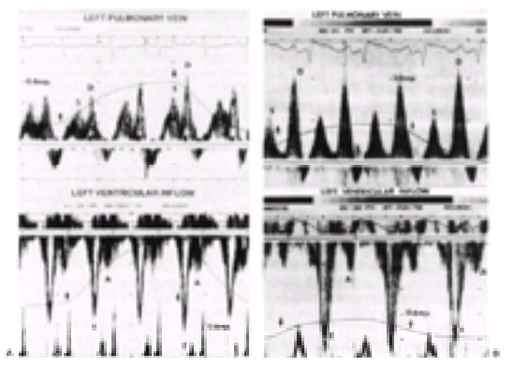

FIGURE 26.11 A: Constrictive pericarditis. Doppler transesophageal echocardiogram of the left upper pulmonary venous flow (*top*) and left ventricular inflow (*bottom*) in a 30-year-old man with constrictive pericarditis with respiratory monitoring with inspiration (*up arrow*) and expiration (*down arrow*). **B:** Restrictive cardiomyopathy. Doppler transesophageal echocardiogram of the left upper pulmonary venous flow (*top*) and left ventricular inflow (*bottom*) in a 64-year-old man with restrictive cardiomyopathy secondary to advanced cardiac amyloidosis during inspiration (*up arrow*) and expiration (*down arrow*). A, late filling velocity, D, peak diastolic; E, early filling; S, peak systolic. (From Klein AL, Cohen GI, Pietrolungo JF, et al. Differentiation of constrictive pericarditis from restrictive cardiomyopathy by Doppler transesophageal echocardiographic measurements of respiratory variations in pulmonary venous flow. *J Am Coll Cardiol* 1993;22:1935–1943, with permission.)

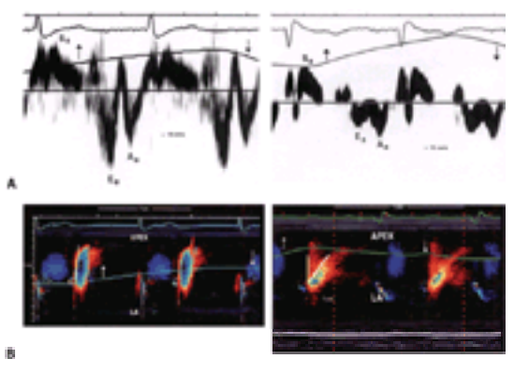
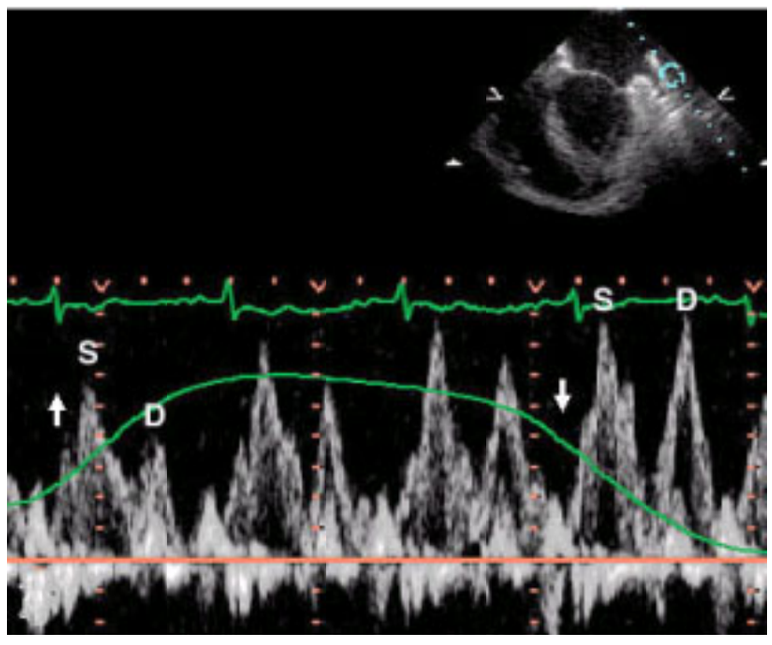
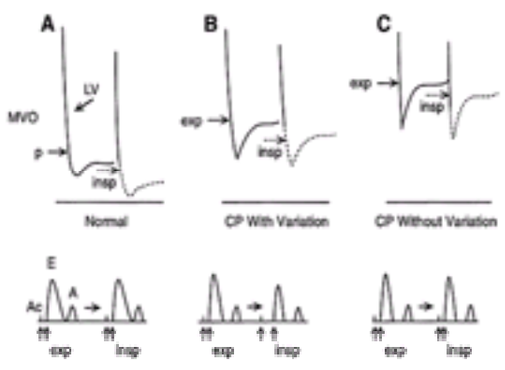


***e*FIGURE 26.11.1 A:** Representative tracings of the tissue Doppler echocardiographic velocities in the longitudinal axis in a patient with constrictive pericarditis (*left panel*) and a patient with restrictive cardiomyopathy (*right panel*) with respiratory monitoring with inspiration (*up arrow*) and expiration (*down arrow*). Note the peak systolic velocities are similar in both patients (10 cm/s), but a marked difference in early diastolic longitudinal axis velocities E_a was noted for the patient with constriction (15 cm/s) compared with the patient who had restrictive cardiomyopathy (5 cm/s). **B:** Color Doppler M-mode echocardiography of diastolic flow from the left atrium (LA) toward the ventricular apex as imaged from the four-chamber view with constriction (*left panel*) and restriction (*right panel*), with respiratory monitoring with inspiration (*up arrow*) and expiration (*down arrow*). The flow propagation slope of the first aliasing contour (*white line*) is steep (110 cm per second) for constrictive pericarditis (*left panel*) but the slope is significantly slower (35 cm per second) in restrictive cardiomyopathy (*right panel*). Note the color/no color transition (*yellow line*) is rapid for restrictive cardiomyopathy and represents isovolumic flow. A significant difference in the time delay of the maximal velocities is evident as well. (From Rajagopalan N, Garcia MJ, Rodriguez L, et al. Comparison of new Doppler echocardiographic methods to differentiate constrictive pericardial heart disease and restrictive cardiomyopathy. *Am J Cardiol* 2001;87:86–94, with permission.)



Pulsed wave Doppler of the pulmonary veins of a patient with constrictive pericarditis. Note the inspiratory decrease of the S and P waves and the expiratory increase due to interventricular dependence. (Inspiration is denoted by the upward arrow and expiration by the downward arrow).

There are several pitfalls in using Doppler echocardiography with respiratory monitoring in distinguishing constriction from restriction (eTable 26.6.1). Factors including depth of respiration, position of the sample volume, level of left atrial pressure, presence of concomitant myocardial disease, and atrial fibrillation may influence the accuracy of the diagnosis. Transesophageal echocardiography may be used to delineate the anatomy (pericardial thickening) as well as describe the physiology better than transthoracic echocardiography (101). In a large series of 192 patients undergoing transesophageal echocardiographic evaluation of complex diastolic function, 39% of patients had evidence of restrictive physiology, 30% had constriction, and 12% had mixed constriction and restriction, whereas the remainder had abnormal relaxation, pseudonormalization, or large pericardial effusion or tamponade (119). Preload reduction maneuvers may be useful in lowering the left atrial pressure to enhance the respiratory variation, whereas volume loading may be used if the filling pressures are decreased (584,585) (eFig. 26.11.2). Mixed restriction and constriction may occur postirradiation and may have features of localized pericardial thickening with restrictive physiology (119). Also, atrial fibrillation may make it difficult to perform a Doppler evaluation of constriction and restriction; however, a series of 31 patients with constrictive pericarditis showed a similar respiratory variation of pulmonary venous flow and mitral inflow in patients with atrial fibrillation compared with normal sinus rhythm (586). Occasionally, ventricular pacing can be used to regularize the RR intervals in patients with atrial fibrillation. Constrictive pericarditis can also be evaluated in the operating room during mechanical ventilation. In a series of 15 patients, it was noted that positive pressure ventilation reverses the pattern of respiratory variation of the mitral inflow and pulmonary venous flow velocities (587).



***e*FIGURE 26.11.2** Possible mechanism of decreased mitral flow velocity variation in some patients with constrictive pericarditis (CP). Left ventricular (LV) pressure

decrease and pressure at mitral valve opening (MVO; *horizontal arrows*) are shown during expiration (exp; *solid lines*) and inspiration (insp; *dashed lines*) together with mitral flow velocity and the time from aortic closure (Ac) to the start of mitral flow. Vertical arrows indicate LV isovolumic relaxation time. **A:** In healthy persons, the inspiratory decrease in LV minimal pressure and pressure at MVO is approximately equal, so that there is little change in early diastolic transmitral pressure gradient, mitral flow E velocity, or LV isovolumic relaxation time. **B:** In contrast, most patients with CP have less inspiratory change in LV minimal pressure than in pressure at MVO, resulting in increased variation in the early diastolic (transmitral) pressure gradient and early mitral flow velocity. **C:** However, if the constrictive process is severe and filling pressures are markedly increased, the flow velocity variation could be blunted because MVO occurs on a steeper portion of the exponential LV pressure gradient. In these cases, decreasing left atrial and MVO pressure by head-up tilt or diuresis may result in increased respiratory variation in mitral flow velocities and LV isovolumic relaxation time, as seen in **(B)**. (From Oh JK, Tajik AJ, Appleton CP, et al. Preload reduction to unmask the characteristic Doppler features of constrictive pericarditis; a new observation. *Circulation* 1997;95:796–799, with permission.)

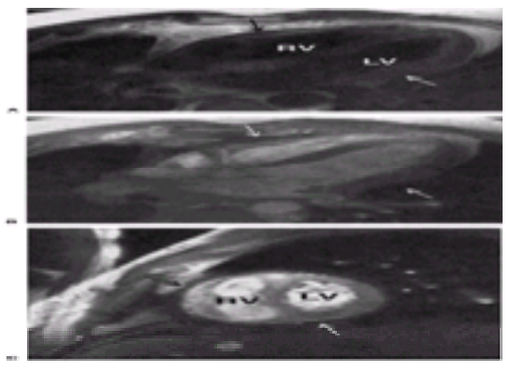
Magnetic Resonance Imaging for Pericardial Disease Direct visualization of the pericardium is possible with MRI in health (588,589) and disease states (590). This imaging modality is evolving as part of the routine workup of suspected pericardial disease (5,166,591). In constrictive pericarditis, the pericardium is seen as a thickened low-intensity signal band, related to its fibrocalcific nature (162) (eFig. 26.11.3).



***e*FIGURE 26.11.3** Constrictive pericarditis (spin-echo and cine; horizontal long-axis and short-axis). On the “dark blood” image **(A)**, thickened pericardium is represented by curvilinear signal void (*arrows*) separated by the bright signal of the epicardial and pericardial fat. There is associated conical/tubular compression deformity of the basal and middle portions of the right ventricle (RV) and left ventricle (LV). On the “bright blood” images **(B,C)**, the fibrous/calcified nature of the pericardium is confirmed by the dark appearance of the pericardium (*arrows*). The abnormal pericardium caused abrupt limitation of diastolic filling of the ventricles on the cine image loops. (Courtesy of R. D. White, MD, The Cleveland Clinic Foundation.)

The increased pericardial thickening can be measured easily by MRI, but does not necessarily indicate pericardial constriction (161). Ancillary findings by MRI include the conical or tubular narrowing of the ventricular cavities by the thickened pericardium, atrial dilatation, IVC enlargement, hepatomegaly, and ascites. The sensitivity, specificity, and accuracy of MRI in the diagnosis of constrictive pericarditis was 88%, 100%, and 93%, respectively, in one study (5). Cine MRI is useful in assessing the functional impairment of the abnormal filling in constriction compared with restriction (592), whereas phase flow mapping may show abnormal flow patterns in the superior vena cava that improve postpericardial stripping (593). However, MRI may have difficulty distinguishing between calcification and fibrous tissue and thus, CT scanning may be better to assess pericardial thickening, when calcification is present (102,554,594). Gadolinium-enhanced MRI has been used in the diagnosis of tuberculous constrictive pericarditis (595).

Clinical Presentation Patients with significant pericardial constriction present with congestive heart failure. Gross dependent edema, effusions and ascites (596), hepatic congestion with dysfunction, splenomegaly, poor exercise tolerance, and cachexia constitute anasarca, of which constriction is one of the few remaining causes in developed nations. Jugular venous distention is common with a prominent ‘y’ descent (Friedreich’s sign) (597), and the classical Kussmaul’s sign, a rise in central venous pressure with inspiration due to the inability of the right atrium to receive volume, is seen in some cases. The syndrome is relentless and progressive, responding poorly to conservative medical therapy.

Pulsus paradoxus is seen in one-third of cases. Auscultation of the chest reveals quiet heart sounds, often with a pericardial knock, which correlates with the abrupt cessation of early diastolic filling (E wave), when the ventricles reach their finite volume limit.

Electrocardiography demonstrates low voltages with nonspecific T-wave changes. Atrial fibrillation is seen in a minority of patients. Chest roentgenography may demonstrate “eggshell” calcification of the pericardium, particularly in tuberculous pericarditis, and pleural effusions (598).

There may be variation in the presentation of constriction. These variants include localized constriction (localized scarring) (599), effusive constriction (after the

pericardial fluid is drained), elastic constriction (thick pericardial fluid), latent or occult constriction (volume depleted), and transient constriction (600).

Treatment. Conservative medical management of constrictive pericarditis is at best palliative, with no substantial effect on the natural history of the disease. Diuretics decrease the intensity of fluid overload symptoms and atrioventricular blocking agents and antiarrhythmics are useful for the management of atrial fibrillation. Surgical pericardiectomy remains the only definitive management of this problem and should be performed before calcification and myocardial involvement progress (102,601,602 and 603).

In one series, a worse prognosis following pericardiectomy was associated with inadequate resection, higher New York Heart Association functional class, radiation, myocardial involvement, residual coronary artery disease, older age, chronic disease, and arrhythmias (600). A second contemporary series of 135 patients with constrictive pericarditis found a 6% 30-day perioperative mortality for pericardiectomy, and a 78% and 57% 5- and 10-year survival, respectively, with improvement in functional class in most patients. Predictors of poor prognosis, similar to prior studies, included advanced age, New York Heart Association class, and postradiation etiology. Symptomatic benefit postpericardiectomy has been correlated with improvement in diastolic filling pattern and shorter duration of symptoms (604).

Specific Causes of Pericardial Disease

Idiopathic and Viral Pericarditis

The majority of cases of acute pericarditis has no specific cause detected and is designated idiopathic. Many of these cases represent acute viral pericarditis. Attacks of this syndrome follow the seasonal epidemics of enterovirus infection (coxsackie B and echovirus) (605). Proven viral cases are more likely to occur in immunocompromised hosts. Cytomegalovirus pericarditis has increased in frequency in association with immunocompromised hosts and early human immunodeficiency virus infection (606,607 and 608). *e*Table 26.6.2 shows the most etiologies of infectious pericarditis.

***e*TABLE 26.6.2** ETIOLOGY OF INFECTIOUS PERICARDITIS
Viral diseases (coxsackie A and B viruses, echovirus, influenza, adenovirus, Epstein-Barr virus, chicken pox, psittacosis, acquired immunodeficiency syndrome, mumps, infectious mononucleosis)
Mycobacterial infections (*Mycobacterium tuberculosis*, *M. avium*, *M. intracellulare*)
Protozoa (toxoplasmosis, *Entamoeba histolytica, Trypanosoma cruzi*)
Fungal infections (histoplasma, *Coccidioides,* blastomycosis, *Candida*, *Aspergillus*)
Bacterial infections (*Staphylococcus*, *Streptococcus*, gram-negative bacilli, *Meningococcus*, *Pneumococcus*, *Salmonella* species, *Brucella*, *Legionella*, *Campylobacter*, *Haemophilus influenzae,* Lyme disease)
Rickettsial infections
Parasitic infections (trichinosis, microfilaria, echinococcus disease)
Anaerobic organisms (*Clostridium*, anaerobic *Streptococcus*)
Miscellaneous infections (*Nocardia*, *Actinomyces*, *Mycoplasma*, *Psittacosis-lymphopathia venereum* group)

From Fowler NO. Pericardial disease. *Heart Dis Stroke* 1992;1:85–94, with permission.

Pathology. Viral infection of the pericardial layers is associated with a polymorpholeukocyte accumulation followed by a mononuclear perivasculitis. Pericardial fluid is often observed, usually in small amounts. In a minority of cases, large effusions cause the clinical presentation of cardiac tamponade. The fluid is typically serosanguineous, often with a leukocytosis (with variable polymorpholeukocyte and monocyte composition). Biochemical analysis of the fluid typically shows elevated lactate dehydrogenase and protein levels. It is possible to culture cytomegalovirus from the pericardium or fluid in some cases. Serology in viral cases may demonstrate high titers of cytomegalovirus IgG by latex agglutination, cytomegalovirus IgM by enzyme-linked immunosorbent assay, influenza A or B antibodies by complement fixation, or coxsackie B antibodies by complement fixation (605,607).

Clinical Presentation. Idiopathic and viral pericarditis in the immunocompetent host is typically a self-limited illness, beginning with a nonspecific flu-like illness. There is often a history of a prodromal upper respiratory tract infection. There may be associated arthralgias and myalgias. Patients present with a syndrome of chest pain as described previously. The pain is often severe, distressing, and associated with sympathetic activation such as clamminess, pallor, and tremor. There is often an associated low-grade fever. Significant dyspnea is uncommon in simple cases, unless there is hemodynamic compromise by a large pericardial effusion or associated viral pneumonitis (609).

The specific diagnosis of viral pericarditis should be entertained in all cases, after other etiologic agents have been considered. However, the identification of the viral agent from serologic markers or from pericardial fluid occurs infrequently in clinical practice. A fourfold rise in serum antibody levels is highly suggestive of an underlying viral cause. Associated myocarditis is often associated with modest elevation of cardiac isoenzymes (529,605,610).

Pericardial collections in viral and idiopathic pericarditis are usually relatively small, being diagnosed and sized simply by transthoracic echocardiography. Having detected an effusion, it is important to exclude significant hemodynamic compromise or tamponade. Because of the relatively acute time frame of the fluid accumulation, tamponade may be present with only modest volumes of pericardial fluid. Pericardiocentesis is not usually indicated unless there is hemodynamic compromise, which occurs in up to 15% of cases of acute viral pericarditis (531). In a series of 57 patients, pericardial biopsy and fluid sampling identified cytomegalovirus in only four cases (607).

Uncomplicated acute pericarditis is a self-limited benign illness, with few sequelae and a course ranging from days to a few weeks. Complications are infrequent and include relapsing attacks of acute pericarditis (see following discussion), acute tamponade, acute myocarditis with ventricular dysfunction and late cardiomyopathy, and chronic constrictive pericarditis (609).

Management. Specific antiviral therapy is not indicated for viral idiopathic pericarditis in the immunocompetent host. Treatment is directed toward symptom relief. The mainstay of therapy has always centered on the oral antiinflammatory drugs, particularly aspirin (325 to 650 mg every 4 to 6 hours) or most often nonsteroidal antiinflammatory agents including ibuprofen (600 to 800 mg every 6 to 8 hours) (611). Indomethacin (25 to 50 mg four times per day) should be reserved in adults due to deleterious effects on coronary blood flow and myocardial infarcts. Thus, other nonsteroidal agents are commonly used. No specific studies have used the COX-2 inhibitor agents. Colchicine (0.6 mg every 12 hours), with or without a load of 2 to 3 mg, may be used when added to the antiinflammatory agent or by itself in treating the initial attack or preventing recurrences (612,613 and 614). There is no role for antibiotics, unless purulent pericarditis has been documented. Systemic corticosteroid therapy with prednisone has been used in severe and intractable cases (609,615). Some patients may have recurrent or incessant pericarditis that may be related to an immunopathic etiology (616). Frequently, these patients may be corticosteroid dependent. Colchicine may be an effective drug to attempt to wean patients off corticosteroids (617).

Purulent Pericarditis

Epidemiology and Etiology. The incidence and spectrum of purulent pericarditis have changed considerably with the advent of the antibiotic era and the increasing frequency of cardiac surgery and immunocompromised hosts (618,619). Previously, the most common presentation of purulent pericarditis was as an associate of pneumococcal pneumonia (619). A wide variety of organisms has been implicated as etiologic agents, depending on the clinical scenario. Following cardiac surgery, staphylococcal infection, including multiply-resistant strains, gram-negative rods including *Pseudomonas*, *Escherichia coli*, and *Klebsiella* (618), and streptococcal groups A and B (620) have been documented. Sporadic cases of other infectious agents have included *Legionella* (621,622), *Neisseria gonorrhoeae* (623), *Salmonella* sp (624), Lyme disease (625), anaerobes such as *Bacteroides fragilis* (626,627), and nonbacterial agents such as *Candida albicans* (628,629), *Nocardia*, *Asteroides* (630), *Mycoplasma pneumoniae* (631), and *Aspergillus* species (632). Meningococcal infection has been associated with purulent pericarditis (633,634), with or without clinical meningitis.

In a large hospital-based series of patients from 1972 to 1991 (619), purulent pericarditis was seen in only 33 of 600,000 patients reviewed and was detected premortem in only 19 of these. All but two patients had a remote source of infection such as pneumonia, skin infection, or oral sepsis as the probable primary source. In 8 of 33 cases, no bacteria could be isolated or grown from pericardial, pleural, cervical, or blood cultures. The outcome for the group was poor, with constriction requiring surgery developing in 6 patients, and only 16 surviving to be discharged from the hospital. Notably, only approximately one-third of the patients presented with the typical symptom complex of acute pericarditis.

Direct trauma to the chest may cause pericarditis directly, via penetration (635,636), or extensive soft tissue injury with secondary superinfection. An indirect, often late form of inflammatory sterile pericarditis is seen in blunt trauma cases (637,638). This is thought to be an autoimmune phenomenon, similar to Dressler's syndrome (see the section Dressler's Syndrome).

Management. A provisional diagnosis of purulent pericarditis is an indication for a drainage procedure, either percutaneous or preferably surgical. Complete clearance

and lavage of the pericardial space should be attempted (636,639). Urgent bacterial, acid-fast, and fungal staining of the fluid, followed by complete culture is mandatory. Broad-spectrum antibiotic therapy should be narrowed on identification of the specific etiologic agent. Pericardectomy may be indicated in cases with significant pericardial adhesions to avoid late constriction.

Fungal Pericarditis

Pericarditis due to fungal infection is a relatively uncommon condition, occurring in areas where certain strains are endemic. Histoplasmosis pericarditis—a usually benign self-limited clinical syndrome—is seen in young healthy adults who present with a typical acute pericarditis syndrome. Patients should be observed in-hospital, as large, hemodynamically significant effusions can accumulate rapidly, requiring drainage (640). This organism is endemic in the Ohio and Mississippi river valleys, Arkansas, and the western Appalachians (641). Other fungal agents such as coccidioidomycosis (642), *Candida* species, (628,629), and *Aspergillus* species (632) have been documented to cause pericarditis, particularly in immunocompromised hosts.

Tuberculous Pericarditis

Although tuberculosis is not endemic in many developed countries, it remains a major public health issue in nonindustrialized nations (643), and typical and atypical mycobacterium infection is an increasing problem in immunocompromised hosts (644,645 and 646). Pericardial involvement is responsible for up to 4% of acute pericarditis and 7% of tamponade presentations (647,648). The feared long-term sequelae of tuberculous pericarditis is calcific pericardial constriction, occurring in 30% to 50% of cases (647,649,650).

Pathology. Tuberculous pericarditis develops either from lymphangial spread from mediastinal or peribronchial nodes or direct or hematogenous spread from pulmonary lesions. The inflammatory process has four stages (651). Initially, the inflammation is dry or fibrinous, with little fluid accumulation and the presence of live acid-fast bacilli. The inflammatory response comprises a mononuclear infiltrate with typical giant cells and foci of caseating necrosis. Pericardial fluid accumulates in large volumes (600 to 1,500 mL), often causing significant hemodynamic compromise. With time, the effusion resolves, and fibrous adhesions develop between visceral and parietal layers and between pericardium and surrounding tissues. Late, the adhesions become dense, and calcification occurs with the appearance of clinical constriction and radiographic calcification (650).

The pericardial fluid has a high specific gravity with high protein levels and has a high white cell count comprising a majority of lymphocytes. The fluid appears serous in the majority of cases. The majority of cases has high levels of antimyolemmal and antimyosin antibodies (652). Polymerase chain reaction technology has successfully been employed to amplify and identify *Mycobacterium tuberculosis* DNA from pericardial fluid (653,654).

Clinical Presentation. Tuberculous pericarditis may present in several ways. Early involvement is often manifest by a nonspecific systemic syndrome of lethargy, fever, night sweats, weight loss, tachycardia, and dyspnea. Pericardial chest pain is seen in less than one-half of cases. Most cases present later, as pericardial fluid accumulates with the clinical manifestations of tamponade with elevated venous pressure, pulsus paradoxus, and anasarca. A pericardial rub is present in approximately one-half of all patients (655).

Approximately one-half of patients with treated tuberculous pericarditis proceed to constrictive pericarditis, even with treatment. This can occur over a prolonged period or may occur rapidly over weeks. The clinical manifestations of constrictive pericarditis have been discussed previously. The presence of pericardial tamponade at presentation and the degree of fibrosis at the start of treatment are predictors of late constriction (655).

Investigations. The diagnosis of tuberculous pericarditis can be made if one or more of the following criteria are met: (a) histologically proven tuberculous pericarditis at surgery or pericardial biopsy; (b) positive *M. tuberculosis* culture from pericardial fluid; (c) pericarditis with proven extracardiac tuberculosis (lymphadenopathy, pleural or peritoneal effusion, pulmonary infiltrate, positive tuberculin skin test result); (d) pericardial effusion without obvious cause, responding to antituberculous therapy (656,657). The presence of high levels of adenosine deaminase activity (greater than 50 U per L) in the pericardial fluid is supportive of the diagnosis (658). Tuberculin skin test results may be negative in one-third of patients with tuberculous pericarditis (659) and positive in one-third of patients with idiopathic or viral pericarditis (531), making it less than useful in this diagnostic algorithm.

Management. Before the availability of antituberculous agents, tuberculous pericarditis was almost universally fatal. Even with modern therapy, death occurs from tamponade and late constriction. The goals of management are to treat the active infection, monitor and treat developing effusions, and prevent and treat late constriction (650,660,661). A nonrandomized trial suggests a beneficial effect for supplementary corticosteroid therapy and complete open surgical pericardial drainage.

Human Immunodeficiency Virus–Associated Pericardial Effusion

Human immunodeficiency virus infection is a common cause of pericardial effusion. In one series of 122 patients with pericardial effusion, 33% had human immunodeficiency virus infection as the underlying condition. Cardiac tamponade is common in this disease population associated with various infectious agents including *Mycobacterium*, fungi, viruses, lymphoma, and Kaposi's sarcoma (662).

Uremic Pericarditis

Pericardial involvement in patients with end-stage renal disease has been recognized for 150 years to be a marker of preterminal disease (663,664). With the introduction of modern dialytic therapy, the incidence of pericarditis and effusion in these patients has decreased significantly, from almost one-half (663) to approximately 10% (665,666). Pericarditis is responsible for the death of a similar proportion of patients (666).

Pathophysiology. Uremic pericarditis and effusion occur in patients with severe renal failure and abate with dialysis or successful transplantation. However, among patients with severe uremia, those who suffer pericarditis are not biochemically discernible from those who do not (665). Established pericardial effusions in patients on dialysis often resolve with increased frequency of dialysis (665,666). Stressors such as surgery, trauma, or intercurrent illness are often seen to precipitate pericarditis (664,667).

Insults other than elevated serum urea levels have been postulated as causal in pericarditis in renal failure patients. Hypercalcemia, hyperuricemia (668), and heparin-associated hemorrhagic pericarditis have all been cited (664). The immunocompromised state has been suggested as a mechanism, allowing viral infection to become active (669). This latter mechanism does not fully explain the abatement of the syndrome with increased dialysis therapy. Finally, end-stage renal disease is an associate of many multisystem diseases, particularly immunologic syndromes such as lupus, which are well recognized to have an associated autoimmune serositis.

Gross inspection of the pericardium in cases of uremic pericarditis shows the classic "bread and butter" appearance. This is caused by the fibrin exuding into the pericardium forming fine adhesions between the visceral and parietal layers. The pericardium itself may have focal hemorrhagic areas or generalized erythema. The process may organize and calcify to a chronic constrictive state (670).

Clinical Presentation. Pericardial chest pain is the most common presenting feature of this syndrome, occurring in three-fourths of cases. This pain has the typical features of acute idiopathic pericarditis as discussed previously. The majority of cases has a pericardial rub heard at some point in the clinical course. Fewer than 30% have fever. Dyspnea is commonly experienced, particularly as pericardial tamponade develops. The presentation and diagnostic workup of cardiac tamponade is discussed earlier in this chapter (see the section Pericardial Tamponade). Tamponade poses a significant risk to the patient, especially at times of hemodynamic stress, such as during hemodialysis. Small asymptomatic pericardial effusions are seen in many dialysis patients (671,672) and of themselves are not diagnostic of uremic pericarditis.

Management. The approach to patients with uremic pericarditis is governed by the hemodynamic stability of the individual. In stable cases, intensive hemodialysis has been shown to reduce the size of effusions and severity of symptoms and is recommended (668,673,674), being successful in only 50% to 60% of cases (665,666). Such dialysis should use a minimal dose of heparin to avoid intrapericardial bleeding. Ongoing pericarditis and increasing pericardial fluid collection is predicted by high fever (greater than 39°C), significant leukocytosis (greater than 15,000 per mm^3), and the use of peritoneal dialysis alone (675). Large pericardial effusions are less likely to resolve with such medical therapy than small collections (666,676,677).

Pericarditis Associated with Myocardial Infarction

Differentiation of pericardial chest pain from that of acute myocardial ischemia is important for the clinician. Pericarditis as an associate of acute myocardial infarction occurs in up to 30% of cases at autopsy (678,679), significantly complicating the situation. In life, pericarditis is observed clinically in 7% to 10% of acute infarcts (680,681). An incorrect diagnosis of primary pericarditis has important implications in this setting as it will most likely preclude the patient from receiving timely revascularization therapy. Conversely, an incorrect diagnosis of myocardial ischemia in the setting of simple acute pericarditis may lead to the patient suffering the consequences of thrombolytic or anticoagulant therapy. In 16 such cases reported in the decade ending in 1995, there has been one death (in a young man), one hemorrhagic tamponade, and two nonhemorrhagic effusions managed conservatively (682,683,684,685,686 and 687). Two forms of pericardial involvement have been observed in association with myocardial infarction.

Early Acute Pericarditis

Pathophysiology. An early pericarditis syndrome is seen in the days following an acute infarction, resolving over approximately 1 week. Pathologically, a fibrinous exudate is seen, localized over the area of the infarct. Small pericardial effusions, without clinical pericarditis, are quite common after myocardial infarction, occurring in 25% to 40% of such patients (688,689). These effusions are usually of little clinical significance and are frequently detected incidentally on echocardiography assessing regional wall motion abnormalities. In such cases, it is important to consider and exclude contained rupture into the pericardium.

Clinical Presentation. The clinical presentation of pericardial-type pain often occurs after the abatement of ischemic pain. This syndrome should be considered during each physical examination of the postinfarct patient. The presence of a pericardial rub is diagnostic, occurring more commonly than the pericardial pain. It is important to differentiate this sound from intracardiac murmurs, which may represent mechanical complications of infarction such as acute mitral regurgitation and ventricular rupture. The typical electrocardiographic changes of pericarditis are seen in a small minority of cases of postinfarct pericarditis (680). In a large retrospective series of autopsy-proven postinfarct regional pericarditis, a pattern of atypical T-wave evolution was observed: specifically at 48 hours, persistent upright T waves *or* normalization of transiently inverted T waves (690).

The clinical course of early postinfarct pericarditis is usually benign. However, pericarditis seems to be associated with larger transmural infarcts and therefore more complications. Despite this, poorer prognosis is not predicted by the presence of periinfarct pericarditis or effusions (688,689,691,692 and 693). In the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI) trials of thrombolytic therapy for myocardial infarction, pericardial involvement was associated with a higher long-term mortality, but was not an independent risk factor when infarct size was considered (694). Further evidence that pericarditis is a by-product of more severe myocardial damage and not an independent prognostic factor is provided by the data from analysis of incidence of pericardial involvement in patients treated with thrombolytic therapy compared with those who did not receive this treatment. In the GISSI trials, the incidence of periinfarct pericarditis was halved by the use of thrombolytic therapy, and this effect was more pronounced with earlier institution of treatment (694,695).

Management. Management is symptomatic, with aspirin or nonsteroidal antiinflammatory drugs. Caution is recommended with the latter as there have been anecdotal reports of pronounced thinning and even rupture of infarct sites when these drugs have been used (696). For similar reasons, corticosteroid therapy (697) is not recommended.

Dressler's Syndrome. The second pericardial associate of myocardial infarction is the late-appearing Dressler's syndrome (698). Dressler suggested an incidence of 4% of infarct patients, but more recent studies have shown rates of 1% or less (699,700). Indeed, in patients treated with thrombolytics, this syndrome has been observed at rates of less than 0.5% (701).

Clinical Presentation. Dressler's syndrome of chest pain, pleurisy, pericarditis with friction rub, severe malaise, moderate fever, and leukocytosis occurs at 3 weeks to several months postinfarct (681). Pericardial collections of fluid are not uncommon and can be hemodynamically compromising.

Management. Consideration should be given to hospital admission, as these patients are often severely debilitated. Furthermore, recurrent ischemia, significant pericardial effusion, bacterial superinfection, and hemorrhagic complications need to be examined for and excluded. Anticoagulant therapy should be temporarily discontinued. Symptoms are relieved usually with aspirin or nonsteroidal antiinflammatory drugs (see the section Acute Pericarditis for doses). Because of the recurrent nature of the syndrome and the possible immunologic nature of the insult, some authors recommend corticosteroid therapy (prednisone, 40 to 60 mg daily, tapering over a week) (702). Pericardiocentesis is indicated only for hemodynamic compromise or tamponade.

Trauma and the Postpericardiotomy Syndrome

After open or closed pericardial trauma or cardiac surgery requiring pericardotomy, a late inflammatory process may be observed, with fever and clinical pericarditis (703). his phenomenon is probably mediated by similar mechanisms to Dressler's syndrome following myocardial infarction (704). The syndrome usually presents with fever, malaise, and pericarditic chest pain 2 to 3 weeks after the inciting event. There is often a pericardial rub. The patient may exhibit leukocytosis, eosinophilia, and elevated sedimentation rate (705). Chest radiographic examination may show cardiomegaly related to pericardial effusion, associated pleural effusion, or both. Such fluid is usually serous and may be of sufficient volume to cause hemodynamic compromise in up to 1% of cardiac surgical patients (706). Patients should be treated with nonsteroidal antiinflammatory drugs, with corticosteroids being reserved for intractable cases and pericardiocentesis for cases with tamponade.

Radiation Pericarditis

Thoracic and mediastinal radiation for hematologic and breast malignancies has been routine practice for three decades. Accordingly, there is a growing population of patients suffering the late consequences of radiation to the heart and pericardium (707). Indeed, the heart and spinal cord appear to be the dose-limiting organs for thoracic radiation (708). The severity of these complications is variable from individual to individual and relates to the volume of heart exposed to the source, the total dose, duration and fractionation of the therapy, and nature of the source (^{60}Co being worse than linear accelerator). Early large studies of patients with Hodgkin's disease showed radiation-induced pericardial abnormalities in 6.6% (709), whereas more current series report an incidence of 2.2% (710). The modern use of anterior and posterior fields combined with subcarinal and apical shielding has contributed significantly to this improvement (711).

Pathology. The common pathogenetic feature of radiation-induced complications is microcirculation injury with endothelial cell damage, platelet adhesion, and capillary rupture. Radiation injury to the pericardium has an acute inflammatory phase with associated hyperemia and thickening of the serosal membranes, fibrin deposition, and pericardial fluid, which may be serous or bloody (712). This inflammatory response may resolve or may organize to form adhesions between the visceral and parietal pericardium, with late constriction. Pericardial effusions may resolve or become chronic. Myocardial fibrosis with diastolic dysfunction and scarring of the valves leading to poor coaptation are associated features of cardiac radiation injury.

Clinical Presentation. Acute pericarditis associated with radiation therapy is usually asymptomatic and self-limiting. When clinically evident, patients present with a typical acute pericarditis syndrome with pain, fever, lethargy, and electrocardiographic changes. Delayed pericardial involvement, usually occurring within 1 year of therapy (713), but with latent periods of up to 45 years reported (714), presents most commonly as a chronic pericardial effusion. This presentation is most commonly in the setting of an elevated sedimentation rate, elevated lymphocyte count, presence of bulky mediastinal disease, and concomitant chemotherapy (715). Such effusions most commonly present with hemodynamic compromise causing dyspnea, edema, and poor exercise tolerance. A smaller number of patients present with full-blown tamponade. Most cases of pericardial effusion secondary to radiation resolve spontaneously (715). Superinfection of the pericardial space with *Staphylococcus aureus* can lead to abscess formation. Thyroid dysfunction is common after mantle irradiation (15% to 25%) (710,716) and must be considered as a possible contributor to pericardial effusion.

Organization of the process may lead to the typical presentation of constrictive pericarditis, with congestive cardiac failure. An intermediate stage with pericardial fibrosis and effusion under pressure is manifest as the effusive-constrictive syndrome (717). Constrictive pericarditis evolves 5 to 10 years after therapy (718,719) and is not surprisingly predisposed to by the presence of pericardial fluid. Radiographic evidence of pericardial calcification is uncommon. A new condition of mixed constriction and restriction has been described that may occur from radiation injury to the myocardium and pericardium (119).

Diagnosis and Management. Pericardial effusion, with or without tamponade following radiotherapy, suggests either malignant or radiation pericarditis. Malignant pericarditis can be diagnosed by percutaneous pericardiocentesis with cytology in 85% of cases (720). Malignant effusions tend to be larger in volume and associated with other evidence of tumor recurrence. Percutaneous pericardiocentesis offers adequate relief of tamponade. Recurrent large pericardial collections should be treated with surgical pericardiectomy, as the pleuropericardial window procedure is associated with a high rate of progression to constriction (721). Pericardial stripping for constriction is associated with a higher mortality and poorer outcome than for constriction of other causes because of wound dehiscence and

infection and myocardial dysfunction related to associated radiation injuries.

Pericardial Involvement in Autoimmune Diseases

Pericardial involvement in the multisystem connective tissue diseases is not uncommon. Pericarditis, with or without effusion, is commonly a component of a multiserositis, together with pleuritis and ascites.

Rheumatoid Arthritis. Autopsy studies show evidence of some pericardial involvement in up to one-half of all patients with rheumatoid arthritis (722). This involvement consists of acute and chronic inflammatory changes, effusions, adhesions, and scar and, rarely, rheumatoid granulomata. In life, pericardial involvement is detected in 2.0% of adult cases and 7.6% of juvenile rheumatoid arthritis (Still's disease) (723).

Clinical Presentation. Classic pericarditis is not typically manifest in these patients. Chest pains are often atypical for pericarditis and may be confused with the myriad musculoskeletal pains suffered by these patients. Pericardial effusions are often small, with tamponade being uncommon. The fluid has high protein levels, low glucose, and high titers of rheumatoid factor. Rheumatoid arthritis may be associated with cholesterol ("yellow paint") pericarditis (724,725 and 726). Elevated levels of interleukin-6 in the pericardial fluid has been associated with tamponade (727).

Chronic pericardial involvement in rheumatoid arthritis may manifest as constrictive pericarditis. This has been associated with the presence of subcutaneous rheumatoid nodules (728). The diagnosis and management of constrictive pericarditis are discussed in detail earlier in this chapter. In addition, abnormal diastolic filling patterns have been noted in adults and children with rheumatoid arthritis compared with matched controls, suggesting undetected myocardial involvement (729,730).

Systemic Lupus Erythematosus. Pericardial involvement in lupus (both idiopathic and drug-induced) occurs in approximately one-third of all patients (731), being the most common cardiovascular complication of the disease. The process involves a serositis, with a fibrous exudate high in protein, low in glucose, and a polymorpholeukocyte count less than 10,000 per mm^3. This volume of fluid may be large and cause tamponade in a small minority of cases (less than 10%) (732). Pericardial fibrosis and thickening with constriction are rare late sequelae (733).

Clinical Presentation. In large series of patients with SLE, documented pericarditis is present in one-fourth to one-fifth and tamponade in 2.5% (734,735 and 736). The clinical presentation is often indistinguishable from simple idiopathic acute pericarditis, manifesting the characteristic symptom complex and electrocardiographic changes (737). Pericarditis can be the presenting feature of systemic lupus erythematosus and should be excluded in all cases of suspected idiopathic pericarditis, especially in women. The presence of antiphospholipid antibody in serum has been associated with cardiac complications of lupus (738) but not with a higher prevalence of pericardial effusion. Pericardiocentesis is not specifically indicated unless complications such as sepsis or tamponade are apparent (739).

Myocardial disease may also occur in patients with systemic lupus erythematosus or antiphospholipid antibodies without apparent systolic dysfunction or pericardial disease. Abnormal diastolic filling patterns have been demonstrated relative to controls in these patients, suggesting subclinical myocardial disease (740,741).

Management. Attacks of pericarditis parallel the systemic activity of the illness. Pericarditis usually abates with systemic immunosuppressive therapy. Pericardial drainage is reserved for cases with hemodynamic embarrassment. Close observation, often in the hospital, for the development of tamponade is warranted (733).

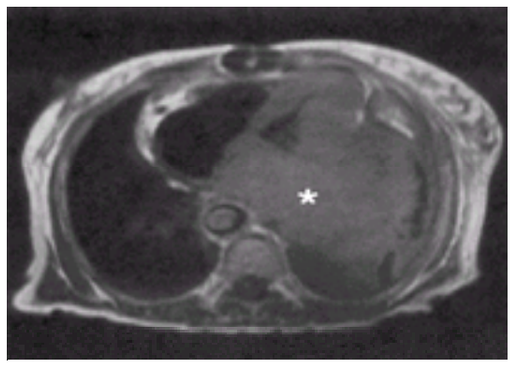
Scleroderma. Cardiac involvement in scleroderma (progressive systemic sclerosis) is seen in approximately 50% of cases, whereas clinical pericarditis occurs in 10% (742). Pericardial effusion detected by echocardiography, sometimes massive, has been reported in up to 40% of patients (743,744,745,746 and 747). Late pericardial constriction has an extremely poor prognosis. Associated cardiac abnormalities include myocardial fibrosis with diastolic dysfunction, conduction system abnormalities, valvular fibrosis, and arrhythmias (748,749 and 750). Acute scleroderma pericarditis is managed with antiinflammatory measures, in a manner similar to idiopathic pericarditis.

Myxedema

Untreated hypothyroidism is associated with peritoneal, pleural, and pericardial serous fluid collections related to sodium and water retention and increased capillary permeability (751,752). The fluid may be straw colored, with fibrin strands or have a gold paint appearance (753) related to a high cholesterol content (754). The pericardium may be coated with cholesterol deposits, related to the hypercholesterolemia of hypothyroidism. Associated cardiac abnormalities include accelerated coronary disease (755) and cardiomyopathy (756). Clinically, pericardial involvement is often silent, being detected as cardiomegaly on chest radiography. Fluid accumulation is gradual and may reach enormous volumes (greater than 4 L) (757). Pericardial effusion may be the presenting symptom of hypothyroidism and thus thyroid function testing should be routine in the workup of pericardial effusion of unknown origin. With institution of adequate thyroid hormone replacement therapy, the effusions usually resolve slowly (758). Pericardiocentesis should be reserved for cases with hemodynamic compromise.

Malignant Pericarditis

Malignant invasion of the heart and pericardium occurs in one-tenth of all cancer patients, and one-third of these die as a consequence of such involvement (759,760). Primary tumors of the pericardium are exceedingly rare. Angiosarcomas (including hemangiopericytoma, hemangiosarcoma, Kaposi's sarcoma), rhabdomyosarcomas, and fibrosarcomas are malignant primary cardiac tumors that involve the myocardium and may directly invade the pericardium. Medical and surgical management of these tumors is at best palliative, with a poor short-term prognosis. Primary malignant tumors of the pericardium (including fibrosarcoma and mesothelioma) have a similarly poor outcome (761) (*e*Fig. 26.11.4). Secondary or metastatic malignant pericardial disease arises from lung, breast, melanoma, or hematologic malignancies in the majority of cases (759,762). Malignancies from below the diaphragm (gastrointestinal tract and renal) rarely reach the pericardium. Autopsy studies show that less than one-third of cases are diagnosed antemortem (760).



***e*FIGURE 26.11.4** Primary pericardial malignancy (spin-echo; horizontal long-axis). A large heterogeneous mass (*asterisk*) represents a malignant fibrous histiocytoma originating in the pericardium and extending into the cardiac chambers at the level of the left atrium and outward into the left lung. (Courtesy of R. D. White, MD, The Cleveland Clinic Foundation.)

Clinical Presentation. The majority of patients with malignant involvement of the pericardium is asymptomatic (760,763,764 and 765). Malignant pericarditis may present as effusion, with or without tamponade, cardiac encasement with constrictive physiology, impaired coronary circulation, and cardiac denervation. Clinical manifestations include dyspnea, cough ascites, and edema (760). Indeed, malignancy is a leading cause of cardiac tamponade in developed nations. Electrocardiography demonstrates low voltages in the majority of patients, but classical electrical alternans in only 5% (766). Radiographic cardiomegaly is common. Echocardiography easily diagnoses pericardial effusion and can often identify a tumor mass in the pericardial space or encasing the heart. MRI has emerged as a useful diagnostic tool for assessing mass lesions in the pericardium (161).

Pericardiocentesis is useful as a diagnostic and therapeutic tool. Diagnostic information includes the nature of the fluid (exudate, transudate, serous, sanguineous, chylous), cellularity, infection, and presence of tumor cells by cytology. Pericardial tamponade is an indication for urgent pericardiocentesis from the apical or subxyphoid approach. Effusions may be large in volume and should be drained over hours. Loculated effusions may not drain completely. Fluid recurrence after

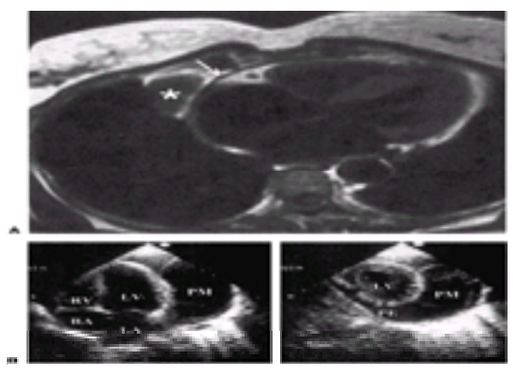
pericardiocentesis has been managed with pericardial sclerosis using several instillations of 500 to 1,000 mg of tetracycline over 8 days (767,768).

In situations in which no suitable percutaneous window exists for pericardiocentesis or fluid recurrence is significant, a surgical pleuropericardial or pleuroperitoneal window may be created. This procedure can be performed under local anesthetic in less than 1 hour with minimal risk. It is highly efficacious with a low recurrence rate. These advantages have led many clinicians to favor this as a first approach bypassing pericardiocentesis (766). Radiotherapy is a third treatment option for malignant pericardial effusions. External beam therapy of 25 Gy over 3 to 4 weeks gave short-term relief (mean, 4 months) in 60% of a series of 38 patients (765).

Prognosis. The diagnosis of malignant pericardial disease has ominous implications. Nonhematologic tumors involving the pericardium respond poorly to all therapeutic interventions, with life expectancies in the weeks to months range (720). Patients presenting with tamponade have an even worse outlook.

Congenital Abnormalities of the Pericardium

Cysts of the pericardium are rare, and clinically benign lesions usually present as asymptomatic masses along the cardiac margin on chest radiography (eFig 26.11.5). The most frequent sites of occurrence are the right followed by the left cardiophrenic angles (769,770). Nonspecific symptoms such as chest pain, dyspnea, and cough may occur (769). Serious complications such as airway obstruction, erosion into cardiovascular structures, and cardiac tamponade have been reported (770).



***e*FIGURE 26.11.5 A:** Pericardial cyst (spin-echo; transaxial). A well-circumscribed, oval-shaped mass lesion (*asterisk*) is seen along the right cardiac margin, separate from the pericardium (*arrow*); it represents a simple pericardial cyst. (Courtesy of R. D. White, MD, The Cleveland Clinic Foundation.) **B:** Two-dimensional echocardiography. *Left*: Apical four-chamber view. *Right*: Parasternal short-axis view. Echolucent structure seen adjacent to the left ventricle (LV) that was identified as a pericardial cyst. LA, left atrium; PE, pericardial effusion; PM, pericardial mass; RV, right ventricle; RA, right atrium. (From Bava GL, Magliani L, Bertoli D, et al. Complicated pericardial cyst: atypical anatomy and clinical course. *Clin Cardiol* 1998; 21:862–864, with permission.)

Complete or partial absence of the pericardium is rare, occurring in male more often than female subjects, and is associated with congenital cardiac abnormalities such as atrial septal defect and bicuspid aortic valve and lung malformations. Patients may develop chest pain while lying on the left side, and the character of the pain may be described as “stabbing” (771). Complete absence of the pericardium is associated with leftward displacement of the heart and RV dilatation. Partial absence usually occurs over the atria and may lead to herniation and pseudoaneurysm formation (772), which must be differentiated from true atrial aneurysms (773). Connolly et al. described the echocardiographic features most commonly seen in patients with congenital absence of the pericardium. They included unusual imaging windows, hypermobility or swinging of the heart, and abnormal septal motion (774).

Drugs

Pericardial reactions to drugs are rare and idiosyncratic. Pericarditis is seen in patients who develop lupus syndrome in response to procainamide, hydralazine, reserpine, and methyldopa (775). Other drugs such as penicillin, dantrolene, minoxidil, and practolol produce pericardial reactions by non-lupus mechanisms (776).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Definition, Prevalence, and Utility of Diastolic Function

In 2001, the exact definition and prevalence of diastolic heart failure are controversial, as well as the appreciation of its importance in clinical practice. A good working definition of diastolic dysfunction has been proposed by the European Working Group (30), but modification of this definition has been proposed by other investigators and will likely continue to evolve (31,32,250).

The exact prevalence of diastolic function is still debatable (31,250,777). The prevalence of diastolic function has varied widely from 13% to 74% (250). The reasons for this heterogeneity include variability in the criteria, duration and chronicity of congestive heart failure, the effect of age, the presence of coronary artery disease, selection bias in obtaining the patients, the type of imaging modality, the variables for assessing systolic performance, and the timing of the study (250). Despite this variability, it is the authors’ opinion that in a tertiary referral practice, elderly patients with hypertension and coronary disease commonly have diastolic heart failure, in keeping with the estimated 40% prevalence. A large population-based study (Cardiovascular Health Study) in older patients (66 to 103 years) found a prevalence of 55% of patients with heart failure and normal systolic function, and a total of 80% with normal or mildly reduced systolic function, especially in women (778).

Furthermore, the prognosis of patients with diastolic dysfunction is uncertain. The annual mortality was reported to vary from 1.3% to 17.5% (250). A worse prognosis is associated with older patients, men, coronary artery disease, and valvular heart disease (250). Relatively recent work in elderly patients (50% greater than 80 years age) with heart failure from Olmstead County showed similar poor prognosis in patients with normal (greater than or equal to 50%) or reduced systolic function. Despite the variability of these studies, the mortality of patients with diastolic dysfunction is generally lower than in patients with systolic dysfunction, with an annual mortality of 15% to 20% (24). It is the authors’ opinion that it is important to recognize an episode of diastolic heart failure so that early detection of underlying causes and treatments can be initiated.

The newer noninvasive tools to diagnose diastolic function including TDE and color M-mode Doppler are less load dependent than mitral inflow and pulmonary vein flow and have now been increasingly validated by hemodynamic standards. They may be useful especially in patients with isolated diastolic dysfunction, because they are more closely associated with myocardial relaxation. This will permit these techniques to be included into consensus and guideline papers in the measurement and reporting of diastolic dysfunction. The goal of determining diastolic function and estimating cardiac filling pressures in patients with depressed and normal systolic function by means of a comprehensive echocardiographic evaluation can be achieved for most patients (Fig. 26.12).

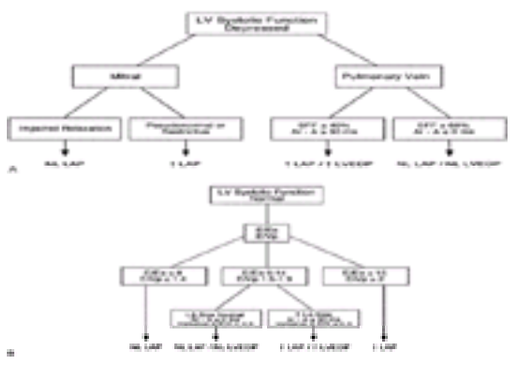


FIGURE 26.12 A: An algorithm for assessment of left atrial pressure and left ventricular end diastolic pressure (LVEDP) in patients with depressed LV systolic function. Ar-A, difference in duration of the atrial reversal wave (pulmonary vein) and of the atrial wave of mitral inflow; NL LAP, normal left atrial pressure; SFF, systolic filling fraction; ↑ LAP, increased left atrial pressure. **B:** Algorithm for estimation of LAP and LVEDP in individuals with normal LV systolic function using the new indices of diastolic function, mitral inflow E velocity (E), pulmonary vein velocity and left atrial size. Ea, early diastolic velocity at the mitral annulus; Vp, flow propagation velocity.

(Adapted from Nagueh SF, Zoghbi WA. Clinical assessment of LV diastolic filling by Doppler echocardiography. *ACC Curr J Rev* 2001;10:45–49.)

Treatment of Diastolic Function and the Need for Clinical Trials

The treatment of patients with diastolic heart failure is also controversial and limited to small studies (250). In fact, there have been no published clinical trials of patients with diastolic heart failure; thus the treatment is highly empiric. It is not generally appreciated that Doppler echocardiography may be useful in guiding medical therapy depending on the filling pattern, LV dimensions, and etiology of diastolic function (15).

There are ongoing studies to evaluate the role of new therapies including angiotensin receptor blockers, beta-blockers, including carvedilol and nitric oxide donors in patients with diastolic heart failure (104). These studies will evaluate not just the hemodynamic, biochemical, and histologic effects on the myocardium, but also exercise capacity and prognosis (246,779). Recent studies have targeted the direct cellular mechanisms leading to diastolic dysfunction. Animal experiments have shown that diastolic function can be improved in senescent rat hearts through adenoviral gene transfer of sarcoplasmic reticulum Ca^{2+} ATPase protein (SERCA 2a) (780) and through the use of the advanced glycation end-product cross-link breaker (ALT-711) in older dogs (781).

Controversies in Restrictive Cardiomyopathy and Constrictive Pericarditis

In 2001, the classification of restrictive cardiomyopathy still remains a controversial issue (see previous discussion) (269). The exact definition of restrictive cardiomyopathy has evolved over time and is not uniformly accepted by clinicians (255,256,257,258 and 259). Furthermore, there is still confusion about separating restrictive cardiomyopathy with diastolic heart failure from other cardiac diseases that manifest diastolic heart failure and restrictive hemodynamics (dip and plateau physiology) such as dilated cardiomyopathy with restrictive hemodynamics (263). The WHO/ISFC 1995 classification allays some of the confusion and preserves the old clinical entities of dilated, hypertrophic restrictive cardiomyopathies, and arrhythmogenic RV cardiomyopathy, but now considers the dominant pathophysiology or pathologic factors (254). Now, restrictive cardiomyopathy can be either idiopathic (which is rare) or more commonly be associated with an etiology (i.e., amyloidosis). Using this approach, restrictive cardiomyopathy is a disease within a large group of disorders which manifest diastolic heart failure.

There is also controversy about whether restrictive hemodynamics should be considered as a mandatory part of the disorder, as dictated by the 1995 WHO/ISFC classification (254). For example, as mentioned previously, cardiac amyloidosis may have an early (not restrictive) and advanced stage (restrictive) pattern (275). Similarly, hemochromatosis may present as a dilated cardiomyopathy in the majority of cases, and as a restrictive cardiomyopathy in others (439). It is the authors' opinion that a definite diagnosis of restrictive cardiomyopathy should show restrictive filling in a nondilated, nonhypertrophied ventricle with near-normal systolic function and dilated atria.

Differentiation of Restrictive Cardiomyopathy from Constrictive Pericarditis

Distinguishing restrictive cardiomyopathy from constriction is still an important clinical problem (119,166,269,272). The importance of this distinction is that in restrictive cardiomyopathy, the disease is often treated medically and has a poor prognosis, whereas in constriction, the disease is treated with surgery and usually has a good prognosis (269). Furthermore, to highlight the importance of this differentiation, making the wrong diagnosis in sending a patient with restrictive cardiomyopathy for pericardial stripping is totally unacceptable and dangerous. Since the 1970s, there have been countless diagnostic tests that have been used to differentiate these two similar conditions (166,261). It is the authors' opinion that no single test is perfectly reliable in making the distinction, and good clinical judgment and a stepwise approach should be used (119). The history and physical examination often provide clues to the diagnosis but by no means are definitive. The history of a systemic disorder such as amyloidosis may favor restriction, whereas a history of idiopathic pericarditis or previous cardiac surgery may favor constriction. On the other hand, a history of radiation may show evidence of both constriction and restriction (119,269). It is also the authors' opinion that the noninvasive workup is most important in distinguishing restriction from constriction (15). In most patients, diastolic functional abnormalities can be adequately characterized using noninvasive modalities such as transthoracic echo, transesophageal echo with respirometry, and MRI (119). Furthermore, they have added new information regarding the actual structure and physiologic function of the myocardium and pericardium. MRI may be better suited to demonstrate the abnormal pericardial thickness, whereas echocardiography may show the physiologic abnormalities including interventricular dependence, limited filling, and dissociation between intrathoracic and intracardiac pressures. As with most tests, there may be some overlap (584); other noninvasive tools have also emerged such as color M-mode and tissue Doppler imaging to help distinguish these disorders (121). Finally, endomyocardial biopsy may be necessary for cases in which other modalities are inconclusive or ambiguous (295).

THE FUTURE

There will be further recognition of the importance of diastolic function and the prevalence of diastolic heart failure, especially in the elderly. Future refinements in the noninvasive modalities will aid the consistent diagnosis of patients with diastolic dysfunction and elevated filling pressures, thus allowing for more uniform criteria for organization of large clinical trials. A diastolic stress test may be used as part of the assessment of patients with exertional dyspnea. There will be greater use of these newer modalities as part of the treatment algorithms for patients with diastolic dysfunction. There may be specific targeted therapies derived from the cellular, biochemical, neurohormonal, and physiologic mechanisms in these patients. There will be ongoing refinements in the differentiation of constrictive pericarditis and restriction. The genetic framework for all restrictive cardiomyopathies will aid in the assessment, prognosis, and treatment of these patients.

OVERVIEW

Pulmonary arterial hypertension causes an increased pressure load on the right ventricle (RV) that subsequently results in the normal adaptive response of hypertrophy and dilation. Right ventricular failure occurs when the ventricle is unable to respond further to the hemodynamic burden (1). *Cor pulmonale* is defined as right ventricular hypertrophy, dilation, and dysfunction as a result of pulmonary hypertension secondary to a variety of chronic lung diseases (Table 27.1). Pulmonary hypertension may also develop in the absence of cardiac or pulmonary parenchymal disease.

TABLE 27.1 PULMONARY HYPERTENSION: NOMENCLATURE AND CLASSIFICATION

HISTORICAL PERSPECTIVE

In 1852, Beutner recorded the pulmonary artery pressure in dogs during open thoracotomy and demonstrated that the pulmonary artery pressure was considerably lower than that in the systemic circulation (2). Similar observations were made in the horse by Chauvau in 1856 (2). Measurement of the pulmonary artery pressure in humans was ultimately accomplished with the development of right atrial catheterization by Cournand and Ranges in 1941 (3), followed by pulmonary artery catheterization in 1946 by Bloomfield and colleagues (4). In 1953, Fowler and associates (5) found that the pulmonary artery systolic pressure in healthy individuals ranged from 11 to 29 mm Hg, the diastolic pressure from 4 to 13 mm Hg, and the mean pulmonary artery pressure from 8 to 19 mm Hg. These developments, followed by the widespread use of the pulmonary artery catheter (6), led to enhanced understanding of the pulmonary circulation in chronic lung disease and in primary pulmonary vascular disorders.

Because of the diverse causes of pulmonary hypertension and cor pulmonale, the historical perspective is complex. Fishman (1) outlined the state-of-the-art approach to cor pulmonale in 1976 after years of research dedicated to the understanding of the pulmonary circulation. Investigations into the pathophysiology of cor pulmonale have, to a significant extent, involved the influence of hypoxemia or pharmacologic agents on the pulmonary circulation in chronic lung disease (7,8,9,10,11 and 12). Fishman (13) also described in detail the history of research efforts in patients with pulmonary hypertension, particularly primary pulmonary hypertension (PPH) as it has evolved since the beginning of the twentieth century. Syphilitic arteritis had frequently been invoked as the cause of pulmonary hypertensive disorders. Interest in determining the cause of “Ayerza’s disease” ultimately led to the conclusion that most of these cases were secondary pulmonary hypertension caused by either congenital or acquired heart disease or by chronic obstructive pulmonary disease (COPD) (14). Significant contributions by Motley et al. (11), as well as by von Euler and Liljestrand (12), led to further studies that involved the hypoxic pressor response and pulmonary vasomotor reactivity. Experimental studies by Dresdale et al. (14) evaluating tolazoline, and by Harris (15) and Wood (16) with acetylcholine, led to the ultimate concept that vasodilator therapy was effective in some patients with PPH. In the late 1960s, a pulmonary hypertension epidemic occurred in Switzerland, Germany, and Austria and was attributed to aminorex, an over-the-counter diet pill (17).

In 1973, prompted in part by this epidemic, the World Health Organization (WHO) assembled a working group to assess the current understanding of PPH. The knowledge base for this disease was rather limited at that time, but this effort resulted in the initial pathologic classification of PPH (18). In 1998, on the 25-year anniversary of the original WHO meeting, the World Symposium on PPH, cosponsored by the WHO, was held in Evian, France (19). Substantial progress had been

made since the prior meeting. One of the significant outcomes of this most recent symposium was to propose a new, more clinically useful classification system for pulmonary hypertension. Over recent years, a number of therapeutic vasodilator agents have been investigated, with the hope that selective pulmonary arterial vasodilation could be achieved. The advent of prostacyclin therapy appears to have come the closest to accomplishing this goal. The importance of vascular remodeling in addition to vasoconstriction has been realized. Lung transplantation has become the final therapeutic step for PPH.

INCIDENCE AND RISK FACTORS

Right ventricular failure is an important predictor of increased mortality in patients with chronic lung disease. It commonly occurs in individuals with COPD, which causes an estimated 70,000 deaths each year in the United States (20). A study of patients with COPD found that 40% had evidence of cor pulmonale at autopsy (1). Furthermore, in the National Institutes of Health (NIH) Primary Pulmonary Hypertension National Registry, mortality was found to correlate best with indices of right ventricular hemodynamic function (21). Cor pulmonale is also associated with increased morbidity in patients with chronic lung disease leading to reduced exercise tolerance, increased sensation of dyspnea, and reduced functional status (22). Other causes of cor pulmonale are less common. The incidence of PPH is estimated to be one to two cases per million in the general population (21). Pulmonary vascular disease that is clinically and pathologically indistinguishable from PPH can occur in association with human immunodeficiency virus infection, portal hypertension, cocaine inhalation, monocrotaline (a compound from the plant *Crotalaria* that is found in bush tea), and drugs, including appetite suppressants and chemotherapeutic agents (23,24,25,26 and 27). In the 1960s, the anorexigenic agent aminorex was found to be associated with an increased risk of pulmonary hypertension (28). Use of the appetite suppressants fenfluramine and dexfenfluramine has been found to be associated with an increased risk of pulmonary hypertension (odds ratio 6.3) (27). This risk increased to an odds ratio of greater than 20 when the drugs were taken for more than 3 months, independent of body mass index. Other entities such as progressive systemic sclerosis and CREST (*c*alcification, *R*aynaud's, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasis) may present with progressive, severe pulmonary hypertension, often without associated parenchymal lung disease.

GENETICS OF PRIMARY PULMONARY HYPERTENSION

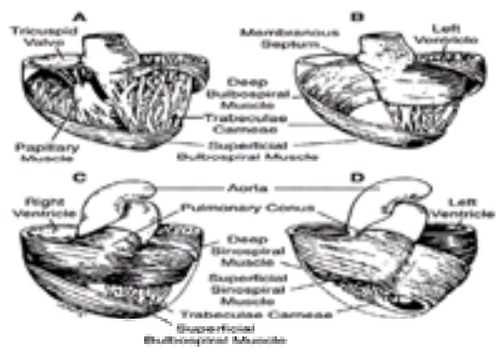
The genetics of PPH are becoming unraveled. Approximately 6% of patients with PPH have the familial variety. This disease is transmitted in the autosomal dominant manner with a risk of clinical expression of approximately 10% to 20% and demonstrates genetic anticipation. Studies of genetic linkage revealed that the locus for familial PPH is on chromosome 2q31–32. The known genes in this region have been surveyed for biologically plausible candidates. The results of a detailed genetic study of a large kindred of familial PPH patients has now provided additional information (28a). The gene that is associated with a unique member of the transforming growth factor-b (TGF-b) receptor family, known as *bone morphogenetic protein receptor II* (BMPR2), appears to be a likely candidate. Investigators have detected a missense mutation that involves a substitution of guanine for thymine at position 354 of *BMPR2*. This mutation was located in exon 3 of the gene and was present in all of the affected family members. More recently, it was discovered that the sporadic form of PPH is also associated with germline mutations of *BMPR2* (28b).

Bone morphogenetic proteins were previously identified as cellular products found in normal bone that promote ectopic bone formation and healing of fractures. Members of the TGF-b receptor superfamily of circulating proteins regulate growth and repair of tissue in all organs (28c,28d). Bone morphogenetic proteins exert their effects through the activation of receptors I and II, which are expressed adjacent to each other on cell surfaces and transduce intracellular signaling. The effect of activation of these receptors depends on the cell type and the circumstances and can result in either promotion or inhibition of growth. It appears that clinical PPH develops in only 10% to 20% of carriers of BMPR2 mutations; it has been speculated that gene modifiers, such as environmental factors, estrogens, or other mutations in unknown regulatory genes, may be required for clinical expression of the disease (28a). It may be that the normal function of bone morphogenetic receptor protein II in the pulmonary vasculature is antiproliferative. Based on these genetic discoveries, genetic testing and counseling will become increasingly important for PPH patients and their families.

PATHOPHYSIOLOGY

Normal Right Ventricular Anatomy and Function

The RV can be divided into an inflow tract, consisting of the tricuspid valve, papillary muscles, chordae tendineae, and trabeculated myocardium, and an outflow tract, consisting of the infundibulum (eFig. 27.0.1). It has a pyramidal geometric configuration, with the inflow region constituting the triangular base and the three sides composed by the interventricular septum and the anterior and the posterior aspects of the free wall. The thin free wall of the RV anchors anteriorly and posteriorly to the interventricular septum, which bulges into the RV cavity. Thus, on a cross-sectional view, the RV has a crescentic shape. It is this configuration and its thin wall that make the RV highly compliant and able to accommodate large volumes and filling pressures (20,29). Under normal circumstances, the pulmonary vasculature is a low-pressure system, thus providing low vascular resistance to right ventricular outflow (30). The pulmonary vascular bed is also able to accommodate large increases in blood flow without much change in pressure, preventing pressure overload of the RV. Cardiac output can increase substantially during exercise in normal individuals, with increases of up to fivefold in pulmonary blood flow (31,32). Recruitment of vessels in the poorly perfused upper lung and distention of the compliant vessels in the dependent areas appear to be the major mechanisms involved in accommodating increases in cardiac output and pulmonary blood flow (1,33). With the development of pulmonary disease, alterations in the pulmonary vasculature develop, often leading to pulmonary arterial hypertension and right ventricular pressure overload. The mechanisms that lead to the development of pulmonary arterial hypertension are complex and not completely understood.



***e*FIGURE 27.0.1** Spiraling muscle fibers are shown **(A–D)** that enclose both ventricles and help the two contract in synchrony. (From Rushmer RF. *Cardiovascular dynamics*. Philadelphia: WB Saunders, 1970, with permission.)

Mechanisms of Pulmonary Hypertension

Vascular Bed Destruction or Obliteration

Destruction or obliteration of the pulmonary vascular bed appears to account for some of the increase in pulmonary artery pressure as pulmonary disease develops. Nonetheless, the extent of pulmonary disease, as in COPD, does not correlate with the degree of pulmonary hypertension (34). In addition, in the absence of significant underlying lung disease, pulmonary artery pressure and pulmonary vascular resistance (PVR) remain normal after pneumonectomy (1), although right ventricular ejection fraction (RVEF) at rest can be significantly decreased up to 3 weeks postoperatively. Right ventricular dysfunction during exercise also occurs with increases in right ventricular end diastolic volume, pulmonary artery pressure, and PVR (35). Significant elevation in mean pulmonary arterial pressure develops only after one-half to two-thirds of the pulmonary vascular bed is occluded experimentally (36,37). Therefore, vascular bed obliteration does not appear to be a major mechanism in the development of pulmonary hypertension and cor pulmonale.

Hypoxic Pulmonary Vasoconstriction

Alveolar hypoxia is a major contributor to the development of pulmonary hypertension. In 1947, Motley and associates (11) found in five human subjects that breathing 10% oxygen for 10 minutes caused increases in pulmonary artery pressure with a concomitant decrease in cardiac output as determined by the Fick method. This was subsequently confirmed, in 1952, by Fishman and colleagues (7) in the steady state, despite the finding that the application of the Fick principle by Motley and associates was found to be erroneous. Hypoxic pulmonary vasoconstriction involving small arteries and arterioles is thought to be a defense mechanism that determines local ventilation-perfusion ($\dot{V}/\dot{Q}$) relationships, as first suggested by von Euler and Liljestrand (12) in 1946. It is unclear, however, if the vasoconstriction is due specifically to the hypoxia or whether it is caused by vasoactive mediators, including prostaglandins, endothelin, bradykinin, acetylcholine, angiotensin,

catecholamines, histamine, or serotonin, which lead to calcium influx (30).

In recent years, advances have been made in understanding the regulation of pulmonary vascular tone with the discovery of nitric oxide (NO). Endothelium-derived relaxation factor, discovered in 1980 (38), is produced by endothelial cells in a constitutive manner from arginine and is now identified as NO (39) or a nitroso compound that ultimately releases NO (40). NO synthase produces NO and citrulline from L-arginine, and the endothelial form of this enzyme depends on calcium and calmodulin to regulate NO production in a constitutive manner (41,42 and 43). Endothelium-dependent relaxation has been found in isolated pulmonary arteries from most mammalian species, including humans (44,45,46,47 and 48). Studies have demonstrated that inhibition of NO production by L-arginine analogs markedly enhances the pulmonary pressor response to acute hypoxic challenges, which demonstrates the role that NO has in regulating pulmonary vascular tone at rest and during acute hypoxia (49,50,51,52 and 53). In addition, impaired NO production or release by endothelial cells, or both, is seen in chronic hypoxic vasoconstriction (54,55 and 56). A number of mediators cause calcium influxes into vascular smooth muscle cells, activating the endothelial constitutive NO synthase (43). Impairment of NO production allows for excessive vasoconstriction and reduces the ability of the pulmonary vasculature to relax.

Chronic vasoconstriction eventually leads to structural changes in the walls of the pulmonary vasculature. Changes in the vasculature begin to appear even 1 hour after the onset of hypoxia in experimental models (57). Although the mechanisms that lead to these changes are not fully understood, lack of NO production may allow mitogenesis and proliferation of cells within the vessel walls (55). The changes in the pulmonary vasculature include increases in the percentage of vessels with a muscular layer due to proliferation of vascular smooth muscle cells, medial hypertrophy, and eccentric intimal fibrosis (58). These changes may also allow for increased platelet aggregation and development of thrombi, causing further increases in PVR (58,59). As a result, the cross-sectional area of the pulmonary vasculature decreases, and pulmonary arterial hypertension is irreversible (30).

Myocardial Blood Flow

Inadequate blood supply to the RV may also contribute to the development of right ventricular failure. The RV responds to chronic increases in PVR with dilation and hypertrophy. With increases in muscle mass, oxygen demands increase (60,61). Oxygen also demands an increase in the LV with the development of systolic hypertension. Nonetheless, left ventricular coronary perfusion pressures are maintained or even increased because of increased diastolic pressures (60,62). Unlike the case with the LV, the perfusion (diastolic) pressure of the right coronary artery is unchanged or reduced when oxygen demands increase because right ventricular cardiac output remains unchanged or is diminished (62). In addition, the systolic component of right ventricular coronary blood flow is reduced due to the increase in chamber pressure that occurs with dilation of the RV (63).

The relationship between right coronary blood flow and right ventricular performance was studied in experimental animal models by Brooks et al. (37,64). Pigs were subjected to increases in pulmonary artery pressure by pulmonary artery occlusion. Right ventricular failure and shock developed at or above a pulmonary artery pressure of approximately 70 mm Hg. Hemodynamic collapse occurred at a lower pulmonary artery pressure when the right coronary was occluded. With reinstitution of coronary blood flow by a coronary artery perfusion pump, the RV could be resuscitated despite maintenance of high pulmonary artery pressures (37) (Fig. 27.1). This would also explain the findings that right ventricular failure and hemodynamic compromise are more likely to develop in patients with coronary artery disease in the setting of pulmonary embolism.

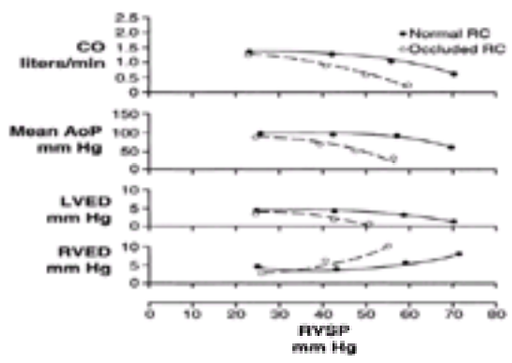


FIGURE 27.1 Effect of increasing right ventricular systolic pressure (RVSP) on cardiac output (CO), aortic pressure (AoP), left ventricular end diastolic pressure (LVED), and right ventricular end diastolic pressure (RVED). Solid lines join points with an intact right coronary artery (RC). Decompensation occurs at a much lower level of RVSP, with an occluded compared with intact RC. (From Brooks H, Kirk G, Vokonas P, et al. Performance of the right ventricle under stress: relation to right coronary flow. *J Clin Invest* 1971;50:2176–2182, with permission.)

Afterload and Preload

Increasing PVR increases afterload for the RV. By increasing preload and dilating, right ventricular function can improve via the Frank-Starling mechanism with increased cardiac output (29,65). Myocardial wall hypertrophy allows for reduction in wall stress and maintains adequate stroke volume. Spann and colleagues (66) showed that cardiac output and stroke volume were not different in cats who had pulmonary artery banding for 30 days compared with the normal control subjects. Nonetheless, right ventricular end diastolic volume and weight were significantly increased; in addition, contractile performance of the intact ventricles and isolated papillary muscles was reduced (66). Thus, normal hemodynamics were maintained by compensatory dilation and hypertrophy.

Severe right ventricular hypertrophy resulting from pulmonary hypertension. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Chronic Obstructive Lung Disease and Interstitial Lung Disease

COPD and interstitial lung disease (ILD) are common causes of pulmonary parenchymal disease. In the United States, COPD is the most common pulmonary disease that results in right ventricular dysfunction, and it is a factor that adversely affects survival (1,30). In 1966, a Veterans Administration cooperative trial found that patients with cor pulmonale had a 4-year mortality of 73% (67). These findings were reproduced by Lindsay and Read in 1972 (68), as well as by Traver and colleagues in 1979 (69).

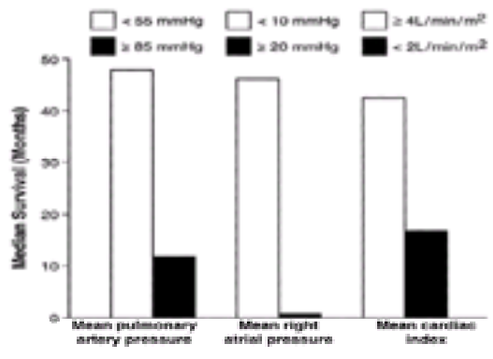
Assessment of right ventricular systolic function is commonly done in patients with pulmonary disease by measuring the RVEF. Despite the variability of RVEF in patients with COPD, it has been shown that those with clinically evident cor pulmonale consistently have a reduced RVEF (70). In addition, patients without clinical cor pulmonale, but with a depressed RVEF, have severe obstructive ventilatory defects. In COPD patients with a history of cor pulmonale and elevated pulmonary artery pressure, the latter measure is inversely related to arterial oxygen tension, and increased PVR has been found to correlate with mortality (71). Therefore, it appears that increased right ventricular afterload leads to a depressed RVEF. Nonetheless, when right ventricular contractility was measured with load-independent methods, it did *not* appear to correlate with RVEF (72). Thus, RVEF may be a poor indicator of intrinsic contractility, although it is usually depressed in the setting of pulmonary artery hypertension.

The ILDs are disorders that cause thickening and fibrosis of the alveolar walls, resulting in disruption of the alveolar-capillary unit. The majority of these is of unknown etiology. The fibrosis can entrap segments of the pulmonary vasculature, compressing the vessels and subsequently leading to thrombosis and fibrous organization of the vessels with complete obliteration of some areas of the vasculature (73). This leads to hypoxemia from diffusion impairment and $\dot{V}/\dot{Q}$ mismatching. Patients with ILD die from respiratory failure or right ventricular failure. Initially, hyperventilation at rest allows for normal oxygenation, and desaturation occurs during exercise. As the disease progresses, oxygen consumption increases as the work of breathing increases, leading to hypoxemia at rest (1,30). Eventually, pulmonary artery hypertension develops that correlates with the degree of hypoxemia. The pulmonary artery pressure is moderately elevated in such patients until late in the disease. Again, as in their counterparts with COPD, pulmonary artery pressures are important predictors of survival (74). Sarcoidosis may result in significant parenchymal disease with hypoxemia and pulmonary hypertension. Alternatively, the predominant abnormality may appear to be intrinsic to the vasculature or due to compression/tethering of the vessels. Pulmonary hypertension may also result from left ventricular dysfunction in sarcoidosis.

Pulmonary Arterial Hypertension

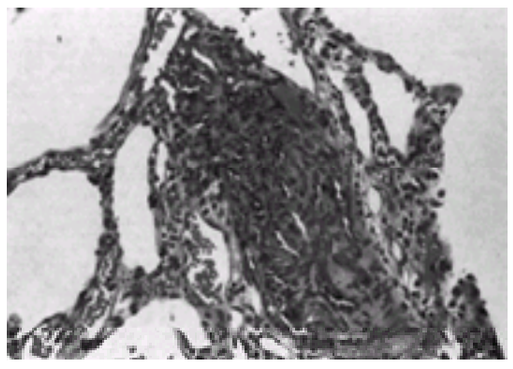
In 1998, on the 25-year anniversary of the original WHO meeting, the World Symposium on PPH, cosponsored by the WHO, was held in Evian, France (19). Substantial progress had been made since the prior meeting. One of the significant outcomes of this symposium was to propose a new, more clinically useful classification system for pulmonary hypertension. Traditionally, pulmonary hypertension has been classified as being either “primary” or “secondary.” Although PPH is relatively rare, secondary pulmonary hypertension is distinctly more common and includes a heterogeneous group of diseases. A consensus was reached at the 1998 symposium to develop a more inclusive and clinically useful classification system (Table 27.1). An important result was to emphasize the significance of the entity of pulmonary *arterial* hypertension. The latter indicates that the disease is a pulmonary *vascular* process caused by direct involvement of the pulmonary arteries.

PPH is a clinical condition characterized by an unexplained persistent elevation of pulmonary artery pressures. The criteria for the diagnosis established by the NIH PPH Registry include a mean pulmonary artery pressure of greater than 25 mm Hg at rest or 30 mm Hg or greater with exercise and the exclusion of any known cause of pulmonary hypertension, including left-sided cardiac valvular disease, myocardial disease, congenital heart disease, and clinically important pulmonary, connective tissue, or thromboembolic disease. According to this registry, the median survival of 187 patients was estimated at 2.8 years and was independent of age, sex, age at onset of symptoms, symptom duration, or family history of PPH (21). The hemodynamic profiles of these patients demonstrated an average mean pulmonary artery pressure of 60 mm Hg, and those with worse functional class had higher pulmonary artery pressures. The abnormalities in pulmonary hemodynamics persist over time, leading to decline in cardiac output and increase in PVR. Very high correlations with mortality were obtained for the independent variables of pulmonary artery pressure, right atrial pressure, and cardiac index as determined by catheterization (eFig. 27.1.1). Additional studies have shown a correlation between mixed venous oxygen saturation, functional class, exercise tolerance, and response to vasodilators (75,76,77,78 and 79). Patients with PPH die primarily of right ventricular failure or, less commonly, of sudden death. It is unusual for patients who are clinically stable, and who have early New York Heart Association class III or milder symptoms, to die unexpectedly.

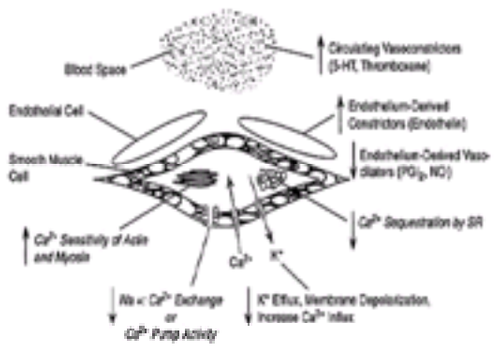


***e*FIGURE 27.1.1** Median survival in months for patients with primary pulmonary hypertension compared with three hemodynamic variables. It is likely that long-term mortality in patients fitting one or more of these categories is significantly improved on continuous intravenous prostacyclin. (From D’Alonzo GE, Barst RJ, Ayres SM, et al. Survival in patients with primary pulmonary hypertension. *Ann Intern Med* 1991;115:343–349, with permission.)

The pathology of PPH is not unique to this disease entity. It includes medial hypertrophy of the pulmonary arteries, intimal hyperplasia, muscularized pulmonary arterioles, thrombotic microangiopathy, and plexiform lesions (eFig. 27.1.2). Increased PVR is thought to occur as a result of a combination of vasoconstriction, vascular wall remodeling, and *in situ* thrombosis (58). Sustained vasoconstriction may be due to several mechanisms that can lead to altered vasoreactivity (eFig. 27.1.3). The proposed mechanisms include an imbalance in the production of specific vasodilators, such as prostacyclin, endothelium-derived relaxation factor or NO, and vasoconstrictors, such as thromboxane, endothelin, or serotonin (55,58,80,81). Another mechanism that has been considered includes impaired smooth muscle relaxation as a primary event or secondary to endothelial cell injury (58). Nonetheless, the lack of supportive data makes this hypothesis less likely. Finally, alterations that are present in potassium ion channels may lead to calcium influx causing smooth muscle contraction (82).



***e*FIGURE 27.1.2** A plexiform lesion in primary pulmonary hypertension. Experimental evidence suggests that these abnormalities arise from repair, recanalization, and formation of small collateral channels that may originate or be predominantly from the bronchial circulation.



***e*FIGURE 27.1.3** Mechanisms that might increase pulmonary vascular tone. 5-HT, serotonin; NO, nitric oxide; PGI_2, prostacyclin. (Modified from Voelkel NF, Tuder RM, Weir EK. Pathophysiology of primary pulmonary hypertension: from physiology to molecular mechanisms. In: Rubin LJ, Rich S, eds. *Primary pulmonary hypertension.* New York: Marcel Dekker Inc, 1997:83–133, with permission.)

A thrombophilic state that contributes to the formation of microthrombi may contribute to the development of PPH. Abnormalities in the coagulation system, such as abnormal fibrinolysis or von Willebrand's factor production, have been found in some PPH patients (83,84,85 and 86). Microthrombi are frequently noted in advanced vascular lesions of patients with PPH, making this finding difficult to categorize as a cause or a secondary event in the disease process (87).

Smooth muscle migration and proliferation can be a consequence of the increased production, increased availability or upregulation of receptors, or increased production of growth factors (88). Growth factors, such as TGF-b, basic fibroblastic growth factor, platelet-derived growth factor, and insulin-like growth factor-1, have been implicated (89,90 and 91). These growth factors, in turn, can lead to increased levels of extracellular matrix proteins, such as thrombospondin, tropoelastin, and fibronectin, which have been found in patients with PPH (92). The increased levels of extracellular matrix proteins can also be due to increased proteolytic activity (93).

In a distinct minority of patients with pulmonary hypertension, the vascular lesions involve predominantly the pulmonary veins with occlusive intimal lesions. This disorder has been termed *pulmonary venoocclusive disease* and mimics classic PPH in many respects (94). The pathologic diagnosis is based on the presence of obstructive, eccentric, fibrous intimal lesions and sinusoidal channels that fill long segments of the pulmonary vein and venule lumina. Arterialization of pulmonary veins may occur, with the development of a distinct medial muscle coat bounded by internal and external laminae. Because of pulmonary venous flow obstruction, the alveolar capillaries are markedly congested, the interstitial space is edematous, and the lymphatics are dilated. This may lead to interstitial and alveolar hemorrhage.

Chronic Thromboembolic Pulmonary Hypertension

In normal patients without prior cardiopulmonary disease, acute pulmonary vascular obstruction results in an increase in PVR, pulmonary artery pressure, and right ventricular work (30). The degree of afterload increase is related to the degree of obstruction of the vascular bed, as well as the degree of vasoconstriction apparently due to vasoactive substances released from the thrombus. When previously healthy patients with pulmonary embolism were studied angiographically and hemodynamically, an increase in mean pulmonary artery pressure was found in 14 of 20 patients (95).

Patients with obstruction of greater than 25% of the vascular bed had increases in pulmonary artery pressures. Nonetheless, the mean pulmonary artery pressure did not exceed 40 mm Hg, even in patients with greater than 50% occlusion of the vascular bed. Therefore, a mean pulmonary artery pressure of greater than 40 mm Hg is rarely generated acutely by the previously normal, thin-walled RV. The RV dilates and increases its filling pressure, and there is a linear correlation between right atrial pressure (and pulmonary artery pressure) and the degree of obstruction by angiography (95). Patients with acute pulmonary embolism and mean pulmonary artery pressure greater than 40 mm Hg nearly always have prior cardiopulmonary disease (96). In such patients, less obstruction is required to increase the pulmonary artery pressure. In patients with right ventricular hypertrophy, however, no correlation is seen between the extent of obstruction and the elevation in pulmonary artery pressure (95). On the other hand, right atrial and pulmonary artery pressures correlate closely, indicating that the RV still makes use of its preload reserve in the setting of increased afterload (30).

Pulmonary Hypertension and Normal Lung Parenchyma

A number of entities can result in pulmonary hypertension in the absence of structural cardiac disease and with normal lung parenchyma. These include sleep apnea, chronic alveolar hypoventilation, high-altitude sickness, and neuromuscular disease. Chest wall and neuromuscular disease as well as sleep apnea are briefly discussed, offering some potential explanations for the resulting pulmonary hypertension.

Thoracic Cage Deformities and Neuromuscular Disease

Neuromuscular diseases, including muscular dystrophy, amyotrophic lateral sclerosis, postpolio syndrome, and numerous others, can result in respiratory failure, hypoxemia, and, occasionally, pulmonary hypertension (97), as may thoracic cage deformities including severe kyphoscoliosis. The management of hypoventilation in neuromuscular and chest wall disorders is based on the premise that preventing further reductions in alveolar ventilation during sleep will result in an improvement in nocturnal and subsequently daytime arterial blood gases, a reduction in pulmonary hypertension and cor pulmonale, and the prevention of premature death. Patients who have been previously disabled by profound dyspnea, sleep fragmentation, cor pulmonale, and unstable respiratory failure have in many instances returned to full-time activities.

Hypoventilation and Sleep Apnea

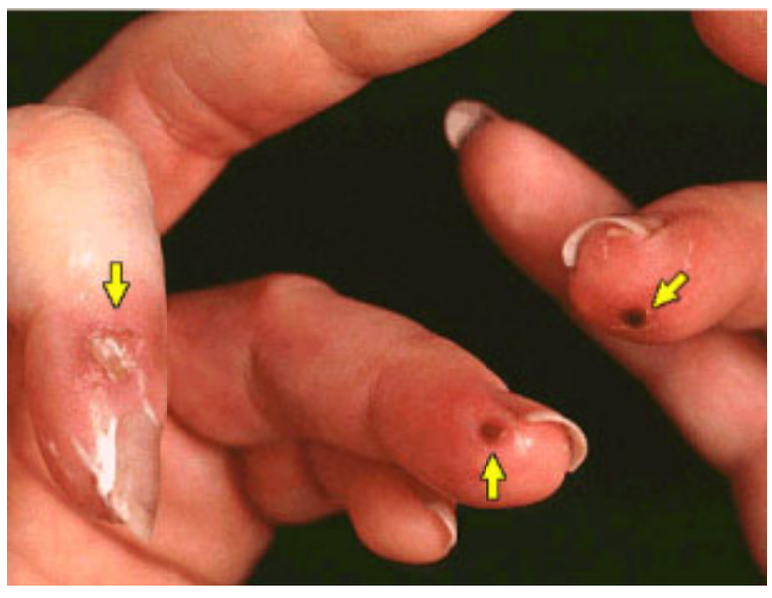
Sleep apnea may lead to the development of pulmonary hypertension and right ventricular failure (98). In obstructive sleep apnea, airflow ceases as a result of complete occlusion of the upper airway despite continued activity of the inspiratory muscles. In central sleep apnea, airflow ceases because there is transient loss of central drive to the respiratory muscles. Most individuals with sleep apnea have a mixed obstructive and central picture. Obstructive apneas are often accompanied by intermittent elevations in pulmonary artery pressure above the baseline level that occur during wakefulness. The maximum increase in pulmonary artery pressure occurs at, or shortly after, the onset of arousal and ventilation, which usually coincides with the maximum extent of arterial oxyhemoglobin desaturation. Supplemental oxygen markedly attenuates but does not abolish these increases in pulmonary artery pressure. Hypoxia-induced pulmonary vasoconstriction certainly plays a role in the pathogenesis of these elevations in pulmonary artery pressure, but it is probably not the only contributing factor. Hypercapnia and acidosis can also induce pulmonary vasoconstriction, leading to elevations in pulmonary artery pressure (1). Thus, it is not surprising that elevations in pulmonary artery pressure are not completely abolished by supplemental oxygen. Although a number of factors contribute to the development of chronic hypercapnia and cor pulmonale in patients with obstructive sleep apnea, reversal of the obstruction alone is sufficient in most cases to alleviate symptoms and reverse right ventricular failure.

CLINICAL PROFILE: EVALUATION OF THE PATIENT WITH PULMONARY HYPERTENSION

History and Physical Examination

Because the development of right ventricular failure and pulmonary hypertension in the patient with chronic pulmonary disease has important prognostic implications, it is important to assess for symptoms that can herald such development. One of the main difficulties is that, in general, symptoms tend to develop gradually. In the NIH PPH Registry, a period of 2 to 5 symptomatic years before diagnosis was documented (99). This is also true of other chronic lung diseases including COPD.

Dyspnea is commonly reported early in the pulmonary patient. With the development of hypoxemia and right ventricular failure, this symptom increases in severity and is uniformly present in nearly all patients. Chest pain is also common and can be difficult to distinguish from angina. Orthopnea is relatively common in patients with severe COPD, although it is not necessarily accompanied by worsening cardiac function. Orthopnea in these patients is believed to be related to hyperinflation of the lungs and the subsequent effects on ventricular function or reduction, or both, in venous return. Evidence of right ventricular dysfunction with increased venous and hepatic congestion can present with the development of early satiety, increasing lower extremity edema and fluid overload. Finally, in patients with PPH, Raynaud's phenomenon is common but also suggests the possibility of collagen-vascular disease. Presyncope and syncope are usually exertional in patients with severe pulmonary hypertension due to the inability to increase cardiac output in response to the increased demand.



Raynaud's disease. Ulcers and gangrene on the fingertips are shown (*arrows*) caused by vasospasm and abnormalities of digital vessels. Associated

cardiac findings are coronary vasospasm and primary pulmonary hypertension.

Certain physical findings may suggest pulmonary hypertension or cor pulmonale, independent of their cause. The presence of a loud and occasionally palpable pulmonic valve closure sound is a common finding in patients with pulmonary hypertension. A parasternal or epigastric lift may be present due to the hypertrophied RV. With progression to cor pulmonale, tricuspid valvular regurgitation develops as a result of dilation of the RV, which causes a prominent jugular V wave. Progressive signs of chronic right ventricular dilation and failure include pulmonic valve insufficiency, a right ventricular third heart sound, jugular venous distention, hepatojugular reflux, hepatomegaly, lower extremity edema, ascites, and eventually anasarca.

Patients with cor pulmonale and pulmonary hypertension due to COPD invariably have findings that are associated with their obstructive lung disease, including decreased breath sounds and hyperinflation. Individuals with cor pulmonale secondary to ILD often have dry crackles at the lung bases. Auscultation of the lungs in PPH and chronic thromboembolic pulmonary hypertension are generally unremarkable, although bruits may be evident over the peripheral lung in the latter group. Clubbing is a common finding in chronic pulmonary disorders, particularly pulmonary fibrosis, cystic fibrosis, and other bronchiectatic disorders. It is also very common in individuals with pulmonary hypertension due to congenital heart disease. Cyanosis, either peripheral or central, may be present in individuals with hypoxemia due to advanced cardiopulmonary disease. Other pertinent physical findings include those associated with collagen-vascular disease, such as telangiectasias, sclerodactyly, or calcinosis, and findings that might suggest alveolar hypoventilation, such as muscle weakness, kyphoscoliosis, and extreme obesity. Algorithms for determining the presence and the cause of pulmonary hypertension are presented (Fig. 27.2 and Fig. 27.3).

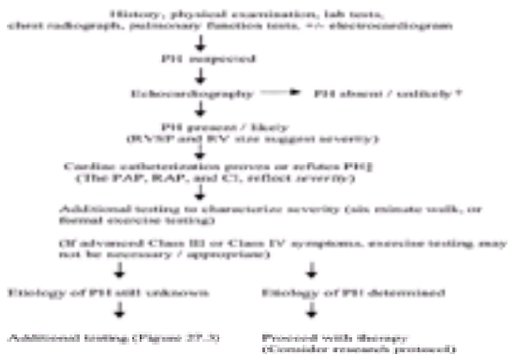


FIGURE 27.2 An approach to the diagnosis of primary pulmonary hypertension (PH). CI, cardiac index; PAP, pulmonary artery pressure; RAP, right atrial pressure; RV, right ventricle; RVSP, right ventricular systolic pressure. †The absence of perceived tricuspid insufficiency by echocardiography may not absolutely exclude PH. ‡Other tests may already have revealed potential etiology(ies) of PH. These tests may also strongly suggest the etiology. (From D'Alonzo GE, Dantzker DR. Diagnosing primary pulmonary hypertension. In: Rubin LJ, Rich S, eds. *Primary pulmonary hypertension.* New York: Marcel Dekker Inc, 1997:227–252, with permission.)

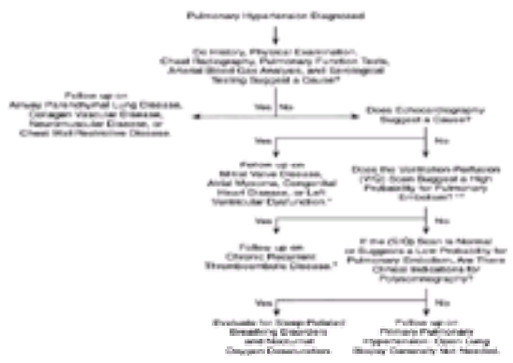

FIGURE 27.3 An approach to determining the cause of primary pulmonary hypertension. *Radionuclide ventriculography may be needed to confirm. **** Spiral computed tomography may also suggest pulmonary embolism. In addition to emboli, a mosaic perfusion pattern may indicate chronic thromboembolic pulmonary hypertension. † Pulmonary angiography may be needed to confirm. (From D'Alonzo GE, Dantzker DR. Diagnosing primary pulmonary hypertension. In: Rubin LJ, Rich S, eds. *Primary pulmonary hypertension.* New York: Marcel Dekker Inc, 1997:227–252, with permission.)

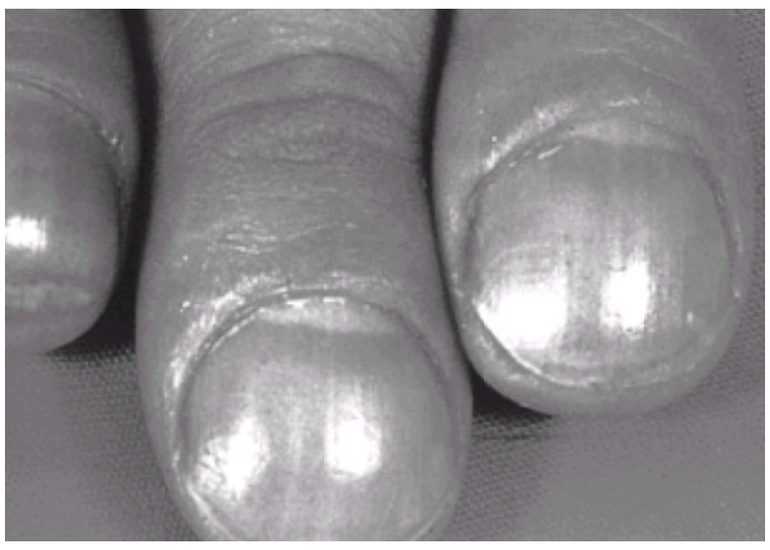


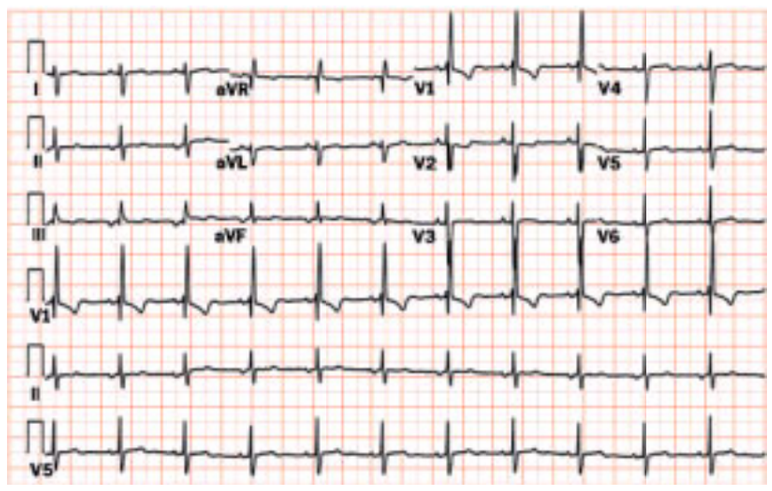
Clubbing. There is bullous enlargement of the distal portion of the digit as a result of increased soft tissue. This may be associated with cyanotic heart disease.

Clubbing. There is enlargement of the distal digits as a result of long-standing endocarditis.

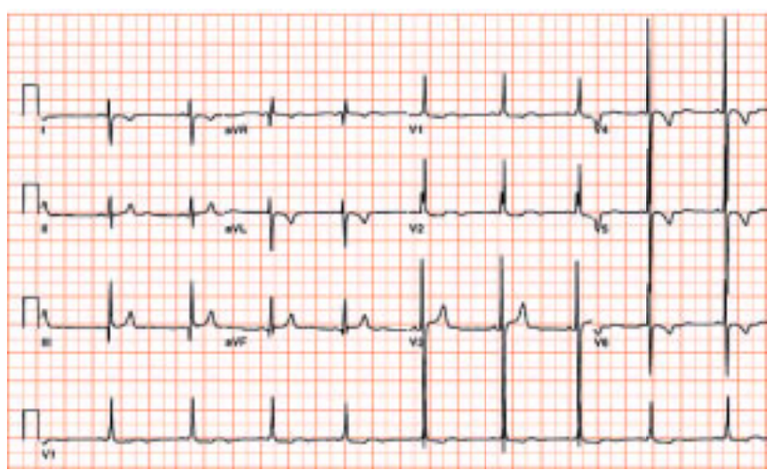
Electrocardiography

The electrocardiogram in the patient with pulmonary hypertension and cor pulmonale reveals evidence of right heart strain, including P-pulmonale, right-axis deviation, right ventricular hypertrophy, and a right ventricular strain pattern. In addition, atrial fibrillation, atrial flutter, and paroxysmal atrial tachycardia often occur in the setting of chronic pulmonary disorders. Although the electrocardiogram may not be sensitive in the presence of mild or early pulmonary hypertension, it is more often abnormal in those with advanced disease. In PPH patients, evidence of right heart strain appears to be present in approximately 80% of patients (99). However, particularly with the ready availability of echocardiography, electrocardiography does not offer much useful information regarding the cause or severity of pulmonary hypertension in the vast majority of settings.

A 22-year-old Caucasian female patient with primary pulmonary hypertension.



Right ventricular hypertrophy. Note incomplete right bundle branch block pattern, right axis deviation, and ST-T–wave changes secondary to right ventricular hypertrophy.



A 16-year-old male patient with biventricular hypertrophy secondary to ventricular septal defect and Eisenmenger's syndrome.

A 19-year-old Caucasian female patient with primary pulmonary hypertension.

Mitral stenosis. Left atrial enlargement and right ventricular hypertrophy have developed secondary to mitral stenosis, causing fixed pulmonary hypertension.

Chest Radiography

The chest radiograph is an important tool in the evaluation of patients with suspected pulmonary hypertension or cor pulmonale (Fig. 27.4). It may be helpful in identifying parenchymal lung abnormalities such as pulmonary fibrosis or hyperinflation associated with emphysema. Skeletal abnormalities that may lead to right ventricular failure, such as kyphoscoliosis, can also be identified. In addition, the chest radiogram allows for assessment of cardiac size, especially of the RV. Abnormalities in distribution of pulmonary blood flow may offer clues to the presence of vascular obstruction due to thromboembolic disease. Prominence of the proximal pulmonary arteries is usually present in patients with pulmonary hypertension and may be accompanied by pruning of the distal vessels (100). Unlike classic PPH, even rarer entities such as pulmonary venoocclusive disease may be associated with interstitial infiltrates and Kerley B lines due to alveolar septal lymphatic edema.

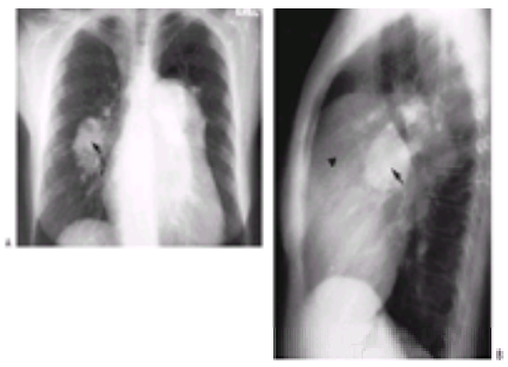


FIGURE 27.4 Chest radiograph in a patient with primary pulmonary hypertension. The proximal pulmonary arteries are dramatically enlarged. This is evident on the posteroanterior **(A)** and the lateral **(B)** views (*arrow*). The lateral film also reveals severe right ventricular enlargement (*arrowhead*).

Pulmonary Function Testing

Pulmonary function tests sometimes suggest the presence of pulmonary vascular disease and may aid in identifying the etiology of pulmonary hypertension and right ventricular failure. Spirometry may reveal evidence of, as well as determining the extent of, obstructive abnormalities. Measurement of lung volumes may identify restrictive lung disease as well as its severity. An isolated reduction in the carbon monoxide diffusing capacity is often noted in PPH, although mild reductions in lung volumes or spirometric values may be present also (101).

Pulmonary gas exchange abnormalities are commonly found in patients with pulmonary hypertension and cor pulmonale. Hypoxemia is frequently observed in patients with significant pulmonary hypertension and cor pulmonale, although the severity depends on the underlying disease. Nevertheless, arterial oxygen tensions are normal or mildly abnormal early in the disease process. Patients with PPH may have normal oxygen tension values until very late in the disease. In patients with sleep-related disorders, oxygen desaturation occurs during apneic or hypopneic episodes. Therefore, abnormalities may not be present during wakeful periods. In the majority of such patients, gas exchange abnormalities with hypercarbia are present early in the course of the disease. Mild sleep apnea in the setting of more severe pulmonary hypertension could represent either coincident disease or an unusually low threshold for the development of pulmonary hypertension. Clinically significant hypoxic vasoconstriction occurs at an arterial oxygen tension of less than 60 mm Hg, which may further exacerbate pulmonary hypertension, regardless of the cause.

Echocardiography: Anatomic Correlations and Clinical Use

Cor pulmonale is defined to some extent by structural changes of the RV including right ventricular hypertrophy and dilation. On gross inspection, right ventricular hypertrophy is usually defined as a posterior wall thickness of greater than or equal to 5 mm at the level of the inferior border of the posterior leaflet of the tricuspid valve, excluding the papillary muscles (102). However, the sensitivity of this measurement as an indicator of pulmonary hypertension has been shown on multiple occasions to be poor (103,104,105 and 106). The most accurate method to determine the presence of cor pulmonale pathologically includes measurement of the weight of the free wall of the RV and the ratio of the combined weight of the septum and the free left ventricular wall to the right ventricular weight (104). These measurements in normal adult hearts are right ventricular weight less than 65 g, combined ventricular weights less than 250 g, and the ratio (as defined above) of 2.3 to 3.3. Evidence of right ventricular failure, defined by the presence pathologically of chronic hepatic congestion, was seen in 27% of cases with a right ventricular weight of 75 to 99 g, in 64% of those with weights of 100 to 150 g, and in 93% of cases with weights greater than 150 g (107). Gross examination of the RV also reveals a change in its shape with the development of cor pulmonale. The volume of the RV appears to decrease relative to its mass; in addition, it becomes less C-shaped and more concentric, the so-called left ventricularization of the RV (107).

VIDEO

Video 27.1 Apical four-chamber transthoracic view demonstrating a patient with severe pulmonary hypertension with a markedly dilated right ventricle with right ventricular dysfunction and a dilated tricuspid annulus. This annular dilatation causes severe tricuspid regurgitation. Because of the severe tricuspid regurgitation, there is significant right atrial dilatation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 27.2 Apical four-chamber view with color Doppler demonstrating severe tricuspid regurgitation due to annular dilatation. There is right ventricular dilatation and significant right ventricular dysfunction. Note the large zone of proximal flow convergence on the right ventricular side of the tricuspid valve. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

In the past, the echocardiographic evaluation of the RV was more difficult because of its crescentic shape and substernal location, which limited adequate visualization of its chambers and subjected it to near-field acoustic artifacts. With the advent of two-dimensional echocardiography—Doppler and color Doppler imaging—came a growing interest in right heart function and evaluation. The echocardiographic views that best depict right-sided anatomy include the apical four-chamber, the right ventricular inflow long-axis, the oblique short-axis, the subcostal, the long-axis pulmonary, the short-axis view of the great vessels, the angulated short-axis view of the pulmonary artery, and the short-axis ventricular view (108).

The ideal method to evaluate the RV in cor pulmonale adequately includes measurement of chamber sizes, volumes, flow, and pressures. The echocardiogram is helpful in establishing secondary causes for pulmonary hypertension, such as left ventricular dysfunction, mitral valve abnormalities, or congenital heart disease. Although echocardiography is not foolproof in detecting mild to moderate pulmonary hypertension, it is quite sensitive in detecting severe elevations in pulmonary artery pressure. Patients with pulmonary hypertension exhibit an early peak velocity on pulsed-wave Doppler patterns in the proximal pulmonary artery because of poor compliance of the pulmonary vascular bed (108). The majority of such patients has tricuspid regurgitation, thereby allowing a reasonably accurate estimate of pulmonary artery systolic pressure. In the absence of right ventricular outflow tract obstruction, the relationship of the squared peak velocity of the tricuspid jet multiplied by four (Bernoulli equation) equals the pressure gradient across the valve. In a study by Currie et al. (109), analyzable Doppler regurgitant velocities were accurate in 80% of patients with elevated right ventricular systolic pressures, compared with 57% of normal patients. Such predictions, however, are only accurate for outflow tract waveforms. Pulmonary artery flow patterns do not allow for accurate predictions of systolic pressures, but they do allow for accurate predictions of diastolic pressures (108). Pulmonary hypertension can also be estimated by studying the flow characteristics in the inferior vena cava, although this technique has not been studied prospectively. Other echocardiographic findings that are associated with pulmonary hypertension and cor pulmonale include the presence of a dilated pulmonary artery and dilation and hypertrophy of the RV, even though the posterior wall often is not adequately visualized. Diastolic flattening of the interventricular

septum also occurs with progressive pulmonary hypertension, eventually leading to a concave septal configuration.

Video 27.3 Transesophageal echo of a patient with congenital pulmonary stenosis. Note the severe hypertrophy of the right ventricular outflow tract, causing infundibular pulmonary stenosis as well as valvular pulmonary stenosis. The pulmonic leaflets are thin and pliable; however, there is marked doming caused by tethering of the leaflet tips. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Because echocardiography is noninvasive, it is generally used early to determine the presence and severity of pulmonary hypertension and cor pulmonale. It is also extremely useful for following patients with established pulmonary hypertension after therapeutic interventions. Patients with markedly depressed RVEF measurements (10% or less) who have undergone lung transplantation appear to have considerable improvement of right ventricular function by echocardiography (110). Another study in patients who underwent pulmonary thromboendarterectomy for chronic thromboembolic pulmonary hypertension compared catheterization data with echocardiography. Strong correlations were seen between the maximal velocity of the regurgitant tricuspid jet by Doppler and the measurements of pulmonary artery pressures by cardiac catheterization postoperatively (111). Although transesophageal echocardiography can be used to evaluate the RV, there do not appear to be any major advantages with the latter technique for this particular indication. Three-dimensional echocardiography is being increasingly investigated, and although the technique has not yet been systematically investigated in patients with right ventricular dysfunction, this approach appears promising (112).

Nuclear Imaging Modalities

Ventriculography

The gold standard for the measurement of cardiac volumes and ejection fractions is usually considered to be contrast ventriculography. These measurements are normally calculated from geometric models that closely resemble the shape of the structure being studied (113). Nonetheless, unlike the left ventricle, the complex shape of the normal RV renders the methods that make use of such mathematical models prone to error. Additionally, in cor pulmonale, the changes in the shape of the RV can further invalidate measurements derived from models of the normal ventricle. Nuclear imaging techniques may overcome some of these difficulties because they are count based and relatively independent of the geometric constraints of the RV. Images in the septal left anterior oblique view are used in determining RVEF (114). Because inclusion of right atrial counts can falsely lower RVEF, the gated first-pass technique minimizes activity in adjacent structures. This technique performed with a multicrystal scintillation camera with high count rate capacities is the best way to measure RVEF.

Ventilation-Perfusion Scanning

When evaluating a patient with pulmonary hypertension, $\dot{V}/\dot{Q}$ scanning is only useful in differentiating whether the cause of the pulmonary hypertension is secondary to chronic thromboembolic disease (115). The latter patients typically have significant $\dot{V}/\dot{Q}$ abnormalities. The high-probability scans of such patients have at least one major perfusion defect. In contrast, patients with PPH generally have either normal or low-probability lung scans. Patients with cor pulmonale due to significant obstructive or restrictive lung diseases may have large perfusion defects, but these correlate with ventilation abnormalities. It is difficult to exclude thromboembolism using the $\dot{V}/\dot{Q}$ scan in the setting of severe COPD.

Computed Tomography

The use of computed tomographic (CT) scanning is increasingly being used to characterize the lung vasculature and parenchyma in patients with pulmonary hypertension. The pulmonary vasculature can be examined for thromboembolism, and the nature and extent of parenchymal disease can be evaluated. For example, patients with scleroderma and pulmonary hypertension may have variable degrees of interstitial disease; CT scanning may help determine whether the process is related primarily to pulmonary vascular involvement or to underlying fibrosis. The CT scan may reveal a mosaic perfusion pattern that suggests the presence of chronic thromboembolic pulmonary hypertension. In spite of the ability to visualize the pulmonary arteries with contrast-enhanced CT scanning, pulmonary arteriography should be performed if there is any question about proceeding with a potentially curable pulmonary thromboendarterectomy.

Pulmonary Arteriography

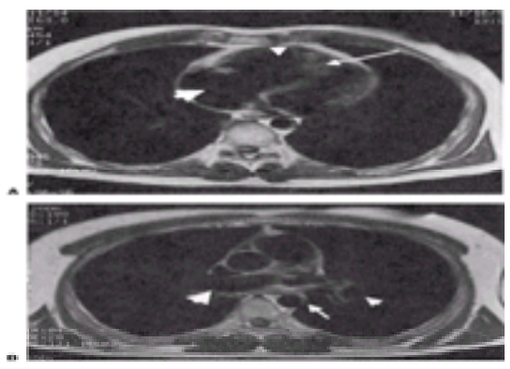
The role of the pulmonary arteriogram in the evaluation of the patient with pulmonary hypertension and cor pulmonale is to diagnose thromboembolic disease, and it is especially useful if the $\dot{V}/\dot{Q}$ scan is nondiagnostic. In chronic thromboembolic disease, the arteriogram can reveal convex-bordered occlusions, stenoses, intravascular webs, and large central thrombi with filling defects and vessel cutoffs (116). The arteriogram in the PPH patient reveals dilation of the proximal vessels with pruning of the distal vessels. Performing pulmonary arteriography in patients with severe pulmonary hypertension carries a small risk, although it is enerally safe in the absence of overt, severe right ventricular failure. In the NIH PPH Registry, 50 patients underwent the procedure without significant adverse events (99). One patient experienced transient hypotension. The risk is likely inversely proportional to the experience of the center performing the procedures (116). Pulmonary angioscopy may be necessary to determine the precise extent of thromboembolism (117).

Right Heart Catheterization

The gold standard for the diagnosis of pulmonary hypertension remains the right heart catheterization. This technique uses a thermodilution balloon catheter to measure right atrial, right ventricular, pulmonary artery, and pulmonary capillary wedge pressures (6). Patients with pulmonary arterial hypertension should have normal wedge pressures. The presence of an abnormal capillary wedge pressure usually requires left heart catheterization for further evaluation. In addition, right heart catheterization allows for comparisons between the oxygen saturations in the central veins, right atrium, RV, and pulmonary artery. This helps determine if a left-to-right shunt is present. The right heart catheterization may supplement the echocardiographic data in the diagnosis and evaluation of congenital heart disease.

Magnetic Resonance Imaging

The use of magnetic resonance imaging (MRI) has been introduced to evaluate ventricular volume and ejection fraction (118) (eFig. 27.4.1). The potential use of MRI in the evaluation of right ventricular function is suggested by a study in 11 patients in which a correlation coefficient of 0.86 was found between measurements of RVEF by MRI compared with radionuclide ventriculography (119). The measurement of stroke volumes in healthy subjects, including children, by MRI has been validated in numerous studies (120). MRI has also been used for the determination of wall stress, by measuring end systolic and end diastolic wall size (121). A study in seven patients who underwent single-lung transplantation for pulmonary hypertension revealed significant reductions in right ventricular wall stress and remodeling of the RV within 3 to 6 months (121). However, unlike the case with the left ventricle, such data with regard to the RV have not been validated. MRI is also being used in the evaluation of patients with thromboembolic disease, especially those with emboli in the proximal pulmonary arteries (122).



***e*FIGURE 27.4.1** Cardiac magnetic resonance image (MRI). The image was acquired using a T1-weighted, gated spin-echo technique. The patient has moderately severe primary pulmonary hypertension with a pulmonary artery pressure of 65/35 (mean 43). Mild obstructive lung disease is present, but the pulmonary hypertension is disproportionately severe. All other causes of secondary pulmonary hypertension were ruled out. A high natural contrast exists between the blood pool and the

cardiovascular structures, making MRI a favorable technique for cardiac imaging. In **(A),** the right atrium (*large arrowhead*) and right ventricle (*small arrowhead*) are enlarged, resulting in septal flattening (*arrow*) with encroachment on the left ventricle. In **(B)**, the pulmonary arteries are enlarged (*large arrowhead*). The left descending pulmonary artery (*small arrowhead*) is as large as the descending aorta (*arrow*).

PRINCIPLES OF MANAGEMENT

Oxygen

As was previously stated, a low arterial oxygen tension value is a predictor of reduced survival in patients with cor pulmonale. Supplemental oxygen not only relieves tissue hypoxia but can also reduce hypoxic pulmonary vasoconstriction, thereby reducing PVR, pulmonary artery pressures, and afterload. The reduction in such hemodynamic parameters might then allow right ventricular dysfunction to reverse. Two large trials have demonstrated the benefit of supplemental oxygen therapy in patients with hypoxemia and cor pulmonale: the Nocturnal Oxygen Therapy Trial Group (NOTT) (123) and the Medical Research Council Working Party (MRC) (124). The NOTT study enrolled 203 patients with hypoxemia and COPD at six treatment centers in the United States. The patients were randomized to continuous versus nocturnal oxygen therapy. Mortality was significantly reduced in patients who received continuous oxygen when compared with the other treatment group (Fig. 27.5). Nonetheless, statistically significant differences in mortality between each group were not evident when considering the specific subset of patients with altered pulmonary hemodynamics, despite an improvement in PVR with continuous oxygen therapy.

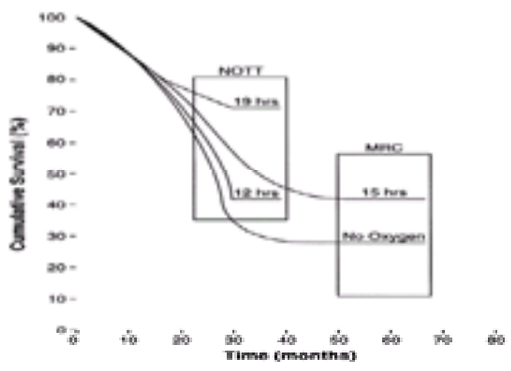


FIGURE 27.5 Composite graph of the British Medical Research Council Working Party (MRC) and the U.S. Nocturnal Oxygen Therapy Trial (NOTT) studies. Survival was poor with no oxygen, better with some oxygen, and best as they approached continuous oxygen (19 hours). (From Tiep BL. Long-term home oxygen therapy. *Clin Chest Med* 1990;11:505–521, with permission.)

The MRC trial performed in the United Kingdom enrolled 87 patients with COPD and severe arterial hypoxemia and hypercarbia (124). The patients were randomized to oxygen therapy for at least 15 hours per day versus no oxygen. Again, mortality was significantly reduced in the treatment group versus the control group (Fig. 27.5) after 500 days of therapy. When examining the hemodynamic data, mean pulmonary artery pressure in the treatment group remained stable, whereas it increased significantly in the control group. Therefore, in both trials the decrease in mortality did not appear to correlate with improvement in pulmonary hemodynamics. However, Weitzenblum and colleagues (125) subsequently evaluated a small group of patients with pulmonary hypertension and underlying COPD. Twelve of the 16 patients had improvement in their pulmonary hypertension after the institution of oxygen therapy of 15 to 18 hours per day. During long-term oxygen therapy, there was a yearly decrease in pulmonary artery pressures of 2.15 ± 4.4 mm Hg. Thus, long-term oxygen therapy is recommended when the arterial oxygen tension is 55 mm Hg or less or when the oxygen tension is 60 mm Hg or less in patients with cor pulmonale, polycythemia, or other evidence of cardiac disease.

Treatment of Airflow Obstruction and Parenchymal Lung Disease

The therapy of patients with cor pulmonale due to COPD involves maximizing lung function. Several classes of drugs are used in patients with obstructive lung diseases for their bronchodilatory properties. Theophylline has been shown in animal models to have a bronchodilator effect and inotropic effects and to improve diaphragmatic contractility (126,127 and 128). The effects on ventricular function are attenuated by beta-receptor or calcium channel blockade (126). However, the use of this agent to improve diaphragmatic as well as cardiac function appears to be controversial in humans. Beta-adrenergic receptor agonists are primarily used for their bronchodilator properties. These are also vasodilators of the systemic and pulmonary vascular beds, although the latter effect does not appear to be clinically significant when used at standard doses via the inhaled route. The development of tolerance with the use of these agents is common, and potential hemodynamic effects seem unlikely to be long term. These agents, including albuterol, salmeterol, terbutaline, and others, can be used for acute exacerbations of COPD or for chronic maintenance therapy. Ipratroprium bromide is also commonly used in the setting of acute and chronic airflow obstruction. A major advantage of this agent is the paucity of adverse effects, even at relatively high doses. Finally, steroid therapy plays a role in certain patients with obstructive as well as interstitial lung disease. Treatment of the underlying lung disease may improve airflow and potentially oxygenation, theoretically offering a chance for improvement in cor pulmonale.

Digoxin

The use of digoxin as an agent to improve cardiac contractility in patients with impaired right ventricular function is controversial. A randomized placebo-controlled trial studied the effect of digoxin on RVEF after 8 weeks of treatment in COPD patients (129). Improvement in RVEF was seen in those patients with concomitant left ventricular dysfunction, but not in individuals with isolated right ventricular dysfunction. In addition, digoxin does not improve cardiac function or oxygen consumption during exercise in patients with COPD (130). Finally, patients with chronic lung disease and gas exchange abnormalities tend to develop digoxin toxicity at lower serum levels than patients with right ventricular dysfunction without gas exchange abnormalities. Additional clinical trials would appear warranted.

Vasodilator Therapy

Because pulmonary arterial muscularization and vasoconstriction are believed to be major pathophysiologic mechanisms for the development of pulmonary hypertension and pressure overload of the RV, a number of vasodilator agents have been studied. Guidelines for their use are provided in *e*Table 27.1.1 and *e*Table 27.1.2 and in *e*Figure 27.5.1.

***e*TABLE 27.1.1** ASSESSMENT OF VASODILATOR RESPONSE IN PULMONARY HYPERTENSION

Parameter	Desired acute change	Comments
Mean pulmonary artery pressure (MPAP)	>25% decrease ↓	Avoid ↓ systemic BP
Pulmonary vascular resistance (PVR)	>33% decrease ↓	Should be associated with ↓ MPAP and ↑ CO
Right atrial pressure (RAP)	No change or ↓	↑ RAP suggests impending RV failure
Pulmonary capillary wedge pressure (PCWP)	No change	↑ PCWP may suggest PVOD or LV failure and may be dangerous
Systemic blood pressure (BP)	Minimal ↓ (keep systolic BP >90 mm Hg)	Significant ↓ BP precludes use of agent
Cardiac output (CO)	Increase	↑ CO should be related to ↑ stroke volume, not ↑ HR
Heart rate (HR)	No significant change	Chronic ↑ HR may precipitate RV failure
Systemic arterial O_2 saturation (Sa_{O_2})	If baseline is ↓, Sa_{O_2} may ↑	↓ Suggests right-to-left shunt or underlying lung disease
Pulmonary artery (mixed venous) O_2 saturation ($P\bar{v}_{O_2}$)	Increase	Reflects ↑ CO and ↑ tissue O_2 saturation

LV, left ventricle; PVOD, pulmonary venoocclusive disease; RV, right ventricle; ↑, increase; ↓, decrease.

***e*TABLE 27.1.2** ACUTE DOSING OF VASODILATORS IN PRIMARY PULMONARY HYPERTENSION

Agent	Route	Dose range	Half-life

Prostacyclin	Intravenous	2–10 ng/kg/min[a]	3–5 min
Adenosine	Intravenous	50–200 µg/kg/min	5–10 sec
Nitric oxide	Inhaled	5–80 ppm	15–30 sec
Nifedipine[b]	Oral	30–240 mg/kg	2–5 h
Diltiazem[b]	Oral	120–900 mg/d	2.0–4.5 h

[a]Many cardiac catheterization laboratories infuse prostacyclin only at 2 ng/kg per minute without dose titration to ascertain that the patient tolerates the drug. The lack of a vasodilator response to this drug does not preclude a long-term response. Dose increases at weekly intervals may lead ultimately to doses as high as 100 ng/kg per minute.
[b]The half-life values shown refer to preparations dosed every 6 to 8 hours. If the medication is tolerated, it can be changed to a sustained-release preparation administered once a day.

Calcium Channel Blockers

Calcium channel blockers have been the most widely tested and used group of drugs in patients with PPH. In such individuals, sustained improvement occurs in 25% to 30% (76,87). Nifedipine and diltiazem are the most commonly used, because verapamil has been shown to have negative inotropic effects. Typically, the patients who experience the most sustained improvement in hemodynamics during an acute vasodilator challenge are those who show improvement in symptoms and prolonged survival (76). However, these agents may also result in significant adverse effects such as hypotension, which can be life threatening in patients with severely compromised right ventricular function. Therefore, indiscriminate use of these agents should be avoided.

Data from the NIH PPH Registry suggested that patients with greatly depressed right ventricular function are at greatest risk of adverse outcomes with acute administration of vasodilators (131). If oral calcium channel blocker doses are changed in PPH patients who have already undergone right heart catheterization, the change should take place with careful monitoring of the blood pressure. In patients with other causes for pulmonary hypertension and cor pulmonale, the use of these agents is controversial. A study of 11 patients with COPD and cor pulmonale who were treated with nifedipine revealed no improvement in survival over age- and disease-matched control subjects despite improvements in PVR (132,133 and 134). Other studies have shown improvement in the hemodynamics of COPD patients, but these were accompanied by worsening of arterial oxygenation due to $\dot{V}/\dot{Q}$ mismatching. Therefore, treatment of COPD patients should be carefully considered on an individual basis. Other oral vasodilators have been evaluated. Despite a possible role of angiotensin-converting enzyme in the pathophysiology of pulmonary hypertension (135), the evaluation of inhibitors of this enzyme has not revealed significant benefit, and these drugs have not been studied in large prospective, randomized trials (136).

Prostacyclin

The use of prostacyclin (epoprostenol, PGI_2) as long-term therapy developed from observations of hemodynamic parameters during its acute administration (137). It has a very short half-life, and it is rapidly inactivated by the low gastric pH. Therefore, it must be given as a continuous intravenous infusion via a permanent indwelling catheter with a portable infusion pump. Substantial preliminary data (138,139) led to a large prospective, randomized multicenter trial that compared prostacyclin plus conventional therapy with conventional therapy alone in patients with class III and IV PPH (79). The patients who were treated with prostacyclin had significant improvements in exercise capacity, hemodynamics, and survival (Fig. 27.6). More recently, patients with severe pulmonary hypertension due to the scleroderma spectrum of diseases were randomized in a similar prospective trial (140). Improvement in exercise capacity and hemodynamics at 3 months was demonstrated in the prostacyclin cohort. Long-term benefits have also been reported, even in patients who have not demonstrated hemodynamic improvement during the acute infusion. The dose of the drug is increased, generally once or twice per week, and tolerance develops if it is not increased. The long-term effects have been suggested to be due not only to the vasodilator properties but also to antiplatelet or anti–smooth muscle proliferation properties. Adverse events are related to catheter-related infections and thrombosis and pump malfunction. Dose-related side effects include diarrhea, jaw pain, flushing, and arthralgias. This drug should be administered by a team of individuals who are experienced with its use and aware of the time commitment that is required for proper teaching and maintenance. Alternatives to this form of prostacyclin are under investigation and include inhaled prostacyclin (141,142), nebulized iloprost (a prostacyclin analog) (142), and oral prostacyclin in the pill form (143). Subcutaneous prostacyclin delivered by a small pump (UT-15/Remodulin) is pending approval by the U.S. Food and Drug Administration.

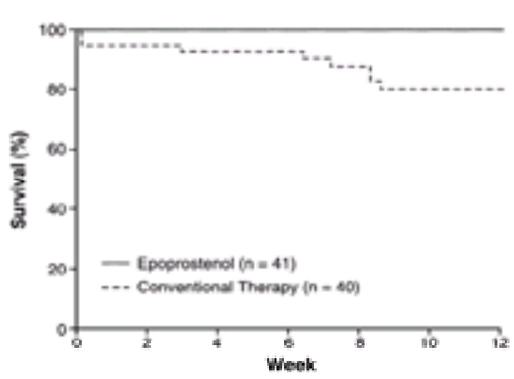

FIGURE 27.6 Survival among the 41 patients treated with epoprostenol and the 40 patients receiving conventional therapy. Data on patients who underwent transplantation during the 12-week study were censored at the time of transplantation. Estimates were made by the Kaplan-Meier product-limit method. The two-sided *p* value from the log-rank test was .003. Survival analysis with data on patients receiving transplants not censored at transplantation resulted in the same level of significance (two-sided *p* = .003 by the log-rank test). No deaths occurred in the epoprostenol group, and there were eight deaths in the conventional therapy group. [From Barst RJ, Rubin LJ, Long WA, et al. A comparison of continuous intravenous epoprostenol (prostacyclin) with conventional therapy for primary pulmonary hypertension. *N Engl J Med* 1996;334:296–301, with permission.]

Endothelin Antagonists

Because endothelin levels have been shown to be elevated in patients with PPH, and because the production and activity of this substance may be two of several important mechanisms in the development of pulmonary hypertension, endothelin antagonism has been studied as potential therapy in pulmonary arterial hypertension. Results in animal models with pulmonary hypertension have appeared to be favorable (144). Channick and colleagues (145) conducted a large randomized, double-blind, placebo-controlled multicenter trial that compared bosentan, an orally active antagonist receptor of both endothelin receptor subtypes (A and B). The Borg dyspnea index, 6-minute walk distance, WHO functional class, and PVR all improved to a statistically significant degree in patients who received the drug compared with placebo. Ultimately, it may prove most effective to combine this form of treatment with therapies that use other mechanisms of action for optimal therapy. Bosentan

(Tracleer) was recently approved by the U.S. Food and Drug Administration for use in patients with New York Heart Association class III and IV PPH and those with pulmonary arterial hypertension due to the scleroderma spectrum of diseases.

Inhaled Nitric Oxide

Because abnormalities in NO production, regulation, and effect appear to be involved in the pathophysiology of pulmonary hypertension, its use as a therapeutic agent is being investigated. It is a selective pulmonary vasodilator (146,147), delivered via inhalation, with a short half-life. It appears to be useful as a “screening vasodilator” in the therapy of pulmonary hypertensive states (148). Two prospective randomized trials using inhaled NO in neonates with pulmonary hypertension revealed no reduction in mortality but a decrease in the need for more invasive therapy such as extracorporeal membrane oxygenation (149,150). The delivery of the inhaled gas has been a major obstacle in its use, because administration has been via ventilators or face masks. An ambulatory delivery system is being developed for the widespread use of inhaled NO, and it appears to be a promising alternative in the future (151,152). The effects of pulsed inhaled NO in eight patients with PPH revealed improvement in hemodynamic parameters over a short period of time (151). Long-term effects have not been studied, but a few patients have been maintained on this therapy.

Anticoagulation

Anticoagulation is recommended in the treatment of patients with pulmonary hypertension due to their increased risk of *in situ* thrombosis. In a subgroup of these patients, microscopic thrombi may play a role in the pathogenesis of the disease (152). In addition, these individuals appear to be at risk of thromboembolism due to right ventricular dilatation and dysfunction as well as relative immobility. A retrospective clinical trial and a nonrandomized prospective study have suggested improved survival with anticoagulation therapy (76,152). Despite the fact that heparin is beneficial in animal models of hypoxic pulmonary hypertension due to its inhibitory effects on smooth muscle proliferation (153), the drug of choice is warfarin; an international normalized ratio of 1.5 to 2.5 is considered therapeutic (76). The risk-benefit ratio has to be considered on an individual basis when using anticoagulant therapy.

Atrial Septostomy

Patients with PPH often begin to shunt blood from right to left as the pulmonary artery pressure rises. This is due to the opening of a patent foramen ovale. It is likely that, in some patients, this serves as a means by which to “unload” the RV to some degree. Creation of a shunt, atrial septostomy, has been performed as palliation in a few cases with severe PPH (154,155 and 156). In such patients, the RV is massively dilated, thereby encroaching on left ventricular filling. A right-to-left shunt is created in an attempt to improve forward output and allow for better filling of the left ventricle. The unfortunate tradeoff is the potential for causing profound systemic arterial hypoxemia or pulmonary edema by overloading the left ventricle. Therefore, this procedure is still considered investigational but may be used in extreme cases.

Surgical Treatment

Pulmonary Thromboendarterectomy

Thromboendarterectomy has been the treatment of choice for pulmonary hypertension that is associated with chronic thromboembolic disease. Anticoagulation should be instituted and inferior vena cava filters are recommended in patients with this entity, but the only means by which to alleviate symptoms and to have an impact on survival is surgery. Pulmonary thromboendarterectomy is performed via median sternotomy on cardiopulmonary bypass. The overall mortality continues to improve and is now less than 5%. The response to therapy is often impressive, with dramatic reversal of right ventricular dysfunction (157,158). Lung transplantation can be performed in patients in whom thrombi are too distal to extract.

Lung Transplantation

Lung transplantation and heart-lung transplantation are being used as surgical therapy for patients with a variety of pulmonary parenchymal and vascular disorders (159). Patients should be referred for evaluation for transplantation if class III or class IV symptoms are present. The length of the waiting list at a given center (generally 6 to 18 months) helps to determine the appropriate time for listing and transplantation. Patients with PPH or pulmonary arterial hypertension due to the scleroderma spectrum of diseases should undergo a trial of prostacyclin therapy by continuous infusion before proceeding to lung transplantation, because this drug has proved so efficacious in these settings. Single and bilateral lung transplantation, rather than heart-lung transplantation, are the procedures of choice due to the limited availability of organs. The RV has a tremendous capacity to recover in spite of severe dysfunction once the afterload posed by the abnormal pulmonary vasculature is removed. Single-lung transplants are done in all patients with pulmonary parenchymal disorders, except those with suppurative diseases such as cystic fibrosis, in which case bilateral lung transplantation is performed. Most centers prefer bilateral lung transplantation for PPH as well. One advantage of the bilateral approach may be that the new lung is less likely to suffer from reperfusion pulmonary edema immediately after operation. Chronic rejection may also be more easily tolerated with a bilateral transplant than when the extremely abnormal native PPH lung remains (160). However, the waiting time on the list is shorter for a single-lung transplant, and a set of donor lungs can be offered to two patients when single-lung transplantation is used for PPH. Many transplant teams prefer the single-lung procedure. Heart-lung transplantation is reserved for patients with associated left heart disease or congenital heart disease with pulmonary hypertension when the atrial or ventricular septal defect cannot be repaired. Markedly depressed right ventricular function is not a contraindication to single or bilateral lung transplantation because right ventricular function improves considerably after transplantation (159). Right ventricular shape also appears to normalize after single and bilateral lung transplantation. One-year survival rates for lung transplantation are approximately 80%. Obliterative bronchiolitis (chronic rejection) is the major long-term complication of transplantation. Patients with PPH appear to have higher mortality as well as a higher frequency of obliterative bronchiolitis. Recurrence of the primary pulmonary disorder in the transplanted lung can occur in certain conditions but has not been reported in PPH.

SUMMARY

Pulmonary hypertension and cor pulmonale result in substantial morbidity and mortality. The etiologies are numerous because nearly any chronic lung disease can result in cor pulmonale. Other entities such as neuromuscular disease and thoracic cage abnormalities can result in hypoxemia and ultimately in pulmonary hypertension with right ventricular failure. Basic scientific efforts indicate the importance of growth factors and of smooth muscle proliferation in the pathogenesis of PPH. The diagnosis and an assessment of severity begin with the history and physical examination. Chest radiography and echocardiography may be useful in elucidating the etiology and severity of pulmonary hypertension, and pulmonary function testing may clarify the physiology and severity of underlying lung disease. Certain diseases such as chronic thromboembolic pulmonary hypertension require specific diagnostic testing, including $\dot{V}/\dot{Q}$ scanning and pulmonary arteriography. Helical CT scanning and MRI may be useful in diagnosing and characterizing the extent of this disease. Right heart catheterization remains the gold standard for quantifying the severity of pulmonary hypertension. Appropriate therapy involves treatment of underlying lung disease as well as direct measures to reduce pulmonary artery pressures without causing systemic hypotension. The prognosis depends to some extent on the nature of the underlying disease. The underlying causes of pulmonary hypertension and cor pulmonale followed by the diagnostic and therapeutic approaches are described. Continuous intravenous prostacyclin has revolutionized the treatment of primary and some forms of secondary pulmonary hypertension. Finally, newer diagnostic and therapeutic modalities, some of which remain theoretical or unproven, are emphasized. The recently approved endothelin antagonist will likely be used in substantial numbers of patients with PPH and with pulmonary arterial hypertension due to scleroderma and related diseases.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Despite tremendous progress in basic scientific and clinical research, pulmonary hypertension and cor pulmonale remain among the more difficult cardiopulmonary disorders to treat. Because (except in the case of PPH) they are the result of *other* disease processes, they may go clinically undetected for months or years, with the assumption that the COPD or ILD itself, for example, is responsible for the dyspnea, fatigue, and other clinical symptoms. The implications of missing the diagnosis of pulmonary hypertension and right ventricular failure are substantial. For PPH, prostacyclin and anticoagulation appear to improve mortality, and listing for transplantation is important because waiting lists are increasing in length. Patients with PPH are often young, do not have hypoxemia or abnormal pulmonary function testing early in the course of the disease process, and may not have glaring chest radiograph abnormalities. Thus, in the past, these individuals were often labeled as having psychogenic dyspnea until symptoms were quite advanced. Over the past decade, the level of awareness for PPH among cardiology and pulmonary specialists has increased, particularly with the advent of newer therapies. However, the diagnosis is more difficult for general practitioners, who may see only one case in a lifetime. It is appropriate for patients with PPH to be evaluated and followed at centers with expertise in this area, particularly as the disease advances.

Organizations such as the Pulmonary Hypertension Association have made tremendous progress in the education and support of patients with PPH. Their biannual conference is a very unique one, at which physicians as well as patients and their family members mutually attend lectures and conferences about pulmonary hypertension, ranging from drug therapy and lung transplantation to coping with a potentially fatal disease. Among the important controversies that clinicians continue to struggle with at present are the timing of the initiation of intravenous prostacyclin and the timing of lung transplantation. A massive effort is currently under way to evaluate all patients who have received intravenous prostacyclin in the past and to evaluate future patients prospectively to better characterize appropriate dosing of the drug and to examine the mortality and outcome. Although lung transplantation is the final therapeutic step for many patients with PPH and other patients with cor pulmonale, conquering the ultimate cause of death in many of these patients (chronic rejection) will be crucial. The genetics of PPH are being unraveled; this may

contribute substantially to disease prevention and treatment in the future.

THE FUTURE

The diagnostic and therapeutic approach to pulmonary hypertension and right ventricular failure will change substantially over the next 10 years. Noninvasive technology, including multidimensional echocardiography, ultrafast CT, and MRI techniques, will facilitate accurate characterization of right ventricular size and function, eliminating the need for invasive testing with cardiac catheterization. With the advent of this technology, evaluation of the RV and pulmonary circulation will, when necessary, be performed more frequently, permitting more effective assessment of therapeutic benefit. At the present time, the need for right heart catheterization for evaluation of pulmonary hypertension and cor pulmonale prevents rigorous accurate follow-up in these patients.

Clinical trials will be conducted, enabling better understanding of the utility of older treatment modalities, such as digoxin and other inotropes, on right ventricular function, as well as enhancing our knowledge base with regard to newer therapies, such as oral, subcutaneous, and inhaled prostacyclin; endothelin antagonism; and inhaled NO; and related therapies. Treatment of underlying lung disease that leads to cor pulmonale may become more feasible. Enhanced understanding of the role of various inflammatory mediators in primary pulmonary vascular disease as well as chronic fibrotic lung disorders will also have an impact on therapy. Surgical therapy will continue to become more sophisticated. Advances in lung transplantation (including xenotransplantation), pulmonary thromboendarterectomy, and lung volume reduction surgery for emphysema may lead to increases in survival in patients with end-stage lung disease. Perhaps direct right ventricular surgery with removal of hypokinetic myocardial tissue will enhance the function of the ventricle.

Our understanding of the basic biology of the vascular endothelium and its role in the development of pulmonary hypertension as well as the importance of its interaction with red blood cells is essential. The respective roles of platelet-derived growth factor B, TGFs, insulin-like growth factor-1, and basic fibroblast growth factor will be clarified, as will the regulation of endothelin and NO. The key elements of tissue repair and vascular remodeling will be elucidated. The relative role of the coagulation pathway in PPH will be essential to determine. The genetics of PPH are already becoming clearer. The *BMPR2*, a component of the TGF-b family, plays a key role in cell growth. This gene has been shown to be associated with familial PPH (28a). MORE RECENTLY, IT HAS BEEN DISCOVERED THAT THE SPORADIC FORM OF PPH IS ALSO ASSOCIATED WITH GERMLINE MUTATIONS OF *BMPR2* in a significant minority of patients (28b). The importance of this gene and its relationship to pulmonary hypertension will be clarified. Regulation of gene expression may be a key method through which pulmonary hypertension can be controlled. The basic mechanisms that underlie hypoxic vasoconstriction are essential to understand; if this process can be unraveled, it may permit us to prevent right ventricular failure *completely*.

HISTORICAL PERSPECTIVE

In 1819, Laennec wrote about "pulmonary apoplexy," stating, "The disease I call by this name is very common, but nevertheless its features are almost unknown" (1). Ten years later, Cruveilhier began his work meticulously describing thrombi in central and peripheral veins as well as describing multiple pulmonary emboli pathologically (2). Despite their important discoveries, neither Laennec nor Cruveilhier made the association between the development of deep venous thrombosis (DVT) and pulmonary embolism (PE). The true discovery of this association is attributed to Virchow, who described it in 1858 (3). Virchow also determined that PE did not always result in infarction because of the dual circulation of the lung. Several years later, Trousseau reported the high incidence of DVT in patients with gastric carcinoma (4). In 1880, Beniamino Luzzatto described at least 160 cases of PE in a manuscript titled "Embolism of the Pulmonary Artery," in which he emphasized the predilection for the lower lobes and the predisposing role of stasis and preexisting cardiopulmonary disease (5). He also credited a number of other individuals for their observations. Shortly after the turn of the century, Trendelenburg attempted pulmonary embolectomy (6), and in 1924, Kirschner, a student of Trendelenburg, performed the first successful embolectomy for acute PE (7). Ljungdahl described the concept of chronic PE in 1928 (8). In 1931, Moniz et al. reported the first pulmonary angiogram, although this technique did not become widely used for PE until decades later (9). In 1940, Bauer, a Swedish surgeon, diagnosed DVT by venography and investigated the natural history of untreated venous thrombosis using serial venography (10). He was also among those who first reported the use of heparin therapy for this disease (11,12) despite the discovery of heparin in 1916 by McLean, then a medical student (13).

The ability to diagnose PE changed dramatically with the development and availability of new diagnostic techniques after 1960. The advantages of pulmonary angiography became more widely recognized in 1963, when Chrispin and colleagues (14) injected contrast material into the right atrium and pulmonary arteries, delineating emboli within the large pulmonary arteries. Williams, Sasahara, and their respective associates reported the utility of selective pulmonary angiography exclusively for the diagnosis of PE (15,16). Stein et al. (17) evaluated the angiographic signs of PE in 1967 and concluded that an intraluminal filling defect and vessel cutoff with a trailing edge were the only two primary angiographic criteria that could be relied on to diagnose PE. Radionuclide imaging was further explored in 1964 when Taplin developed a method of generating and radiolabeling macroaggregated albumin particles (18). Wagner et al. (19) reported the diagnosis of PE in humans by radioisotope scanning the same year. These diagnostic discoveries helped to usher in a new era in the approach to venous thromboembolism (VTE). Substantial research has been undertaken since. Although much more has been learned about this entity, it remains elusive and is all too frequently discovered at autopsy.

INCIDENCE

VTE constitutes a clinical spectrum encompassing DVT and PE. This disorder occurs extraordinarily commonly in hospitalized patients particularly after major surgery, and the care of these patients spans all specialties and subspecialties. PE most commonly results from DVT occurring in the veins of the proximal lower extremities—that is, including and proximal to the popliteal veins. Both DVT and PE are frequently clinically unsuspected, leading to significant diagnostic and therapeutic delays and accounting for substantial morbidity and mortality. Although there are as many as 260,000 patients in the United States in whom VTE is diagnosed and treated each year, more than half of the cases that actually occur are never diagnosed, and as many as 600,000 cases may therefore occur. Many patients dying from acute PE have coexisting terminal illnesses; however, it would appear that this disease entity is responsible for the deaths of 50,000 to 100,000 patients with an otherwise good prognosis, and many of these deaths would appear preventable (20,21). Autopsy studies have repeatedly documented the high frequency in which PE has gone unsuspected and undetected (22). Despite advances in diagnostic technology and therapeutic approaches, VTE remains underdiagnosed, and prophylaxis continues to be dramatically underused (23).

RISK FACTORS AND PATHOPHYSIOLOGY

Risk Factors

The pathogenesis of DVT as proposed by Virchow is based on several potential initiating events, including stasis, venous injury, and hypercoagulability. Risk factors for DVT are based on these processes (Table 28.1). Frequently more than one risk factor is present, and knowledge of these risk factors provides the rationale for both prophylaxis and clinical suspicion.

Clinical factors
Age >40 yr
History of venous thromboembolism
Prior major surgical procedure/trauma
Hip fracture
Immobilization/paralysis
Varicose veins
Congestive heart failure
Myocardial infarction
Obesity
Pregnancy/postpartum
Oral contraceptive therapy
Cerebrovascular accident
Cancer
Paroxysmal nocturnal hemoglobinemia
Antiphospholipid antibody syndrome (including lupus anticoagulant)
Genetic/molecular factors
Antithrombin III deficiency
Factor V Leiden (activated protein C resistance)
Protein C deficiency
Protein S deficiency
Prothrombin gene (G20210A) defect
Dysfibrinogenemia
Disorders of plasminogen
Elevated factor VIII levels
Elevated factor XI levels

TABLE 28.1 RISK FACTORS FOR VENOUS THROMBOEMBOLISM

Clinical Factors

Most venous thrombi arise in valve pockets, where blood flow tends to stagnate. The increased frequency of thrombosis with advanced age and immobilization further suggests the causal relationship between stasis and thrombogenesis. Immobility of any cause results in decreased venous return and stasis. Patients with acute cerebrovascular accidents commonly develop venous thrombi in the paralyzed lower extremity but only rarely in the unaffected limb. Acute paraplegia may be associated with a significantly increased risk of developing DVT, and the period of highest risk appears to be the first two weeks after the onset of the illness (24). Prolonged bedrest or long automobile or airplane trips may lead to the development of thromboemboli. The risk presented by air travel has been somewhat controversial (25,26 and 27). Although one recent trial suggests that the risk is not significant (25), more than 5 hours was the longest travel time evaluated, and this group of patients was not further subdivided. Thus, longer travel times were not independently analyzed. A more recent clinical trial does demonstrate a relationship between distance traveled and incidence of PE (27a). Obesity also appears to increase the risk of VTE. Information extrapolated from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) suggests that the role of obesity as a risk factor requires further clarification; there were not enough patients with morbid obesity included to draw firm conclusions (28). Immobility and resultant stasis are likely contributing factors. Age appears to increase mortality due to PE (29). This risk is particularly high in those with cardiac disease or cancer. It appears that PE is suspected premortem less commonly in the elderly patient (30).

Previous thromboembolic disease predicts a substantial risk of recurrence in the hospitalized patient. Surgical patients with a history of VTE who do not receive prophylaxis develop postoperative DVT in more than 50% of cases (31). Surgery itself places a patient at significantly increased risk. General surgery patients not receiving pharmacologic or mechanical prophylaxis have been shown to develop venography-proven DVT in as many as 19% of cases (32). Traditionally, heparin prophylaxis has been initiated perioperatively to prevent the development of intraoperative and early postoperative thrombosis. Patients undergoing spinal or pelvic surgery appear to be at particularly high risk (31). Total hip and total knee replacement patients not receiving prophylaxis develop DVT in more than 50% of cases (33). These orthopedic settings have been extensively investigated, prompted by clear evidence in clinical trials that low-molecular-weight heparin (LMWH) preparations are more effective than standard heparin in the setting of total joint replacement (33).

Lower extremity and pelvic trauma enhance the risk of DVT. Emboli are discovered at autopsy in as many as 60% of patients with fractures of the lower extremities (34), and mortality has been attributed to PE in 38% to 50% of patients dying after hip fracture (35). The duration of immobility after trauma influences the development of DVT. The frequency of autopsy-confirmed PE in patients surviving for less than 24 hours after trauma has been shown to be 3.3%, increasing to 5.5% in those surviving up to 7 days. Pulmonary emboli occurred in 18.6% of those surviving for a longer period (36). Other causes of venous trauma include placement of central venous catheters in the jugular, subclavian, or femoral veins. Clinically significant PE arising from upper extremity thrombosis can occur but is significantly less likely than from a lower extremity source.

Other disease processes are associated with a high risk of VTE. Autopsy studies as well as recent epidemiologic analyses suggest that patients with cardiac and malignant disease are particularly susceptible to VTE (29,37). Although myocardial infarction without anticoagulation resulted in a significant incidence of DVT, more recent therapeutic strategies have had a favorable impact (38). A reduction in the incidence of VTE resulting from the use of thrombolytic therapy was demonstrated in a number of large placebo-controlled trials for acute myocardial infarction, including the Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico and the second International Study of Infarct Survival (39,40). Patients with malignancies have an increased risk of developing VTE (41). Cancers of the pancreas, lung, stomach, genitourinary tract, and breast are associated with a particularly high risk of DVT and PE. In addition to thrombophilia, these disorders are frequently associated with significant weakness and decreased ambulation with venous stasis. Treatment with chemotherapy with resulting neutropenia and sepsis often necessitates hospitalization and bedrest, which contributes further to the high risk of VTE. A recent analysis based on data from the PIOPED trial revealed that of 399 patients with PE, 73 (18.3%) had cancer (29).

Pregnancy and the postpartum period are the most common settings in which women younger than age 40 develop DVT or PE. DVT develops in these settings five times more often than in women not on oral contraceptives (42). Thrombosis appears to be more common in the third trimester and postpartum than before delivery, but the risk is clearly significant throughout pregnancy (42). Delivery by cesarean section further increases the risk. Oral contraceptives are associated with the development of VTE (43). The risk increases with third-generation agents (agents containing desogestrel or gestodene as the progestin component) (44,45). In a clinical trial evaluating hormonal replacement therapy, it was determined that such therapy increased the incidence of VTE in women 45 to 64 years of age. It appears that an annual total of 16.5 cases of VTE out of 100,000 individuals may be attributed to hormonal replacement therapy (46). The risk of VTE also appears to be highest in the first year of exposure to hormonal replacement (47). Past use may not increase the risk (48). Although such therapy is associated with clear benefits, physicians should take risk factors for VTE into account before prescribing hormonal replacement therapy. A recent review of oral contraceptive use and VTE further emphasizes that, with the increased risk associated with third-generation progestins in combination preparations, these agents should not be the first choice for new users (49).

Disease states associated with the development of VTE include paroxysmal nocturnal hemoglobinuria, inflammatory bowel disease, homocystinuria, Behçet's syndrome, polycythemia, and thrombocythemia. Most intensive care unit patients can be considered at risk for VTE because of their multiple risk factors, including significant underlying disease, immobility, and the frequent presence of venous injury due to trauma. With few exceptions, these patients should receive some form of DVT prophylaxis, and a high index of suspicion for VTE should be maintained in appropriate clinical circumstances. Hospitalized general medical patients represent an increasingly ill population frequently requiring medical prophylaxis.

Molecular Defects

Inherited coagulopathies result in variable degrees of VTE risk (50). Patients with antithrombin III or protein C or S deficiency may remain free of thromboembolic disease until another risk factor such as immobilization is superimposed. Factor V Leiden is a common genetic polymorphism associated with activated protein C resistance and appears to be present in approximately 4% to 6% of the general population (51). The relative risk of a first idiopathic venous thrombosis among men heterozygous for the mutation has been shown to be three- to sevenfold higher than those not affected (51). The more recently identified prothrombin gene mutation (G20210A) and factor V Leiden are common among healthy whites but are rare among Asians and Africans. The presence of these genetic defects does not at present, in and of itself, mandate lifelong anticoagulation therapy, nor does it mandate increased intensity of prophylaxis, although more data are needed and patients should be scrutinized individually and carefully (50).

Gas Exchange and Hemodynamic Alterations in Acute Pulmonary Embolism

The hypoxemia occurring in the majority of patients with PE has been explained by various mechanisms. In patients without previous cardiopulmonary disease, regions with low ventilation-perfusion (V/Q) ratios and shunting secondary to perfusion of atelectatic areas are likely the dominant mechanisms of hypoxemia.

When emboli obstruct a significant portion of the pulmonary arterial bed, profound hemodynamic alterations occur. The impact of the embolic event depends on the extent of reduction of the cross-sectional area of the pulmonary vasculature as well as on the presence or absence of underlying cardiovascular disease. Submassive emboli in normal individuals may actually augment cardiac output (CO). Hypoxemia leads to an increase in sympathetic tone with systemic vasoconstriction and an increase in venous return with augmentation of stroke volume. With massive emboli, CO is diminished but may be sustained as the mean right atrial pressure increases. The ensuing increase in pulmonary vascular resistance impedes right ventricular outflow and reduces left ventricular preload. In a patient without previous cardiopulmonary disease, occlusion of 25% to 30% of the vascular bed by emboli is associated with a significant rise in pulmonary artery pressure (PAP). With increasing vascular obstruction, hypoxemia worsens, stimulating vasoconstriction and a further rise in PAP. More than 50% obstruction of the pulmonary arterial bed is usually present before substantial elevation of the mean PAP evolves. When the extent of obstruction of the pulmonary circulation approaches 75%, the right ventricle must generate a systolic pressure in excess of 50 mm Hg and a mean PAP of greater than 40 mm Hg to preserve pulmonary perfusion (52). The normal right ventricle

is unable to achieve this and ultimately fails (52). Patients with underlying cardiopulmonary disease are more inclined to experience more substantial deterioration in CO than normal individuals in the setting of massive PE. A depressed CO *without* elevation of the right atrial pressure suggests cardiac dysfunction superimposed on PE. Right ventricular failure is more common in the setting of PE in patients with coronary artery disease (53). It is important to realize that although supportive measures may sustain a patient with massive embolism, any additional increment in embolic burden may be fatal.

CLINICAL PROFILE

The diagnostic technology for acute DVT has developed considerably with the evolution of convenient and inexpensive techniques such as compression ultrasound as well as highly accurate yet more expensive diagnostic modalities such as magnetic resonance imaging (MRI). For PE, V/Q scanning followed by pulmonary arteriography remains the gold standard approach to the diagnosis, although newer techniques such as MRI and helical computed tomography (CT) scanning are being used increasingly. The presence of risk factors together with the history and physical examination generally leads to further diagnostic testing in the setting of suspected VTE.

History and Physical Examination

The clinical diagnosis of both DVT and PE based on the history and physical examination are notoriously insensitive and nonspecific. Patients with lower extremity DVT often do not exhibit erythema, warmth, pain, swelling, or tenderness. These findings, however, although not specific for DVT, merit further evaluation. PE should always be considered whenever unexplained dyspnea is present. Dyspnea as well as pleuritic chest pain and hemoptysis are common in PE but are nonspecific. Anxiety, lightheadedness, and syncope are all symptoms that may be caused by PE but may also result from a number of other entities that result in hypoxemia or hypotension. Tachypnea and tachycardia are the most common signs of PE but are also nonspecific. PE should always be considered in the setting of syncope or sudden hypotension. The cardiac and pulmonary physical examinations are both nonspecific. The index of clinical suspicion does, however, become a more useful parameter when considered in conjunction with V/Q scanning (54). Diagnostic efforts directed at possible VTE may be appropriate despite alternative explanations if risk factors and the clinical setting are suggestive. Dyspnea, tachypnea, clear lung fields, and hypoxemia may often be attributed to a flare of chronic obstructive disease or asthma when underlying PE is present.

Venous stasis eczema. Stasis dermatitis as a result of chronic edema and venous incompetence. There is erythema, scaling, pigmentation, crusting, and exudation.

Varicose veins. There are dilated, tortuous, superficial lower-extremity veins as a result of dysfunction of the valves of the saphenous veins.

Laboratory Testing

Electrocardiographic findings in acute PE are generally nonspecific and include T-wave changes, ST-segment abnormalities, and left or right axis deviation. In the Urokinase Pulmonary Embolism Trial, electrocardiographic abnormalities were documented in 87% of patients with proven PE who were without underlying cardiac or pulmonary disease (55). These findings were not specific for PE, however. In this clinical trial, 26% of patients with massive or submassive PE and 32% of those with massive PE had manifestations of acute cor pulmonale such as the S1 Q3 T3 pattern, right bundle branch block, P-wave pulmonale, or right axis deviation. Such changes are thus seen in a minority of patients. The low frequency of specific electrocardiographic changes associated with PE was confirmed in the PIOPED study (56).

Hypoxemia is common in acute PE. Some individuals, particularly young patients without underlying lung disease, may have a normal partial pressure of arterial oxygen (PaO_2). In a retrospective study of hospitalized patients with PE, the PaO_2 was greater than 80 mm Hg in 29% of patients younger than 40 years old, compared with 3% in the older group (57). The alveolar-arterial (A-a) difference was elevated in all patients, however. A subset of patients participating in the PIOPED study suspected of PE with no history or evidence of preexisting cardiac or pulmonary disease was evaluated and the PaO_2 and A-a difference values compared (54). Patients with and without PE could not be distinguished based on either of these values. The A-a difference was elevated by more than 20 mm Hg in 76 of 88 (86%) patients with PE, however. The diagnosis of acute PE cannot be excluded based on a normal PaO_2, and although the A-a difference is usually elevated, it may rarely be normal in patients without preexisting cardiopulmonary disease.

The usefulness of plasma measurements of circulating D-dimer, a specific derivative of cross-linked fibrin, as a diagnostic aid in PE has been extensively evaluated. A normal enzyme-linked immunosorbent assay appears sensitive in excluding PE. When the D-dimer level is 500 µg per liter or greater, the sensitivity and specificity for PE have been shown to be 98% and 39%, respectively (58). The sensitivity of the plasma D-dimer appears to remain high up to 1 week after presentation. In another prospective analysis, 96% of 79 patients with high-probability V/Q scans had an elevated D-dimer concentration (59). Thus, increased levels of cross-linked fibrin degradation products are an indirect but suggestive marker of intravascular thrombosis in addition to indicating fibrinolysis. A D-dimer assay together with a respiratory rate of less than 20 breaths per minute and a partial pressure of oxygen of more than 80 mm Hg was shown to be very sensitive in ruling out acute PE (60). Wells and

colleagues (60a) have refined simple but very useful pretest probability criteria with a scoring system and found that, in the setting of a low score and a negative simplified D-dimer, PE is exceedingly unlikely. Although the sensitivity of the D-dimer appears high, the specificity is not high enough to be diagnostic. Thus, symptoms, signs, radiographic findings, electrocardiographic measurement, and the plasma D-dimer measurement cannot be considered diagnostic of PE or DVT, and when these entities are suspected, further evaluation with noninvasive or invasive testing is necessary. A recent exhaustive review of the various D-dimer assays and clinical trial results reinforces the above findings (61).

Chest Radiography, Ventilation-Perfusion Scanning, and Pulmonary Arteriography

Most patients with PE have abnormal but nonspecific findings on chest radiograph. Common radiographic findings include atelectasis, pleural effusion, pulmonary infiltrates, and mild elevation of a hemidiaphragm (56). Classic findings of pulmonary infarction such as Hampton's hump or decreased vascularity (Westermark's sign) are suggestive but infrequent. Normal chest radiograph findings in the setting of severe dyspnea and hypoxemia without evidence of bronchospasm or anatomic cardiac shunt are strongly suggestive of PE. The presence of a pleural effusion increases the likelihood of PE in young patients who present with acute pleuritic chest pain (62). Under most circumstances, however, the chest radiograph cannot be used to conclusively diagnose or exclude PE. Although exclusion of other processes such as pneumonia, pneumothorax, or rib fracture, which may cause symptoms similar to acute PE, is possible, PE may frequently coexist with other underlying lung diseases.

V/Q scanning should be performed when PE is suspected. Normal and high-probability scans are considered diagnostic. A normal perfusion scan rules out the diagnosis of PE with a high enough degree of certainty that further diagnostic evaluation is unnecessary. Matching areas of decreased ventilation and perfusion in the presence of a normal chest radiograph generally represent a process other than PE. However, low- or intermediate-probability (nondiagnostic) scans are commonly found with PE, and in such situations further evaluation with pulmonary arteriography is often appropriate. Normal, high-, low-, and intermediate-probability lung scans are shown in Figure 28.1, Figure 28.2, Figure 28.3, and Figure 28.4. In the PIOPED study, the use of V/Q scanning combined with clinical assessment of patients with suspected PE was prospectively evaluated (54). Patients with PE had scans that were high, intermediate, or low probability, but so did most patients without PE. Although the specificity of high-probability scans was 97%, the sensitivity was only 41%. Of interest, 33% of patients with intermediate-probability scans and 12% of patients with low-probability scans were diagnosed definitively with PE by pulmonary arteriography. When the clinical suspicion of PE was considered very high, PE was found to be present in 96% of patients with high-probability scans, 66% of patients with intermediate scans, and 40% of patients with low-probability scans. The diagnosis of PE should be rigorously pursued, even when the lung scan is low or intermediate probability, if the clinical scenario suggests PE. Therefore, although the V/Q scan may sometimes be diagnostic of PE or exclude the possibility with sufficient certainty, it is often nondiagnostic. Even in such circumstances, however, it may serve as a useful guide for limited pulmonary arteriography.

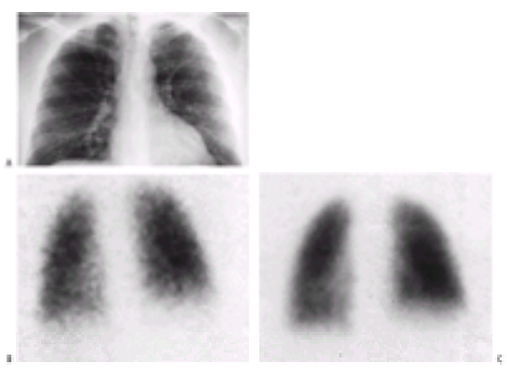

FIGURE 28.1 Normal ventilation-perfusion scan. Multiple views are always performed for the perfusion images; only the posterior view is shown in each of these cases. Ventilation scans are done as breath-hold, equilibrium, and washout phases; only one phase is shown in each of these cases. The chest radiograph **(A)**, ventilation scan **(B)**, and perfusion scan **(C)** are normal in this patient. Pulmonary embolism is excluded.

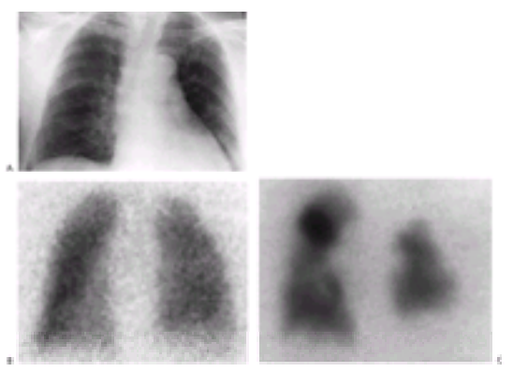

FIGURE 28.2 High-probability lung scan. This patient with metastatic cancer developed sudden dyspnea and unexplained hypoxemia after prolonged bedrest. The chest radiograph **(A)** reveals a right hilar mass. The ventilation scan **(B)** is normal, but the perfusion scan **(C)** demonstrates multiple bilateral perfusion defects, virtually diagnostic of pulmonary embolism.

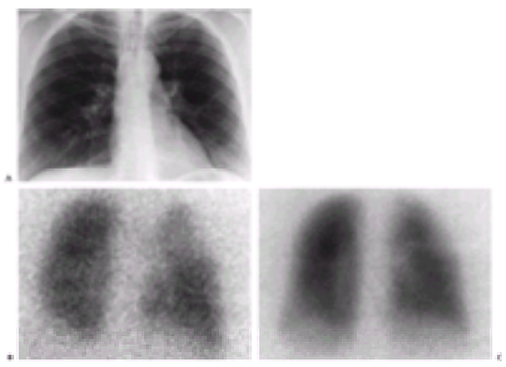

FIGURE 28.3 Low-probability lung scan. This patient had a significant smoking history and developed dyspnea with hemoptysis. The chest radiograph **(A)** reveals enlarged central pulmonary arteries consistent with pulmonary hypertension. The ventilation scan sequence revealed xenon retention consistent with chronic obstructive lung disease, and the image shown **(B)** demonstrates ventilation abnormalities, especially at the bases. Matched perfusion abnormalities were present on the perfusion scan **(C)**. Because of purulent sputum and a rapid response to bronchodilator therapy, pulmonary embolism was believed unlikely, and further evaluation was deemed unnecessary. Obstructive lung disease commonly results in nondiagnostic ventilation-perfusion scans. Further studies depend on level of clinical suspicion.

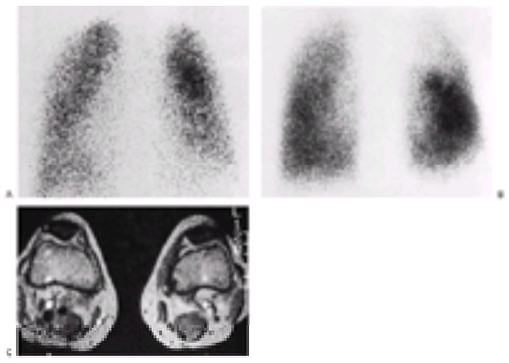

FIGURE 28.4 Intermediate probability. This patient developed sudden dyspnea and pleuritic chest pain after surgery. The chest radiograph (not shown) was clear. The ventilation scan **(A)** reveals a defect at the right base. The perfusion scan **(B)** reveals a solitary defect in the right upper lobe; this unmatched defect was not large enough to qualify as a high-probability reading. The clinical suspicion was high for pulmonary embolism, but pulmonary arteriography could not be performed because of significant renal insufficiency. Magnetic resonance imaging **(C)** was used to document proximal deep vein thrombosis of the right lower extremity. The completely occlusive thrombus (*arrow*) appears as a hypodense region adjacent to the high-intensity white signal representing normal arterial flow. The patient was heparinized for acute deep vein thrombosis (and presumed pulmonary embolism).

Pulmonary arteriography has remained the accepted gold standard technique for the diagnosis of PE. It is a very sensitive, specific, and safe test. Complications of pulmonary arteriography among 1,111 patients suspected of PE in the PIOPED study included death in 0.5% and major nonfatal complications in 1% (63). An alternative to pulmonary arteriography is to perform lower extremity studies when the lung scan is nondiagnostic, and if these are negative, the chances of significant PE or morbidity from a subsequent event appear unlikely (64). This practice is gaining acceptance and in patients with cardiopulmonary stability may be appropriate. Finally, pulmonary angiography has been performed at the bedside using a Swan-Ganz catheter (65). This may prevent the need to transport critically ill patients. A pulmonary arteriogram diagnostic of PE is shown in Figure 28.5.

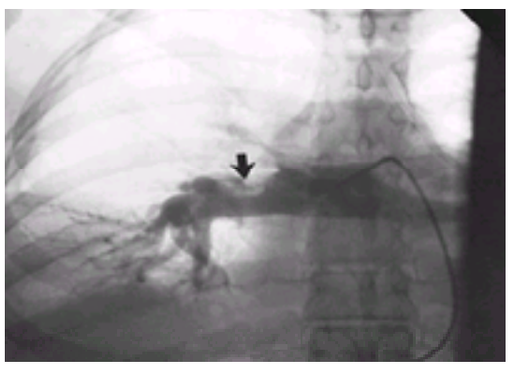

FIGURE 28.5 Pulmonary arteriography demonstrating acute pulmonary embolism. There is a large filling defect in the right pulmonary artery (*arrow*) and marked hypoperfusion to the right upper and middle lobes. A ventilation-perfusion scan had been performed and was nondiagnostic because of extensive air space disease in the right lung.

Echocardiography in Acute Pulmonary Embolism

Other diagnostic techniques sometimes prove useful particularly in the setting of massive PE. Echocardiography, which can often be obtained more rapidly than either lung scanning or pulmonary arteriography, may reveal findings that strongly support hemodynamically significant PE (66). Studies of patients with documented PE have revealed that more than 80% of patients have imaging or Doppler abnormalities of right ventricular size or function that may suggest acute PE (66,67). Unfortunately, because patients with PE often have underlying cardiopulmonary disease such as chronic obstructive lung disease, neither right ventricular dilation nor hypokinesis can be reliably used even as indirect evidence of PE in such settings. Goldhaber and colleagues (68) demonstrated that echocardiography could be used to document improvement in right ventricular wall motion in patients with PE treated with recombinant tissue-type plasminogen activator (t-PA). Intravascular ultrasound imaging has been shown in both the experimental and clinical setting to adequately image large emboli (69,70 and 71). This procedure may be performed at the bedside. Although the technique may be less sensitive and specific and more time-consuming in the setting of smaller emboli, further investigation may be warranted.

Computed Tomography and Magnetic Resonance Imaging

The usefulness of CT scanning and MRI for diagnosing PE has recently been explored. Preliminary data suggest comparable accuracy for these techniques (72). Helical (spiral) CT has been explored in patients with both acute and chronic PE. This technique involves continuous movement of the patient through the scanner with concurrent scanning by a constantly rotating gantry and detector system that takes 1 second for a 360-degree rotation (73). A helix of raw projecting data is obtained. Continuous volume acquisitions can be obtained during a single breath and rapid scans can be obtained, facilitating imaging in critically ill patients. Retrospective reconstructions can be performed. A contrast bolus is required for vascular imaging. Limitations of helical CT scanning include poor visualization of horizontally oriented vessels in the right middle lobe and lingula because of volume averaging. The peripheral areas of the upper and lower lobes may be inadequately scanned and intersegmental lymph nodes may result in false-positive studies. Multiplanar reconstructions in coronal or oblique planes may aid in differentiating lymph nodes from emboli.

Helical and electron beam CT may reveal emboli in the main, lobar, or segmental pulmonary arteries with more than 90% sensitivity and specificity (74,75,76 and 77). Others have reported very accurate results for large PE (78,79). Oser and colleagues (80) determined retrospectively that of 76 consecutive pulmonary angiograms, 23 (30%) revealed only subsegmental emboli. Nineteen studies (25%) revealed only a single PE. Thirteen of the 19 single emboli were subsegmental only. The PIOPED study, however, revealed that only 6% of patients had isolated subsegmental emboli (54). The latter prospective evaluation is likely more representative. Interestingly, however, two referee angiographers from the PIOPED agreed on the presence or absence of subsegmental emboli in only 66% of cases (54). Using selective pulmonary arteriography, Quinn and colleagues (81) emphasized excellent agreement on main, lobar, and segmental emboli but only 13% agreement on subsegmental emboli. Thus, this apparent limitation with helical CT scanning is also a concern with angiography. Goodman and others (82) have strongly endorsed the incorporation of CT scanning into diagnostic algorithms for PE. Examples of bilateral, central emboli imaged by helical CT are shown in *e*Figure 28.5.1. Sensitivity and specificity data from several large studies evaluating helical CT scanning for acute PE are shown in *e*Table 28.1.1. Contrast-enhanced electron beam CT also appears useful in diagnosing acute PE (77,83). The rapid (100 ms) scanning time makes breath holding unnecessary, and respiratory and cardiac motion artifact are minimized. In one comparison with pulmonary angiography, only 8 of 720 vascular zones (1.1%) were considered inadequately visualized with electron-beam CT. The entire chest examination took approximately 10 to 15 minutes in each case. As with helical CT, three-dimensional reconstruction techniques can be applied to the opacified pulmonary vasculature to better define vessels located within the plane that has been sectioned. Another important advantage of these CT techniques includes the concomitant ability to define nonvascular structures such as airway abnormalities, lymphadenopathy, lung tumors, and other parenchymal abnormalities, as well as pleural and pericardial disease. One recent helical CT study suggested a significantly lower sensitivity for acute PE than previous studies (84). Two sets of readers performed with 53% and 61% sensitivity, respectively. The specificities were 97% and 81%. It is feasible that reading cut films instead of evaluation of the images at the computer workstation accounted for the low sensitivity by these experienced readers. Prospective, randomized, clinical trials comparing these techniques with the standard diagnostic approach to PE are currently under way. PIOPED II is a prospective clinical trial sponsored by the National Institutes of Health in which approximately 1,000 patients with suspected PE will undergo V/Q scanning and helical CT to better assess the appropriate role of the latter modality. Data from a large European CT scan clinical trial is currently being analyzed also. These efforts will help to determine their precise role.

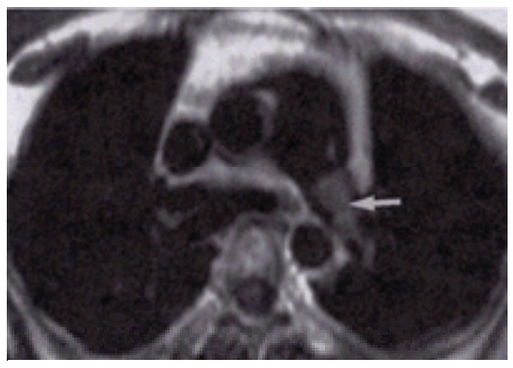
[b]All emboli, including peripheral.
[c]Two sets of readers from different institutions were used, resulting in two sensitivity/specificity values.

MRI is also being used to evaluate clinically suspected PE (72). In a comparison with helical CT, the average sensitivity of CT for five observers was 75% and of MRI 46%. The average specificity of CT was 89%, compared with 90% for MRI. Sensitivity and specificity values for expert readers were higher, however (72). Helical CT may be somewhat more useful than MRI for detecting PE at the present time, but MRI has several attractive advantages, including excellent sensitivity and specificity for the diagnosis of DVT (see Detection of Deep Venous Thrombosis). This technique may ultimately allow simultaneous accurate detection of both PE and DVT. PE proven by MRI is demonstrated in *e*Figure 28.5.2. Future investigation will determine the roles of these modalities in the evaluation of PE.



***e*FIGURE 28.5.2** A T2-weighted magnetic resonance image of a large pulmonary embolus (*arrow*) in the left pulmonary artery. No contrast is necessary for these images.

Detection of Deep Venous Thrombosis

The available technology used to pursue the diagnosis of DVT has expanded over the past several decades. Each technique has advantages and limitations. Impedance plethysmography has been shown to be reliable for detection of DVT occurring above the knee. Early studies suggested greater than 90% sensitivity and 97% specificity for DVT involving the proximal lower extremity, although less than 30% of isolated calf vein thromboses were detected (85,86). Other reports have emphasized the limitations of impedance plethysmography (41). In a more recent retrospective analysis at a university-based tertiary care center, impedance plethysmography was abnormal in only 37 of 56 patients, with proximal vein thrombosis confirmed by venography for a sensitivity of only 66% (87). The specificity was equally poor. Although this modality is sometimes portable, it does require access to the calf and thigh for electrode and cuff placement. The specificity is affected by disorders that obstruct venous outflow such as tumor or hematoma. External fixation or plaster immobilization of extremities reduces the usefulness of this technique. It is being used decreasingly.

Compression ultrasonography is a portable and accurate diagnostic technique for proximal lower extremity DVT. The sensitivity and specificity for symptomatic proximal DVT have been well above 90% in most recent clinical trials (88,89). Limitations include insensitivity for asymptomatic DVT, operator dependence, the inability to accurately distinguish acute from chronic DVT in symptomatic patients, and the insensitivity to calf vein thrombosis (90,91). A recent prospective evaluation of the utility of bilateral color Doppler ultrasound in asymptomatic high-risk (elective unilateral hip or knee replacement) patients revealed that ultrasound was only 38% sensitive for proximal DVT using contrast venography as the diagnostic standard (92). Compared with other technology, it is relatively inexpensive and is the preferred diagnostic modality for the straightforward case of symptomatic presumed proximal DVT.

Although contrast venography remains the gold standard technique for the diagnosis of DVT, it is less commonly performed since the advent of compression ultrasonography (93). Venography should be performed whenever noninvasive testing is nondiagnostic or impossible to perform. It is an invasive procedure that may result in superficial phlebitis or hypersensitivity reactions, but it is generally safe and accurate.

MRI is being increasingly used to diagnose DVT and appears to be an accurate noninvasive alternative to venography (94). A major advantage of this technique is excellent resolution of the inferior vena cava (IVC) and pelvic veins (95,96). Preliminary experience with this technique suggests that it is at least as accurate as contrast venography or ultrasound imaging and perhaps more sensitive than either for pelvic vein thrombosis. It offers the opportunity for simultaneous bilateral lower extremity imaging and appears to accurately distinguish acute from chronic DVT. It offers the additional advantage of lower extremity and lung imaging during the same session. DVT imaged by MRI is shown in Figure 28.4C.

At Duke University Medical Center, duplex ultrasound is commonly used as the first test to evaluate suspected acute DVT. MRI is frequently used subsequently when the ultrasound is nondiagnostic or to distinguish acute from chronic DVT. Another useful aspect of MRI lies in distinguishing other entities such as cellulitis or a Baker's cyst from acute DVT. The utility of this technique depends to a certain degree on the experience of the reader. Finally, helical CT scanning has been studied for suspected acute DVT. The contrast dye from the bolus injected for lung imaging is followed into the deep veins of the legs for viewing. Initial data are promising (97) and the utility of "CT venography" will be further studied in PIOPED II. These techniques may fit into diagnostic algorithms for DVT and PE, but these algorithms are

institution-specific at present, depending on resources and expertise with certain techniques.

PRINCIPLES OF MANAGEMENT

Prophylaxis of Deep Venous Thrombosis

A significant reduction in the incidence of DVT can be achieved when patients at risk receive appropriate prophylaxis. Such preventive measures appear to be grossly underused. A review of the use of prophylaxis for DVT in 16 Massachusetts hospitals indicated that such therapy was administered to only 44% of high-risk patients in teaching hospitals and only 19% in nonteaching hospitals (98). The frequency of prophylaxis ranged from 9% to 56% among hospitals. Patients can be stratified according to DVT risk, and certain prophylactic measures are more appropriate for some patients than for others. In general, for medical patients at risk for DVT, subcutaneous heparin at 5,000 U every 8 to 12 hours is generally adequate. Intermittent pneumatic compression devices should be used in the unusual situation when such prophylactic doses of heparin are contraindicated. Both methods combined would be reasonable in patients deemed to be at exceptionally high risk, but an additional reduction in risk in such patients has not been well substantiated.

In the general surgery population, a number of prophylactic methods have been used. In a large metaanalysis, Colditz et al. (99) not only confirmed the value of prophylaxis to reduce the incidence of DVT but also suggested that intermittent pneumatic compression plus gradient compression stockings may result in the lowest incidence of postoperative DVT. Other combined treatments were associated with lower rates than heparin alone. Another overview of the results of randomized trials in surgical patients demonstrated the benefit of DVT prophylaxis (100). In this review of more than 70 randomized trials involving 16,000 patients, it was demonstrated that perioperative use of subcutaneous heparin can prevent approximately half of all pulmonary emboli and approximately two-thirds of all DVT.

A number of investigators have evaluated the efficacy and safety of LMWH for DVT prophylaxis (101). LMWH may have an advantage in producing a more predictable dose response and is administered subcutaneously once or twice per day depending on the preparation (eTable 28.1.2 and eTable 28.1.3). Enoxaparin has been approved by the U.S. Food and Drug Administration (FDA) for three surgical prophylaxis indications, including elective total hip or knee replacement and general abdominal surgery (eTable 28.1.4). The approved dose is either 30 mg subcutaneously twice daily or 40 mg once daily for the orthopedic indications and 40 mg once daily for abdominal surgery. Prophylaxis is generally recommended for 7 to 10 days. Longer regimens may be appropriate depending on associated additional risk factors and on whether the patient is ambulatory. A large, randomized, placebo-controlled trial in patients undergoing total hip replacement compared enoxaparin prophylaxis during hospitalization (average, 10 to 11 days) with more prolonged outpatient prophylaxis (102). Blinded outpatient therapy (or placebo) was continued long enough that the total treatment period (inpatient plus outpatient) was 1 month for each patient. In the 233 patients with adequate venography, there were 43 episodes of DVT and two PE in the placebo group compared with only 21 episodes of DVT and no PE in the group receiving 1 month of prophylaxis. The incidence of thromboembolic events was 39% and 18%, respectively (p <.001). Another clinical trial recently confirmed the potential benefit in these patients (103). Thus, more prolonged outpatient prophylaxis may be appropriate in this patient population. Further investigation in such high-risk patients appears warranted. A second preparation, dalteparin, has been approved for once-daily use as prophylaxis for elective abdominal surgery. A number of other preparations are currently being investigated. Recent clinical trials emphasize the increased thromboembolic risk of general medical patients (104). Although this concept is not new, it is important to stress, as the population of hospitalized patients is becoming increasingly complex. The recent MEDENOX (Prophylaxis of Medical Patients with Enoxaparin) clinical trial compared two doses of enoxaparin (20 mg and 40 mg) with placebo in 1,102 hospitalized medical patients at moderate risk for VTE (104). Most of these patients had acute respiratory failure, congestive heart failure, or acute infectious diseases. The primary outcome was DVT detected by venography or ultrasonography between day 6 and 14 or PE. VTE developed in 14.9% of the patients receiving placebo, in 15% of patients receiving 20 mg of enoxaparin, and in only 5.5% of patients receiving the 40-mg enoxaparin dose (p <.001 for enoxaparin vs. placebo). There was no difference in major bleeding or death between the three groups. Enoxaparin is now FDA-approved for prophylaxis in this group of patients. Preliminary results from two European studies suggest that enoxaparin is at least as effective and as safe as standard heparin as VTE prophylaxis at a dose of 5,000 U every 8 hours in medically ill patients (105,106). Further prophylaxis studies in the medically ill evaluating LMWH preparations and standard heparin at 5,000 U every 12 hours would appear appropriate. It is important to realize that LMWH preparations are not identical and the results of clinical trials with one agent cannot be extrapolated to another agent. Evidence-based recommendations for DVT prophylaxis have recently been published (American College of Chest Physicians Consensus) and are updated every 2 years (33).

***e*TABLE 28.1.2** COMPARISON OF LOW-MOLECULAR-WEIGHT HEPARIN WITH UNFRACTIONATED HEPARIN

Characteristic	Unfractionated heparin	Low-molecular-weight heparin
Mean molecular weight	12,000–15,000 daltons	4,000–6,000 daltons
Protein binding	Substantial	Minimal
Anti-X_a activity	Substantial	Substantial
Anti-II_a activity	Substantial	Minimal
Platelet inhibition	Substantial	Minimal
Vascular permeability	Moderate	None
Microvascular permeability	Substantial	Minimal

Comparable or superior efficacy
Comparable or superior safety
Superior bioavailability
Once- or twice-daily dosing
No laboratory monitoring[a]
Less phlebotomy
Subcutaneous administration
Earlier ambulation
Home therapy in certain patient subsets

[a]Measurement of anti–factor X_a levels is recommended in significantly obese patients, very small patients (e.g., <40 kg), and patients with renal insufficiency.

***e*TABLE 28.1.4** GUIDELINES FOR USE OF ENOXAPARIN PROPHYLAXIS AFTER KNEE OR HIP REPLACEMENT

Dose: 30 mg subcutaneously twice daily or 40 mg once daily
Duration: 7–10 d (or until discharge or risk of postoperative deep venous thrombosis has diminished[a])
Initial dose: Begin 12–24 h after surgery
Delivery method: Deep subcutaneous administration
Monitoring: None

[a]Several randomized, prospective, placebo-controlled trials strongly suggest that extending prophylaxis in total hip replacement patients to a total of 1 mo (inpatient plus outpatient) significantly reduces the incidence of venous thromboembolism (102,103).

Anticoagulation Therapy

Anticoagulation has been proven to reduce mortality in acute PE. When VTE is diagnosed or strongly suspected, heparin therapy should be promptly instituted unless contraindications exist. Confirmatory testing should always be planned if anticoagulation is to be continued. Heparin exerts a prompt antithrombotic effect, preventing thrombus growth. Although it does not directly prevent the development of acute PE or dissolve thrombus, it allows the fibrinolytic system to act unopposed and more readily reduces the size of the thromboembolic burden (107). Although thrombus growth can be prevented, early recurrence can develop even in the setting of therapeutic anticoagulation.

With the institution of continuous intravenous heparin, the activated partial thromboplastin time (aPTT) should be aggressively followed at 6-hour intervals until it is consistently in the therapeutic range of 1.5 to 2.0 times control values (107). This range corresponds to a heparin level of 0.2 to 0.4 U per mL as measured by protamine sulfate titration. In general, heparin should be administered as an intravenous bolus of 5,000 U followed by a maintenance dose of at least 30,000 to 40,000 U per 24 hours by continuous infusion (108). The lower dose is administered if the patient is considered at high risk for bleeding. This aggressive approach decreases the risk of subtherapeutic anticoagulation, and although supratherapeutic levels are sometimes achieved initially, bleeding complications do not appear to be increased (109). More recent data continue to support aggressive heparin dosing. An alternative regimen consisting of a bolus of 80 U per kg followed by 18 U per kg per hour has been recommended (110). Further adjusting of the heparin dose should also be weight-based (Table 28.2). This weight-adjusted approach is recommended in the recent American College of Chest Physicians Consensus Conference on Antithrombotic Therapy (111). Warfarin therapy may be initiated as soon as the aPTT is

therapeutic, and heparin should be maintained until a therapeutic international normalized ratio of 2.0 to 3.0 has been overlapped with a therapeutic aPTT for 2 consecutive days. Although proximal lower extremity thrombus is more likely to result in PE, calf thrombi should either be followed for proximal extension over 10 to 14 days with noninvasive testing, or anticoagulation should be instituted (112,113). Documented proximal DVT or PE should be treated for at least 3 months. Longer treatment is appropriate when significant risk factors persist. Both short- and long-term anticoagulation guidelines are outlined in the American College of Chest Physicians Consensus Conference guidelines (111).

Initial heparin dose = 80 U/kg bolus, then 18 U/kg per h		
Subsequent modifications		
aPTT		
(sec)	(times control)	Heparin dose adjustment
<35	<1.2	80 U/kg bolus, then increase by 4 U/kg per h
35 to 45	1.2 to 1.5	40 U/kg bolus, then increase by 2 U/kg per h
46 to 70	1.5 to 2.3	No change
71 to 90	2.3 to 3	Decrease infusion rate by 2 U/kg per h
>90	>3	Hold infusion 1 h, then decrease rate by 3 U/kg per h

aPTT, activated partial thromboplastin time.

TABLE 28.2 WEIGHT-BASED NOMOGRAM FOR HEPARIN THERAPY IN ACUTE VENOUS THROMBOEMBOLISM

A number of clinical trials have strongly suggested the efficacy and safety of LMWH for treatment of established acute proximal DVT using recurrent symptomatic VTE as the primary outcome measure (111,114,115 and 116). The incidence of DVT and recurrent bleeding in these trials indicates that LMWH preparations are at least as effective and as safe as unfractionated heparin. These agents can be administered once or twice per day subcutaneously even at therapeutic doses and do not require monitoring of the aPTT. Antifactor X levels appear reasonable to monitor in certain settings such as in obese patients, in very small patients (less than 40 kg), and in those with renal insufficiency. There is no proven benefit in monitoring other patients. In two large randomized (Canadian and European) trials, therapy with LMWH was safely initiated at home or continued at home after a brief hospitalization (114,115). A number of outpatient studies have followed these two pivotal trials. Four metaanalyses examined the use of LMWH compared with unfractionated heparin in the initial treatment of acute proximal DVT (117,118,119 and 120). Although there was overlap between the analyses, they have helped to confirm the efficacy and safety of LMWH for the treatment of established DVT. The most recent of these studies has suggested a reduced mortality in patients treated with LMWH, although the precise reason for this is not absolutely clear (117). In the United States, at the present time, two LMWH preparations are FDA-approved for use in patients presenting with DVT with or without acute PE. Enoxaparin is approved for both inpatient and outpatient use at a dose of 1.0 mg per kg subcutaneously every 12 hours or at 1.5 mg per kg once daily for inpatient use. The latter regimens were both proven effective in a large study of inpatients in which both doses proved as effective and as safe as unfractionated heparin (121). The second preparation, tinzaparin, is administered as 175 U once daily, with FDA approval being based on therapy of inpatients. The latter treatment indication is the only approved use for this drug in this country at present. Neither enoxaparin nor tinzaparin is approved for use in patients presenting with acute PE, although tinzaparin has proven effective in a large, randomized European trial of patients with PE (122). The FDA-approved indications for the three LMWHs approved for use in the United States are shown in Table 28.3. It should be noted that the prophylactic doses of these agents differ from the doses used for treating active disease.

	Low-molecular-weight heparin		
Indication[a]	Enoxaparin	Dalteparin	Tinzaparin
Patients presenting with acute DVT[b]	X		X
Prophylaxis for acute DVT in			
Total hip replacement	X	X	
Total knee replacement	X		
General abdominal surgery	X	X	
Hospitalized medical patients	X		
Acute coronary syndromes[c]	X	X	

DVT, deep venous thrombosis.
[a]It must be recognized that prophylactic doses differ from therapeutic doses.
[b]Enoxaparin is approved for use in both inpatients with DVT with or without pulmonary embolism at 1 mg/kg every 12 h or 1.5 mg/kg once daily and for outpatients (1 mg/kg every 12 h). The data supporting treatment with tinzaparin (175 units once daily) are based on studies of hospitalized patients. Neither drug is approved in patients presenting with acute pulmonary embolism.
[c]Unstable angina and non–ST-segment elevation myocardial infarction.

TABLE 28.3 U.S. FOOD AND DRUG ADMINISTRATION–APPROVED INDICATIONS FOR SPECIFIC LOW-MOLECULAR-WEIGHT HEPARINS

Novel Anticoagulants and Experimental Models of Thrombosis

Newer agents are being explored. Although heparin is the best studied antithrombotic agent, it works indirectly, requiring antithrombin III as a cofactor. Heparin's effects vary considerably between patients. Hirudin is a direct thrombin inhibitor that has several advantages over heparin, including efficacy against fibrin clot–bound thrombin. It does not require any cofactors and is not inactivated by platelet factor 4 or plasma proteins. This drug, derived from the saliva of the medicinal leach (*Hirudo medicinalis*), appears promising. Data from several clinical trials including the Global Use of Strategies to Open Occluded Coronary Arteries IIB trial suggested a small advantage of hirudin without increased bleeding when compared with heparin, in the setting of acute coronary syndromes (123). The results of the Thrombolysis In Myocardial Infarction 9B trial suggested that heparin and hirudin are equally effective and safe as adjunctive therapies for t-PA or streptokinase in preventing unsatisfactory thrombotic outcomes in acute myocardial infarction (124). Other agents such as the hirudin analogue bivalirudin await study. There are less data available for treatment of acute VTE. As with heparin, these direct thrombin inhibitors have very narrow therapeutic indices.

Inogatran, a new selective active-site inhibitor of thrombin was recently evaluated in a rat model of both arterial and venous thrombosis (125). This drug appears to be an effective antithrombotic agent in both models as well as an effective adjunct to t-PA in a thrombolysis model. Napsagatran, a new synthetic direct thrombin inhibitor, has been compared with heparin in a canine model of coronary thrombosis (126). In this model, arterial antithrombotic effects appeared similar to those of heparin. The direct thrombin inhibitor, argatroban, has been used during pulse-spray pharmacomechanical thrombolysis in a rabbit model of venous thrombosis (127). The use of intrathrombic argatroban together with t-PA significantly improved clot lysis when administered in this manner.

P>A selective factor X_a inhibitor, tick anticoagulant peptide, appears effective in restoring coronary blood flow and preventing reocclusion in a canine model of coronary thrombosis (128). Tissue factor pathway inhibitor (TFPI) controls activation of blood coagulation; antithrombin regulates the final stage (129). Both inhibitors inhibit the intermediate stage of activation. Heparin strongly accelerates antithrombin and releases TFPI in the blood. Thus, TFPI may contribute to the antithrombotic effect of heparin.

In summary, newer agents such as direct thrombin inhibitors, selective factor X_a inhibitors, and substances such as TFPI appear to merit further investigation in the prophylaxis and treatment of venous thrombosis.

Complications of Anticoagulation

Complications of heparin include bleeding and heparin-induced thrombocytopenia (HIT). The rates of major bleeding in recent trials using heparin by continuous infusion or high-dose subcutaneous injection are less than 5% (33). HIT (defined as a platelet count of less than 150,000 per µL) typically develops 5 or more days after the initiation of heparin therapy, occurring in 5% to 10% of patients. The syndrome is caused by heparin-dependent immunoglobulin G antibodies that activate platelets via their crystallizable fragment receptors (130). It has been demonstrated that these antibodies recognize heparin complexed with platelet factor 4 (131). Visentin and associates (132) have shown that such antibodies also react with endothelial cells coated with platelet factor 4, and such potential antibody-mediated vascular injury may help to explain the predisposition of patients with HIT to thromboembolism when challenged with heparin. Positive platelet aggregation tests for antibodies to heparin may be present in the absence of significant thrombocytopenia, and such tests may be negative despite a progressive decrease in platelet count (130). If a patient is placed on heparin for VTE and the platelet count progressively decreases to 100,000 per µLor less, heparin therapy should be discontinued. The formation of heparin-dependent immunoglobulin G antibodies and the risk of HIT appears to be lower with this form of heparin. HIT occurred in 9 of 332 patients receiving standard unfractionated heparin compared with none of 333 patients receiving enoxaparin (133). Eight of the nine patients receiving standard heparin developed one or more thrombotic events. However, it is important for clinicians to realize that HIT can occur with the use of either form of heparin. Newly developed

solid-phase assays that use complexes of heparin and platelet factor 4 as targets for the detection of heparin-induced antibodies are much more sensitive than the serotonin-release test used in the above study (133). Both argatroban and lepirudin are approved by the FDA for the treatment of VTE in the setting of HIT.

Heparin complication. Extensive purpura from heparin treatment.

Vena Cava Interruption

If heparin therapy cannot be continued, IVC filter placement can be undertaken to prevent lower extremity thrombus from embolizing to the lungs. These devices have been widely used for nearly two decades. The primary indications for filter placement include contraindications to anticoagulation, recurrent embolism while on adequate therapy, and significant bleeding complications during anticoagulation (134). Filters are sometimes placed in the setting of massive PE when it is believed that any further emboli might be lethal (135). A number of filter designs exist, but the Greenfield filter has been most widely used. Filters can be inserted via the jugular or femoral vein. These devices are effective and complications are unusual (135). Potential mechanisms of IVC filter failure include migration of the filter either distally or proximally to a point that no longer protects the vena cava, improper filter positioning allowing thrombi to bypass the filter, and formation of thrombosis proximal to the filter or on the proximal tip of the filter with subsequent embolization. Rare complications include clinically significant perforation of the IVC, cephalad migration, and displacement of the filter during insertion. IVC filters may rarely erode into the wall of the IVC. Occasionally, IVC obstruction due to thrombosis at the filter site may occur. Deaths due to filter placement are exceedingly uncommon. In general, anticoagulation is continued when a filter is placed unless it is contraindicated.

Thrombolytic Therapy

The National Institutes of Health consensus guidelines for PE thrombolysis issued in 1980 recommended thrombolytic therapy for patients with obstruction of blood flow to a lobe or multiple pulmonary segments and for patients with hemodynamic compromise, regardless of the size of the PE (136). The recommendations for use of lytic therapy in PE have recently been carefully reviewed (137). Current guidelines are presented in Table 28.4. We favor the use of thrombolytic therapy in patients with hemodynamic instability (hypotension) or severely compromised oxygenation (138). Stable patients with a significant embolic load are individualized, often receiving treatment in the absence of absolute or relative contraindications. For example, strong arguments for thrombolytic therapy can be made when the perfusion defect by lung scan or pulmonary arteriogram is extensive (defect approaching the equivalent of one-half of the pulmonary vascular bed) even without clear hemodynamic instability. Another setting in which thrombolytic therapy may be considered is when extensive DVT accompanies a submassive PE. There are no clinical studies suggesting a reduction in mortality in the latter settings, and perhaps future clinical trials will clarify appropriate guidelines.

Hypotension related to pulmonary embolism[a]
Severe hypoxemia
Lobar or greater perfusion defect[b]
Right ventricular dysfunction associated with pulmonary embolism
Extensive deep venous thrombosis

[a]This indication is widely accepted. All indications require careful review of contraindications to thrombolytic therapy.
[b]National Institutes of Health Consensus 1980 (136). This indication is not widely accepted.

TABLE 28.4 THROMBOLYTIC THERAPY IN VENOUS THROMBOEMBOLISM: POTENTIAL INDICATIONS

Acceleration of clot lysis in PE using thrombolytic therapy was first documented several decades ago (139,140 and 141). The multicenter, prospective, randomized Urokinase Pulmonary Embolism Trial evaluated 160 patients with arteriographically proven PE (55). Thrombolysis was accelerated in patients receiving urokinase compared with those on heparin when pulmonary arteriograms and lung perfusion scans were examined 24 hours after treatment. Thereafter, the difference between the two groups diminished, and by day 5 the improvement in each group was similar. There was no difference in the frequency of recurrent PE or mortality rate within 2 weeks of treatment. However, only 7% of the patients in the study were classified as having massive PE with shock. Although hemorrhagic complications in this trial were relatively high, further experience with thrombolytic therapy has suggested that adverse effects are reduced when venous cutdowns and unnecessary arterial phlebotomy are avoided. The second phase of this clinical trial also documented the efficacy of streptokinase administered over 24 hours. Finally, recombinant t-PA is approved for use in the treatment of PE and is administered as a 100-mg intravenous infusion delivered over 2 hours (142). Even shorter infusion durations have been evaluated, and future clinical trials may lead to wider acceptance of these regimens. At present, the above t-PA regimen is the most rapidly administered protocol that is currently approved for use.

Thrombolytic regimens approved by the FDA for the treatment of PE are presented in Table 28.5. Coagulation assays are unnecessary during thrombolysis because the approved regimens are administered as fixed doses. It is recommended that heparin be withheld until the thrombolytic infusion is completed. The aPTT is then determined, and heparin is initiated without a loading dose if this value is less than twice the upper limit of normal. If the aPTT exceeds this value, the test is repeated every 4 hours until it is safe to proceed with heparin. The method of delivery of thrombolytic agents has also been investigated. Although a number of investigators have used standard- or low-dose intrapulmonary arterial thrombolytic infusions to deliver a high concentration of drug in close proximity to the clot (143,144), intravenous therapy appears adequate in most cases (145). More direct techniques such as catheter-directed administration of intraembolic thrombolytic therapy are discussed below.

Streptokinase: 250,000 U i.v. (loading dose over 30 min), then 100,000 U/h for 24 h[a]
Urokinase: 2,000 U/lb i.v. (loading dose over 10 min), then 2,000 U/lb/h for 12 to 24 h[b]
Tissue-type plasminogen activator: 100 mg i.v. over 2 h

[a]Streptokinase administered over 24–72 h at this loading dose and rate has also been approved for use in patients with extensive deep venous thrombosis.
[b]Urokinase is not currently available in the United States.

TABLE 28.5 THROMBOLYTIC THERAPY FOR ACUTE PULMONARY EMBOLISM: APPROVED REGIMENS

The use of thrombolytic therapy for DVT is more controversial. A comprehensive review of the literature suggests that use of streptokinase may be associated with a reduction in postphlebitic syndrome when used for acute DVT, although bleeding is increased with thrombolytic therapy (146). Future studies may clarify the role of thrombolytic therapy for DVT. It is reasonable to consider systemic thrombolytic therapy in patients with proximal occlusive DVT associated with significant swelling and symptoms when there are no absolute or relative contraindications. Although agents other than streptokinase have been studied, there are no firm dosing recommendations for them. Catheter-directed techniques have been used for the treatment of acute DVT (see Pulmonary Embolectomy and Catheter-Extraction Techniques).

Hemorrhage is the primary adverse effect associated with thrombolytic therapy and generally occurs at sites of invasive procedures such as pulmonary arteriography or arterial line placement (147). Thus, when thrombolytic therapy is administered, invasive procedures should be minimized. The most devastating complication associated with this form of treatment is the development of intracranial hemorrhage (148). Clinical trials have suggested that this occurs in significantly less than 1% of patients. Contraindications to systemic thrombolytic therapy in VTE are listed in Table 28.6. Bleeding related to thrombolytic therapy requires immediate diagnosis and management. Bleeding from vascular puncture sites should be addressed with manual compression followed by a pressure dressing. Intracranial bleeding requires immediate discontinuation of thrombolytics or heparin, and emergent neurologic and neurosurgical consultation should be obtained. A noncontrasted brain CT scan should be performed. Retroperitoneal hemorrhage may result from a vascular puncture above the inguinal ligament and may be life-threatening. Patients with severe or refractory bleeding should be transfused with 10 U of cryoprecipitate and 2 U of fresh frozen plasma, and heparin can be reversed with protamine.

Absolute
Intracranial tumor or hemorrhagic stroke
Recent head trauma or cranial surgery
Active or recent internal bleeding
Relative
Thrombocytopenia or coagulopathy
Uncontrolled severe hypertension
Cardiopulmonary resuscitation
Surgery or biopsy within the previous 10 days

TABLE 28.6 THROMBOLYTIC THERAPY FOR ACUTE PULMONARY EMBOLISM: CONTRAINDICATIONS

Brachial artery hematoma. Hematoma complication after brachial artery catheterization and urokinase administration.

Pulmonary Embolectomy and Catheter-Extraction Techniques

Pulmonary embolectomy may be performed in the setting of acute massive PE. Although many patients die from PE before surgical embolectomy would be feasible, some deteriorate hours after the initial episode, suggesting that surgery may occasionally be appropriate. In one series of 71 embolectomies performed with cardiopulmonary bypass, hospital mortality was 29% (149). The mortality in those patients who had not sustained a cardiac arrest preoperatively was only 11%, however. Transvenous embolectomy via a suction-catheter device has been used by some (150,151) but has not received widespread acceptance. Timsit and associates (151) treated 18 patients over a 7-year period with massive PE using this technique. Clot extraction was successful in 11 of the patients. Thirteen survived their hospital stay, and five died.

Although the intravenous route has been the primary method of delivery, local thrombolytic therapy has been used in massive PE and may preclude the need for surgical embolectomy. Intrapulmonary arterial delivery of thrombolytic agents by bolus or prolonged infusion with or without concomitant heparin has been used for massive PE (see Thrombolytic Therapy) (152,153). These studies have generally been small and uncontrolled. Although intrapulmonary arterial delivery of thrombolytic agents appears to offer no advantage over the intravenous route (145), *intraembolic* thrombolytic infusions may offer advantages over merely infusing the agents into the pulmonary artery. Such techniques have been applied in both animal models of PE and in patients, with enhanced thrombolysis (152,153). Less than conventional doses of t-PA or urokinase are delivered via a catheter imbedded directly within massive emboli over 10 to 20 minutes (153). Combining thrombolytic therapy via direct delivery (at low doses) with the possible mechanical benefits of direct intraembolic infusion may have promise and could prove advantageous over the intravenous route, particularly in the setting of contraindications to thrombolytic therapy. Larger randomized studies are needed to demonstrate the efficacy, potential advantages, and safety of such techniques. The implementation of these techniques and the catheter-directed administration of intraembolic thrombolytic therapy described above depend on the experience of the medical team involved. Finally, catheter-directed techniques have been successfully used in the setting of acute iliofemoral DVT using urokinase doses ranging from 1,400,000 U to 16,000,000 U delivered over an average of 30 hours (154). Further investigation in this area is under way.

Hemodynamic Management of Massive Pulmonary Embolism

Massive PE should always be suspected in the setting of the sudden onset of hypotension or extreme hypoxemia. The presence of electromechanical dissociation or

sudden cardiac arrest should always make massive PE a consideration. If the patient is stable enough, V/Q scanning should be performed when possible. Although PE should be proven with either a high-probability V/Q scan (helical CT or MRI may also offer proof) and when necessary pulmonary arteriography, echocardiography may support the diagnosis of massive PE and may also suggest the need for aggressive intervention, including thrombolytic therapy (155). Once massive PE associated with hypotension and/or severe hypoxemia is suspected, supportive treatment is immediately initiated. Intravenous saline should be infused rapidly but cautiously because right ventricular function is often markedly compromised. Dopamine or norepinephrine appear to be the favored choices of vasoactive therapy in massive PE and should be administered if the blood pressure is not rapidly restored (155). General guidelines for the approach to massive PE are offered in Table 28.7. Because death in this setting results from right ventricular failure, dobutamine has been recommended by some as a means by which to augment right ventricular output (156,157). A vasopressor such as norepinephrine combined with dobutamine might offer optimal results, and further exploration of such combined therapy would prove enlightening. Oxygen therapy is administered, and thrombolytic therapy is considered as described above. Intubation and institution of mechanical ventilation are instituted as needed to support respiratory failure.

Oxygen therapy
Intubation and mechanical ventilation
Intravenous heparin
Fluid administration
Norepinephrine or dopamine
Thrombolytic therapy
Catheter or suction cup embolectomy
Surgical embolectomy
Vena caval filter placement

TABLE 28.7 ACUTE MASSIVE PULMONARY EMBOLISM: THERAPEUTIC CONSIDERATIONS

CHRONIC THROMBOEMBOLISM

Although the vast majority of acute PE cases resolves with treatment, occasionally a substantial residual thromboembolic burden remains (158,159). In this setting, the clot becomes organized and adherent and is not amenable to thrombolysis. If the obstruction becomes extensive, pulmonary hypertension develops. This syndrome most commonly occurs in patients 40 to 70 years of age but can occur at any age. At least 50% of patients who develop chronic thromboembolic pulmonary hypertension have no documented history of DVT or PE. This feature greatly impedes the diagnosis. Most patients have no identifiable coagulopathy. Fatigue and dyspnea with exertion are the most common complaints. The nonspecific nature of these findings may substantially delay the correct diagnosis. The physical examination generally reveals a right ventricular heave, a loud pulmonary component of the second heart sound, and tricuspid regurgitation consistent with pulmonary hypertension. In more severe cases, a right ventricular third heart sound may be present. In 20% of patients, one or more murmurs may be auscultated over the lung fields.

Once the diagnosis is suspected, the diagnostic evaluation is generally revealing. The chest radiograph usually reveals right ventricular enlargement and enlarged main pulmonary arteries. Electrocardiographic changes are consistent with pulmonary hypertension. Arterial blood gases generally reveal hypoxemia with a widened A-a difference, although some patients may only demonstrate exercise-induced hypoxemia. Echocardiography documents pulmonary hypertension and enlargement of the right ventricle. It is prudent to perform chest CT scanning, which may reveal other rare causes of pulmonary hypertension such as mediastinal fibrosis; it may, in fact, demonstrate evidence of chronic thrombi. Helical CT scanning may be particularly useful in this regard. The V/Q scan is nearly always high probability for PE but occasionally is less impressive. Right heart catheterization and pulmonary arteriography are performed, both to establish the diagnosis with certainty and to determine operability. Pulmonary angioscopy frequently has proven complementary to arteriography in assessing these patients (160).

Although anticoagulation should be instituted and IVC filters are recommended in patients with chronic thromboembolic pulmonary hypertension, the only means by which to alleviate symptoms and impact on survival is with surgery. The group from the University of California at San Diego has had tremendous experience with evaluation and surgical therapy of these patients. Pulmonary thromboendarterectomy is performed via median sternotomy on cardiopulmonary bypass, and the overall mortality, which has continued to improve, is now less than 5%. Lung transplantation can be performed in patients in whom thrombi are too distal to extract.

CONTROVERSIES AND PERSONAL PERSPECTIVES

VTE is difficult to study in large randomized trials because of the varying presentations of acute PE and DVT, the difficulty with diagnosis, and the many different settings and specialties involved. A number of questions remain unanswered. Cost-effective approaches to the diagnosis and therapy of DVT and PE remain unclear. In view of the numerous controversies currently facing us, several groups such as the American College of Chest Physicians and the American Thoracic Society have taken steps to form consensus guidelines for areas in which substantial data exist and opinion and position statements to address issues and plan research strategies for areas that remain less clear (111,161,162).

Diagnostic Approach to Venous Thromboembolism

There are no firm consensus guidelines for the diagnostic approach to VTE. Critical pathways have been constructed by experts in the field for the diagnostic approach to DVT, for example, but these approaches suffer from institutional variability, availability of certain diagnostic studies, and lack of incorporation of newer technologies such as MRI. The American Thoracic Society has recently formulated consensus guidelines for the diagnostic approach to VTE (162). These include algorithms and the role of new technologies and account for institution-specific differences in approach.

The International Cooperative Pulmonary Embolism Registry represents the largest prospective PE registry ever undertaken (163). This effort has helped to answer a number of clinical questions and contribute to future strategies in clinical investigation. It has already enhanced international communication, which should increase the number and quality of international randomized clinical trials and help to unify the approach to VTE.

The roles of newer methods to diagnose DVT and PE such as MRI and helical CT scanning need to be clarified, and recommendations may change as the technology continues to improve. How often are venography and pulmonary arteriography still necessary? When should MRI be used in addition to, or instead of, ultrasonography? Can all patients with a negative helical CT be safely followed without therapy?

Screening and Prophylaxis

Determining a practical means by which to identify patients with recently characterized thrombophilias such as activated protein C resistance and determining their significance will facilitate the implementation of more meaningful prophylaxis and treatment protocols. Who should be screened for activated protein C resistance? Do patients with this disorder require lifelong prophylaxis? When should combined mechanical and pharmacologic prophylaxis be applied? What is the appropriate duration of prophylaxis in different clinical settings? What *are* the differences between the different LMWH compounds? Although the American College of Chest Physicians guidelines are useful, more data are needed to enhance their usefulness. *At present, recommendations in specific settings must be made for specific agents that have been studied in that setting*.

Therapeutic Approaches

A number of anticoagulation issues require clarification. The duration of therapy in different subsets of patients with VTE needs to be determined. Should patients with PE and without residual DVT be treated for a shorter period of time than patients with extensive DVT? Is it beneficial to use MRI to document the extent of DVT in every patient? Is it appropriate to repeat lower extremity studies in patients with DVT to help determine treatment duration? We are treating increasing numbers of outpatients, and this is simplified with the LMWH preparations. Which agents (and doses) are appropriate? Where do the direct thrombin inhibitors, selective factor X_a inhibitors, and TFPI fit in?

What are appropriate guidelines for thrombolytic therapy in DVT and PE? Is one thrombolytic agent or regimen superior to others? When should acute pulmonary embolectomy be performed? Although some individuals believe that thrombolytic therapy should be reserved for patients with “hemodynamic compromise,” the latter term is not clearly defined. I believe that patients with PE, extreme hypotension, and evidence of end-organ dysfunction, or those with extreme hypoxemia refractory to

maximal oxygen therapy, should receive intravenous thrombolytic therapy even in the presence of certain “absolute contraindications” such as occult blood in the stool if other methods such as surgical embolectomy or catheter-based therapy are not immediately accessible. Even severe gastrointestinal bleeding can be controlled more easily than PE associated with shock. It is difficult to make blanket guidelines, and presence at the bedside may continue to be a prerequisite for rational decisions in such settings. Guidelines need to be investigated and clarified. The precise roles of systemic and local thrombolytic therapy and catheter-directed techniques, including indications, doses, duration of therapy, and delivery methods, all need clarification. The number of meaningful clinical trials planned and under way suggest that we may ultimately be able to resolve many of these controversies.

THE FUTURE

The future will be productive with regard to characterization of genetic risk factors, diagnosis, therapy, and prevention. The discovery of additional thrombophilic disorders appears inevitable, as does the development of standardized methods to screen patients for these. This, in turn, will undoubtedly affect current prophylaxis and treatment guidelines. Efforts currently under way include the PIOPED II, a prospective clinical trial evaluating the utility of helical CT scanning for suspected PE. Analysis of such data will assist in the delineation of appropriate algorithms for diagnosis. Nuclear imaging technology may improve, but the imaging of actual thromboses and emboli with MRI and CT appears to be much more promising. Our understanding of the utility of these techniques and the technology itself continue to evolve. The use of MRI, with its potential ability to distinguish acute from chronic thrombosis, may not only lead to more appropriate initiation of therapy but also may aid in the determination of the length and aggressiveness of therapy. CT scanning will become faster and undoubtedly more accurate. The latter techniques will likely replace arteriography and venography altogether. Hematologic studies such as the D-dimer may evolve into more useful techniques. The evolution of diagnostic technology will affect therapy. The ability to diagnose the presence and extent of acute DVT will permit refinement of treatment stratification. How issues such as extent of DVT, number of persisting risk factors, and specific therapeutic modality affect treatment duration should become more clearly defined. We are treating larger numbers of outpatients and using LMWHs. Newer agents such as direct thrombin inhibitors, selective factor X_a inhibitors, and TFPI, as well as more fibrin-specific thrombolytic agents, should have more clearly defined therapeutic roles. It is likely that we have an easier drug to use than warfarin. The means by which we monitor anticoagulation will improve. The roles of systemic and local thrombolytics, including indications, doses, duration of therapy, and delivery methods, need clarification. Guidelines for diagnostic and therapeutic approaches to VTE will become substantially more refined. It is very important to note that preventive efforts are of paramount importance. We are making strides in characterizing prolonged air travel as a risk factor for VTE. Paul Egermayer, a physician and VTE researcher, passed away in May 2001 in the midst of a very productive research career. This insightful and energetic individual wisely emphasized the importance of VTE prevention by stating that “the real problem is not the 10% of patients who survive long enough to receive treatment, but the 90% in the first hour after the event. For both groups, more systematic prophylaxis is clearly the way forward. Treatment is merely the ambulance waiting at the bottom of the cliff” (164).

OVERVIEW

Hypertrophic cardiomyopathy (HCM) is caused by mutations in genes that encode cardiac sarcomeric proteins. The disease is characterized by myocardial hypertrophy, most commonly affecting the interventricular septum, and disorganization (disarray) of cardiac myocytes and myofibrils. Myocardial fibrosis is common and may be associated with small-vessel disease. Twenty-five percent of patients have a dynamic left ventricular outflow tract gradient caused by the combined effects of rapid ventricular ejection, a narrowed outflow tract, and systolic anterior motion (SAM) of the mitral valve.

The characteristic pathology of HCM contributes to a spectrum of functional abnormalities that includes myocardial ischemia, diastolic dysfunction, ventricular and atrial arrhythmias, and congestive cardiac failure. Patients can present at any age with chest pain, dyspnea, palpitations, and syncope. The most important complication of the disease is sudden death, which occurs throughout life with an annual incidence (in referral populations) of 2% to 4% in children and adolescents and approximately 1% in adults. Other complications include thromboembolism, infective endocarditis, and conduction system disease. Clinical features associated with an increased risk of sudden death include nonsustained ventricular tachycardia (NSVT), syncope, a family history of sudden death, an abnormal exercise blood pressure response, and severe left ventricular hypertrophy.

The principal aims of management are the alleviation of symptoms and the prevention of sudden death. In patients with substantial left ventricular outflow tract obstruction, interventions that reduce the magnitude of the outflow tract gradient (e.g., disopyramide, beta-blockade, alcohol ablation of the interventricular septum, dual-chamber pacing, and surgery) often result in significant symptomatic improvement. Therapeutic options in patients without left ventricular outflow tract obstruction are more limited, but chest pain and, to a lesser extent, dyspnea may be alleviated by pharmacologic therapy. Clinical risk-stratification can identify the risk of sudden death in most adults and many adolescents, allowing effective prophylactic treatment with an implantable cardioverter-defibrillator (ICD) or reassurance where appropriate.

HISTORICAL PERSPECTIVE

HCM is currently defined by the presence of unexplained myocardial hypertrophy (1). Patients fulfilling this criterion have been described for more than 100 years (2,3,4,5,6,7,8,9,10 and 11), but it was not until the publication of Sir Russell Brock’s paper on “functional obstruction of the left ventricle” in 1957 (12) and Donald Teare’s description of asymmetric myocardial hypertrophy in 1958 (13) that HCM was established as a distinct clinical and pathologic entity. Since that time, clinical diagnostic criteria have evolved in parallel with the technology available to cardiologists. In the 1960s (14,15,16,17,18,19,20,21 and 22), reliance on stethoscope and cardiac catheterization meant that left ventricular outflow tract obstruction was considered to be the diagnostic hallmark of HCM. In the 1970s, the widespread use of M-mode echocardiography (23,24,25,26 and 27) emphasized the asymmetric nature of left ventricular hypertrophy and established asymmetric septal hypertrophy (ASH) as the sine qua non of the disease. However, with the advent of two-dimensional echocardiographic imaging, it became clear that the spectrum of ventricular involvement is much more heterogeneous and that virtually any pattern of unexplained myocardial hypertrophy is consistent with the diagnosis of HCM (28,29 and 30).

After reports described families in which a high incidence of premature sudden death, left ventricular hypertrophy, and subaortic stenosis was seen (10,11), early clinical studies suggested that HCM was inherited in 30% to 50% of patients (31). Subsequent M-mode echocardiographic studies reported higher figures but may have overestimated the prevalence of ASH (32,33). Prospective clinical genetic studies using two-dimensional echocardiography suggested that 50% to 60% of cases were inherited in an autosomal dominant fashion (34,35), but with more detailed pedigree analysis, this figure increased to more than 80%. The identification of numerous sarcomeric protein mutations in individuals with HCM (36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66,67 and 68) in the last decade has confirmed that sporadic disease is relatively uncommon. Genetic testing has also highlighted the phenomena of incomplete penetrance and age-related disease expression, and as a result diagnostic criteria are once again being revised (69).

ANATOMY

Macroscopic

HCM is defined by the presence of unexplained myocardial hypertrophy (1). In Teare’s original series (13), myocardial hypertrophy was asymmetric, involving the interventricular septum more than the posterior or free wall of the left ventricle (Fig. 29.1). Subsequent studies have shown that, although asymmetric septal hypertrophy is present in approximately two-thirds of patients (70,71), virtually any pattern can occur. Hypertrophy confined to the left ventricular apex is uncommon, except possibly in Japanese patients (72). Isolated right ventricular hypertrophy is unreported. Macroscopically, the cut surface of involved myocardium has a

characteristic appearance reminiscent of a uterine fibroid, with abnormally short and broad muscle fibers running in different directions. An additional feature occasionally seen during post mortem examination is a patch of subendocardial thickening on the septum caused by repeated contact with the anterior leaflet of the mitral valve.

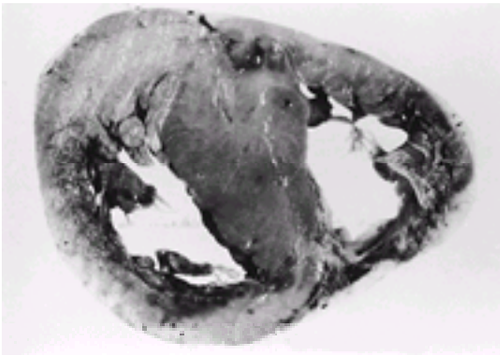

FIGURE 29.1 Myocardial section demonstrating the classical appearance of severe asymmetric septal hypertrophy in a patient with hypertrophic cardiomyopathy. (From Teare D. Asymmetrical hypertrophy of the heart in young adults. *Br Heart J* 1958;20:1–8, with permission.)

Microscopic

The cardinal microscopic feature of HCM is myocyte disarray (70,71,73,74,75 and 76) (Fig. 29.2). This is recognized by a loss of the normal parallel arrangement of myocytes, with cells forming circles around foci of connective tissue. Individual myocytes may show marked variation in diameter and nuclear size and have abnormal intercellular connections. Myofibrillar architecture within cells is also disrupted—so-called myofibrillar disarray. Myocyte disarray is described in congenital heart disease, hypertension, and aortic stenosis, but in HCM it is typically more extensive, occupying 20% or more of at least one ventricular tissue block and more than 5% of total myocardium at post mortem examination. Disarray is often associated with myocardial fibrosis, ranging from extensive scarring in the interventricular septum, free wall of the left ventricle, and occasionally the left ventricular papillary muscles (77) to a more diffuse interstitial pattern (78). The demonstration of abnormal small intramural arteries (external diameter less than 1,500 mm) within fibrotic areas and in patients with ventricular dilatation and reduced systolic function (79,80) (Fig. 29.3) has suggested that contiguous myocardial scarring may be caused by myocardial ischemia. However, more recent data have shown that small-vessel disease may be just as widespread in patients without extensive fibrosis and may occur in the absence of myocardial hypertrophy (81).

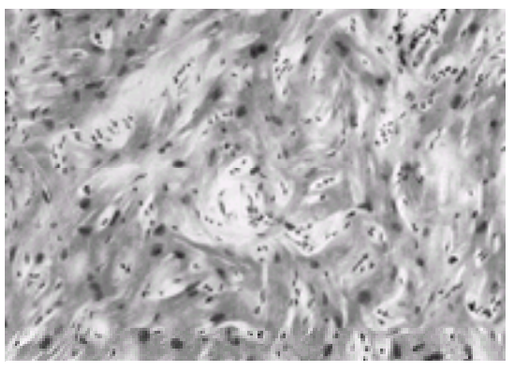

FIGURE 29.2 Myocyte disarray. Myocytes cross at right angles and display abnormal intercellular connections. Myocyte nuclei are large and of different sizes. Foci of fibrosis containing spindle-shaped connective-tissue cells are present. Evidence of marked disorganization of the intracellular myofibrillar structure is also seen (hematoxylin-eosin stain). (Courtesy of M. Davies, St. George's Hospital Medical School, London.)

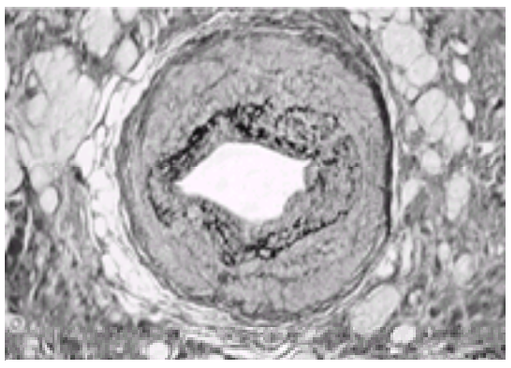

FIGURE 29.3 Section through a small artery demonstrating smooth-muscle disorganization in the intima and media, resulting in an abnormally high medial width–to-lumen ratio. In the adjacent myocardium, extensive replacement of myocytes by fibrous tissue can be seen (Elastica van Gieson stain). (Courtesy of M. Davies, St. George's Hospital Medical School, London.)

PATHOPHYSIOLOGY

Molecular Genetics

HCM is usually familial, with autosomal dominant inheritance. Early reports of autosomal recessive patterns of transmission (31) have not been confirmed. A cardiac phenotype similar to that seen in HCM is described in association with a number of rare genetically determined disorders, including Friedreich's ataxia (chromosome 9) (82,83), neurofibromatosis (chromosome 17) (84), hereditary spherocytosis (chromosome 14) (85), aniridia with catalase deficiency (chromosome 11) (86), and Noonan's syndrome (chromosome 12) (87,88 and 89). Because the clinical phenotype of these disorders differs considerably from that seen in most patients with familial HCM, and none of the genes associated with these disorders encode known cardiac proteins, the identification of candidate genes in familial HCM has until quite recently relied on linkage analysis and a positional candidate gene approach. The first disease locus to be identified was situated in the chromosome 14q1 region in a large French Canadian family (36). The genes encoding the two cardiac myosin heavy chains (a and b) are arranged in tandem on chromosome 14 band q11.2-13, and further analysis involving this Canadian family revealed that each affected member had a missense mutation in exon 13 of the b-myosin heavy-chain gene (38). Since this discovery, numerous mutations in seven other genes that encode thick and thin filament sarcomeric proteins have been reported (Fig. 29.4): cardiac troponin T (chromosome 1), cardiac troponin I (chromosome 19), a-tropomyosin (chromosome 15), cardiac myosin-binding protein C (chromosome 11), the essential and regulatory myosin light chains (chromosomes 3 and 12, respectively), and cardiac actin (chromosome 15) (36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52,53,54,55,56,57,58,59,60,61,62,63,64,65,66 and 67). In addition, a locus on chromosome 7 has been identified in a large Irish family with HCM and Wolff-Parkinson-White syndrome (90,91), and a further unconfirmed mutation in the gene encoding another sarcomeric protein, Titin (chromosome 2) (68), has been reported.

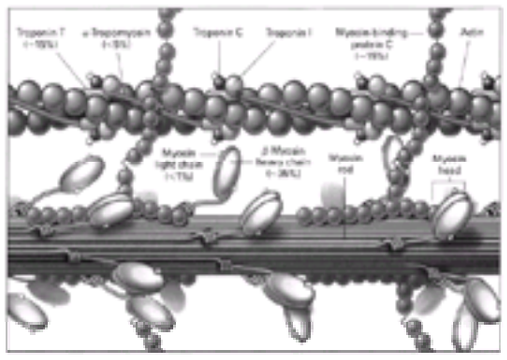

FIGURE 29.4 Structure of the human sarcomere. Cardiac contraction occurs as a consequence of actin-myosin interaction. This is initiated by the binding of calcium to the troponin complex (C, I, and T) and a-tropomyosin. Actin then stimulates adenosinetriphosphatase activity in the globular myosin head, resulting in the generation of contractile force. Cardiac myosin-binding protein C binds to myosin and modulates contraction. The estimated frequency of sarcomeric protein gene mutations that cause hypertrophic cardiomyopathy is shown. (From Spirito P, Seidman CE, McKenna WJ, et al. The management of hypertrophic cardiomyopathy. *N Engl J Med* 1997;336:775–785, with permission.)

Family studies have shown that disease-causing mutations are associated with considerable variation in disease penetrance and clinical expression. This is not surprising, given the extent of genetic heterogeneity in HCM and the different structural, regulatory, enzymatic, and force-generating properties of individual sarcomeric proteins. Preliminary data suggest that mutations in particular genes tend to be associated with a common phenotype—for example, patients with troponin-T gene mutations may experience sudden death with mild left ventricular hypertrophy, whereas most patients with b-myosin heavy-chain mutations that cause sudden death have at least moderate hypertrophy (92,93,94,95 and 96). However, considerable heterogeneity exists in the expression of different mutations within the same gene, and also between patients with identical mutations.

Allelic heterogeneity may be explained by the effect of a given mutation on the structure and function of the complete peptide. For example, b-myosin consists of a globular head, an a-helical rod and a hinge region. The globular head contains a catalytic adenosine triphosphatase-binding site, an actin-binding site, and interaction sites for regulatory and essential light chains in the head-rod region (47,97). Most mutations in the b-myosin gene are missense DNA nucleotide substitutions that change a single amino acid in the polypeptide sequence. The majority of disease-causing b-myosin heavy-chain mutations are found in one of four locations: the actin-binding site, the nucleotide-binding pocket, a region adjacent to the binding site for two reactive thiols in the hinge region, and the a-helix, close to the essential light-chain interaction site (47). Therefore, depending on the position of the mutation, changes might be expected in adenosine triphosphatase activity, actin-myosin interaction, and protein conformation during contraction.

The functional consequences of HCM mutations have been studied using isolated cardiac and skeletal muscle preparations, baculovirus-based systems, and transgenic animal models (97,98 and 99). Most data suggest that the majority of mutations have a dominant negative effect on sarcomere function, that is, the mutant protein may be sufficiently stable to be incorporated in the sarcomere, but its interaction with the normal wild-type protein may disrupt normal sarcomeric assembly and/or function. Studies of b-myosin heavy-chain mutations suggest that they reduce force generation and thus may cause compensatory hypertrophy—the so-called hypocontractile hypothesis. Mutations in the a-tropomyosin and possibly the essential and regulatory myosin light-chain genes, however, are reported to cause an increase in calcium sensitivity and hypercontractility. The effect of mutations in troponin T on contractility is more complex, but the overall effect seems to be a reduction in contractile performance and diastolic abnormalities. Recent work on a troponin T truncation mutation has shown that the functional effects of the mutation may be substantially altered by the ratio of wild-type to mutant protein expressed within the myocardium (100).

Variable expression of identical mutations indicates that other genetic and possibly environmental factors are important in disease expression. The effect of age is perhaps the best-characterized influence; most patients develop electrocardiographic (ECG) and echocardiographic manifestations of the disease after puberty and before the age of 30 years (101). Patients with mutations in the cardiac myosin-binding protein C gene may be an exception to this rule; in them, the prevalence of hypertrophy continues to rise beyond the third decade into old age (63,102). A single case of late disease expression has also been described in a patient with a troponin-T gene mutation (103).

Although no clinical study has demonstrated any convincing evidence for an effect of sex on disease expression, most large series show a predominance of male subjects. In one animal model (99), male mice with an a-myosin heavy-chain mutation developed more severe disease at an earlier age than their female counterparts. The relevance of this to human disease is unknown. Potential genetic modifiers of disease expression include renin-angiotensin-aldosterone system gene polymorphism (104,105,106,107,108,109 and 110) and the possibility of homozygosity and compound heterozygotes, both of which have now been described in HCM families (111,112 and 113).

Catecholamines

A role for excess catecholamine activity in HCM pathophysiology was first suggested by histologic studies describing the presence of increased myocardial sympathetic nerve fibers and norepinephrine content (73). Although these initial observations were subsequently found to be erroneous (114) and most studies in humans have failed to show convincing evidence for increased myocardial catecholamine concentration (115), the adrenergic hypothesis has persisted. Several studies have demonstrated evidence for decreased neuronal uptake and metabolism of norepinephrine, as well as reduced myocardial beta-adrenoceptor density (116,117 and 118). These abnormalities may simply reflect a loss of sympathetic nerve endings in areas of fibrosis or possible secondary disturbances in myocardial metabolism.

Myocardial Ischemia

Several studies have shown that patients with HCM have reduced coronary flow reserve and metabolic evidence for myocardial ischemia during pacing and pharmacologic stress (119,120,121,122,123,124 and 125). It is likely that myocardial ischemia is the cause of chest pain and dyspnea in many individuals, and limited data are available to suggest that myocardial ischemia may be a trigger for fatal ventricular arrhythmia (126,127). However, the clinical evaluation of patients with chest pain remains problematic. For example, whereas ST segment depression occurs in up to 40% of patients during exercise (118), lactate production during atrial pacing is seen in more than one-half of those with negative results of exercise tests. ST segment depression also occurs during ambulatory ECG monitoring in 25% of symptomatic young patients (128), but its metabolic significance in unknown. A number of pathophysiologic mechanisms have been suggested as causes of myocardial ischemia in patients with HCM (Table 29.1), but the predominant mechanism in individual patients is usually impossible to determine.

TABLE 29.1 POTENTIAL MECHANISMS OF MYOCARDIAL ISCHEMIA IN HYPERTROPHIC CARDIOMYOPATHY

Diastolic Dysfunction

Several of the characteristic pathophysiologic features of HCM impair diastolic function, specifically, myocyte hypertrophy, myocyte and myofibrillar disarray, abnormal

intracellular calcium metabolism, myocardial fibrosis, abnormal ventricular geometry, and myocardial ischemia (129,130,131,132,133,134,135,136,137,138,139 and 140). In a minority of patients, a restrictive hemodynamic picture may predominate, with marked elevation of filling pressures, biatrial dilatation, and predominantly right-sided signs, often in the absence of substantial myocardial hypertrophy (137,138). In the majority of cases, a mixed picture with slow relaxation and elevated end diastolic pressures is observed. Invasive hemodynamic studies have demonstrated a flat pressure-volume relationship with a response to off-loading similar to that seen in patients with constrictive pericarditis, suggesting the presence of increased pericardial or possibly myocardial constraint (140).

CLINICAL PROFILE

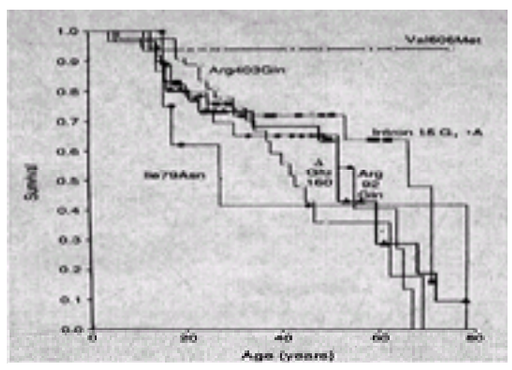
Epidemiology

Whereas HCM occurs in all racial groups, most of the published literature comes from populations in North America, Europe, and Japan. Of five studies that have examined the prevalence of HCM (141,142,143,144 and 145), all but one suggest a prevalence of 0.2% to 0.5% in the general population. The exception (144) was a disease surveillance study that examined the prevalence of HCM in a population of patients already suspected of having cardiac disease on clinical grounds.

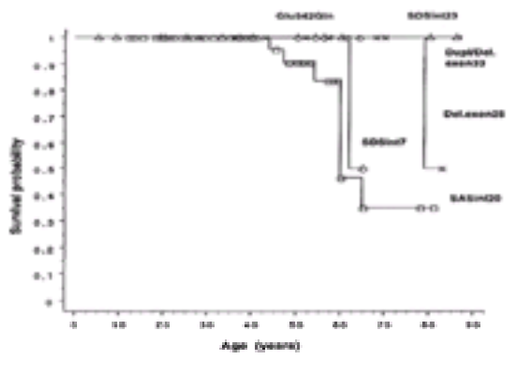
Natural History

Ventricular hypertrophy usually develops during periods of rapid somatic growth, sometimes during the first year of life, but more typically during adolescence (101). De novo myocardial hypertrophy in early middle age is not reported, but the diagnosis of idiopathic or inappropriate left ventricular hypertrophy in patients older than 60 years is well described (146,147,148,149 and 150). The pattern of disease in this age group is said to differ from that observed in younger patients with HCM, in that symptoms occur late in life, the prognosis for most patients is relatively good, and many have mild hypertension. A number of morphologic differences are also described, including restricted anterior excursion of the mitral valve, mitral annular calcification, and a crescent-shaped left ventricular cavity. Whether the majority of patients with this so-called elderly phenotype has a separate disease entity reflecting a polygenic response to hypertrophic stimuli remains uncertain, but recently gathered data from families with mutations in the cardiac myosin-binding protein C gene have shown that a phenotype identical to that of young patients can be seen in older patients (63,102).

In most patients with HCM, progression of symptoms is slow and age related and associated with a gradual deterioration in left ventricular function. This course may end at any point in sudden death. Early data from referral institutions reported annual mortality rates of approximately 2% per annum in adults and 2% to 4% during childhood and adolescence (151,152 and 153). More recent data from regional and tertiary adult populations (154,155,156,157,158 and 159) suggest a lower figure of approximately 1% per annum. Sudden death in the first decade of life is thought to be relatively uncommon, although only limited data about this age group are available (160). In fewer than 10% of patients, rapid symptomatic deterioration may occur in association with progressive myocardial wall thinning, a reduction in systolic performance, and an increase in left ventricular end systolic dimensions (161). Survival in patients with late-onset disease has been thought to be relatively benign in comparison with younger patients, but in some families with myosin-binding protein C mutations, the rate of death or adverse cardiovascular events can be similar to that of the most severe troponin-T or b-myosin heavy-chain mutations once disease is expressed (*e*Fig. 29.4.1 and *e*Fig. 29.4.2) (63,92,93,94,95 and 96,102).



***e*FIGURE 29.4.1** Kaplan-Meier survival curves in patients with hypertrophic cardiomyopathy caused by b-myosin heavy-chain and cardiac troponin-T mutations. The survival of patients with a “benign” b-myosin heavy-chain mutation Val606Met is much longer than patients with either troponin-T mutations (Intron 15 G1-A, Ile79Asn, D Glu160 and Arg92Gln) or a “malignant” b-myosin heavy-chain mutation Arg403Gln. (From Watkins H, McKenna WJ, Thierfelder L, et al. Mutations in the genes for cardiac troponin T and alpha-tropomyosin in hypertrophic cardiomyopathy. *N Engl J Med* 1995;332:1058–1064.)



***e*FIGURE 29.4.2** Kaplan-Meier survival curves in patients with hypertrophic cardiomyopathy associated with six different mutations in the MYBPC3 gene. Del., deletion; Dupl, duplication. (From Charron P, Dubourg O, Desnos M, et al. Clinical features and prognostic implications of familial hypertrophic cardiomyopathy related to the cardiac myosin-binding protein C gene. *Circulation* 1998;97:2230–2236, with permission.)

Symptoms

Patients may present at any age with dyspnea, chest pain, unexplained syncope, or arrhythmia, or the disease may be identified after sudden death (13,14,20,28,151,152,153,154,155,156,157,158,159,160,161 and 162). Many patients have no or only minor symptoms, and in children and adolescents, the diagnosis is often made during family screening. Exertional chest pain occurs in up to 30% of adults, and many complain of atypical pain that is prolonged and occurs at rest and after meals (163). Dyspnea is common in adult patients, probably as a consequence of elevated pulmonary venous pressure resulting from impaired ventricular relaxation and filling. Patients less commonly present with paroxysmal nocturnal dyspnea and orthopnea, sometimes in the presence of apparently mild disease. The mechanism is uncertain, but myocardial ischemia or arrhythmia may be responsible.

Approximately 15% to 25% of patients experience syncope, and 20% complain of presyncope. In some, these symptoms are caused by paroxysmal arrhythmia, conduction system disease, or abnormal vascular responses during exercise, but in most cases, no underlying cause is identified even after extensive investigation. Recurrent unexplained syncope is associated with a higher incidence of sudden death when it occurs during adolescence (151,152 and 153,162). Palpitations are a frequent complaint. Symptomatic cardiac contractions and ventricular ectopy are not uncommon, but most sustained palpitation is caused by supraventricular arrhythmia (151,152).

Examination

In the majority of patients with HCM, physical examination is unremarkable. Patients may have a rapid upstroke to the arterial pulse, occasionally followed by a secondary peak, reflecting hyperdynamic left ventricular contraction (13,14 and 15,20). The left ventricular impulse may be forceful, and a palpable left-atrial beat may be present. In approximately one-third of patients, a prominent ‘a’ wave is seen in the jugular venous pressure wave caused by reduced right ventricular compliance. On auscultation, the first and second heart sounds are usually normal, but a fourth heart sound, reflecting atrial systole into a poorly compliant left ventricle, may be heard in patients who are in sinus rhythm. Occasionally, reverse splitting of the second heart sound may be heard in patients who have severe left ventricular outflow tract obstruction. In one-fourth of patients, a systolic murmur caused by left ventricular outflow obstruction can be heard at the left sternal edge, radiating to the aortic

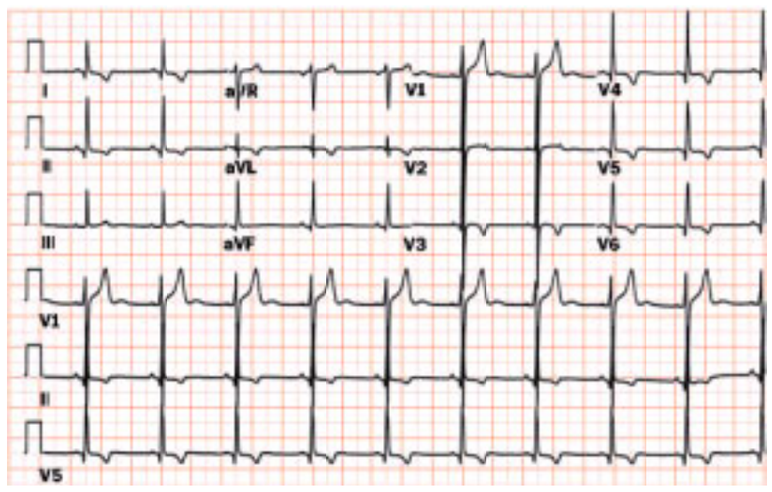
and mitral areas, but not into the neck or axilla. A characteristic feature of the murmur is its dependence on ventricular volume. Physiologic and pharmacologic maneuvers that decrease afterload or venous return (e.g., standing, Valsalva's maneuver, administration of amyl nitrate) increase the intensity of the murmur, whereas interventions that increase afterload and venous return (e.g., squatting and administration of phenylephrine) reduce it. The majority of patients with significant left ventricular outflow gradients also has mitral regurgitation. This can be difficult to distinguish clinically from the outflow gradient (13,14), but its presence is suggested by the length of the murmur (starting 30 to 40 ms before the onset of the outflow gradient), radiation to the axilla, and, in patients with severe regurgitation, a mid-diastolic rumble. Rarely, a systolic murmur may be heard in the pulmonary area as a consequence of right ventricular outflow obstruction.

HEART SOUNDS

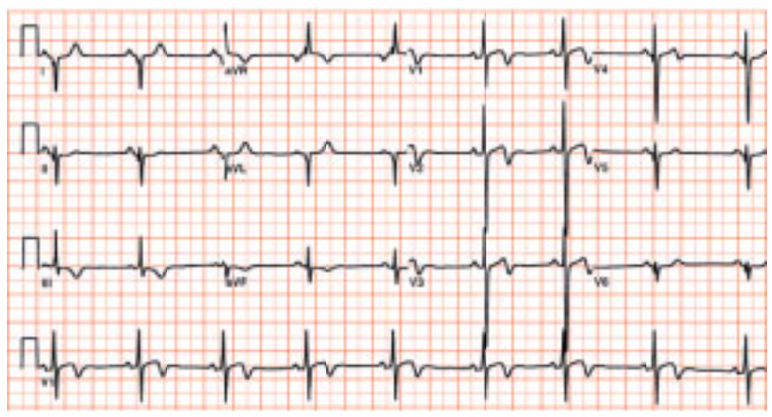
Audio 29.1 Hypertrophic cardiomyopathy. Auscultation performed in a 60-year-old male patient. The systolic gradient across the left ventricular outflow tract was 55 mm Hg at rest and increased to 121 mm Hg after amyl nitrate inhalation. The mid-systolic, crescendo-decrescendo ejection murmur is observed.Valsalva maneuver and sudden squatting are helpful in distinguishing this from fixed aortic valvular stenosis. Left upper sternal border. (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Electrocardiogram

Although ECG abnormalities occur in the majority of patients with HCM, no changes are specific to the disease (13,14 and 15,28,162,164,165,166,167,168,169,170 and 171). ECG evidence of right- and left-atrial enlargement is frequent. Voltage criteria for left ventricular hypertrophy in association with repolarization abnormalities are also common, but isolated increases in voltage without ST segment and T-wave changes are infrequent. Abnormal Q waves occur in 25% to 50% of patients (165,166 and 167), most commonly in the inferolateral leads and in young patients.



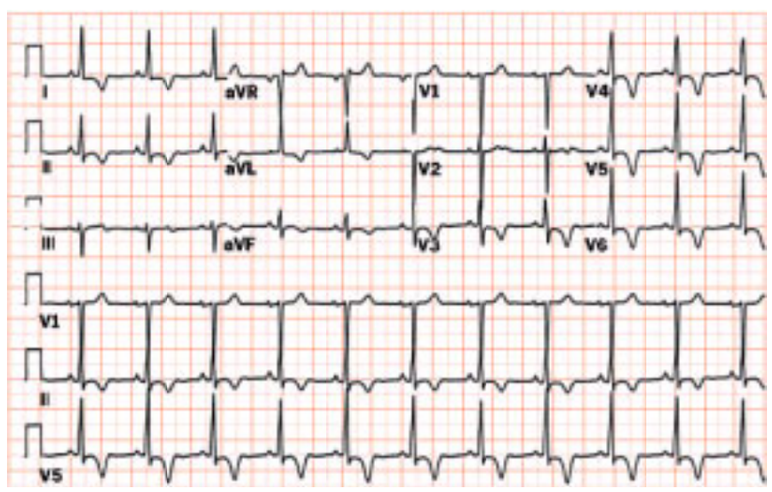
Hypertrophic cardiomyopathy. Inverted precordial T waves associated with hypertrophic cardiomyopathy.



A 28-year-old Caucasian male patient with hypertrophic obstructive cardiomyopathy.

Many mechanisms have been suggested for Q waves in HCM, including massive septal hypertrophy, abnormal septal activation, and myocardial ischemia. The presence and location of Q waves is predicted by the ratios of upper anterior–septal to mean right ventricular wall thickness and to upper posterior wall thickness (166).

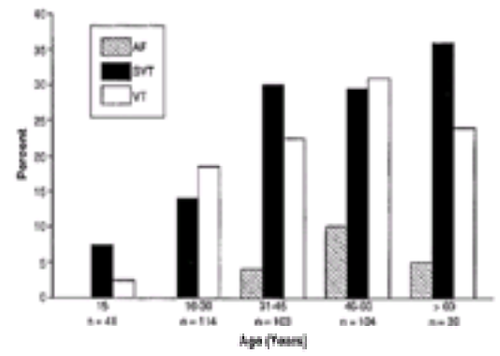
Giant negative T waves in the mid-precordial leads are said to be characteristic of Japanese patients with apical involvement (72), but they are also seen in Western patients with hypertrophy in other myocardial segments (169). Some patients have a short PR interval with a slurred QRS upstroke, which in a few patients is associated with Wolff-Parkinson-White syndrome (90,91,170,171). Personal experience suggests that the majority of individuals with this ECG abnormality do not have accessory pathways.



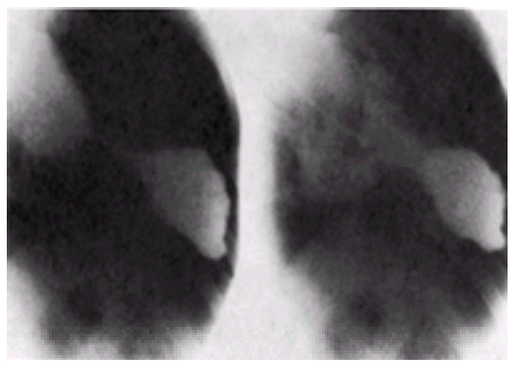
Yamaguchi's disease. Note anterior precordial T wave inversion in this Asian patient with apical hypertrophy.

In children and adolescents, the ECG may be a more sensitive marker of early disease than the echocardiogram (172,173). In adults, preliminary data indicate that a normal ECG and two-dimensional echocardiogram in adult patients with b-myosin mutations occur rarely, but minor ECG abnormalities with a normal echocardiogram may be more frequent in patients with mutations affecting other genes that are responsible for familial HCM, in particular, troponin T.

The frequency of detection of arrhythmias during 48-hour ambulatory ECG monitoring is age related (eFig. 29.4.3). NSVT occurs in 25% of adults with HCM during ambulatory ECG monitoring (174,175). Most episodes are relatively slow and asymptomatic and occur during periods of increased vagal tone (e.g., sleep). Clinical sustained ventricular tachycardia is uncommon and may occur in association with apical aneurysms (176) (eFig. 29.4.4). Paroxysmal supraventricular arrhythmias occur during ambulatory ECG monitoring in 30% to 50% of patients. Sustained atrial fibrillation (AF) is present in 5% of patients at diagnosis and develops in an additional 10% in the 5 years after diagnosis (177). Predisposing factors include left-atrial enlargement and marked left ventricular hypertrophy. AF is usually well tolerated, but loss of atrial systole can result in catastrophic hemodynamic collapse in some patients who have significant impairment of diastolic filling (178).



***e*FIGURE 29.4.3** Age-related incidence of supraventricular tachycardia (SVT), atrial fibrillation (AF), and nonsustained ventricular tachycardia (VT) in a referral population. (WJ McKenna and PM Elliott, *unpublished data*.)



***e*FIGURE 29.4.4** Diastolic and systolic frames during left ventricular angiography in an asymptomatic 40-year-old patient with asymmetric septal hypertrophy. Hyperdynamic contraction of the base of the left ventricle can be seen, with mid-systolic cavity obliteration and an apical aneurysm. (From Alfonso F, Frenneaux MP, McKenna WJ. Clinical sustained uniform ventricular tachycardia in hypertrophic cardiomyopathy: association with left ventricular apical aneurysm. *Br Heart J* 1989;61:178–181, with permission.)

Echocardiograph

The first echocardiographic diagnostic criteria in HCM were established using M-mode imaging (23,24,25,26,27,28,29 and 30,179). They include ASH of the interventricular septum, SAM of the mitral valve, a small left ventricular cavity, septal immobility, and premature closure of the aortic valve. With the experience of two-dimensional echocardiography, diagnostic criteria have been broadened to include virtually any pattern of hypertrophy (Fig. 29.5 and Fig. 29.6). The proportion of patients with asymmetric and concentric hypertrophy depends on what definitions are used. When a septal to free-wall thickness ratio of 1.3:1.0 is used to define asymmetry (29), concentric hypertrophy accounts for only 1% to 2% of cases. However, this proportion rises to approximately 31% when a septal to free-wall thickness ratio of 1.5:1.0 is used (180).

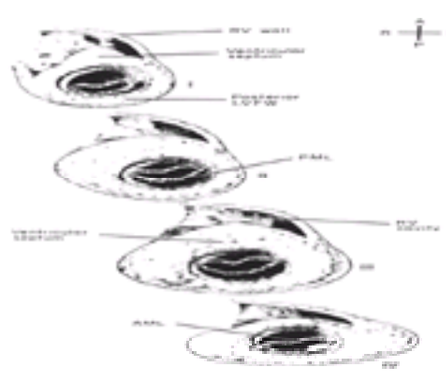


FIGURE 29.5 Maron classification. Artist's impression of four patterns of hypertrophy identified in 153 patients using two-dimensional echocardiography and shown on the short-axis plane at mitral valve level. **I:** Type I (10% of patients) hypertrophy confined to the anterior portion of the ventricular septum. **II:** Type II (20% of patients) hypertrophy involving the anterior and posterior septum. **III:** Type III (52% of patients) hypertrophy involving the anterior and posterior septum as well as the lateral free wall. **IV:** Type IV (18% of patients) hypertrophy involving left ventricular regions other than the anterior septum and the posterior free wall. A, anterior; AML, anterior mitral leaflet; L, patient's left; LVFW, left ventricular free wall; P, posterior; PML, posterior mitral leaflet; R, patient's right; RV, right ventricular. (From Maron BJ, Wolfson JK, Ciro E, et al. Relation of electrocardiographic abnormalities and patterns of left ventricular hypertrophy identified by 2-dimensional echocardiography in patients with hypertrophic cardiomyopathy. *Am J Cardiol* 1983;51:189–194, with permission.)

VIDEO

Video 29.3 A four-chamber transesophageal echo (TEE) of a patient with hypertrophic obstructive cardiomyopathy before myectomy (*first video*). Note the mitral regurgitation due to systolic anterior motion of the mitral valve leaflets. Intraoperative TEE after myectomy (*second video*) for hypertrophic cardiomyopathy. Note that there is no longer mitral regurgitation from systolic anterior motion of the mitral valve leaflets, and the left ventricular outflow tract is opened up compared with the preoperative TEE. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 29.4 Intraoperative transesophageal echo of a patient with hypertrophic obstructive cardiomyopathy and left ventricular outflow tract (LVOT) obstruction. The septum is hypertrophied, and the mitral leaflets show some systolic anterior motion of the mitral valve leaflets. An accessory mitral leaflet is located on the left ventricular septum. Note the independent motion of this leaflet in the LVOT. The pressure gradient across the LVOT/AV was greater than 100 mm Hg; however, the aortic valve opens freely. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Several scoring systems have been used to describe the severity of hypertrophy in HCM. One uses a point scoring system to grade the degree of septal thickness and the extension of hypertrophy to the left ventricular apex (30), using the apical four-chamber view to determine the extent of septal involvement and the parasternal short-axis view at the level of the mitral valve leaflet tips to assess anterolateral wall involvement (eTable 29.1.1). A simpler method defines the extent of hypertrophy as mild if only one left ventricular segment is involved, moderate if two segments are involved, and severe if three or more segments are involved.

***e*TABLE 29.1.1** WIGLE'S SCORING SYSTEM FOR LEFT VENTRICULAR HYPERTROPHY

Characteristic	Septal thickness (mm)	Point score
Extent of hypertrophy (basal one-third of septum)	15–19	1
	20–24	2
	25–29	3
	>30	4
Extension to papillary muscles (basal two-thirds of septum)		2

Extension to apex (total septal involvement)	2
Anterolateral wall extension	2
Total points possible	10

From Wigle ED, Sasson Z, Henderson MA, et al. Hypertrophic cardiomyopathy—the importance of the site and extent of hypertrophy: a review. *Prog Cardiovasc Dis* 1985;28:1–83.

Criteria for abnormal wall thickness vary, but a wall thickness more than 2 standard deviations from the mean, corrected for age, sex, and height (typically = 1.5 cm in an adult) is generally accepted as diagnostic. Right ventricular hypertrophy is diagnosed when at least two right ventricular wall measurements exceed 2 standard deviations from the mean recorded in healthy subjects. Using this criterion, right ventricular hypertrophy occurs in more than one-third of patients with HCM (181).

Approximately 25% of patients with HCM have a resting pressure gradient between the body and outflow tract of the left ventricle (13,14 and 15,23,24,25,26,27,28,29 and 30). This is almost always accompanied by SAM of the anterior mitral valve leaflet and ASH (Fig. 29.7). Some patients who show no evidence of outflow obstruction at rest have gradients that can be provoked by physiologic and pharmacologic interventions that diminish left ventricular end diastolic volume or augment left ventricular contractility. The clinical relevance of provokable obstruction is uncertain, but some workers advocate the use of such maneuvers in patients with ASH but no resting SAM, or whenever dynamic outflow tract obstruction is clinically suspected.

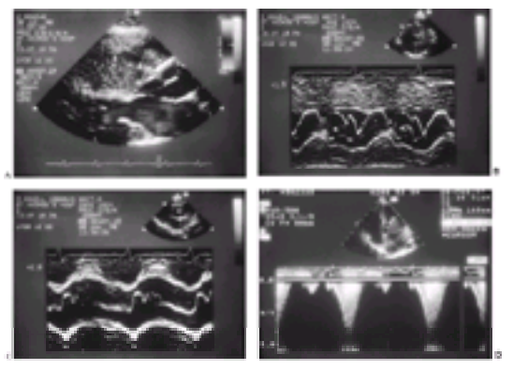

FIGURE 29.7 Sequence of four panels demonstrating **(A)** two-dimensional echocardiogram in the parasternal long-axis view that shows complete systolic anterior motion of the mitral valve and contact between the anterior mitral valve leaflet and the interventricular septum; **(B)** M-mode echocardiogram that shows asymmetric septal hypertrophy, systolic anterior motion of the mitral valve, and contact between the anterior mitral valve leaflet and the interventricular septum; **(C)** M-mode echocardiogram that shows mid-systolic closure of the aortic valve in a patient with left ventricular outflow obstruction; and **(D)** continuous-wave Doppler image that shows characteristic “dynamic” left ventricular outflow tract obstruction.

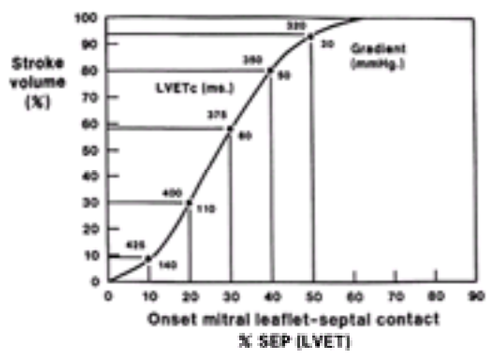
“True SAM” is characterized by an abrupt anterior movement of the mitral valve that reaches its maximum when approximately two-thirds of systole is completed and before maximum anterior movement of the posterior left ventricular wall. “Pseudo-SAM” is an exaggeration of the normal anterior movement of the mitral valve in systole that reaches its peak at the end of systole when the posterior left ventricular wall has fully contracted (182).

Until recently, the most commonly accepted theory for the cause of SAM was that septal hypertrophy and consequent outflow tract narrowing produced a high-velocity stream above the mitral valve that caused the tip of the anterior mitral valve leaflet to be sucked against the septum by the Venturi effect (28,30,183,184 and 185) (Fig. 29.7). However, this hypothesis does not explain a number of features seen in HCM, including the onset of SAM before aortic valve opening, the presence of SAM in patients who have primary mitral abnormalities and no septal hypertrophy, and the predominance of SAM at the center of the mitral valve. Experimental and observational data suggest that anterior papillary muscle displacement and primary mitral valve abnormalities create sufficient leaflet “slack” to allow SAM at low flows and in the absence of substantial septal hypertrophy (186,187,188,189,190,191 and 192).

The time of onset and the duration of mitral leaflet–septal contact in systole correlates with the magnitude of the outflow tract pressure gradient. M-mode recordings can be used to predict the severity of the outflow gradient by measuring the duration of septal contact (X) and the period from the onset of SAM to mitral leaflet–septal contact (Y) (30,193). The pressure gradient is then calculated using the regression equation: peak gradient = 25(X/Y) + 25. More commonly, Doppler echocardiography is used to calculate the gradient across the left ventricular outflow tract using the modified Bernoulli equation (194,195): peak gradient = $4Vmax^2$, where Vmax is the maximum velocity across the left ventricular outflow tract (Fig. 29.7).

The clinical significance of the outflow gradient in HCM has been hotly debated for many years (28,30,196,197,198,199 and 200). The hypothesis that the outflow gradient represents genuine and important obstruction to left ventricular ejection is based on several observations: the subaortic gradient develops simultaneously with mitral leaflet–septal contact; gradient severity correlates with the time of onset and the duration of mitral leaflet–septal apposition; a significant proportion of ventricular ejection can occur in the presence of the subaortic gradient and elevated intraventricular pressures; left ventricular ejection time is prolonged; and aortic flow profiles in patients with severe gradients demonstrate a characteristic mid-systolic deceleration coincident with mitral leaflet–septal contact. In addition, surgical or pharmacologic relief of obstruction is associated with clinical improvement in many patients. However, other studies have shown that in many patients with outflow gradients, more than 80% of ventricular ejection has been completed *before* the onset of mitral leaf–septal contact (197,198,199 and 200). Thus, some workers assert that the gradient does not represent true obstruction but is merely an inevitable consequence of rapid ventricular ejection. In addition, few studies have convincingly demonstrated any direct relation between left ventricular gradients and symptoms, arrhythmia, or sudden death.

The theoretical relationship between stroke volume and outflow gradient is shown in *e*Figure 29.7.1 (30). This predicts that in patients with modest gradients of less than 50 mm Hg, more than 80% of ventricular ejection occurs before the development of the outflow gradient. As the outflow gradient increases beyond 50 mm Hg, the percentage of ventricular ejection that occurs before mitral leaf–septal contact rapidly declines. The major clinical implication of this model is that the possibility of significant obstruction should only be considered when the outflow gradient is more than 50 mm Hg. Occasionally, outflow tract obstruction may be caused by contact between the interventricular septum and an anomalously inserted papillary muscle. This abnormality may be associated with SAM, but it is important to recognize, because conventional myectomy may not relieve the obstruction (201). Mid-cavity gradient may occur in association with cavity obliteration and is sometimes associated with paradoxical diastolic flow in the sequestered apical segments (202,203).



***e*FIGURE 29.7.1** Hypothetical relationship between the percentage of obstructed versus nonobstructed stroke volume (y axis), left ventricular outflow gradient, and left ventricular ejection time corrected for heart rate (LVETc). The LVET is equivalent to the systolic ejection period (SEP). (From Wigle ED, Sasson Z, Henderson MA, et al. Hypertrophic cardiomyopathy—the importance of the site and extent of hypertrophy: a review. *Prog Cardiovasc Dis* 1985;28:1–83, with permission.)

Mitral regurgitation occurs in almost all patients who have obstructive HCM, as a consequence of SAM and abnormal mitral leaflet coaptation (204). When no mitral valve abnormality other than SAM is present, a direct relationship exists between the pressure gradient and the severity of mitral regurgitation. In approximately 20% of patients with outflow gradients, mitral regurgitation is exacerbated by calcification of the mitral valve annulus, leaflet fibroelastosis caused by repeated traumatic septal contact, mitral valve prolapse, or rheumatic valve disease. Mitral regurgitation occurs in approximately 30% of patients with nonobstructive HCM but is usually mild and

may be associated with leaflet abnormalities.

Conventional M-mode and two-dimensional indices of systolic function are typically normal or supranormal in both obstructive and nonobstructive HCM. However, regional systolic function may be reduced, particularly in the interventricular septum, and indices of long-axis shortening are often abnormal (205,206,207,208 and 209). Thinning of hypertrophied myocardium and increases in end systolic dimensions occur in some adult patients as the disease progresses (161).

Early left ventricular filling velocities assessed using pulsed-wave Doppler imaging are, on average, very similar to control values, reflecting “pseudonormalization” of the transmitral Doppler filling pattern (210,211 and 212). E-wave deceleration time and isovolumic relaxation times are often increased. Pulmonary vein Doppler imaging often shows increased duration and peak velocity of the atrial reversal signal, reflecting increased left ventricular end diastolic pressure (210,211 and 212).

Cardiac Catheterization

Two-dimensional echocardiography has largely replaced cardiac catheterization in the diagnosis of HCM. Catheterization is indicated when the measurement of intracardiac pressures is likely to be useful in planning therapy (e.g., in patients who have severe mitral regurgitation), and for the exclusion of coronary atherosclerosis in older patients with chest pain. Left ventricular end diastolic pressure is often raised, secondary to increased stiffness and impaired relaxation. The characteristic left ventricular outflow gradient may be detected when careful pull-back across the aortic valve is performed (Fig. 29.8) or by measuring simultaneous aortic and left ventricular inflow pressures. An outflow gradient may be associated with an initial early spike in the aortic pressure wave, followed by a secondary dome-shaped tidal wave before the dichrotic notch (Fig. 29.8). In addition, the aortic pressure wave often fails to show post-extrasystolic potentiation and may actually reduce in amplitude after an extrasystole. This phenomenon may reflect worsening of the outflow gradient during the potentiated post-extrasystolic beat. Right atrial and right ventricular pressures are usually normal, except in patients with significant right ventricular outflow gradients or severe restrictive physiology. Pulmonary capillary wedge pressure may be elevated, particularly when mitral regurgitation is severe. An increased ‘v’ wave can also be seen in the pulmonary capillary wedge tracing in the absence of significant mitral regurgitation, when reduced left atrial compliance is present. Resting cardiac output is usually normal or increased, except in patients with advanced disease and systolic impairment. Left ventricular angiography may show a septal bulge encroaching on the left ventricular outflow tract during systole, together with SAM of the anterior mitral valve leaflet and mitral regurgitation. In patients with hypertrophy that is confined to the left ventricular apex, the ventricular angiogram may show a characteristic spade-shaped appearance in the right anterior oblique projection. Coronary arteriography is usually normal, but obliteration of epicardial vessels and a “sawfish” appearance during systole are described (213,214).

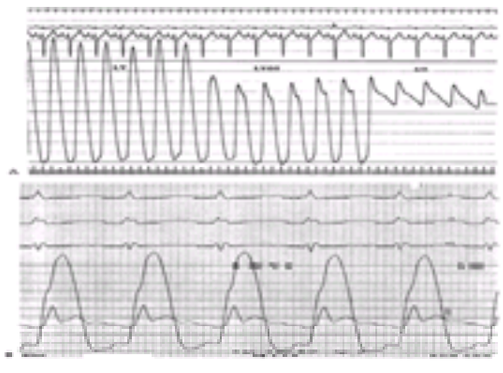


FIGURE 29.8 A: Pull-back pressure tracing shows sequential pressure pulses in the body of the left ventricle (LV), the left ventricular outflow tract (LVOT), and the aorta (AO). A pressure gradient exists between the body and outflow of the LV, and pulsus alternans is observed in the left ventricular pressure trace before the level of obstruction. **B:** Simultaneous LV (*upper trace*) and aortic (*lower trace*) pressure tracings in a patient with severe LV outflow obstruction. In the LV tracing, a prominent atrial contraction wave contributing to elevated LV end diastolic pressure can be seen. The aortic trace demonstrates a rapid upstroke with a second peak in late systole (“spike and dome”) before the incisura. The notch on the upstroke of the LV pressure tracing corresponds approximately with the time of mitral leaflet–septal contact.

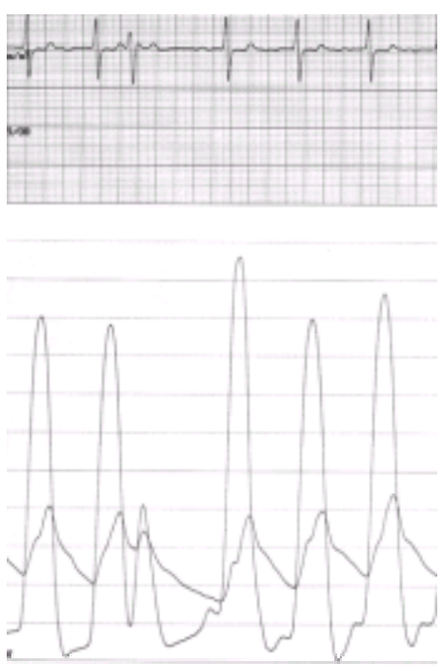
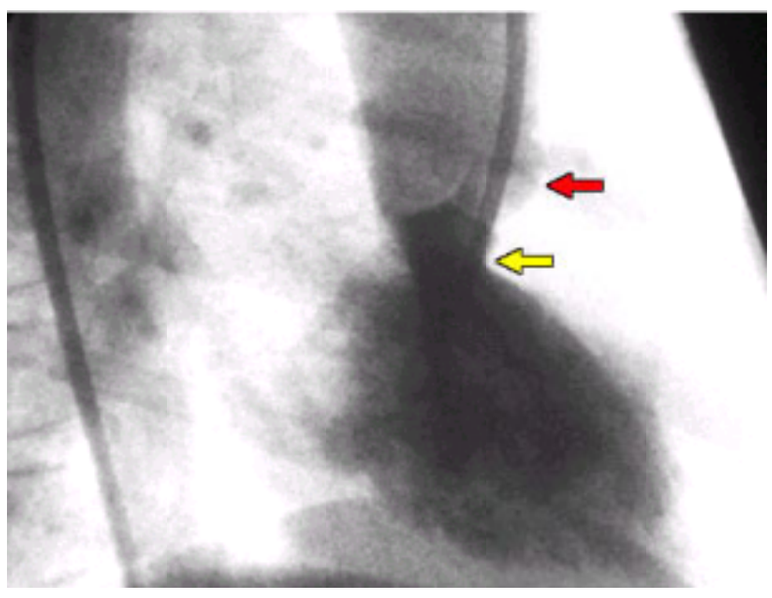


A 57-year-old female patient with hypertrophic cardiomyopathy. This figure shows the Brockenbrough response after a ventricular premature beat. The Brockenbrough response includes an increase in left ventricular systolic pressure, a decrease in aortic systolic pressure, an increase in left ventricular–to-aortic gradient, and diminished aortic pulse pressure.



Subaortic stenosis. This right anterior oblique left ventriculogram demonstrates the presence of a stenosis in the left ventricular outflow tract (*yellow arrow*) just below the level of the aortic valve (*red arrow*).

Although anecdotal reports have been made of improved symptoms in patients who undergo surgery for myocardial “bridges,” the significance of systolic compression

of epicardial or intramural vessels is uncertain, because data showing an association between sudden death and myocardial bridging in a highly selected cohort of young patients have not been confirmed by more recent studies (215,216).

Radiography/Radionuclide Scanning

The chest radiograph of patients with HCM may be normal or show evidence of left or right heart enlargement, or both. Upper lobe blood diversion may be seen in patients with chronically raised left atrial pressures. Occasionally, mitral annular calcification is present.

Several studies have examined the relationship between stress-induced thallium-201 perfusion abnormalities and clinical features in patients with HCM. Fixed defects, thought to represent myocardial scars, are associated with increased left ventricular cavity dimensions, reduced shortening fraction, and impaired exercise capacity (119,217,218). Reversible regional thallium-201 defects occur in more than 25% of patients but correlate poorly with symptomatic status (119,121,124,127,219,220 and 221). Conflicting data also exist on the association between reversible defects and inducible myocardial ischemia (119,121). Some workers have described “apparent cavity dilatation” in patients (119,217) and have suggested that this represents subendocardial hypoperfusion. Radionuclide angiography has also been used to investigate global and regional left ventricular function. Several studies have demonstrated prolonged isovolumic relaxation; delayed peak filling; reduced relative volume during the rapid-filling period; and increased atrial contribution to filling and regional heterogeneity in the timing, rate, and degree of left ventricular relaxation and diastolic filling (129,134,136). A reduced peak filling rate has been shown to be associated with an increased disease-related mortality rate (136), but its predictive value is not high and adds little to conventional risk-stratification.

Studies using nitrogen-13 ammonia and positron emission tomography have shown that myocardial blood flow in the interventricular septum and in the left ventricular free wall are similar to normal controls at baseline but significantly less during dipyridamole-induced coronary vasodilatation (122). Positron emission tomography has also demonstrated subendocardial hypoperfusion across the septum of patients with asymmetric septal hypertrophy (222). The relation of flow abnormalities to myocardial metabolism has been investigated using fluorine-18–labeled deoxyglucose (FDG). Areas of mismatch between blood flow and FDG [thought to indicate the presence of ischemic myocardium (223)] have been described in patients at rest and during exercise (224). However, other studies have demonstrated only matched reductions in myocardial blood flow and FDG uptake in the septum (225), and more recent studies have suggested that heterogeneous FDG uptake may be related to regional systolic function and age (226,227).

Magnetic Resonance Imaging

In most patients with HCM, high-quality echocardiography suffices for diagnostic and therapeutic purposes, but magnetic resonance imaging may be useful in selected cases to assess right ventricular and apical involvement (eFig. 29.8.1). Technological advances have made it possible to use magnetic resonance imaging to assess structure, regional function, myocardial perfusion, and myocardial energetics in a single study (228,229,230,231 and 232).

VIDEO

Video 29.8 Subaortic poststenotic flow in hypertrophic cardiomyopathy (long-axis). Asymmetric hypertrophy is noted, resulting in dynamic narrowing of the left ventricular outflow tract with a signal-void jet in the subaortic region. In addition, a signal-void jet in the left atrium is also seen, representing mitral regurgitation due to systolic anterior motion of the anterior leaflet of the mitral valve. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

DIFFERENTIAL DIAGNOSIS

Existing diagnostic criteria for adults are based on the demonstration of unexplained left ventricular hypertrophy on echocardiography. That some individuals with HCM do not fulfill conventional echocardiographic criteria is, however, increasingly recognized. Because the probability of disease in a first-degree relative of a patient with HCM is 50%, minor ECG and echocardiographic abnormalities assume a far greater significance in the context of an affected family than in the general population. Based on this premise, new diagnostic criteria for HCM have been proposed (69) (Table 29.2). It is important to realize that these criteria only apply to unexplained ECG and echocardiographic abnormalities in first-degree adult relatives. Diagnosis in children and adolescents, athletes, and adults with hypertension and obesity can present problems and requires specific consideration in each circumstance. A number of rare clinical syndromes overlap with idiopathic HCM (Table 29.3) and should also be considered in the differential diagnosis.

Major criteria	Minor criteria
Echocardiography	
Left ventricular wall thickness ≥13 mm in the anterior septum or posterior wall or ≥15 mm in the posterior septum or free wall	Left ventricular wall thickness of 12 mm in the anterior septum or posterior wall or of 14 mm in the posterior septum or free wall
Severe SAM of the mitral valve (septal leaflet contact)	Moderate SAM of the mitral valve (no mitral leaflet-septal contact)
	Redundant mitral valve leaflets
Electrocardiography	
Left ventricular hypertrophy with repolarization changes (Romhilt-Estes)	Complete bundle branch block or (mild) intraventricular conduction defects (in left ventricular leads)
T-wave inversion in leads I and aVL (≥1 mm) (with QRS-T wave amplitude difference ≥500), leads V_3-V_6 (≥ 3 mm), or leads II and III and aVF (≥5 mm)	Minor repolarization changes in left ventricular leads
	Deep S wave in lead V_1 (≥25 mm)
Abnormal Q waves (≥40 ms or ≥25% R wave) in at least two leads from I, II, aVF (in the absence of left anterior hemiblock), and V_3-V_6, V_1-V_2, aVR, and V_3-V_6	Unexplained syncope, chest pain, dyspnea

aVF, augmented voltage unipolar left foot lead; aVL, augmented voltage unipolar left arm lead; SAM, systolic anterior motion.
Note: It is proposed that diagnosis of hypertrophic cardiomyopathy in first-degree relatives of patients with the disease be made based on the presence of one major criterion or two minor cardiographic criteria, or one minor echocardiographic and two minor electrocardiographic criteria.
From Willems IE, Spirito P, Devine W, et al. Experience from clinical genetics in hypertrophic cardiomyopathy: proposal for new diagnostic criteria in adult members of affected families. Heart 1995;77:138-142.

TABLE 29.2 PROPOSED NEW DIAGNOSTIC CRITERIA FOR HYPERTROPHIC CARDIOMYOPATHY IN FIRST-DEGREE RELATIVES OF AFFECTED PATIENTS

Primary genetic disorders characterized by LVH
Noonan's syndrome
Friedreich's ataxia
Lentiginosis
Exaggerated physiologic response
Renal and Afro-Caribbean hypertension
Athletic heart syndrome
Obesity
Metabolic disorders
Infants of diabetic mothers
Amyloid
Glycogen storage disease
Mitochondrial myopathy
Phaeochromocytoma
Inborn errors of fatty-acid metabolism
Fabry's disease

TABLE 29.3 DIFFERENTIAL DIAGNOSIS OF UNEXPLAINED LEFT VENTRICULAR HYPERTROPHY (LVH)

Friedreich's Ataxia

Friedreich's ataxia is an autosomal recessive disorder characterized by progressive degeneration of the corticospinal and posterior spinocerebellar tracts and the posterior columns. Coexistent cardiac involvement is described in 90% to 100% of patients during follow-up and is often the cause of death (82,83). Typically, progressive ataxia occurs before the development of overt cardiac disease, but initial presentation with heart disease is recognized. Concentric and asymmetric left ventricular hypertrophy are the commonest abnormalities, but progression to dilated cardiomyopathy and left ventricular outflow gradients are also described.

Noonan's Syndrome

Noonan's syndrome occurs with an estimated incidence of 1 in 1,000. Although some patients have a phenotype similar to Turner's syndrome, with short stature, neck webbing, and hypertelorism, the somatic manifestations may be very subtle and easily overlooked. Approximately 25% of affected individuals have left ventricular hypertrophy, predominantly affecting the upper ventricular septum (87,88 and 89). SAM and outflow obstruction are uncommon but, when present, are always associated with severe hypertrophy. Myocyte disarray is also described in Noonan's syndrome, but its significance in relation to familial HCM is uncertain. Of the other cardiac abnormalities described in Noonan's syndrome, pulmonary stenosis (24%) and secundum atrioseptal defects (10%) are the most frequent.

VIDEO

Video 29.9 Subaortic stenosis. A radiolucent membrane is visualized just below the aortic valve cusps (left anterior oblique view). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Mitochondrial Cytopathies

It is increasingly recognized that mitochondrial DNA mutations are associated with HCM (233,234,235,236,237,238 and 239). One study (239) suggests that specific mitochondrial DNA mutations are associated with particular patterns of hypertrophy: asymmetric septal hypertrophy in patients with an adenine-to-guanine mutation at nucleotide position 8344, and symmetric hypertrophy in patients with an adenine-to-guanine mutation at nucleotide position 3243. However, most of the available clinical data in adults are derived from case reports and small pedigrees.

Lentiginosis

HCM is rarely associated with an autosomal dominant cardiocutaneous disorder, LEOPARD syndrome (L, lentigenes; E, ECG abnormalities; O, ocular hypertelorism; P, pulmonary stenosis; A, abnormal genitalia; R, retardation of growth; D, sensorineural deafness) (240,241,242 and 243). Some patients have left ventricular outflow and mid-cavity gradients, and at least one report exists of a patient with LEOPARD syndrome undergoing successful septal myotomy-myectomy (243).

Leopard's syndrome. Figure shows a patient with Leopard's syndrome characterized by multiple basal cell nevi and broad facies. There is an association with pulmonic stenosis.

The Athletic Heart Syndrome

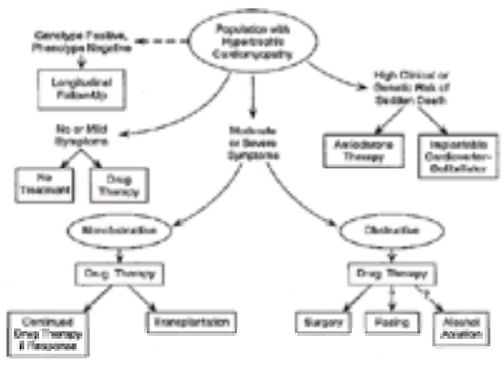
Although HCM is the commonest cause of death in young athletes (244,245), its diagnosis in individuals who regularly participate in competitive sports can be problematic (246,247,248,249 and 250), because the physiologic changes brought on by athletic training can mimic HCM. Athletes who participate in events that combine both isometric and isotonic activities are most at risk of developing increased left ventricular wall thickness. Pure strength training is associated with an increase in left ventricular mass and wall thickness relative to the left ventricular cavity size, but strength training is rarely associated with an increase in absolute wall thickness (251). In a study of more than 900 elite athletes (246), fewer than 2% had a wall thickness greater than 13 mm, and none had a wall thickness greater than 16 mm. In female athletes, maximum wall thickness was less than or equal to 14 mm. A diagnosis of HCM in an elite athlete is more likely when an individual has left ventricular wall thickness exceeding these values and/or when the athlete is symptomatic and has a family history of HCM and premature sudden death. The "athletic" ECG frequently displays voltage criteria for left ventricular hypertrophy, sinus bradycardia, and sinus arrhythmia. Although marked repolarization abnormalities are described in some elite athletes (252,253), they are uncommon and should always raise suspicion of myocardial disease. Echocardiographic features favoring HCM include small left ventricular cavity dimensions (athletes tend to have increased left ventricular end diastolic dimensions), left-atrial enlargement, left ventricular outflow gradients, and evidence on Doppler imaging of diastolic impairment. Recent data suggest that metabolic exercise testing may also be useful in differentiating athletic adaptation from HCM, with a peak oxygen consumption greater than 50 mL per minute per kg or more than 20% above the predicted maximum oxygen consumption that is highly suggestive of athletic adaptation (254).

PRINCIPLES OF CLINICAL MANAGEMENT

The main aims of clinical management in patients with HCM are to provide symptomatic relief and to prevent complications. In most cases, a relatively simple, noninvasive assessment that includes clinical history, echocardiography, ECG, 48-hour ambulatory ECG monitoring, and cardiopulmonary exercise testing is sufficient to identify patients who require specific treatments.

Symptomatic Therapy

Although pharmacologic therapy in patients with HCM is usually administered on an empirical basis, guided by subjective reporting of symptomatic improvement, the choice of therapy is influenced by left ventricular morphology and hemodynamics (eFig. 29.8.2). In patients with significant outflow obstruction, the principal aim of treatment is reduction of gradient using pharmacologic, surgical, or other means. Patients with outflow gradients or mitral regurgitation are also at increased risk of infective endocarditis, and standard antibiotic prophylaxis is recommended. Therapeutic options in patients without left ventricular outflow gradients are more limited, but pharmacologic therapy may improve chest pain and, to a lesser extent, dyspnea.



***e*FIGURE 29.8.2** Treatment algorithm for patients with hypertrophic cardiomyopathy. (Adapted from Spirito P, Seidman CE, McKenna WJ, et al. The management of hypertrophic cardiomyopathy. *N Engl J Med* 1997;336:775–785.)

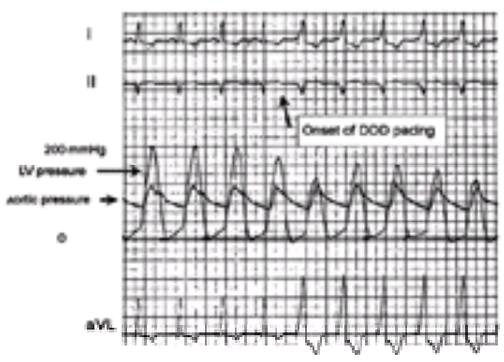
Obstructive Hypertrophic Cardiomyopathy

Patients who have moderate to severe left ventricular outflow tract obstruction may experience exertional chest pain, dyspnea, or syncope. Although some studies have suggested that up to 70% of patients improve with beta-blocker therapy, high doses are frequently required and side effects may be limiting (28,162). Furthermore, little convincing evidence exists that beta-blockers reduce the incidence of serious ventricular arrhythmias or sudden death (255). When beta-blockade alone is ineffective, the addition of disopyramide can be effective in reducing gradients and improving symptoms (256,257 and 258). Disopyramide should be titrated to patient's symptoms and the emergence of side effects, aiming for a maintenance dose of 400 to 600 mg daily. Data comparing beta-blockade and disopyramide are limited, but disopyramide may have a superior effect on exercise tolerance (258). In some patients, particularly elderly patients, anticholinergic side effects may preclude or limit the use of disopyramide. Recent data suggest that an alternative class I antiarrhythmic drug, cibenzoline, which has fewer anticholinergic side effects, may be equally effective (259). Verapamil is also used to treat symptoms in patients with outflow gradients, but its effect is unpredictable, and acute hemodynamic collapse is described in patients with substantial gradients or severe diastolic dysfunction.

Surgery should be considered in all patients with significant (i.e., greater than 50 mm Hg) outflow obstruction and symptoms refractory to medical therapy (260,261,262,263,264,265,266 and 267). The principal aim of surgical intervention is to eliminate SAM of the mitral valve and mitral leaflet–septal contact by widening the left ventricular outflow tract. The most commonly performed procedure is a ventricular septal myotomy-myectomy (Morrow procedure) performed using a transaortic approach. This procedure results in a significant reduction in outflow gradient in 95% of cases, reduced mitral regurgitation, and long-term symptomatic improvement in up to 70% of patients (260,261,262,263,264,265,266 and 267). Operative mortality rate figures in series reported elsewhere are of the order of 5% but are now probably less than 1% to 2% in centers with experienced surgeons. Complications such as atrioventricular block and ventricular septal defects do occur but have become less frequent with modification of surgical technique and the use of preoperative transesophageal echocardiography (268). Aortic regurgitation may occur in patients postoperatively but is not usually of hemodynamic significance (269).

Other techniques that have been advocated include myotomy alone (270) and mitral valve replacement (271). The latter option is controversial because of the subsequent risks of anticoagulation and prosthetic valve dysfunction, but mitral valve replacement may have a limited role in patients with other intrinsic mitral valve abnormalities. Mitral valve plication in conjunction with myotomy-myectomy has been advocated as an alternative to mitral valve replacement in patients who have elongation of the anterior mitral leaflet (272). More recently, elongation of the horizontal diameter of the mitral valve using a glutaraldehyde-preserved autologous pericardial patch has been advocated (273).

Although myotomy-myectomy remains the gold-standard interventional therapy for outflow tract obstruction, the procedure requires a level of expertise and support that are not universally available. Furthermore, additional comorbidities and patient reluctance may preclude this mode of therapy. Two novel approaches to gradient reduction have been recently evaluated. Several studies have suggested that dual-chamber pacing using a short programmed atrioventricular delay to ensure constant activation of the right ventricle from its apex improves symptoms in patients with left ventricular outflow tract gradients (eFig. 29.8.3) (274,275,276,277,278,279,280,281,282 and 283). Success depends on achieving an atrioventricular delay that gives maximum preexcitation while maintaining effective atrial transport. Although preliminary data indicated that pacing is capable of reducing gradients by approximately 50%, several multicenter trials have shown that pacemaker insertion is associated with a substantial placebo effect and little objective improvement in exercise capacity. Few comparative data are available for dual-chamber pacing and myectomy, but one small nonrandomized study has suggested that gradient reduction and exercise duration are greater after surgery (284). Nevertheless, a minority (10% to 20%) of patients do respond to pacing, and therefore pacemaker insertion remains an option in patients who have an unacceptable operative risk with myotomy-myectomy. Pacemaker insertion may also facilitate the use of higher doses of beta-blockers in some patients (280).



***e*FIGURE 29.8.3** Simultaneous left ventricular (LV) and aortic pressure traces in a patient with obstructive hypertrophic cardiomyopathy, demonstrating a reduction in the LV outflow tract gradient after the onset of synchronous atrioventricular pacing. aVL, augmented voltage unipolar left arm lead; DDD, dual-chamber.

The second novel intervention involves selective injection of alcohol into one or more septal perforator branches of the left anterior descending coronary artery to create of localized septal scar (285,286,287,288,289,290,291,292 and 293). Published data suggest that the procedure-related mortality rate is lower than 1% in centers with experienced clinicians, but deaths due to conduction system damage and inadvertent injection of alcohol into other myocardial segments have occurred. The latter problem is minimized by the injection of intracoronary echo contrast agents before injection of alcohol to ensure that only the septal bulge at the point of mitral leaflet–septal contact is opacified. Alcohol injection is contraindicated if opacification is present in other regions of the myocardium, such as the distal septum, the right ventricle, or the papillary muscles. In contrast to the results of surgery, most patients develop right and not left bundle branch block after alcohol ablation. Higher

degrees of AV block can occur transiently but persist in only 10% to 15% of patients. Prolonged or recurrent AV block after the procedure should prompt consideration of permanent dual-chamber pacing. Interim results suggest that left ventricular cavity dimensions increase slightly after alcohol ablation, but progressive ventricular dilatation and late arrhythmic complications have not yet been described. Results from the largest series show that gradients can be abolished or substantially reduced in 80% of patients. This reduction is paralleled by an improvement in symptom class and exercise tolerance.

Nonobstructive Hypertrophic Cardiomyopathy

Beta-blockade may improve chest pain and dyspnea, but patient response is usually suboptimal. Verapamil, often in high doses (240 to 480 mg per day), is a useful alternative, particularly in patients who experience exertional chest pain (294,295,296 and 297). The mechanism of action is uncertain, but verapamil can improve left ventricular relaxation and exercise tolerance. Data on its effect on myocardial perfusion are conflicting (297,298). Diltiazem (299) also has beneficial effects on symptoms and left ventricular function and provides a useful alternative to verapamil when side effects are problematic. Nifedipine (300) has been advocated, but the potential hazards of vasodilatation, particularly in patients with outflow gradients, preclude its general use. Although diuretics, sometimes in combination with beta-blockers or calcium antagonists, may alleviate symptoms caused by pulmonary congestion, their injudicious use can be dangerous, particularly in patients with severe diastolic impairment.

Supraventricular Arrhythmia

For the management of supraventricular arrhythmia, AF should be cardioverted; when this is not possible, control of the ventricular rate improves symptoms in most patients (177). AF in HCM is associated with a significant risk of thromboembolism, and anticoagulation therapy should be considered in all patients in whom AF is sustained or recurs frequently. Treatment is not usually indicated for other asymptomatic and self-limiting supraventricular arrhythmias, but if they are sustained or associated with symptoms, then specific medical therapy should be instituted. Treatment with low-dose amiodarone (1,000 to 1,400 mg weekly) is effective in maintaining sinus rhythm and in controlling the ventricular rate during breakthrough episodes. Beta-blockers with or without class III action may be useful, but class I agents are untested and potentially proarrhythmic.

Identification of High-Risk Patients

Patients who have HCM are prone to a number of potentially life-threatening complications, including sudden ventricular arrhythmia, thromboembolism, heart block, and congestive cardiac failure. Although the identification of patients who are at risk remains a clinical challenge, recent data show that high-risk patients can be identified and successfully treated.

Sudden death remains the greatest cause of premature death in patients with HCM (151,152,153,154,155,156,157,158,159 and 160). The underlying substrate for sudden death is complex and incompletely understood, but myocyte disarray and fibrosis—the microscopic hallmarks of the disease—provide the conditions for anisotropic conduction and reentry arrhythmia. Circumstantial evidence suggests that expression of this substrate is modified by factors such as myocardial ischemia, autonomic function, and abnormal vascular responses (119,120,121,122,123,124,125,126 and 127,301,302,303,304,305,306 and 307). Fortuitous ECG recordings made before sustained ventricular tachyarrhythmias in patients with HCM have shown that rapid AF may also act as a trigger to fatal arrhythmic events (178). In spite of this potent pathophysiologic substrate for sudden death, survival data in both regional and tertiary center populations indicate that only a minority of patients are at sufficiently high risk to warrant consideration for prophylactic therapy (151,152,153,154,155,156,157,158,159 and 160). Therefore, identifying readily applicable clinical risk markers that allow patients to be stratified into high- and low-risk cohorts is the clinical goal.

Clinical Markers of Risk of Sudden Death

Patients with HCM and a history of sustained ventricular arrhythmia have a risk of a fatal event of approximately 10% per annum (157,308,309). Although this is much lower than the risk seen with some other cardiac diseases (310), patients with HCM who survive a cardiac arrest are often young and are, therefore, at risk for a longer period than most patients with coronary artery disease or congestive cardiac failure. Many sudden deaths occur in patients who have minor symptoms. Children and adolescents who have two or more first-degree relatives with HCM who died prematurely are at risk of dying suddenly themselves (127,128 and 129). Recurrent unexplained syncope in the young is also a highly specific marker of risk (28,151,152 and 153,311). Pooled data from two studies (174,175) indicate that in patients with HCM, NSVT is associated with an increased risk of sudden death, with a sensitivity of 69% and a specificity of 80%. However, its value as a risk marker is limited by a modest positive predictive accuracy of 22%, reflecting the fact that most patients with NSVT do not die suddenly and that the incidence of NSVT in children is low. More recently, some workers have suggested that NSVT is significant only when it is repetitive or when it occurs in symptomatic patients (312), but few data support this. The onset of AF has, in the past, been considered to be an adverse prognostic event. However, at least one prospective study has shown that the 5-year survival rate in patients with AF is similar to that in age- and sex-matched patients who remain in sinus rhythm (177).

Approximately 25% of patients with HCM have abnormal blood pressure responses during exercise (305). This phenomenon is associated with a family history of sudden death, small left ventricular cavity dimensions, and, in patients younger than 40 years, a higher mortality rate (306,313,314). The underlying mechanism for the abnormal response remains speculative, but some evidence suggests that inappropriate vasodilatation in nonexercising muscles is responsible (307). The presence of a pressure-dependent vasodepressor response in patients with HCM may explain the poor tolerance of paroxysmal arrhythmia or sinus tachycardia seen in some patients. In patients who have a particular susceptibility, systemic hypotension may also cause a fall in myocardial perfusion pressure, with consequent metabolic changes that trigger ventricular arrhythmia.

Data from cross-sectional studies and more recent large prospectively followed cohorts in regional and tertiary centers have shown that patients with severe hypertrophy (i.e., a wall thickness ≥30 mm) have an increased risk of sudden death (154,315,316 and 317). However, this marker is of limited value, because the majority of patients who die suddenly has wall thickness values less than 30 mm. To date, there is no conclusive evidence that left ventricular outflow obstruction is associated with sudden death, but a recent series has suggested that substantial gradients may be associated with the overall cardiovascular mortality rate (155).

Electrophysiologic Markers of Risk

In patients with HCM, the QTc (QT corrected for heart rate) is longer, shows greater dispersion, and is correlated with the maximal left ventricular wall thickness (possibly owing to variable volumes of repolarizing tissue) in patients with HCM (318,319,320,321 and 322). In addition, the normal diurnal variation in QT interval is lost in some patients with HCM, suggesting the presence of abnormal autonomic function (319). The sensitivity of QT measurement can be improved by assessment of dynamic behavior and relationship to the preceding RR interval during ambulatory ECG monitoring. The QT/RR regression relationship is steeper when compared to normal controls, but neither the QTc nor the QT/RR slope discriminates between high- and low-risk patients (320).

An abnormal signal-averaged ECG (SAECG) is present in 10% to 20% of patients with HCM (323,324). Abnormal SAECGs are more common in patients with NSVT but are not associated with any other clinical risk factor. In addition, many patients who experience catastrophic cardiac events have normal SAECGs (324).

In patients with ischemic heart disease and heart failure, reduced parasympathetic and/or excess sympathetic activity is associated with sudden death and ventricular arrhythmias. Both global and specific vagal components of heart-rate variability (HRV) are reduced in patients with NSVT (301,302 and 303), but global HRV is increased in patients who have a family history of sudden death, and no differences in HRV are seen in patients who die or are successfully resuscitated from out-of-hospital ventricular fibrillation. The lack of a significant correlation with adverse prognostic indicators may reflect the sudden and short-lived nature of cardiovascular changes in HCM, making them difficult to detect when HRV is measured over long periods.

Several studies have investigated the role of programmed ventricular stimulation in the clinical assessment of patients with HCM. When up to three premature stimuli are delivered during three drive-pacing cycle lengths in the left or right ventricle, or both, 36% of patients have induced sustained ventricular tachycardia (325). Its presence is associated with a higher risk of cardiac events (defined as sudden death, cardiac arrest, or syncope accompanied by ICD discharge). However, this approach to risk-stratification in patients with HCM has important limitations. The response to ventricular stimulation in any patient depends in part on the protocol used. Aggressive protocols that involve three or more premature stimuli produce sustained polymorphic ventricular tachycardia in 30% to 40% of patients, with a low predictive accuracy for sudden death (326). Less aggressive protocols have a lower sensitivity. Furthermore, because ventricular arrhythmias are frequently associated with hemodynamic collapse in patients with HCM, the need to terminate such events rapidly can make it impossible to determine whether induced ventricular arrhythmias are sustained. The low positive and negative predictive accuracy of programmed stimulation in patients with HCM limits its role to use in patients who have sustained and clinically significant ventricular arrhythmias.

One of the consequences of myofibrillar and myocyte disarray is a dramatic variation in myocyte length and diameter. It has been hypothesized that this results in a spectrum of conduction velocities and refractory periods within the yocardium that, together with an increase in the number of potential conduction pathways, creates the necessary substrate for reentrant tachycardia (327). This putative arrhythmogenic substrate has been investigated by analyzing the changes in individual paced ECG transitions (“fractionation”) recorded at three sites in the right ventricle. Patients with a history of ventricular fibrillation have the greatest prolongation of the paced ECG, and prolongation occurs at longer extrastimulus coupling intervals than in other patients (327,328). Premature stimulation causes the least change in ECG

fractionation in control patients and patients with no clinical risk factors for sudden death. Patients with either a family history of premature sudden death or NSVT exhibit responses that span the range from high risk (ventricular fibrillation) to low risk (no adverse prognostic features). The spread of responses seen in patients with NSVT and a family history of sudden death provides a physiologic explanation for the relatively poor positive predictive accuracy of these observations. Although pooled data from two studies (327,328) demonstrate that patients with syncope also have a range of conduction responses, the incidence in patients with ventricular fibrillation is significantly higher. This suggests that the hemodynamic disturbance associated with syncope may act as a trigger for the cascade of events resulting in sudden death in patients with the appropriate electrical substrate.

Treatment of High-Risk Patients

There have been several obstacles to the construction of workable risk-stratification algorithms in patients who have HCM, most notably the low positive predictive accuracy of the majority of suggested risk markers for sudden death and the lack of data on the relative value of different risk markers. The latter problem has been difficult to study because of the relatively low incidence of HCM and the low annual event rates even within tertiary center populations. Some data suggest that a risk model based on a smaller number of easily assessed risk markers (specifically, NSVT, left ventricular wall thickness, abnormal blood pressure responses during exercise, family history of sudden death, and recurrent unexplained syncope) may allow identification of most high-risk patients with sufficient accuracy to permit rational decisions to be made about the necessity for prophylactic therapy (154) (Fig. 29.9). In this study, patients with two and three risk factors had an annual risk of sudden death of approximately 3% and 6%, respectively. Estimation of risk in patients with a single risk factor remains problematic, because the significance of a given risk factor may vary between individual patients, particularly in the context of a family history and syncope. Risk factors also have to be interpreted in the light of other features, such as patient age. Decision making in such patients inevitably has to be pragmatic and guided by physician experience and patient preference.

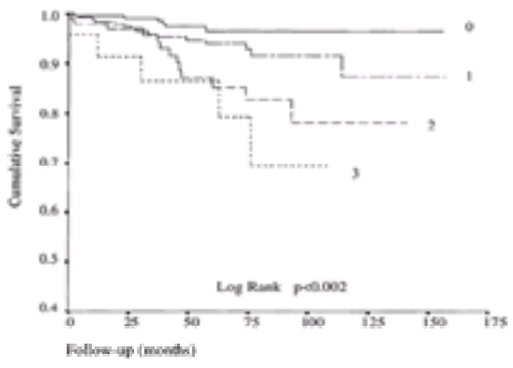


FIGURE 29.9 Kaplan-Meier survival curves in patients with zero, one, two, and three clinical risk factors. The risk factors used in this analysis were nonsustained ventricular tachycardia, family history of sudden death, recurrent unexplained syncope, and abnormal blood pressure during exercise (in patients younger than 40 years). (The original data set and the relationship between these risk factors and wall thickness are reported in Elliott PM, Gimeno Blanes JR, Mahon NG, et al. Relation between the severity of left ventricular hypertrophy and prognosis in patients with hypertrophic cardiomyopathy. *Lancet* 2001;357:420–424.)

All patients who have spontaneous or exertional ventricular tachyarrhythmias should be considered for prophylactic ICD insertion (308,309 and 310,329,330). In patients who do not have a history of sustained ventricular tachycardia or cardiac arrest, the identification of two or more risk factors should also prompt consideration for prophylactic therapy. Low-dose amiodarone therapy has been shown to reduce sudden deaths in patients with NSVT (331) and in high-risk children (152), but evidence from multicenter ICD trials and reports of occasional deaths in patients with a history of ventricular tachycardia or ventricular fibrillation who were taking amiodarone has called into question its use as prophylactic therapy in patients considered to be at risk for sudden death. Because demographic and ethical considerations make a randomized study of ICD therapy in HCM extremely unlikely, patients should be offered the “best” therapy, which in most circumstances will be an ICD. Amiodarone continues to play a role in preventing potential triggers for sudden death or life-threatening arrhythmias, in particular paroxysmal AF and hemodynamically tolerated sustained monomorphic ventricular tachycardia. Other potential trigger factors, such as conduction system disease, accessory pathways, and myocardial ischemia, should also be treated when possible.

Exercise and Hypertrophic Cardiomyopathy

Although 40% of HCM-associated sudden deaths occur after moderate to severe exertion (244,332), the increase in the relative risk of sudden death incurred by regular participation in vigorous exercise is unknown. No systematic data are available to prove that abstention from vigorous physical activity prevents death, but most clinicians agree that young patients with HCM should not participate in competitive sports. The 29th Bethesda Conference (333) has produced guidelines on the eligibility of patients with HCM for participation in sports. It is suggested that athletes with unequivocal HCM should be advised not to take part in most competitive events, regardless of symptoms or the presence of left ventricular outflow obstruction. Because of the risk of sudden death is higher in younger patients, participation of individuals older than 30 years should be assessed on the basis of recognized or potential clinical risk factors, bearing in mind that these guidelines are conservative and based on a consensus view of best practice rather than definitive proof.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Over the past decade, considerable progress was made in unraveling the complex pathophysiology of HCM. We know now that most cases are caused by mutations in genes that encode sarcomeric proteins, and that the spectrum of disease is even more diverse than was previously thought. Nevertheless, many questions relating to pathophysiology remain unanswered, in particular, questions involving the mechanisms that determine disease expression and penetrance. Clinical management of HCM has also progressed, specifically in relation to the treatment options for outflow tract obstruction and the identification and treatment of patients at high risk of sudden death. These advances clearly are good news for patients, but for clinicians they make the management of patients with HCM more, rather than less, challenging. Physicians must now offer specialist genetic counseling, detailed assessment of symptoms and pathophysiology, and a wide range of surgical and invasive cardiologic expertise. This means that the care of patients requires involvement of many specialists and will probably result in centralization of resources in centers with a special interest in “HCMology.” The final result should be a major improvement in the outlook for patients with this capricious disease.

THE FUTURE

Over the past decade, we learned that familial HCM is a genetically heterogeneous disease of the cardiac sarcomere, with variable penetrance and disease expression. One of the major challenges for the next decade is to unravel the complex mechanisms that determine disease expression and thereby develop new therapies that could modify the natural history of the condition. Other therapeutic challenges include the management of the disease in symptomatic patients who do not have left ventricular outflow tract obstruction and the refinement of risk-stratification algorithms, particularly in young patients and in patients who have a single risk factor.

OVERVIEW

This chapter was organized to provide an introduction to congenital heart disease. Although the intent is to be complete, it is by no means exhaustive, and the reader ideally will be encouraged to pursue more extensive query into the literature in an effort to expand on the perspective provided. The section Historical Perspective outlines the historical landmarks in the relatively brief history of clinical pediatric cardiovascular medicine, beginning with pathologic recognition of the nature of congenitally malformed hearts and continuing with a description of the rapid evolution of diagnosis and management strategies. Prevalence, cardiac nomenclature, the segmental and sequential analysis of morphology and pathology, and an introduction to the genetics of congenital heart disease precede a description of the approach to the art of examining a neonate, infant, child, or adolescent with suspected congenital heart disease, including the issue of screening in children with trisomy 21. Naturally, the timing of presentation is important when considering congenital lesions, and in this light the roles of prostaglandin and persistent pulmonary artery hypertension of the newborn are discussed. Before considering individual conditions, the natural history of some of the more common lesions is outlined in an effort to provide a reference for the ensuing discussion. Whereas many systems exist, lesions are classified under the subgroups of those with a left-to-right shunt, obstructive lesions, cyanotic lesions, and those not easily assigned to any of the preceding categories. They are presented with reference to anatomic considerations, with an emphasis on issues important to diagnosis, subsequent treatment, and prognosis. The references listed are not intended to be exhaustive; rather, they should serve as a starting point for further investigation.

HISTORICAL PERSPECTIVE

As we begin the new millennium, we should not forget that it was just slightly more than 100 years ago when the systematic study of congenital heart malformations began in Montreal, Canada, under the aegis of Dr. Maude Abbott (1). In the 1930s, at The Johns Hopkins Hospital, Dr. Helen Taussig (2) used clinical examination, chest radiography, scalar electrocardiography, and cardiac fluoroscopy to catalog most forms of congenital heart disease. In 1937, at the Children's Hospital in Boston, the late Dr. Robert Gross (3) performed ligation of the arterial duct. The benchmark contribution of Taussig and Blalock (4) to the palliation of infants and children with cyanotic congenital heart disease in 1945 and repair of coarctation of the aorta by Crawford (5,6) also contributed to those exciting days of the birth of the study and treatment of congenital heart disease. By the late 1940s and early 1950s, contributions by Blalock and Hanlon to the atrial septectomy (7), Sir Russell Brock to the pulmonary valvotomy (8), and Muller and Dammann (9) to banding of the pulmonary trunk. This was followed by the repair of atrial septal defects and then ventricular septal defects (the latter using cardiopulmonary bypass), and the repair of tetralogy of Fallot all gave impetus to the medical and surgical therapy of the many forms of the congenitally malformed heart (10,11). By the late 1950s and the early 1960s, significant progress had been made in the treatment of complete transposition of the great arteries, with the exciting contributions by Senning (12) and then Mustard (13) with their atrial inversion repairs; but these surgical procedures for the repair of transposition of the great arteries in that era carried a substantial mortality and morbidity until the novel contribution of Rashkind and Miller (14) forever changed the once-dismal natural history of the patient with complete transposition of the great arteries, providing a nonsurgical methodology (balloon atrial septostomy) to enlarge the atrial septal defect, thus enhancing atrial mixing and improving systemic arterial oxygen saturation. In 1968, the use of a conduit to perform reparative surgery in a patient with pulmonary atresia and ventricular septal defect provided the possibility of repairing a wide range of congenitally malformed hearts in which there was no continuity between the ventricular mass and the pulmonary arteries. These surgical innovations were not carried out in isolation, however. Understanding the milieu for the neonate and the ability to regulate acid–base balance and ventilate the critically ill newborn and young infant provided the platform on which such surgical bravado could be conducted with increasingly satisfactory results. The clinical recognition that many forms of serious congenital heart disease presenting in the newborn and neonate were ductal dependent for either systemic or pulmonary blood flow stimulated the desire to define an agent to promote patency of the arterial duct beyond the time of its normal functional and anatomic closure. The recognition that an E-type prostaglandin could be used intravenously or even in an oral preparation to maintain ductal patency was an exciting "from-bench-to-bedside" development that dramatically altered the care of the often critically ill hypoxemic neonate (15).

The realization that blood could be conducted into the lungs without a pumping chamber set the stage for the now landmark contribution of Fontan and Baudet (16), whose signal operation originally was offered to the patient with tricuspid atresia. The Fontan operation, or one of its many surgical modifications, has been extended to a wide range of congenitally malformed hearts once deemed unsuitable for a biventricular repair. The ability to perform reparative heart surgery in the newborn and young infant using profound hypothermia with circulatory arrest gave impetus to primary repair of congenital heart malformations whenever possible. The Boston Children's cardiac surgical group (17) championed primary repair whenever possible, eschewing the two-staged approach of palliation followed by repair at an older age. This philosophy was dramatically demonstrated with the application of the arterial switch procedure to correct the heart anatomically with complete transposition of the great arteries, building on the accomplishment of Adib Jatene (18,19) of Sao Paulo, Brazil, who first performed this operation successfully. As to hypoplastic left-sided heart syndrome, infants with this constellation of varying degrees of severe hypoplasia of the inflow and outflow tract of the left side of the heart, considered by some to be the worst heart disease, were considered inoperable and usually died an early, predictable death. Predicated in large part on the surgical contribution of Fontan and Baudet (16) and data provided by the New England Regional Infant Cardiac Program (20) about babies with the hypoplastic left-sided heart syndrome, the late 1970s and early 1980s witnessed exciting surgical developments extended to these babies: a staged surgical approach initially to provide a stable source of systemic and pulmonary blood flow, eventually concluding in the Fontan operation (21,22 and 23). Most surgical centers in the early to mid-1980s, however, could not achieve the rates of salvage reported by Norwood. Interest in cardiac transplantation in the newborn was pioneered by Bailey and colleagues (24,25,26 and 27) initially with Baby Fae using a baboon's heart, then with same-species allografts, now used by many centers throughout the world.

These surgical accomplishments were not achieved in isolation. The many variations of the congenitally malformed heart were studied and reported in exquisite detail by Lev, Edwards, Van Praagh, Anderson, and their respective colleagues in a large number of publications (28,29,30,31 and 32). Richard Van Praagh and colleagues championed a “language” that could and would provide a segmental and sequential approach to congenital heart disease, an *Esperanto*. The heart was considered in terms of its fundamental building blocks: the atria, ventricles, and great arteries. In the early days of this language, the connections between the cardiac segments were deduced, but this was not acceptable to Robert H. Anderson of Great Britain, who emphasized the importance of connections between the cardiac segments (30). Through debate and publications, these two schools seemed quite polarized, but the implementation of a segmental and sequential nomenclature proved that these various nosologies were not mutually exclusive, but indeed complementary. As we learned more about the form and function of the congenitally malformed heart, through surgical practice and dissection of the specialized conduction tissue, the nature of the conduction tissue in the various forms of congenital heart disease became clearer. Through many forums, some form of a segmental and sequential approach to congenital heart disease was adopted by virtually every unit; whereas some adhered to the Boston/Van Praagh approach, others strongly advocated the European approach, but most developed an amalgam that suited the needs of the particular institution.

Imaging of the congenitally malformed heart has continued to evolve, from plain chest radiography, to cardiac fluoroscopy, then to cardiac angiography, and then with axial projections (historical aspects of cardiac angiography documented in reference 11). M-mode echocardiography added somewhat to the ability to study the form and function of the congenitally malformed heart; but cross-sectional echocardiography, with its subsequent applications of Doppler and color flow mapping and now three-dimensional (3-D) reconstruction, revolutionized the diagnostic algorithms applied to the patient with congenital heart disease. Indeed, the mid-1980s witnessed a dramatic decline in the number of so-designated diagnostic cardiac catheterizations, with imaging and physiologic information provided by cross-sectional imaging. The evolution from transthoracic to transesophageal imaging, and now transabdominal (fetal) imaging, provided even newer dimensions of cardiac imaging. The ability to provide 3-D imaging and tissue characterization has added yet further dimensions to this vital area.

Magnetic resonance imaging (MRI) is now established as an important tool in defining cardiovascular anatomy, physiology, and pathology (33,34 and 35). This technique is being applied in an ever wider spectrum of congenital heart abnormalities and is having a great impact on the management of children with these disorders. Compared with echocardiography, MRI has the advantage of being able to image distant structures, to image through air or bone, to have minimal artifact from most prosthetic materials, and to display images in exact reproducible planes with a wide field of view and 3-D reconstruction. It has several unique features that make it an attractive imaging modality: high natural contrast between flowing blood and the cardiovascular structures, allowing imaging without intravenous contrast, and the ability to display large fields of view in any angled plane without ionizing radiation. The main clinical application of MRI has been in morphologic diagnoses. The role of MRI in cardiac imaging, however, is evolving, with the evaluation of ventricular function, volumes, and mass proving to be highly accurate and reproducible (see Chapter 54). The areas in which MRI has been most useful in congenital cardiovascular disease include central pulmonary artery anomalies, aortic anomalies, complex disease, pulmonary venous anomalies, cardiac masses, and postoperative assessment.

Radionuclide techniques assume an important complementary role in the diagnosis and assessment of pediatric cardiac disorders (33). The major applications of radionuclide imaging in children with cardiac disease include gated blood pool ventriculography, first-pass radionuclide angiocardiography, myocardial perfusion imaging of coronary blood flow, pulmonary scintigraphy, myocardial infarction, and myocardial inflammation detection. Standardized techniques have been developed; with the increasing reliability of these techniques, defined roles in providing both diagnostic and prognostic information have been established. Finally, although we commented earlier on the historical aspects of cardiac angiography in the pediatric population, the introduction of axial angiocardiography virtually revolutionized the approach to the invasive imaging of children (36,37,38,39,40,41 and 42).

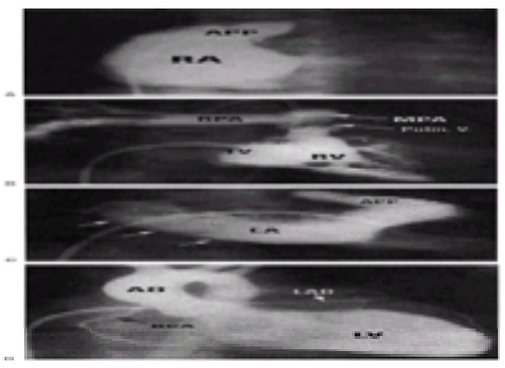
PREVALENCE OF CONGENITAL HEART DISEASE

Congenital heart malformations remain one of the most frequent birth defects, with a liveborn prevalence of approximately 8 per 1,000 liveborn infants in Western countries, where such prevalence data are tracked (43,44,45,46,47,48,49 and 50). Since the introduction of fetal echocardiography almost 20 years ago, fetal surveillance from numerous centers indicates that among some forms of congenitally malformed hearts, there is increased fetal death (50). Thus, for certain congenital heart malformations, the liveborn prevalence is lower than the fetal prevalence. Furthermore, prevalence data may be defined differently, depending on the methodology of recruitment, and data derived from an infant population may differ from a somewhat older population; in the latter, more minor forms of congenital heart disease are ascertained. The surveillance of a population beyond the infant group also may detect those abnormalities, often serious, that do not present invariably in the neonate or young infant, for example, the divided left atrium, so-called cor triatriatum, or coarctation of the aorta. A large number of studies have now been published addressing the prevalence of congenital heart disease from the United States, Canada, Great Britain, Europe, and Japan (literature annotated in references 43, 49, and 50). Clearly, differences between these studies exist, reflecting both the methods used to ascertain the specific type of heart disease and the ability to recruit all autopsy data.

Hoffman prepared a comprehensive overview of both the prenatal and postnatal incidence of congenital heart disease and those factors considered etiologic (49,50). Clearly, the incidence of congenital heart disease appears to be approximately 1 per 100 liveborn infants, but among infants dying before term, the incidence of congenital heart disease, particularly the more complex conditions, is considerably higher. The prenatal incidence ranges from 0.5% to 39.5% (median, approximately 7.9%). Many, but not all, of the fetuses dying of congenital heart disease have associated gross chromosomal abnormalities. Hook, cited in the Hoffman review, found that 39.9% of spontaneous abortions before 28 weeks’ gestation were associated with chromosomal abnormalities; for stillbirths after 28 weeks, the rate was 5.75%; and for all fetal deaths, the rate was 35.8% (50).

CARDIAC NOMENCLATURE: SEGMENTAL AND SEQUENTIAL APPROACH

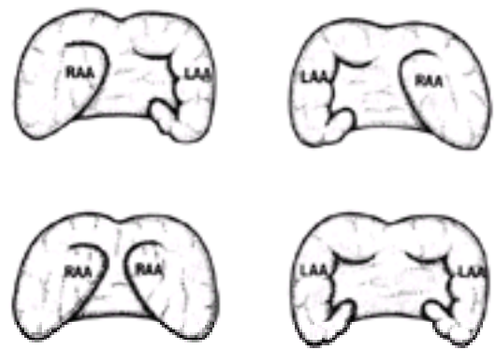
To bring an internal and external consistency to the nomenclature applied to the infinite variety of complex cardiac anomalies, it was self-evident that development of a nomenclature based on cardiac morphology and anatomy and cardiac connections was necessary. The development by Richard Van Praagh of a segmental and, indeed, sequential approach to understanding congenital heart disease, beginning more than 30 years ago, set the stage for a more universal language for persons caring for children who have congenitally malformed hearts (51,52,53,54,55,56,57,58 and 59). The major contribution of Van Praagh was to conceptualize the heart in terms of specific anatomic building blocks that could be connected into a single anatomic and functional unit (*e*Fig. 30.0.1). The building blocks were defined by their specific morphologic characteristics, not by their right or left orientation. Others using the same anatomic cardiac building blocks placed the emphasis of the nosology on the connections between the various segments. Instrumental in espousing the connections approach was Anderson of the United Kingdom (60,61 and 62).



***e*FIGURE 30.0.1** Segmental anatomy. **A:** Normal right atrial appendage (RA APP) with its blunt shape and wide ostium. **B:** Coarsely trabeculated morphologically right ventricle (RV). **C:** Typical morphologically left atrial appendage (LA APP). **D:** Smooth-walled morphologically left ventricle (LV). AO, aorta; LAD, left anterior descending; MPA, main pulmonary artery; Pulm. V., pulmonary vein; RCA, right coronary artery; RPA, right pulmonary artery; TV, tricuspid valve. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

Cardiac Segments

The three cardiac segments are (a) the atria, (b) the ventricles, and (c) the great arteries (25,51,52 and 53,60,63,64,65 and 66) (*e*Fig. 30.0.1 and *e*Fig. 30.0.2). The atria and ventricles are connected by or at the atrioventricular junction, and the ventricles and great arteries are connected by the infundibulum, or conus.



***e*FIGURE 30.0.2** Segmental analysis: types of atrial situs. *Top left*: Atrial situs solitus; *top right*: atrial situs inversus; *bottom left*: so-called isomerism of right atrial appendage (RAA); *bottom right*: so-called isomerism of left atrial appendage (LAA). (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

Atria

The normal atrial arrangement is characterized by a morphologically right atrium to the right and a morphologically left atrium to the left (51,52 and 53,60,63,64,65 and 66) (*e*Fig. 30.0.1). In the healthy heart, the right-sided morphologically right atrium has a broad, triangular atrial appendage with a wide connection at its junction with the smooth-walled atrium. The morphologically right atrium has a conspicuous crista terminalis, or terminal crest, and the right atrium normally receives the superior and inferior caval veins and the coronary sinus. In contrast, the left atrial appendage is thin, hooked, often crenelated, with a narrow junction with the morphologically left atrium. The normal right atrial appendage is remarkably consistent in position. The normal left-sided, morphologically left atrium receives the pulmonary veins, and its atrial appendage is not guarded by a terminal crest. Atrial situs inversus is the inverse arrangement of the aforementioned. Because of the many anomalies of systemic and pulmonary venous connections and because of the large defects of the atrial septum so common to many complex forms of congenital heart disease, most agree that the character of the atrial appendage is the best arbiter of the atrium as morphologically right or left, not atrial septal morphology or the specific systemic or pulmonary venous connections. In one group of hearts, often exhibiting complex anomalies, the atria are morphologically incompletely lateralized, or at least seemingly so (67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83 and 84). Such hearts with incompletely lateralized atria frequently coexist with splenic anomalies. Three types of atrial situs must be considered: (a) atrial situs solitus or the normal atrial relationship; (b) atrial situs inversus or the inverse normal or mirror image of the normal atrial relationship; or (c) ambiguous or isomeric atria, typically found in patients with visceral symmetry. Splenic anomalies, including asplenia or polysplenia as well as other splenic anomalies, are commonly, but not universally, found in patients with an ambiguous or isomeric atrial situs. The initial task in any segmental and sequential approach to the definition of congenital heart disease is definition of the atrial situs.

Without resorting to anatomic inspection, cardiac angiography, or cross-sectional echocardiography, both electrocardiography and the abdominal chest radiography provide some clues as to the determination of atrial situs (51,63,64,65 and 66,85,86,87,88,89,90,91,92,93,94,95,96,97,98 and 99). Normally lateralized atria, and, thus, by assumption, a normally positioned sinoatrial node, are suggested by a positive P wave in leads I, II, III, aV_L, and aV_F, but negative in aV_R in the standard surface electrocardiogram. Conversely, when the P-wave deflection is positive in leads I, II, III, aV_R, and aV_F, but negative in aV_L, this suggests inverted normal atria and would be consistent with inversus of the atria. A leftward and superior P-wave axis has been found in a substantial number of patients with left atrial isomerism, suggesting abnormal morphogenesis of the sinoatrial node. The hepatic and gastric shadows on the plain frontal chest radiograph also may provide evidence as to atrial localization. The presumption here is that viscerovenous right atrial concordance is present. A hepatic shadow lateralized to the right upper quadrant of the abdomen and a gastric air shadow or nasogastric tube in the left upper quadrant are consistent with solitus normal viscera and, by inference, a right-sided inferior cava vein and right-sided morphologically right atrium. There are, of course, exceptions, including isolated dextrocardia and the reality that the determination of visceral and, by deduction, atrial situs from the chest and abdominal radiograph is inaccurate and that hepatoatrial dissociation leads to an erroneous conclusion about situs. Isolated atrial inversion in either situs solitus or inversus is a rare congenital cardiac anomaly (99,100 and 101). In a healthy population with atrial situs solitus and levocardia, the left hemidiaphragm is at a lower position than the right hemidiaphragm. The widespread view is that the liver is responsible for the higher position of the right diaphragm, not the left-sided cardiac apex. Reddy and colleagues challenged this view and concluded that the cardiac mass determines the caudal displacement and lower position of the related hemidiaphragm (96). A midline horizontal liver in a patient with congenital heart disease is consistent with incompletely lateralized viscera and, by inference, nonlateralized atria as well. A midline horizontal liver in a cyanotic baby is considered ominous, raising the specter of complex cardiac disease associated with right atrial isomerism and asplenia (63,64,65 and 66,85,86 and 87) (*e*Fig. 30.0.3). Levocardia with apparent situs inversus of the abdominal viscera in a cyanotic neonate also should provoke concern about the gravity of congenital heart disease. Indirect determination of atrial situs can be inferred from the disposition of the tracheobronchial tree imaged from either the plain chest radiograph or high kilovoltage filtered films. The cross-sectional echocardiogram is certainly diagnostic of the venous connections to the atria, and even the character of the atrial appendages can be imaged, thus defining with some degree of accuracy the atrial situs. Recognition of azygous drainage of the inferior cava vein with connection of the hepatic veins directly to the atrium is highly suggestive of left atrial isomerism, often with multiple spleens (*e*Fig. 30.0.4 and *e*Fig. 30.0.5). Similarly, cross-sectional recognition of the unusual topography of the aorta and inferior caval vein with both on the same side of the vertebral column is highly suggestive of right atrial isomerism (98).

Ventricles

Although there is unanimity of opinion as to what constitutes an atrium and a great artery, there is less agreement as to what constitutes a ventricle (52,54,60). The ventricular mass extends from the atrioventricular junction to the ventriculoarterial junction, and in the healthy heart, there are two distinct ventricles: the morphologically right and the morphologically left; about this, there is consensus. The disharmony, even today, concerns what constitutes a ventricle. Is the morphologically right ventricle a bipartite structure, composed of confluent sinus or body portion and an infundibular portion? Or is it tripartite, with confluent inlet, apical trabecular, and outlet components? Van Praagh advocates a bipartite perspective, whereas Anderson and others, advocating the position of Goor, support the view of the ventricle as a tripartite structure (52,54,60,102,103). What confers “rightness” or “leftness” to a ventricle is the character of the mural trabecular component, as there are so many variations of the ventricular inlets and outlets that it mutes their utility in ventricular designation. It is the coarse trabecular component that confers rightness to the ventricle, and the smooth mural myocardium confers leftness (10) (eFig. 30.0.1).

Great Arteries

The great arteries are rarely so malformed as to make identification difficult. The normal aorta is the arterial trunk that gives origin to the coronary and systemic arteries. The pulmonary trunk supports the right and left pulmonary arteries. Among some malformed hearts, a single common arterial trunk gives origin to coronary, pulmonary, and systemic arteries. Rarely, three great arteries have been identified originating from the base of the heart (104).

Types of Atrioventricular Connection

Anderson et al. differentiate the type of atrioventricular connection from the mode of connection (60,61). The type of atrioventricular connection indicates only how the atria are connected to the ventricles (i.e., concordant, discordant, or ambiguous) (60,61,64,65 and 66). The mode refers more specifically to the morphology of the valves at the atrioventricular junction. Three types of atrioventricular connections when the heart is biventricular can be defined: (a) concordant atrioventricular connection, (b) discordant atrioventricular connection, and (c) ambiguous atrioventricular connection. A concordant atrioventricular connection indicates that the morphologically right atrium connects to a morphologically right ventricle and the left atrium to a morphologically left ventricle. The atrioventricular connection is discordant when the morphologically right atrium connects to a morphologically left ventricle via a mitral valve and the left atrium to a morphologically right ventricle through a tricuspid valve. In hearts where the atria are not lateralized, the atrioventricular connection is by definition ambiguous. One of the areas in which Van Praagh and Anderson and their respective colleagues continue to differ is in the nomenclature applied to those hearts considered by Van Praagh et al. (59) as single ventricle. Anderson et al. (105) use the designation *univentricular atrioventricular connection* when one atrioventricular connection is absent; when both atria are connected to one ventricle, they advocate the designation *double-inlet ventricle*. Hearts with a univentricular atrioventricular connection may have a double-inlet connection or an absent right or left atrioventricular connection. The ventricular morphology receiving the atrioventricular connection may be that of a dominant left ventricle, a morphologically right ventricle, or a solitary ventricle, usually of indeterminate morphology. Abnormalities of the mode of atrioventricular connection include perforate versus imperforate atrioventricular valves, a common atrioventricular orifice, an unguarded atrioventricular orifice, and a straddling or overriding atrioventricular valve. A straddling atrioventricular valve designates one whose tension apparatus is attached to both sides of the interventricular septum. The extent of straddling can vary from mild to severe, and recognition of the presence and severity of straddling affects the choice of a biventricular repair versus atriopulmonary connection with atrial separation (Fontan operation).

Ventriculoarterial Connection

Using the same conventions as defining the type and mode of atrioventricular connection, the type and mode of ventriculoarterial connection can be characterized. The four types of ventriculoarterial connections include (a) concordant or normal ventriculoarterial connection, (b) discordant ventriculoarterial connection, (c) double-outlet ventriculoarterial connection, and (d) single-outlet ventriculoarterial connection. When the ventriculoarterial connection is concordant, the morphologically right ventricle supports the pulmonary trunk, and the morphologically left ventricle supports the aorta. A discordant ventriculoarterial connection defines that connection in which the aorta is supported by the morphologically right ventricle and the pulmonary trunk by the morphologically left ventricle. The more common designation for this type of ventriculoarterial connection is *transposition of the great arteries. Double-outlet ventricle* indicates that more than half of each great artery has its origin from one ventricle, be it right or left, dominant or rudimentary, or indeterminate. Examples of single outlet include hearts with truncus arteriosus, single pulmonary trunk with aortic atresia, and single aortic trunk with pulmonary atresia. In the nomenclature of single outlet of the heart, it is important to state the ventricular origin of the solitary trunk: left or right ventricle, indeterminate ventricle, or a biventricular origin.

Infundibular Anatomy

Four types of infundibular anatomy have been described: (a) subpulmonary infundibulum, (b) subaortic infundibulum, (c) bilaterally present infundibulum, and (d) bilaterally deficient infundibulum. The solitus normal heart has a well-defined subpulmonary infundibulum, whereas the subaortic infundibulum is severely attenuated (*e*Fig. 30.0.1). This attenuation of the left-sided infundibulum brings the aortic valve into fibrous continuity with the mitral valve. The neonate with complete transposition in isolation has a well-defined subaortic infundibulum that connects the transposed aorta to the morphologically right ventricle. Some patients with complex forms of transposition have a bilaterally well-expanded infundibulum, and in such hearts semilunar valves and atrioventricular valves are not in fibrous continuity. Rarely, some hearts with transposition of the great arteries have a bilaterally deficient infundibulum in which there is the potential for fibrous continuity between both semilunar and both atrioventricular valves. These morphologic observations illustrate the reality of differential conal growth and absorption and the spectrum of normal aortic-mitral fibrous continuity. The infundibulum of the heart is responsible in part for the anterior-posterior disposition of the great arteries relative to one another; also, infundibular development, or lack thereof, is responsible for discontinuity or continuity between semilunar valve and atrioventricular valve. Anderson and colleagues (105) reserve the term *crista supraventricularis* for healthy hearts or hearts with a normally connected and structured right ventricular outflow tract. For hearts with complex anatomy, it is useful to view the supraventricular crest in terms of its morphologic components: (a) the ventriculoinfundibular fold, (b) the infundibular septum, and (c) the septomarginal trabecula. The ventriculoinfundibular fold is derived from the inner curvature of the heart tube; this structure separates a semilunar valve from an atrioventricular valve. The infundibular septum is a muscular structure that separates the arterial outlets. It is this structure whose anterosuperior deviation is the essence of Fallot’s tetralogy; whose posterior malalignment or displacement produces in the patient with atrioventricular and ventriculoarterial concordance a particular type of muscular subaortic stenosis with the ventricular septal defect inferior to the malaligned infundibular septum. In the patient with atrioventricular concordance, but discordant ventriculoarterial connections, posterior displacement of the infundibular septum produces subpulmonary stenosis, whereas anterior displacement results in subaortic stenosis. The infundibular septum is usually a septal structure but not invariably. Finally, the septomarginal trabecula is an intrinsic component of the right ventricular septal surface, and this structure does not dissociate from the morphologically right ventricle.

Arterial Relationships

The spatial relationships between the aorta and pulmonary artery show a continuum of right-left and anteroposterior coordinates. An extensive literature demonstrates that spatial relationships between the great arteries, although important, are not predictive of the intracardiac anatomy.

Heart Positions

Levocardia indicates a heart predominantly in the left chest with the apex to the left. Dextrocardia indicates a right-sided heart with the cardiac apex pointing to the right. A midline heart is designated *mesocardia*. A rare type of cardiac malposition is ectopia cordis. Rarely, despite a heart predominantly in the left chest, the apex of

the ventricle points to the right (66).

Cardiac Malpositions

The cardiac malpositions include dextrocardia, isolated levocardia, mesocardia, thoracopagi, and ectopia cordis.

GENETICS OF CONGENITAL HEART DISEASE

Despite incredible advances in the diagnosis and treatment of congenital malformations of the heart, surprisingly little progress has been made in our understanding of the etiology of the defects presented at birth, perhaps in large part because of the severe penalty imposed on a person with congenital heart disease. In many instances, the malformation is lethal to the developing fetus because the cardiovascular system must remain functional during organogenesis, and, until relatively recently, persons born with significant defects of the heart have not attained a fitness to reproduce. This evolutionary disadvantage also seems to be evident across species, as evidenced by the paucity of animal models for many types of congenital heart diseases. It seems apparent that the embryology of the normal heart is under a genetic influence and reliability of its control preserved; however, our understanding of the mechanisms involved in normal cardiovascular embryology remains in its infancy. Decades of anatomic and physiologic information have resulted in classifications of congenital heart disease that are morphologically and pathophysiologically oriented rather than being focused on pathogenesis. Hence, when there is an error in the geometric morphology and topology of the heart, it is difficult to explain recurrence of not only the same lesion, but also of different lesions in subsequent generations. Perhaps in frustration we refer to a *multifactorial etiology* that bears a recurrence risk of 3% to 5%. New investigations may lead to more precise counseling (106,107).

Genetic investigation as it relates to clinical medicine can take several forms. Familiar to all is the epidemiologic observation of the syndrome that clusters individual persons with like features. Perhaps one of the best examples is that of Down syndrome, which was first described in terms of persons with like features. Our understanding grew with the acquisition of techniques to resolve gross abnormalities of chromosomes, which, when refined, allowed a better explanation of recurrence that depended on the type of chromosomal abnormality present in the affected child and parents. To further cloud the issue, familial clustering of related conditions suggesting a genetic influence is tempered by like sociologic influences.

Clinical genetic analysis uses the meticulous analysis of pedigree and mathematics to arrive at a model of inheritance (108,109,110 and 111). Chromosomal abnormalities describe a morphologic problem in genetic anatomy but do not describe pathogenetic mechanisms by which aneuploidy results in the associated cardiovascular features (eTable 30.0.1). Mendelian studies attempt to develop a mathematical model to relate single genes and clusters of genes to a condition. The lethality of malformations of the heart as described previously favors the presence of codominant, recessive, or deletion of genes owing to the reproductive disadvantage described previously.

***e*TABLE 30.0.1** GENETIC INFLUENCES IN CONGENITAL HEART DISEASE

Chromosomal abnormality	**Most common congenital heart lesion**
Aneuploidy	
Trisomy 21	Atrioventricular septal defect, VSD, ASD, PDA, TOF
Trisomy 18	VSD, PDA, double-outlet right ventricle
Trisomy 13	VSD, ASD, PDA
Trisomy 22	PS, VSD, ASD, PDA, TrAtr
Partial trisomy 22 (cat-eye syndrome)	TAPVD, TOF, VSD, TrAtr
4p- (Wolff's syndrome)	ASD, VSD, PDA, AoAtr
5p- (cri-du-chat)	VSD, ASD, PDA
XO (Turner's)	CoA, AS, HLHS
XXY (Klinefelter's)	TOF, VSD, PDA, MVP
13q-	VSD
18q-	VSD
XXXXY	PDA, ASD
Mendelian "recessive" conditions	
Alkaptonuria	Valvar disease
Carpenter's	PDA
Conradi's	VSD, PDA
Cockayne's	Atherosclerosis
Cutis laxa	PPS, pulmonary hypertension
Duchenne's and Dreifuss's muscular	Cardiomyopathy dystrophy (XLR)
Ellis-van Creveld	ASD and other coronary heart disease
Friedreich's ataxia	Cardiomyopathy
Glycogen storage disease (IIa, IIIa, and IV)	Cardiomyopathy
Homocystinuria	Coronary thrombosis
Hurler's (MPS I), also XLR	CAD, AI, MI
Jervell and Lange-Nielsen	Prolonged QT
Laurence-Moon-Biedl	VSD and others
Mucolipidosis III	Aortic valve disease
Scheie's (MPS IS), Morquio's (MPS IV), MPS VI	Aortic valve disease, CAD
Osteogenesis imperfecta	Aortic valve disease
Progeria	Atherosclerosis
Pseudoxanthoma elasticum	CAD, MI, systemic hypertension
Seckel's	VSD, PDA
Smith-Lemli-Opitz	VSD, PDA, others
Thrombocytopenia and absent radius (TAR)	ASD, TOF, dextrocardia
Mendelian dominant/gene monosomy syndromes	
Alpert's	VSD, TOF
Crouzon's	PDA
Catch 22 (deletion 22q11)	Conotruncal abnormalities, IAA, PA, VSD, truncus, DiGeorge
Ehlers-Danlos	Large vessel aneurysm, dissection, rupture
Holt-Oram	ASD, VSD
Hypertrophic cardiomyopathy	Subaortic muscular hypertrophy
Incontinentia pigmenti (XLD)	PDA
LEOPARD	PS, abnormal P waves, increased PR
Marfan (15q21.1)	Defective fibrillin-1: great artery aneurysms, AI, MI
Myotonic dystrophy	Cardiomyopathy
Neurofibromatosis	PS, CoA, pheochromocytoma with hypertension
Noonan's	PS, ASD, idiopathic hypertrophic subaortic stenosis
Osteogenesis imperfecta	AI
Osler-Weber-Rendu (9q33–34)	Abnormal gene product as yet unknown Hereditary telangiectasia
Romano-Ward	Long QT
Treacher Collins	VSD, PDA, ASD
Tuberous sclerosis	Rhabdomyomata
Williams syndrome, supravalvar aortic stenosis (7q11.23) single gene defect: heterozygous at locus	Defect in elastin synthesis: sporadic but likely related to single gene locus; supravalvar aortic stenosis, renovascular abnormalities

AI, aortic insufficiency; AoAtr, aortic atresia; AS, aortic stenosis; ASD, atrial septal defect; CAD, coronary artery disease; CoA, coarctation of the aorta; HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; MI, mitral insufficiency; MVP, mitral valve prolapse; PA, pulmonary atresia; PDA, patent ductus arteriosus; PPS, peripheral pulmonary stenosis; PS, pulmonary stenosis; TOF, tetralogy of Fallot; TrAtr, tricuspid atresia; VSD, ventricular septal defect.

With further understanding, the information contained in eTable 30.0.1 is presented with an organization that reflects an understanding of genetic influence on pathogenesis. In this light, special mention must be made of the condition known as *catch 22*. Clinicians are familiar with patients who have similar features, as described by DiGeorge, and velocardiofacial syndromes. Genetic investigation demonstrated that patients with catch features (*c*ardiac conotruncal abnormalities, *a*bnormal facies, *t*hymic abnormalities, *c*left palate, *h*ypocalcemia) also share monosomy of one region of chromosome 22 (22q11). The deletion must involve a variety

of genes. It has been noted in persons who do not have all features of the condition (20% to 30% of nonsyndromic patients). Pathogenesis is clouded by the observation that it has been noted in approximately 25% of patients without the syndromic features, and patients may be variably affected by learning disabilities, psychiatric conditions, ocular disorders, respiratory problems, and renal difficulties. The complexity of the language is expressed by the alphabet of the genome and our very basic understanding of its intricate nature. It heralds an exciting emerging cooperation of theoretic, basic, and clinical sciences in advancing our understanding of cardiovascular medicine.

PHYSICAL EXAMINATION OF THE PEDIATRIC PATIENT

Elsewhere in this text, the art of the general cardiac examination is detailed. Most of these general principles are, of course, applicable to the pediatric patient as well. It is perhaps more challenging to examine the very young patient, especially the newborn, neonate, and young infant (112,113). In examining the newborn, it is essential to be cognizant of the mother's pregnancy and medical history (e.g., her illnesses, drug history, history of substance abuse) and the infant's birth weight, gestational age, and Apgar scores. Is the infant's weight appropriate for gestational age? Was the baby a product of a precipitous vaginal delivery or urgent cesarian section because of fetal distress? Should the infant be considered for a disorder of the transitional circulation such as persistent pulmonary hypertension of the newborn or transient myocardial ischemia (114,115,116,117 and 118)?

The very young patient must be examined in a warm, comfortable environment. The examiner's hands and stethoscope should be warm, and the examiner must be patient and gentle. Trying to examine a fussy, crying infant will be frustrating for the examiner, and little will be gained by rushing and carrying out a superficial examination. As with the adult, the examination must be carried out with appropriate room illumination. The infant can be examined in a blanket so as not to become chilled or hypothermic, but the entire infant should be examined, with special attention to the general appearance of the patient because there are so many syndromes associated with congenital heart disease. Trisomy 21; Turner's, Noonan's, Williams, and Marfan syndromes; and trisomies 13 to 15 and 18 are but a few conditions in which the patient's appearance may provide strong clinical evidence of a syndrome or at least physiognomy associated with congenital heart disease. Examination of the skin for café au lait spots, multiple lentigines, multiple cutaneous hemangiomas, and cutis laxa are external clues to internal disorders.

As part of the neonatal cardiovascular examination, the infant's apparent sense of comfort or distress should be noted. Is the infant breathing quietly and in an unlabored way? Is the infant dyspneic, with alar flaring, grunting, or stridor? Does the chest move in a symmetric fashion or is one side less active? Both the pattern and number of respirations per minute are important in the overall evaluation. Are the extremities cool, even when the infant is being examined in an appropriately warm environment, such as the isolette? Is the infant pink or cyanotic? If cyanotic, is the infant generally cyanotic, or are just the extremities involved? It is important to assess the color of the mucous membranes in room air, and if the mucous membranes appear dusky or cyanotic, reexamination with an increase in ambient oxygen is important in establishing a respiratory or cardiac causality. After the physical and cardiac examination, this aspect of the physical examination will be complemented with blood gas analysis in room air and with hyperoxia. It is always important to remember that polycythemia with more than 5 g of reduced hemoglobin causes the infant to appear cyanotic, even in the absence of frank cardiac or respiratory disorders. Is there differential cyanosis? The appearance of a pink upper body and head with relatively "bluer" lower body and lower extremities should raise the specter of a heart with concordant atrioventricular and ventriculoarterial connections but with a severe aortic arch obstruction, such as interruption of the aortic arch. The upper body "sees" blood from the left ventricle, which is reflected in a pink upper body, whereas the lower body below the arterial duct "sees" bluer and less well-oxygenated blood because of right-to-left shunting at ductal level. The infant who has reversed differential cyanosis and a relatively bluer head and upper torso and pinker lower torso and lower extremities might have transposition of the great arteries and right-to-left ductal shunting with an obstructive anomaly of the aortic arch. The perception of differential cyanosis can be confirmed by measuring the oxygen saturation in the right hand and foot.

Careful attention must be paid to the caliber of the arterial pulses in the upper and lower extremities. The infant must be comfortable and lying quietly for the examiner to palpate carefully and consistently the brachial or axillary artery pulses and to assess their caliber or amplitude and symmetry. An important difference between the strength of the pulses in the right arm versus those in the left arm could reflect any of a number of important conditions, including the origin of the artery of the weaker pulse at or below an important obstructive anomaly of the aortic arch. Other reasons for asymmetry between the arterial pulses of the right and left arms include congenital stenosis or atresia or hypoplasia of one of the subclavian arteries or ductal origin of one of the subclavian arteries from the pulmonary artery. With constriction of the arterial duct connecting the pulmonary artery to the subclavian artery, the subclavian artery becomes isolated and the pulse weaker or imperceptible. Examination of the caliber of the femoral pulses in the infant or the pedal pulses in the older child or adult is absolutely essential. Palpation of the femoral pulses must be done gently, and it is important to assess simultaneously the caliber or amplitude of the brachial and femoral pulses. An important difference with weaker and delayed femoral pulses is consistent with an obstructive anomaly of the aortic arch. Diffusely weak and feeble arterial pulses may reflect severe impedance to systemic arterial blood flow, indicative of such conditions as the hypoplastic left heart syndrome, critical aortic stenosis, interruption of the aortic arch with severe subaortic stenosis with or without origin of both subclavian arteries below the level of the interruption, or severe obstruction. Diffusely weak and feeble upper and lower limb arterial pulses in the newborn also may be observed in the patient with overwhelming sepsis and shock, myocarditis, profound anemia reflecting blood loss or twin-to-twin transfusion, or cardiogenic shock. If an infant has had an umbilical artery line, diffusely weaker femoral pulses could indicate thrombosis of the aorta or iliofemoral arterial vessels. Spontaneous thrombosis of the ascending or descending aorta also could account for alterations in the caliber of the arterial pulses. Blood pressures must be recorded in all four limbs with an appropriately sized cuff, ideally using Doppler equipment. Bounding pulses are certainly uncommon in the newborn, but have been described in the conditions characterized by important aortic regurgitation.

Examination of the chest to define symmetry of breath sounds is germane to patients of any age. It is also important to auscultate over the head and gently over the eyes to define the presence of a cranial bruit. The absence of a cranial bruit certainly does not exclude a cerebral arteriovenous fistula, but the presence of a cranial bruit in a newborn with congestive heart failure certainly leads to that consideration. In some infants who have a large vein of Galen cerebral arteriovenous fistula, examination of the upper and lower extremity arterial pulses has suggested an obstructive anomaly of the aortic arch, reflecting the arterial steal to the cerebral circulation. Are the heart sounds best heard over the left or the right chest? Do not assume that a chest radiograph will always be labeled correctly. If the infant has a nasogastric tube in place, where can gastric sound be appreciated best: on the right or the left side of the abdomen? Braudo and Rowe and others (118,119,120 and 121) have discussed fully auscultation of the heart of the newborn and young infant.

Examination of the precordium with gentle palpation may provide important information. Remembering the precordial activity of a normal infant, a forceful left parasternal heave or thrust usually implies a volume- or pressure-loaded morphologically right ventricle (assuming normal cardiac relations). Special attention should be focused on the second heart sound: Is it split or single? Soft systolic heart murmurs are not uncommon in perfectly healthy babies; conversely, the absence of a heart murmur does not preclude life-threatening congenital heart disease. Blowing systolic heart murmurs radiating into both axillae and into the back may be consistent with physiologic pulmonary artery branch stenosis and with the normal remodeling of the contour and geometry of the bifurcation of the main pulmonary trunk into its branches; these murmurs usually disappear after the first weeks of life (119,120,121 and 122). Murmurs of grade 4 intensity are always pathologic; similarly, early diastolic murmurs emanating from the semilunar valves are abnormal. It is distinctly abnormal to appreciate a frankly continuous murmur in the newborn. Even a patent arterial duct is not characterized by a continuous murmur with a conspicuous diastolic component in the hour or 24 to 36 hours after birth. A continuous murmur attributed to a patent arterial duct in the first hours after birth must be differentiated from the to-and-fro murmurs of an absent pulmonary valve, as in the tetralogy of Fallot and absent pulmonary valve complex; the systolic and separate diastolic murmurs appreciated in an infant with a common arterial trunk and a regurgitant truncal valve; or the to-and-fro systolic and diastolic murmurs in the infant with an aorto–left ventricular tunnel. Occasionally, in the infant with complex pulmonary atresia and multiple aortopulmonary collaterals, continuous murmurs emanating from the collateral circulation may be noted. Murmurs of atrioventricular valve regurgitation may be transient, especially in infants who have transient myocardial ischemia of the newborn (117,118).

SCREENING IN DOWN SYNDROME

The association between Down syndrome and congenital heart disease is well known (123,124,125,126,127,128,129 and 130); thus, it is not surprising that the question would be raised of whether routine cardiac screening of children with Down syndrome should be done (131,132,133,134,135,136 and 137). The Committee on Genetics of the American Academy of Pediatrics recommends that patients with Down syndrome have a cardiac evaluation, and this task force has recommended an echocardiographic examination. What constitutes adequate screening for congenital heart disease remains the subject of controversy, however. Rosenberg et al. suggest that careful physical examination combined with an electrocardiogram may be adequate and appropriate cardiovascular screening of the infant or child with Down syndrome, referring the patient to a pediatric cardiologist if either is abnormal (11). In a number of situations, this approach could miss important congenital heart disease, at least important enough to warrant protection against endocarditis at the time invasive procedures that may produce bacteremia are done (129,130). Finally, Geggel et al. (138) documented development of valve dysfunction, mitral valve prolapse, and aortic regurgitation in a cohort of adolescents and young adults with Down syndrome and no known congenital heart disease. Because of these findings, they recommend screening adolescents and young adults with Down syndrome before dental or surgical procedures. Schneider and colleagues found cardiac care in infants with Down syndrome to be comparable with infants without Down syndrome. Down syndrome was present in 114 of 142 (80%) infants aged 1 year with the complete form of atrioventricular septal defect undergoing surgery in their institution (135). When viewed from the reverse perspective, 35% to 40% of patients with Down syndrome have an atrioventricular septal defect, and in most cases it is with a common rather than a partitioned atrioventricular orifice. De Biase and colleagues suggest that there is an increased prevalence of left-sided obstructive lesions in patients with atrioventricular septal defect without Down syndrome (139). Marino and colleagues assessed the prevalence of associated cardiac malformations in a large cohort of patients with atrioventricular septal defect compared with patients without Down syndrome (140,141,142 and 143). Among 220 patients with atrioventricular septal defect, 130 had a complete form of atrioventricular septal defect, 80 had Down syndrome (61.5%), and 50 were without Down syndrome (38.5%). Of the 90 patients who had a partial form of atrioventricular septal defect, 25 (28%) had Down syndrome and 65 (72%) were without Down syndrome. Thus, Down syndrome most commonly was associated with a complete form of atrioventricular septal defect (p <.01), and patients without Down syndrome tended to have the partial form of the defect. Addressing the entire spectrum of associated cardiac malformations in these 220 patients, 112 had a total of 137 associated malformations.

The associated cardiac malformations were found significantly more frequently in patients without Down syndrome. Among patients with Down syndrome and the complete form of atrioventricular septal defect, tetralogy of Fallot was more prevalent. In patients without Down syndrome, the hypoplastic left ventricle and coarctation were more common. Marino et al. (140,141,142,143 and 144) also found that patients without Down syndrome and atrioventricular septal defect have a higher risk of left-sided obstructive lesions. Interestingly, Marino and colleagues (140,141,142,143 and 144) documented the rarity of additional ventricular septal defects in the apical muscular septum of patients with atrioventricular septal defect and Down syndrome.

TIMING OF PRESENTATION OF CONGENITAL HEART DISEASE

Ductal-Dependent Congenital Heart Disease

In infants in whom the pulmonary blood flow is mediated in large part or entirely by a patent arterial duct, clinical presentation with an early appearance of cyanosis in the neonatal period can be expected (145,146). Indeed, for infants with critical pulmonary stenosis or pulmonary atresia, functional closure of the arterial duct results in progressive arterial hypoxemia; and if this condition is not treated, relentless metabolic acidosis, hyperkalemia, and death ensue (147). Similarly, in some infants the entirety of the systemic blood flow requires patency of the arterial duct; these infants have the hypoplastic left heart syndrome (148). Thus, it is not surprising that babies with the hypoplastic left heart syndrome usually present within the first hours or days after birth with features of low cardiac output and a progressive and intractable metabolic acidosis, resulting in death unless medical or surgical intervention occurs. Infants who have a profound aortic arch obstruction, including coarctation of the aorta, aortic arch atresia, or aortic arch interruption, also should be anticipated to have an early clinical presentation, again within hours or days after birth coincident with ductal closure (149). A similarly early clinical presentation is seen in infants with critical aortic stenosis, in whom much of the systemic circulation requires patency of the arterial duct (150).

Hearts with “Transposition” Physiology

A group of hearts is characterized by a discordant connection at either the atrioventricular or ventriculoarterial level (151). This single discordance results in cardiac physiology characterized by two parallel circulations (151,152 and 153). By far the most common of these so-called single discordance connections is the patient with complete transposition of the great arteries. The hearts of these patients are characterized by atrioventricular concordance and ventriculoarterial discordance. Approximately 66% to 70% of all patients with complete transposition of the great arteries have an intact ventricular septum, or nearly so (151), and 15% to 20% have a moderate to large ventricular septal defect; 10% have a large ventricular septal defect and important left ventricular outflow tract obstruction; and 5% have important left ventricular outflow tract obstruction and an intact ventricular septum. The hallmark of the circulation in the patient with complete transposition of the great arteries is the presence of two parallel circulations with a systemic and a pulmonary circulation (152,153). Survival for even a short time in infants who have an intact ventricular septum requires mixing between the two circulations at the atrial or ductal level. At the time of birth, and with the normal expansion of the lungs, the flap of the ovale foramen tends to limit any significant mixing at the atrial level, and with normal maturation of the arterial duct to functional and then anatomic closure, it is not surprising that most of these infants present within hours or a few days after birth with increasingly severe hypoxemia. In fact, we have seen infants with transposition of the great arteries dying within minutes of birth, some of whom were recognized antenatally as having premature constriction or closure of the arterial duct. The calculated pulmonary blood flow in an infant with transposition of the great arteries and an intact ventricular septum is high; thus, the chest radiograph of the baby with transposition of the great arteries shows normal to increased pulmonary blood flow, whereas in infants with a ductal-dependent pulmonary circulation, one would anticipate the chest radiograph to show frank pulmonary oligemia. From these clinical observations, it is evident that the systemic arterial oxygenation in an infant with transposition of the great arteries does not correlate with pulmonary blood flow, but rather with effective pulmonary blood flow. The effective pulmonary blood flow measures the amount of systemic venous return that is conducted into the pulmonary arteries and the pulmonary veins (152,153).

Hearts with Obstructed Pulmonary Venous Connections

The most common conditions primarily promoting severe obstruction of all the pulmonary veins are the conditions characterized by bilaterally total anomalous pulmonary venous connections (TAPVC) with severe obstruction (154,155). The usual morphologic expression of bilaterally TAPVCs is a confluence of all pulmonary veins behind the left atrium connecting to a systemic vein. The most common form occurs when confluence of the pulmonary veins is connected with a descending vein coursing through the diaphragm to join the ductus venosus, portal vein, hepatic vein, or left gastric vein. These babies all have severe hypoxemia with profoundly edematous lungs. The pulmonary venous obstruction is so egregious that many of these patients have pulmonary lymphangiectasia (154,155). Although infradiaphragmatic TAPVCs are invariably obstructed, severe obstruction also has been identified in patients with supracardiac connections to the left brachiocephalic vein, to the azygous vein, or to the right superior vena cava. A restrictive atrial septal defect also may promote obstruction in some patients when the actual connection to the systemic venous circulation is not particularly obstructed. A subdivided left atrium or cor triatriatum sinistrum may promote severe impedance to pulmonary venous blood flow, but rarely presents in the newborn period and, in fact, uncommonly presents in isolation at the end of the first month of life. Pulmonary venous obstruction may be particularly severe in infants with the hypoplastic left heart syndrome with a nearly intact atrial septum or premature closure of the foramen ovale. Indeed, it is in the setting of profound left-sided heart hypoplasia that a subdivided left atrium occasionally can be identified. Infants with right atrial isomerism also may have profoundly deranged pulmonary venous connections with severe obstruction (156,157). Not infrequently, the radiographic appearance of pulmonary venous obstruction is masked by the pulmonary outflow tract obstruction that so frequently coexists in these patients.

Miscellaneous Conditions Presenting in the Neonatal Period

Other conditions that certainly can present in the newborn and neonatal period are massive arteriovenous fistulae and severe atrioventricular valve regurgitation (e.g., Ebstein’s anomaly of the tricuspid valve and severe atrioventricular valve regurgitation in the patient with atrioventricular septal defect) (158,159). Common arterial trunk can certainly present early, and the subgroup with a particularly dysfunctional truncal valve (either obstructive or regurgitant) should be anticipated to have an even earlier presentation. Similarly, infants who have complete heart block and a low heart rate and those with supraventricular tachycardia, myocarditis, or other forms of myocardial disease may present in the first days after birth (160).

Presentation at 1 to 3 Months of Age

Infants with large pulmonary blood flow and pulmonary hypertension often present at the end of the first month of life, coincident with remodeling of the pulmonary arterial bed (158,159). Thus, one could anticipate the presentation of the infant with a large ventricular septal defect, atrioventricular septal defect, patent arterial duct, aortopulmonary window, nonobstructed total anomalous pulmonary venous return, common arterial trunk, single ventricle complex, and others. Some infants with obstructive lesions of the right or left side of the heart also present in this period.

Presentation beyond Infancy

Patients with mild to moderate stenosis of a semilunar valve, a bicuspid aortic valve, a restrictive ventricular septal defect, a partial form of atrioventricular septal defect or ostium primum atrial septal defect, a small patent arterial duct, a secundum atrial septal defect, or mild coarctation of the aorta may present with a heart murmur. Infants with these conditions would not be expected to present in heart failure. Rather, it is the presence of a heart murmur considered organic in an otherwise asymptomatic child that raises the specter of congenital heart disease.

ROLE OF AN E-TYPE PROSTAGLANDIN

In 1976, at the Toronto Hospital for Sick Children, Olley et al. (161) documented a unique and novel way to promote and maintain patency of the arterial duct: administration of an E-type prostaglandin. This application revolutionized care of the patient with ductal-dependent congenital heart disease. For infants who are dangerously hypoxemic and have a progressive metabolic acidosis, prostanoid therapy by dilating a severely narrowed or functionally closed arterial duct dramatically improves oxygenation, alleviating the metabolic acidosis as well. In infants with profound obstruction to systemic blood flow, prostanoid therapy improves cardiac output and oxygen delivery to the tissues.

The administration of prostaglandin, by dilating the arterial duct, augments blood flow to the left atrium and thereby increases mixing at that level in the patient with transposition of the great arteries. If the atrial defect is restrictive or intact, prostaglandin therapy may result in pulmonary edema by increasing pulmonary blood flow and left atrial return. In some conditions, of course, prostaglandin does not have its desired effect, as in infants in whom the arterial duct is congenitally absent or anatomically closed (162,163). By virtue of its pulmonary vasodilating effect, however, even when the arterial duct is congenitally absent or anatomically closed, some infants seemingly improve in the degree of hypoxemia (164,165). This effect is usually quite modest and transient. In some instances, a prostaglandin challenge is advisable to unmask obstructed TAPVCs in patients with right atrial isomerism (166).

Debate as to the histopathologic effect of prostanoids on the arterial duct has been ongoing (167,168,169,170 and 171). Hemorrhage and lacerations have been found in the arterial duct after prostanoid administration, but similar changes have been observed in the closing duct in the absence of prostanoid therapy. Cortical hyperostosis is a well-known complication of prolonged prostanoid administration. In addition, gastric outlet obstruction reflecting antral mucosal hyperplasia is a

complication of prolonged prostaglandin administration (172).

PULMONARY HTN IN THE NEWBORN

The fetal circulation is characterized by using the placenta as the organ of respiration. The ductus venosus allows half of the placental return to bypass the hepatic circulation and enter the inferior vena cava directly. This inferior caval flow then is directed to the left atrium via the foramen ovale. In contrast, blood returning to the heart via the superior vena cava is directed to the right ventricle, illustrating the physiologic phenomenon of advantageous streaming that can occur when blood is incompletely mixed. Blood exiting the right ventricle can enter either the systemic or pulmonary circulation as a result of the presence of the arterial duct. As the pulmonary circulation maintains a high resistance in the relative hypoxemia of the fetus and the systemic vascular resistance is low as a result of the low resistance of the placenta, approximately 90% of the blood leaving the right ventricle flows to the systemic circulation. The result from a systemic standpoint is that the postductal systemic circulation directed to the placenta receives blood that is less well oxygenated than the preductal circulation, including the coronary circulation.

The transition from intrauterine to extrauterine life represents a phenomenal example of adaptive physiology. Within minutes, the systemic vascular resistance increases because of loss of the placenta. As a result, baroreceptors decrease the heart rate. Newly inspired oxygen dilates the pulmonary vascular bed and results in increased pulmonary blood flow. The increased pulmonary venous return functionally closes the foramen ovale and also results in increased left ventricular output. With a decrease in the pulmonary vascular resistance and closure of the ductus arteriosus, right ventricular pressure also falls, within 2 to 3 days in most instances, but sometimes as long as 7 days. The neonatal circulation thus differs from that of the older infant in the ability to shunt right to left across the foramen ovale, in the ability to shunt across the ductus arteriosus, and in the presence of right ventricular hypertrophy. In addition, the pulmonary vascular bed is reactive to hypoxemia and acidemia. The neonate, however, is more tolerant of hypoxemia.

A useful clinical test is the hyperoxic test. Administration of 100% oxygen overcomes alveolar hypoventilation and to some degree offers improvement in the setting of ventilation-perfusion mismatch. The PO_2 is measured both preductally and postductally. Subsequently, 100% oxygen is administered and the PO_2 repeated. Both regions must have a PO_2 greater than 150 mm Hg to “pass” the test. The test is also useful for formally documenting differential cyanosis.

Persistent pulmonary hypertension of the newborn is a feature or consequence, not a specific diagnosis. It can result secondary to lesions of other systems or as a primary problem. Pulmonary venous hypertension due to venous atrial and mitral valve abnormalities and poor left ventricular diastolic function can be due to congenital heart lesions or transient in the setting of a healthy heart. Hyperviscosity associated with polycythemia represents a familiar cause of pulmonary hypertension. Primary and secondary pulmonary hypoplasia also may result in pulmonary hypertension. Lastly, cyanosis can be the result of pulmonary vasoconstriction due to the persistence of the ductus arteriosus with right-to-left shunt in the setting of persistent fetal circulation, secondary to pulmonary disease, and due to premature closure of the arterial duct.

PERSISTENT FETAL CIRCULATION

The condition of persistent fetal circulation describes a setting of persistent pulmonary hypertension of the newborn characterized, as the name suggests, by a maintenance of fetal hemodynamics. The pulmonary vascular bed remains vasoconstricted with profound cyanosis resulting from right-to-left shunts at the level of the foramen ovale and the ductus arteriosus. In most instances, the neonate is born at term, often with a history of perinatal hypoxia. The clinical examination may reveal only silent cyanosis; however, often a murmur of tricuspid insufficiency is present. The electrocardiogram reflects right ventricular hypertrophy, but is not diagnostic. Chest radiography reveals a normal heart size if ventricular function is preserved, and the vascular markings may be increased or decreased depending on the amount of blood flow and edema related to ventricular dysfunction and again is not diagnostic. In general, the patient fails the hyperoxic test and may exhibit differential cyanosis with decreased PO_2 noted in the lower extremities due to right-to-left shunt across the arterial duct. Patients must be distinguished from those with ventricular dysfunction and other silent causes of cyanosis, including transposition of the great vessels and total anomalous pulmonary venous return.

Treatment is generally supportive until the condition resolves by approximately 1 week of age. The neonate is kept well oxygenated and hyperventilated. Mechanical ventilation may include the use of high-frequency oscillation in an effort to decrease pulmonary barotrauma while removing CO_2 (173). Alkalemia is encouraged by administering bicarbonate in addition to the hyperventilation. Associated hypoglycemia and hypoxemia must be watched and treated carefully. Ventricular dysfunction may require inotropic support, recognizing that many agents also result in further pulmonary vasoconstriction. Selective pulmonary vasodilation is difficult to achieve because most also result in systemic hypotension due to systemic effects. The use of nitric oxide in this condition is being considered carefully by many investigators (174,175,176,177 and 178). In desperation, extracorporeal membrane oxygenation (179,180) can be used to support the young neonate while the problem resolves spontaneously.

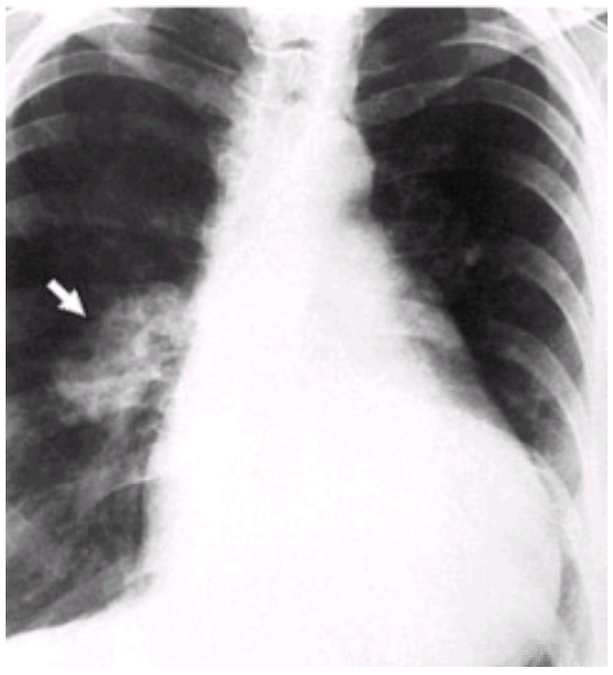
NATURAL HISTORY OF CONGENITAL HEART DISEASE

Ventricular Septal Defect

One of the difficulties and perhaps confounding aspects of the natural history studies of ventricular septal defect is that most do not distinguish between the various types of ventricular septal defects (181,182 and 183). Clearly, different events would be anticipated in patients with a perimembranous ventricular septal defect compared with a doubly committed or juxtaarterial defect or a midtrabecular muscular ventricular septal defect (184).

Acquisition of right ventricular outflow tract obstruction is a well-known phenomenon in the patient with a ventricular septal defect. The incidence of this occurrence has been reported to be 2% to 7%, and the inference of most of these studies is that the ventricular septal defect is perimembranous in position (183,184). Data on the incidence of acquired right ventricular outflow tract obstruction when the defect is muscular are limited. Most patients with a small or restrictive ventricular septal defect demonstrate spontaneous reduction in size of the defect or closure. In addition, spontaneous closure or significant diminution in size is so uncommon that surgical intervention is indicated for patients with a large ventricular septal defect, pulmonary artery hypertension, and an Rp/Rs (ratio of pulmonary to systemic vascular resistance) less than 0.7.

Probably 70% to 80% of all patients born with a ventricular septal defect have a restrictive or small defect, and most should be anticipated to become smaller or close (185,186 and 187). Of those identified in infancy with a moderate-sized ventricular septal defect, approximately 40% to 50% show some spontaneous reduction in size, with reduction of the often substantial left-to-right shunt and normalization of the modestly elevated pulmonary artery pressures. Patients with a large, nonrestrictive ventricular septal defect should not be expected to show spontaneous improvement on the basis of spontaneous reduction in size of the defect (181,182,183,184 and 185). Clinical improvement in such patients could reflect the development of pulmonary outflow tract obstruction, aortic valve prolapse with partial occlusion of the defect, or the development of pulmonary vascular obstruction.



Chest x-ray in patient with a congenital ventricular septal defect. There is fullness in the hilum secondary to an enlarged pulmonary artery (*white arrow*).

Pulmonary Stenosis

The mode of intervention for severe pulmonary valvular stenosis has changed from an operative one to a transcatheter methodology (181,182). Patients with mild or trivial pulmonary stenosis with a catheter gradient less than 25 mm Hg do not require surgery, and almost no significant progression is observed. Some patients with more moderate disease and who are initially treated medically do have a progression in severity, requiring intervention. The Joint Study on Natural History of Congenital Heart Defects recommends that patients with moderate disease do better in the long term with intervention, preferably valvuloplasty. Again, patients with severe obstruction require intervention.

Aortic Valve Stenosis

As with patients with isolated pulmonary valvular stenosis, those identified with severe disease are treated surgically, and those with mild to moderate obstruction tend to worsen (181,182,184,188). Of concern is the observation that many patients with initially mild or moderate obstruction who do not have regular cardiology follow-up are found on reexamination to have developed severe obstruction, not infrequently accompanied by myocardial ischemia (182).

Atrial Septal Defect

The natural history of the large secundum atrial septal defect has been defined, and there is little discussion that such a defect requires closure in childhood or later, assuming that there is no fixed pulmonary vascular obstructive disease. Certainly, fewer data are available on the necessity or advisability of repairing a small atrial septal defect with normal pulmonary artery pressures and a pulmonary to systemic flow ratio (Qp/Qs) less than 2, especially if the echocardiogram does not support significant volume loading of the right ventricle, and with normal or just flattened septal motion. It is still contentious as to whether there is an indication to consider transcatheter clamshell device closure of a patent foramen ovale. The argument put forward for intervention is that the patent foramen ovale presents a mechanism for a paradoxical thromboembolic event.

Infants with an atrial septal defect less than 3 mm need not have follow-up, as these defects close by age 18 months; those with a defect measuring 3 to 5 or 5 to 8 mm should be evaluated by the end of the twelfth and the fifteenth month, respectively, when 80% of these defects are closed. An atrial septal defect with a diameter greater than or equal to 8 mm may have little chance of closing spontaneously, and surgical correction should be considered. Defects less than 3 mm probably do not constitute a cardiac malformation in light of their natural evolution and gender distribution.

Fixed Forms of Subaortic Obstruction

The fixed forms of subaortic stenosis have been characterized as discrete, fibrous or membranous, fibromuscular, and tunnel forms, but clearly there is a continuum between these forms, and one form may progress from a less diffuse to a more diffuse and extensive form (189,190,191,192,193,194,195,196,197,198,199,200,201,202,203,204,205,206,207,208,209,210,211,212 and 213). Somerville et al. emphasized that the discrete form of so-called fibrous subaortic stenosis is rarely simple and discrete, and it is neither membranous nor diaphragmatic (201,202,203 and 204). Increasing clinical evidence, however, has accumulated suggesting that the fixed expressions of subaortic stenosis have both congenital and acquired features (192,193,194,195 and 196,202,203,204,205,206,207,208 and 209,212,213,214 and 215). It is more difficult to define the rate of progression of the fixed forms of left ventricular outflow tract obstruction. Many patients seem to have progression of severity, and there is an increasing incidence of aortic incompetence reflecting damage to and involvement of the aortic valve (10,11,12,13,14 and 15,18,19,20,21,22,23,24 and 25). Because the left ventricular outflow tract may be intrinsically abnormal, more narrow and elongated when compared with normal, it should not be surprising that recurrence of the obstruction is a well-documented phenomenon after surgical intervention (192,193,194,195 and 196,208,209,210 and 211).

Supravalvular Aortic Stenosis

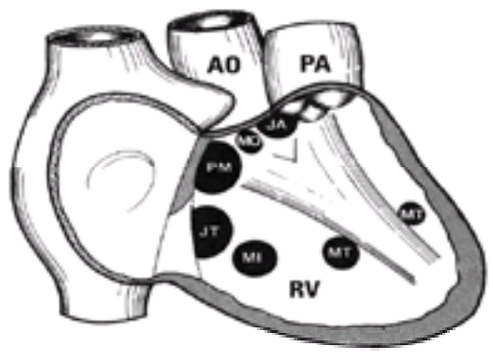
Although there is a spectrum of pathologies producing supravalvular aortic stenosis, the tendency is for progression or worsening of the obstruction over time (192,216,217,218 and 219). This disorder is frequently seen in patients with Williams syndrome, or in the nonsyndromic expression of this disorder (220,221,222,223,224,225,226,227,228,229,230,231,232,233,234,235,236,237,238 and 239). With the supraaortic narrowing of a sinotubular ridge, there is the potential of coronary ostial stenosis (239,240,241,242,243,244,245 and 246). In this regard, pathologic changes in the coronary arteries have received considerable attention in patients with supravalvular aortic stenosis, and the rare instance of sudden death may be related to coronary artery involvement (239,240,247). Of 80 patients with supravalvular aortic stenosis seen at the Mayo Clinic, dilatation of the right coronary artery was found in 29% of the patients and dilatation of the left coronary artery in 20% (245). Vascular lesions may progress in patients with the Williams-Beuren syndrome, sometimes malignantly (277). Ino and colleagues documented the progression of coarctation of the aorta in one patient and renal artery stenosis in another (233). Supravalvular aortic stenosis is a complex disorder with the potential for coronary artery involvement; stenoses in the major conducting arteries, including the cerebral vessels; aneurysms of the ascending aorta; and severe pulmonary arterial stenoses (67).

INDIVIDUAL CONDITIONS

Left-to-Right Shunt Conditions

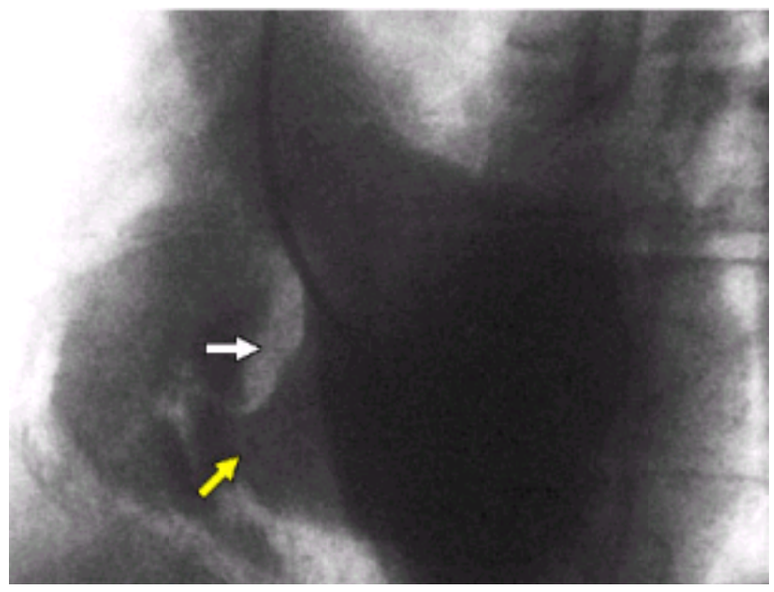
Ventricular Septal Defect

The ventricular septal defect is one of the most common lesions encountered in congenital heart disease, accounting for 25% to 30% of all patients (*e*Fig. 30.0.6). Perhaps more common are the bicuspid aortic valve and mitral valve prolapse; however, these conditions are rarely recognized in the neonate or young infant. Most defects are single and occur with an incidence of 1.2 per 1,000 live births. They can occur in isolation or in the setting of more complex congenital heart lesions, and extracardiac anomalies may be present in as many as 29% of infants. This section considers only the isolated condition, recognizing the dynamic nature of the lesion.



***e*FIGURE 30.0.6** Schematic diagram of ventricular septal defects. This diagram does not indicate that these defects may be confluent. AO, aorta; JA, juxtaarterial; JT, juxtatricuspid; MI, muscular inlet; MO, muscular outlet; MT, midtrabecular; PA, pulmonary artery; PM, perimembranous; RV, right ventricular. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

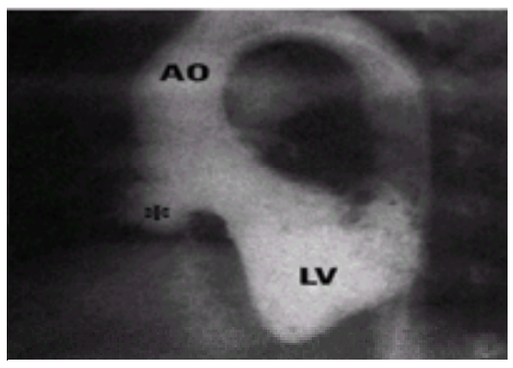
Currently, no consensus exists as to the nomenclature to describe a ventricular septal defect (248); however, the classifications generally agree on four locations of defects (*e*Fig. 30.0.6). The first describes defects of the inlet component of the ventricular septum described by terms such as *inlet septal*, *atrioventricular canal type*, or *muscular inlet*. The second occurs in the outlet septum and is termed *right ventricular outlet*, *conal septal*, or *juxtaarterial/doubly committed subarterial*. The third location is that of the *conoventricular* or *perimembranous septum*, recognizing that the defect is truly paramembranous and can extend to the inlet, trabecular, and outlet septum. Finally, the fourth location is that of the *trabecular* or *muscular septum*, which can be further divided into *inlet*, *apical*, and *anterior defects* (249,250 and 251).



Muscular ventricular septal defect. This left anterior oblique left ventriculogram demonstrates the presence of a muscular ventricular septal defect (*yellow arrow*) with opacification of the right ventricular cavity and pulmonary outflow tract. The ventricular septum (*white arrow*) is seen to divide the right and left ventricular chambers.

Video 30.1 Hepatoclavicular view (left anterior oblique 60, cranial 45) of a membranous ventricular septal defect in a 16-year-old male patient. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The size of the ventricular septal defect is also an important consideration. Large defects are larger than or equal to the size of the aorta, offer no resistance to flow, and result in equal ventricular pressures. The Qp/Qs is dependent on the pulmonary vascular resistance. Conversely, small defects restrict flow to the right ventricle and hence raise the right ventricular pressure beyond half systemic levels in the absence of right ventricular outflow tract obstruction and when the Qp/Qs is less than 1.75:1.00 (eFig. 30.0.7).



***e*FIGURE 30.0.7** A virtually closed perimembranous ventricular septal defect with adherent tricuspid valve producing a so-called aneurysm of the membranous septum (*asterisk*). AO, aorta; LV, left ventricle. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

The natural history of a patient with a ventricular septal defect is dynamic and often depends on the location and extent of the defect. Defects of the muscular or perimembranous septum may close spontaneously in 25% to 50% of patients or remain hemodynamically restrictive and asymptomatic as in the “maladie de Roger” defined in 1879 (252,253,254,255,256 and 257) (eFig. 30.0.7). The major complication associated with a small isolated ventricular septal defect is that of acquired bacterial endocarditis, stressing the importance of prophylactic antibiotic precautions. Large defects may contribute to pulmonary congestion and left ventricular volume load with dysfunction and heart failure. With time, pulmonary vascular obstructive disease develops and can become irreversible (Eisenmenger’s syndrome). Even small defects can be associated with the development of significant muscle bundles contributing to a two-chambered right ventricle, aortic insufficiency due to aortic cusp prolapse into the defect, or a fibrous subaortic ridge (258,259,260 and 261). Especially prone to aortic cusp prolapse with aortic valve deformity and eventual insufficiency is the conal (supracristal, doubly committed subarterial, or infundibular) defect (262,263). In this condition, the defect is effectively roofed by the aortic and pulmonary valve; thus, there is no support for the aortic valve cusps.

Clinical findings are often dynamic and reflect the natural history course of the defect. The patient with a small restrictive defect is asymptomatic with normal growth and development. In the first weeks of life, the neonate with a larger defect may be asymptomatic until the pulmonary vascular resistance falls, resulting in a greater left-to-right shunt. With increasing shunt, the infant becomes tachypneic and diaphoretic as a result of increased sympathetic tone, feeds poorly with poor weight gain and gastroesophageal reflux, and is susceptible to pulmonary infections, atelectasis, and wheezing. Physical examination depends on the size of the defect, the pulmonary vascular resistance, and the presence of associated anomalies. The infant or child with a small defect demonstrates a quiet precordium to palpation, with the exception of the presence of a thrill. The first and second heart sounds are normal with, importantly, respiratory physiologic variation of the second heart sound. The murmur produced by the defect is harsh and pansystolic. Late systolic accentuation is possible if there is tricuspid valve tissue associated with the defect. The murmur may cease before the second heart sound in the setting of a small muscular defect that is obliterated in late systole. In the moderate-sized defect in which the pulmonary to systemic flow ratios are approaching 2:1 or higher, the infant demonstrates a hyperdynamic precordium with a left precordial bulge. The pulmonary component of the second heart sound becomes accentuated, with narrowed splitting. In addition to the pansystolic murmur, a diastolic murmur also can be appreciated at the apex as a result of increased flow across the mitral valve. In the large defect, the second heart sound is loud and single due to pulmonary hypertension. A gallop rhythm may be present in congestive heart failure because of the volume load placed on the left ventricle.

Over time, one must be alert to changes that may signal the development of problems. The small defect with a pansystolic murmur that is spontaneously closing in the muscular septum may be progressing from pansystolic to a more abbreviated softer murmur. Conversely, the child with a large ventricular septal defect that is developing obstructive pulmonary vascular disease also may progress to a decrease in the duration of the murmur. Importantly, however, the second heart sound remains loud and single, and there may be evident cyanosis due to a right-to-left shunt. The pulmonary trunk may click with systole owing to dilation, and the diastolic flow rumble disappears as there is less flow across the mitral valve in the setting of increasing pulmonary vascular disease. A new decrescendo diastolic murmur should alert the clinician to the development of aortic insufficiency, whereas the change from pansystolic to a long ejection-type murmur may indicate right or left ventricular outflow tract obstruction.

The electrocardiogram is not specific for the ventricular septal defect. The QRS axis may be deviated leftward as in many defects of the inlet septum, or it may be normal to rightward. There may be left or combined ventricular hypertrophy; however, for small defects, the complexes appear normal. Changes in the ST-T wave also may be demonstrated. Progression or changes in electrocardiographic findings may herald changes in physiology or morphology. Chest radiography with larger defects demonstrates cardiomegaly with pulmonary plethora.

A 16-year-old male patient with biventricular hypertrophy secondary to ventricular septal defect and Eisenmenger's syndrome.

Echocardiographic imaging, particularly with the addition of Doppler-derived color flow mapping technology, is the mainstay of establishing the morphology of the defect (257,264,265,266,267,268,269,270 and 271). The ventricular septum is complex, necessitating multiple views from subcostal and precordial approaches in an effort to interrogate the entire septum thoroughly. The right ventricular and pulmonary artery pressures can be derived from color flow–directed Doppler indices, recognizing the limitations of the technique and the influence of associated lesions on the accuracy of the estimate (272,273,274,275 and 276). Although an estimation of the pulmonary to systemic flow ratio is possible (277), it is difficult in the small child because small errors in measurement have a profound effect on the calculated indices.

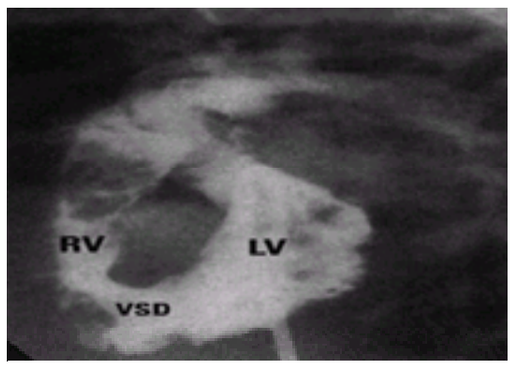
Many infants may proceed to surgical intervention in the setting of a straightforward defect assessed echocardiographically. If uncertainty exists as to the number of defects, the magnitude of the left-to-right shunt, the pulmonary vascular resistance, or the presence of associated anomalies, cardiac catheterization with angiography is necessary. Axial projections in angiography allow specific regions of the ventricular septum to be profiled, thus allowing precise localization of defects (278,279,280 and 281).

The medical management of ventricular septal defects in the symptomatic infant and child consists primarily of diuretic therapy with afterload reduction using an angiotensin-converting enzyme inhibitor. Although no large trials have been reported to support its use, digoxin also remains a medical mainstay of management. Small defects rarely require surgical intervention, and many defects undergo spontaneous closure. Indications for operative intervention include severe intractable heart failure and pulmonary congestion in the first 3 months of life or if the older infant fails to thrive with optimization of dietary needs and medical treatment. In general, the pulmonary vascular resistance is best below 8 Wood units if surgery is to be successful in the long term. Moderate-sized restrictive defects with a Qp/Qs greater than 2:1 and pulmonary congestion with cardiomegaly probably should be repaired. In addition, even the small subarterial defect can result in aortic cusp deformity with resultant insufficiency; hence, repair is recommended. The small defect that has also been subject to infective endocarditis is also repaired. Postoperative complications include the development of heart block, persistent ventricular dysfunction, surgically induced semilunar (especially aortic) or atrioventricular (especially tricuspid) incompetence, persistent shunt due to a postoperative residual patch leak or leak from a previously unrecognized defect, and pulmonary vascular disease.

Ventricular septal defects can be repaired from the right atrium or right ventricle and more rarely the left ventricle or pulmonary artery via a median sternotomy. The ventriculotomy is avoided where possible. Usually, the actual defect is repaired with a patch, with attention directed to avoiding the conduction tissue; however, smaller defects, particularly in the muscular septum, can be closed by using a direct suture technique. Pulmonary artery banding to limit flow to the lungs, hence protecting them from the development of obstructive pulmonary vascular changes, is undertaken only in unusual circumstances in the current surgical era (282,283,284,285,286,287,288 and 289).

Although surgery in the current era is associated with acceptable morbidity and mortality, multiple and apical ventricular septal defects are associated with higher surgical mortality than single defects, and severe deficiency of the muscular septum may preclude a biventricular repair (*e*Fig. 30.0.8 and *e*Fig. 30.0.9). In addition, postoperative residual defects also can contribute to persistent compromise to ventricular and respiratory function and remain a challenging surgical problem (282,290). Intervention is still directed to achieving primary closure when possible and reserving pulmonary artery banding for patients with more complex malformations.

Armonk, NY: Futura Publishing, 1997, with permission.)



***e*FIGURE 30.0.9** A large apical ventricular septal defect (VSD). LV, left ventricle; RV, right ventricle. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

Transcatheter occlusion of ventricular septal defects using a double-umbrella device has been demonstrated to be a feasible strategy in the management of defects of the ventricular septum recognized preoperatively or as a postoperative residual problem (291,292,293 and 294). Although attractive as an alternative to surgery, considerable investigation must precede routine application of this new transcatheter technique.

Atrial Septal Defect

The atrial septal defect rarely presents in infancy and is more commonly a condition recognized in early childhood. It is rarely associated with symptoms unless it is very large or associated lesions or symptoms are present. Incidence of recognized defects ranges from 0.317 to 0.580 per 1,000 live births (295,296). It is the eleventh most frequent diagnosis in the New England Regional Infant Cardiac Program, with a prevalence of 2.9% in this study population (297). Although most cases are sporadic, familial occurrences are well documented. Defects of the atrial septum are also more frequent in patients with chromosomal abnormalities as well as

extracardiac midline defects, such as a cleft palate. Perhaps the most well-known association is that observed by Holt and Oram (298) in which the thumb is "digitalized"; however, other variations of the thumb, radius, and clavicles also have been described in association with a defect of the atrium that appears to be transmitted as an autosomal dominant syndrome. Atrial septal defects seem to occur more commonly in female infants, with a ratio that ranges from 1.5 to 3.5:1.0.

The atrial septum starts embryologically as septum primum grows from the roof of the atrium toward the endocardial cushion. As this occurs, septum primum becomes perforated, resulting in the ostium secundum. Septum secundum overlaps septum primum and forms the superior limb of the fossa ovalis. With increased venous return to the left atrium at birth, the septum primum is opposed to the left atrial side of septum secundum, resulting in fusion of the septae and closure of the foramen ovale by approximately 1 month of age. Up to 25% of persons continue to have a probe patent foramen ovale in autopsy series. Four basic defects of the atrial septum occur. The most common form of atrial defect is the secundum defect, which occurs in the region of the fossa ovalis. The defects may be single, multiple, central, or eccentric and may extend in any direction. Ostium primum defects are a form of atrioventricular (endocardial cushion) defects and are discussed with those defects. The coronary sinus may be "unroofed," particularly in association with a persistent left superior vena cava; however, multiple defects in the coronary sinus are known to occur in isolation. The so-called sinus venosus defect is commonly associated with anomalous drainage of the right upper pulmonary vein and is likely due to irregular absorption of the right pulmonary veins into the superior caval wall because of failure to isolate the appropriate part of the sinus venosus (299). This interatrial communication is really a defect of the sinus venosus and not of the atrium per se.

The left-to-right shunt that occurs across the atrial septum in late systole and during diastole is dependent on the size of the defect, the relative compliance of the ventricles, and the pulmonary relative to the systemic vascular resistance. If the defect is unrestrictive, there is no gradient between the atria. The shunt results in a diastolic volume load of the right ventricle, leading to enlargement as well as increased pulmonary blood flow, which can result in pulmonary hypertension and pulmonary vascular disease. Often, the magnitude of the shunt increases through infancy as a result of the decreasing compliance of the ventricle that occurs with age. In general, the volume load is well tolerated in childhood with low pulmonary pressures and vascular resistance.

Spontaneous closure of the defect in infancy is known to occur (300,301,302 and 303). Similarly, the magnitude of the left-to-right shunt may decrease if associated conditions that increase flow to the left atrium, such as the patent ductus or ventricular septal defect, become smaller or close spontaneously. Such defects likely represent a "stretched" foramen ovale rather than a true defect of the atrial septum. Although usually asymptomatic, the young child may present with decreased exercise tolerance and frequent respiratory infections (304). The defect may complicate concurrent respiratory conditions in the infant (e.g., bronchopulmonary dysplasia) because of the volume load to the lungs. Rarely, pulmonary hypertension complicates the presentation in the young infant (305). The association with mitral valve abnormalities (Lutembacher's syndrome and mitral valve prolapse) is well known. Adolescents and adults may develop atrial arrhythmias, pulmonary vascular disease, and symptoms of heart failure.

Typical findings on examination of a patient with an atrial septal defect include a prominent right ventricular impulse and, at times, a palpable pulmonary pulsation. The first heart sound is normal but may be followed by a click associated with mitral valve prolapse. The second heart sound is typically widely split and does not vary with respiration (306). One must be alerted to the possibility of pulmonary hypertension if the pulmonary component of the second heart sound is particularly loud, especially in the older patient. A systolic pulmonary flow murmur can be appreciated as well as a mid-diastolic rumble due to flow across the tricuspid valve if the left-to-right shunt is large. Cyanosis and clubbing are late findings if the patient develops significant pulmonary vascular disease.

The electrocardiogram typically demonstrates right-axis deviation (except in the ostium primum defects), right ventricular hypertrophy related to volume load, an rSR' or rsR' pattern in lead V_1, and prolongation of the PR interval. Left-axis deviation of the p wave manifests as an inverted complex in lead III and often is associated with the "sinus venosus" type of intraatrial connection. The chest radiograph typically demonstrates right atrial and ventricular hypertrophy, an enlarged pulmonary artery, and increased arterial markings.

The echocardiogram with Doppler evaluation of the atrial septum is the mainstay of diagnosis, particularly in the pediatric population (307,308,309,310,311,312 and 313) (eFig. 30.0.10). In the adult or pediatric patient with poor subcostal or parasternal windows, transesophageal imaging is often required and provides an excellent assessment of the atrial septum. In addition, 3-D ultrasound imaging techniques may serve to delineate the morphology of the septum further in planning some interventions (314,315 and 316). Imaging of the atrial septum is often optimally achieved using subcostal views, which allow visualization of the entire septum (317,318,319 and 320). Doppler echocardiography aids in the understanding of the physiology of the defect and confirms the presence of the defect noted by imaging. Indirect evidence includes the presence of a volume-loaded right ventricle with paradoxical septal motion. The right ventricular pressure may be assessed noninvasively using the tricuspid valve regurgitant jet in the evaluation for concurrent pulmonary hypertension.

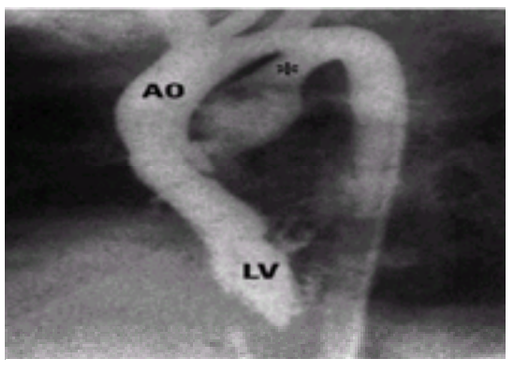
Cardiac catheterization is undertaken when inconsistencies exist in noninvasive assessment or when significant pulmonary hypertension is present. The catheter course across the atrial defect, combined with angiography, outlines the location of the communication. Hemodynamic variables, including the pulmonary to systemic flow ratios and pulmonary vascular resistance, are measured, recognizing that flow ratios can be obtained using Doppler and nuclear medicine techniques. In addition, the pulmonary venous drainage can be demonstrated by selective injection in the pulmonary arteries.

In the asymptomatic child, surgical intervention is undertaken when the child is between 2 and 4 years of age with cardiopulmonary bypass by direct suture or patching of the defect. Results are excellent with low (less than 1%) mortality and morbidity. Closure is recommended for patients with pulmonary to systemic flow ratios greater than 1.5:1.0 in which the ratio of resistances is less than 0.7:1.0. Several surgical techniques were developed in an effort to minimize or avoid the median sternotomy approach to minimize the cosmetic effect of the resultant scar. With this in mind, transcatheter closure is becoming increasingly attractive as an alternative to surgery, with several devices currently in clinical trials (321,322,323,324,325,326 and 327). Whereas the shunt may be effectively reduced to that of being hemodynamically insignificant, large lesions have a higher prevalence of residual leak when rigorously assessed using current technology (328).

Patent Arterial Duct

The patent arterial duct (patent ductus arteriosus), representing persistence of the distal left sixth aortic arch, is usually a left-sided structure, but the arterial duct may be right-sided or bilateral (eFig. 30.0.11). The terms *persistent* and *patent* both have been used to describe the functional and anatomic integrity of the arterial duct. This section considers the arterial duct in isolation. One should remember that the arterial duct has an important role in conditions characterized by a ductal-mediated pulmonary blood flow (i.e., pulmonary atresia with or without ventricular septal defect) or in conditions in which patency of the arterial duct is fundamental to maintenance of part or the entirety of the systemic blood flow (i.e., aortic atresia complexes, interruption of the aortic arch, aortic arch atresia, or severe coarctation) (329,330,331 and 332).



***e*FIGURE 30.0.11** Large patent arterial duct (*asterisk*) demonstrated by long axial left ventriculogram. AO, aorta; LV, left ventricle. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

Incidence

The estimated incidence of an isolated persistent arterial duct is subject to potential error, especially because of the inclusion of cases of prematurity or maternal rubella. Anderson (333) estimated the incidence to be between 1 in 2,500 and 1 in 5,000 births and to account for 12% of all congenital malformations. In a more extensive, relatively homogeneous population, Carlgren (334) found the overall incidence of all cardiac malformations to be 6.4 per 1,000, with persistent arterial duct the third most common lesion seen, or approximately 0.04% of live births. Mitchell et al. (335) reported the incidence at 0.06%, but may have included cases of prematurity or the influence of maternal rubella as well. The incidence in the general population may indeed be higher, however, as more sensitive imaging techniques are applied.

Clinical Findings

The arterial duct may remain patent in the preterm infant and promote the respiratory distress syndrome as well as persistent pulmonary hypertension of the newborn. The cardiac findings of the arterial duct in the newborn and neonate differ from those appreciated in the older infant and child (330,331,332,333,334,335 and 336). The precordium is usually overactive, and the murmur is usually systolic, sometimes breaching into early diastole, but it is not frankly continuous, reflecting the elevated pulmonary artery pressures. The pulses of all four limbs are bounding. When the diagnosis is confirmed by cross-sectional echocardiography and either duct-dependent congenital heart disease or a coarctation of the aorta is excluded, and the duct is considered hemodynamically important, pharmacologic intervention with indomethacin may promote ductal closure (330,331 and 332). When this is unsuccessful, then surgical ligation or division will be required (330,331 and 332).

In the older infant and child, the arterial duct, when small or moderate sized, is usually well tolerated. A dynamic left ventricle, a grade 3 or 4 continuous murmur in the left infraclavicular fossa, associated with multiple eddy sounds, and bounding arterial pulses are all findings typical of an arterial duct (336). When the duct is small, the chest radiograph and electrocardiogram results may be normal. When the duct is more moderate or large, this is reflected in the chest radiograph, which shows some degree of cardiac enlargement and pulmonary overcirculation.

The clinical diagnosis is rapidly confirmed with cross-sectional echocardiography. It is always important to scrutinize the aortic arch and isthmus to ensure that the arterial duct is not masking a coarctation of the aorta. Even the small arterial duct probably should be closed to prevent infective endarteritis or the chronic effects of left

ventricular volume loading. There is unanimity of opinion that the large arterial duct should be closed to prevent or treat congestive heart failure and to prevent the development of pulmonary vascular disease (336). The patient with clear-cut pulmonary vascular obstructive disease is not a candidate for duct closure, and lung transplantation eventually will be required (336).

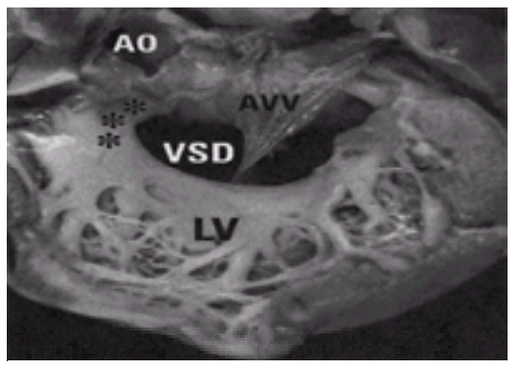
Ductal closure can be accomplished without a thoracotomy with the Rashkind ductal occluder or other systems (337,338,339,340,341,342,343,344,345,346,347,348,349,350,351,352,353,354,355,356,357,358,359,360 and 361) (see Chapter 87). The Rashkind system uses a catheter delivery system from either venous or arterial entry, although the use of a long sheath placed across the ductus from a transvenous route has become the technique of choice. Catheter closure is applicable in infants and young children but is restricted to an arterial duct no larger than 8 or 9 mm in diameter and is not applicable to the premature infant. Successful implantation can be accomplished in most (greater than 98%) with elimination of clinical signs of left-to-right shunting. Within the first 48 hours, few patients retain ductal murmurs despite correct placement, although some may have residual shunts without murmurs. Doppler evidence of residual shunting is often over the superior aspect of the device. Complications of this technique are few. Acute bacterial endarteritis has occurred after implantation when appropriate procedural coverage was not applied. Embolization to both systemic and pulmonary circulations has been encountered, with several patients requiring surgical referral. Severe hemolysis also has been reported (356,357 and 358). Protrusion of the Rashkind ductal device into the left pulmonary artery may be a cause of left pulmonary artery stenosis (345,346,355). Catheter retrieval has been accomplished in both situations, using snares, baskets, or grasping forceps.

Using pulsed and color flow Doppler techniques, occlusion rates have been evaluated. In a study by Hosking et al., 38% had Doppler evidence of shunting detected 1 year after the procedure, falling to 18% at 2 years and 8% at 40 months. Similar observations from several studies have been reported (351,353). A number of patients have undergone additional procedures with successful placement of a second device. The potential for long-term complications associated with a residual shunt, clinically silent, but detected by color flow Doppler mapping in the presence of a foreign body, remains unknown. A few patients have increased Doppler velocity shifts at the origin of the left pulmonary artery postimplantation, resulting from turbulence or encroachment into the ostium of the left pulmonary artery; incidence increased when placement was performed in children under 10 kg in weight.

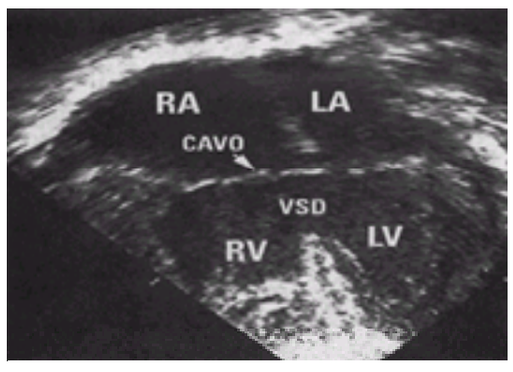
Using embolization spring coils (Gianturco, Cook Inc., Bloomington, IN), Cambier reported successful occlusion of small ductal communications (less than 2.5 mm) using a retrograde approach in three of four children. Lloyd and Moore expanded the early experience with this technique noting the approach to be effective and simple, and this technique can be performed in an outpatient setting. The use of the spring coil has gained popularity because of its significantly lower cost and ease of application. For the large arterial duct, however, surgical division, ligation, and thoracoscopic closure are techniques that can be used.

Atrioventricular Septal Defect

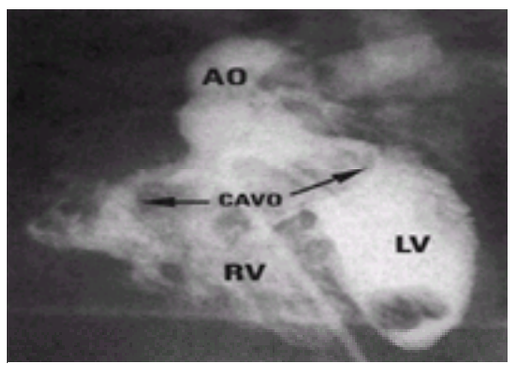
This is a heterogeneous group of cardiac malformations unified by the absence of the membranous and muscular atrioventricular septum (362,363,364,365,366,367,368,369,370,371,372,373,374,375,376,377,378,379,380 and 381) (*e*Fig. 30.0.12, *e*Fig. 30.0.13, and *e*Fig. 30.0.14). The absence of this component of the septum produces unique changes in the morphology of these hearts. The aorta is no longer wedged between the atrioventricular orifices; a characteristic disproportion between the left ventricular inlet and outlet results, and the morphology and disposition of the left-sided atrioventricular valve departs considerably from the normal mitral valve. These findings are germane to almost all hearts with a deficiency of the membranous and muscular atrioventricular septum. Yet there is a considerable variation by absence of the membranous and muscular atrioventricular septum (382,383). Some hearts are characterized by a large ostium primum atrial septal defect and a “cleft” mitral valve, but the clinical findings and hemodynamics are similar to the patient with a secundum atrial septal defect. Other hearts have large confluent atrial and ventricular septal defects and a common nonpartitioned atrioventricular valve. This type of malformation promotes large left-to-right shunts at the atrial and ventricular levels, and because of the large and nonrestrictive character of the ventricular septal component, pulmonary hypertension is at systemic levels. The left atrioventricular valve may or may not be competent in either of these situations, and severe incompetence is usually poorly tolerated. In other patients, deficiency of the atrial or ventricular septum may be relatively minor; rarely, both septa are intact or nearly so (375). In hearts with a complete form of atrioventricular septal defect, the attachments of the common atrioventricular valve, or lack thereof, to the ventricular septum or to the right side of the ventricular septum form the basis of the Rastelli classification (373,374). Designations such as *intermediate* or *transitional* forms of atrioventricular septal defect reflect the sizes of the various components of the defect (i.e., the size of the atrial septal defect; the size of the interventricular component; and the nature of the atrioventricular orifice, partitioned or common).



***e*FIGURE 30.0.12** Complete form of atrioventricular septal defect. Internal view of left ventricle showing the common atrioventricular valve (AVV), the large ventricular septal defect (VSD), and the typically elongated left ventricular (LV) outflow tract. The asterisks indicate the elongated outflow tract. AO, aorta. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)



***e*FIGURE 30.0.13** Apical four-chamber two-dimensional image of an atrioventricular septal defect. Note the deficiency of the inlet ventricular septum, the common atrioventricular valve orifice (CAVO), and the lack of the atrial septum primum. The defect is “balanced,” meaning that the atrioventricular orifice is committed equally to both ventricles. Doppler color-flow mapping of the common atrioventricular valve would assess for valve competency. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; VSD, ventricular septal defect.

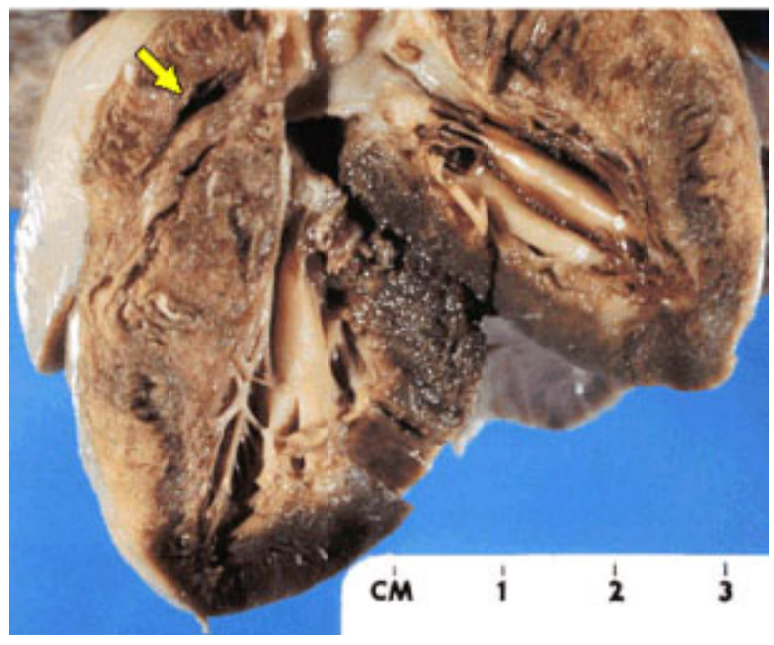


***e*FIGURE 30.0.14** Hepatoclavicular left ventriculogram shows the balanced form of the atrioventricular septal defect with the common orifice (CAVO) committed to both

ventricles. AO, aorta; LV, left ventricle; RV, right ventricle. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

Patients with any form of atrioventricular septal defect may have specific anatomic risk factors that alter both the timing of surgery, mortality, and early and late outcomes (382,383,384,385 and 386):

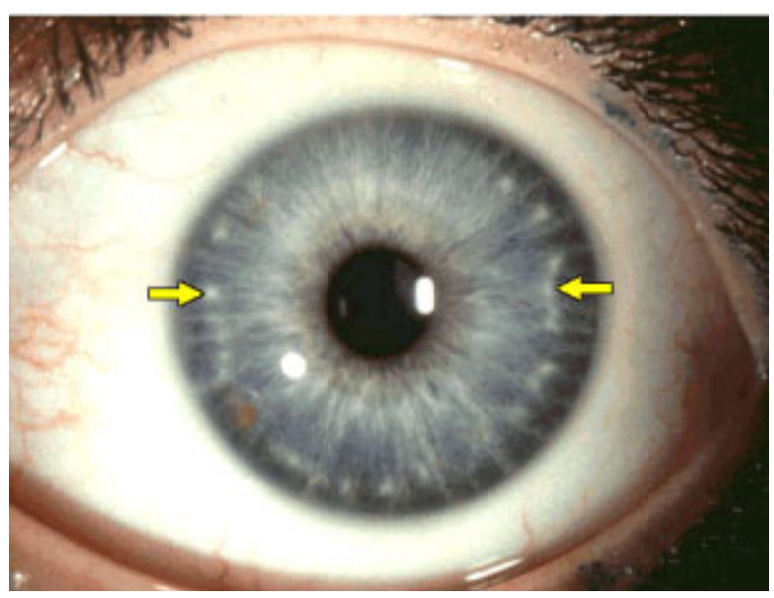
- Ventricular hypoplasia
- Left ventricular outflow tract obstruction
- Double-orifice left atrioventricular valve
- Parachute deformity of left atrioventricular valve
- Double-outlet atrium, right or left
- Association with other forms of congenital cardiac anomalies [tetralogy of Fallot, double-outlet right ventricle (DORV), hearts with right or left atrial isomerism, Ebstein's anomaly, and others]



Hypoplastic right heart in a neonate. The yellow arrow indicates a very small right ventricle chamber.

Relation to Down Syndrome

Beyond those issues of nomenclature, however, are the reality and management of patients, often further compromised by Down syndrome, with those cardiac lesions whose unifying feature is absence of the atrioventricular septum (384,387,388,389,390,391,392,393,394,395,396,397,398,399,400,401,402,403,404,405,406,407,408,409,410,411,412,413,414,415,416,417,418,419,420,421,422,423 and 424). Down syndrome is present in approximately 80% of infants under 1 year of age, and those with the complete form of atrioventricular septal defect undergo surgery (400). When viewed from the reverse perspective, between 35% and 40% of patients with Down syndrome have an atrioventricular septal defect, and in most of these, it is with a common rather than a partitioned atrioventricular orifice. Down syndrome is most commonly associated with a complete form of atrioventricular septal defect, and the patients without Down syndrome tend to have the partial form of the defect. Among those patients with Down syndrome and the complete form of atrioventricular septal defect, tetralogy of Fallot is more prevalent. In patients without Down syndrome, the hypoplastic left ventricle left-sided obstructive lesions and coarctation are associated with more common anomalies.



Brush field spots in association with Down syndrome. The yellow arrows indicate grayish-white spots in the iris, which are associated with trisomy 21.

Surgical results for atrioventricular septal defect have been stratified against patients with and without Down syndrome (401,402,403,404,405 and 406). There is no unanimity of opinion that Down syndrome patients have disadvantageous surgical outcomes. Clearly, in many centers today, repair of the complete form of atrioventricular septal defect can be accomplished with a risk less than 5% (408).

Pulmonary Vascular Disease

The conclusion that patients with Down syndrome and the complete form of atrioventricular septal defect are at increased risk for the development of pulmonary vascular obstructive disease compared with otherwise healthy children with the same heart defect remains debatable (411,412,413,414,415,416,417,418,419,420,421,422,423 and 424). Clapp and colleagues showed that Down syndrome patients with complete atrioventricular septal defect have a greater degree of elevation of pulmonary vascular resistance in the first year of life and more rapid progression to fixed pulmonary vascular obstruction than patients without Down syndrome (406).

Accelerated pulmonary vascular disease in those patients with Down syndrome is well documented (419). Chronic upper airway obstruction with macroglossia and an inherently small hypopharynx, hypotonia, the predisposition to chronic infection, an abnormal capillary bed morphology, and the suggestion of pulmonary hypoplasia all can affect the pulmonary vascular bed (385,386,412). Surgical correction of the complete form of atrioventricular septal defect by 6 months of age is recommended.

Clinical Findings and Diagnosis

The clinical findings may be similar to those of an isolated secundum, atrial septal defect, or congestive heart failure, and pulmonary artery hypertension may reflect the complete form of the defect with a large nonrestrictive ventricular septal defect. Less commonly, the findings of florid "mitral" regurgitation dominate the clinical picture. The electrocardiogram in typical cases demonstrates a leftward and superior counterclockwise frontal QRS axis and not infrequently first arteriovenous block is evident. In the usual expression of the complete defect, one would anticipate right ventricular hypertrophy as well. The heart size and pulmonary vascular markings are, of course, quite variable, depending on the specific defects and age at presentation. Many of the specific risk factors in the patient with atrioventricular septal defect are also better sorted out with echocardiographic examination, including recognition of confounding conditions, including tetralogy of Fallot, DORV, and Ebstein's anomaly (*e*Fig. 30.0.13 and *e*Fig. 30.0.14). Of note, cardiac catheterization and angiography continue to have an important role in the evaluation of these patients, particularly in those with more complex forms of the malformation. Some evidence exists that patients with Down syndrome may be at risk for early development of pulmonary

vascular obstruction, and thus hemodynamics measured in room air, in increased FIO_2, or with the administration of nitric oxide may be important to define vascular reactivity and operability. The hemodynamic measurements may be confounded by the obligatory shunt from left ventricle to right atrium, which might suggest a large Qp and normal or only mildly elevated pulmonary vascular resistance despite severe pulmonary vascular disease. Similarly, in patients with an atrioventricular septal defect and cyanosis, malalignment of the atrial septum with shunting from right atrium to left ventricle must be excluded. In patients with Down syndrome, an effort should be made to obtain the history of mouth breathing and significant snoring. If present, the opinion of an otolaryngologist should be sought regarding tonsillectomy or adenoidectomy before cardiac catheterization. Also, if a cardiac catheterization is required to define the pulmonary vascular resistance, it is always important to sample the pulmonary veins and to obtain PO_2 in room air and in an FIO_2 of 100%, thus excluding any important pulmonary dysfunction. Rabinovitch and colleagues also advocate the role of pulmonary artery wedge angiography, with definition of the rate of vascular tapering and the assessment of the background capillary phase. In some patients, lung biopsy might be the final arbiter of operability.

Aortopulmonary Window, Fenestration, or Septal Defect

The aortopulmonary window septal defect or fenestration (425) is an uncommon cardiac anomaly with an incidence of only 0.1% to 0.2%, characterized by a communication, often large, between the ascending aorta and pulmonary trunk (426,427,428 and 429). Although considered clinically related to truncus arteriosus and located in the same area of the heart, evidence marshaled by Kutsche and Van Mierop suggests that these two anomalies are probably pathogenetically unrelated (427). The shape and size of the aortopulmonary window vary, but always are related to the aortic wall above the aortic sinuses containing the coronary arteries. The aortopulmonary window can occur in isolation, but it has been identified with a wide variety of other cardiac anomalies, including aortic arch interruption, isthmal hypoplasia, origin of the right pulmonary artery from the ascending aorta, transposition of the great arteries, tetralogy with or without pulmonary atresia, and origin of the right coronary artery from the pulmonary trunk (430,431,432,433,434,435,436,437,438,439,440,441,442,443 and 444).

Nonassociation with DiGeorge Syndrome

There is a well-known association between abnormalities of the third and fourth pharyngeal pouch and interruption of the aortic arch and common arterial trunk as well as with other conotruncal abnormalities. This association has not been documented with aortopulmonary septal defect.

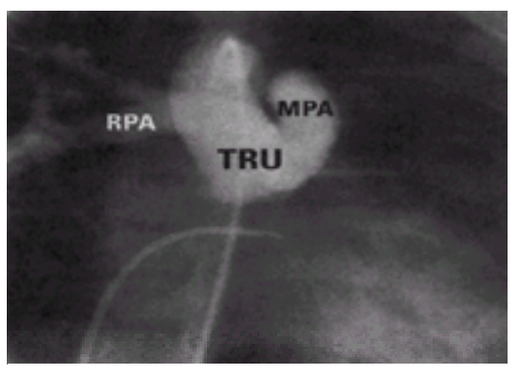
Diagnosis and Therapy

Neither the electrocardiogram nor the chest radiograph is specific for the diagnosis of aortopulmonary window. The echocardiogram is diagnostic of this condition with the following caveat (445,446,447,448 and 449): In the newborn period, while the pulmonary pressure is high, this lesion can be missed if the echocardiographer relies solely on Doppler echocardiography. It is, therefore, imperative that a thorough examination of the aortopulmonary septum is performed. It is also important to understand which lesions occur in association with aortopulmonary window. The diagnosis of aortopulmonary window is readily made by echocardiography; MRI may be helpful for interruption of the aortic arch or aortic origin of the right pulmonary artery (434).

Occasionally, a patient has a small aortopulmonary window, which can be closed in the catheter laboratory (450). For the remainder of patients, surgical intervention is necessary to prevent or treat congestive heart failure and pulmonary vascular obstruction. Repair of the aortopulmonary window in isolation carries a low operative risk (451), but the risk is increased if there are significant associated abnormalities.

Common Arterial Trunk or Truncus Arteriosus

Truncus arteriosus or common arterial trunk is characterized by a single arterial trunk supported by the ventricular mass giving origin to the coronary arteries, at least one pulmonary artery, and the brachiocephalic arteries (452) (eFig. 30.0.15). With rare exception, a ventricular septal defect is present (453,454,455,456,457 and 458). Classification (458) is first stratified by the presence or absence of a ventricular septal defect and by the presence of a main pulmonary trunk, separate origins of the right and left pulmonary arteries from the ascending portion of the arterial trunk, and nonconfluent pulmonary arteries with one pulmonary artery from the ascending portion of the arterial trunk and the other from an arterial duct or aortopulmonary collateral; the final form of common arterial trunk is that characterized by an obstructive anomaly of the aortic arch, coarctation of the aorta, aortic arch atresia, or interruption of the aortic arch. Hearts with truncus arteriosus are usually left sided, and the atrial situs is solitus. With rare exception, the hearts are biventricular, the atrioventricular connections are concordant, and there is often fibrous continuity between the mitral valve and the truncal valve. The right-sided ventriculoinfundibular fold may be attenuated, thus permitting continuity or nearly so between truncal valve and tricuspid valve. Occasionally, the single arterial root originates entirely above the right ventricle. Truncus arteriosus has been observed in the patient with right atrial isomerism and presumed asplenia. Truncus arteriosus also has been observed in the patient with tricuspid atresia as well as other forms of double-inlet ventricle. The truncal valve theoretically can possess one to six cusps, but the unicommissural, pentacuspid, and hexacuspid valves are uncommon (459,460,461,462,463 and 464). The truncal valve may guard the ventriculoarterial junction normally; the valve may be stenotic, regurgitant, or both. Severe truncal valve regurgitation has been reported as a serious complication. Most patients with persistent truncus arteriosus have excessive pulmonary blood flow and, when untreated, die in congestive heart failure. In approximately 10% of patients with truncus arteriosus, the pulmonary blood flow is restrictive. In most of these patients, the mechanism responsible for limiting the pulmonary blood flow is ostial stenosis resulting from an obstructive truncal leaflet.



***e*FIGURE 30.0.15** Common arterial trunk. This aortogram shows the most common form of common arterial trunk with a main pulmonary trunk originating from the base of the truncus (TRU) and dividing into branch pulmonary arteries. MPA, main pulmonary artery; RPA, right pulmonary artery. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

The coronary arteries exhibit a variable pattern of origin independent of the number of truncal valve leaflets (465,466,467 and 468). Abnormally high origin of a coronary artery, usually the right, has been observed in this disorder. Frank myocardial ischemia is usually the result of the disordered hemodynamics with a torrential pulmonary blood flow, a volume-loaded left ventricle, and a low aortic diastolic or coronary artery driving pressure. Rarely, a coronary ostium is congenitally stenotic and promotes an ischemic myocardium. Uncommonly, the coronary ostium is just superior to the truncal valve commissure, and a bulky, fleshy truncal valve leaflet obstructs the coronary ostium, resulting in coronary insufficiency.

Clinical Findings and Treatment

The incidence is between 0.7% and 1.4%, and the prevalence at live birth is 0.03 to 0.06 (469,470). Of 100 infants born with truncus who are surgically untreated, 20 will die in the first week, and at least 86 will have died by 1 year of age (471,472 and 473). A rare patient survives with pulmonary vascular obstructive disease into the fourth decade of life or beyond. Clinical experience also indicates that, uncommonly, some patients with truncus arteriosus survive past infancy without developing pulmonary vascular obstructive disease. Patients with common arterial trunk usually present within days or weeks after birth. The earliest presentation is in the group of infants who have either an obstructive anomaly of the aortic arch or severe truncal valve stenosis or regurgitation. This condition is characterized by the early appearance of congestive heart failure and progressive myocardial ischemia. Congestive heart failure reflects the tremendous increase in pulmonary blood flow, and myocardial ischemia reflects the frequent abnormalities of the coronary arteries and their ostia. Congestive heart failure and myocardial ischemia may be aggravated and accentuated by the presence of significant truncal valve stenosis or regurgitation. In infants with a common arterial trunk and aortic arch interruption, death is precipitated by functional and anatomic closure of the arterial duct. Abnormalities of the third and fourth pharyngeal pouch syndrome, DiGeorge syndrome, is common in these babies (474). The usual presentation is characterized by a mildly cyanotic infant with features of congestive heart failure. The left precordium is active; the second sound is single, and a systolic ejection click is audible at the lower left sternal edge. A grade 2 to 3/6 blowing systolic ejection murmur is heard along the left sternal edge. A soft murmur of aortic insufficiency may be heard along the left sternal edge. Except in infants with an obstructive anomaly of the aortic arch, all the pulses are brisk to frankly collapsing. Neither the electrocardiogram nor the chest radiograph is diagnostic of a common arterial trunk. It is common to see nonspecific

ST-T–wave changes in the limb leads and in the left precordial leads of the electrocardiogram; from the radiographs, a right-sided aortic arch is noted in approximately 20% to 25%.

The echocardiogram is usually diagnostic of common arterial trunk, and a systematic approach can answer most, if not all, questions about the associated anatomy. It is unusual to resort to cardiac catheterization unless questions arise about pulmonary artery nonconfluence or the status of the pulmonary vascular bed and operability in the older patient. Although digoxin and diuretics may improve the patient's well-being transiently, the only definitive therapy is surgery (475), usually performed within a few days of diagnosis. Surgery includes separation of the pulmonary arteries from the common arterial trunk; establishment of continuity between the right ventricle and pulmonary arteries with a valved conduit, usually a homograft; closure of the defect in the truncal wall; and patch closure of the ventricular septal defect. Complete repair can be accomplished with a mortality in the range of 10%, although this rate may be higher in patients with associated aortic arch interruption or those requiring truncal valve replacement (476,477).

Obstructive Lesions

Pulmonary Valvular Stenosis

The terms *valvular* and *valvar* both refer to "a valve" and have been used interchangeably (478). Designations that have been used to define the stenosis as an isolated lesion include *pure* or *uncomplicated* valve stenosis and pulmonary stenosis with normal aortic root or with an intact septum. Isolated pulmonary valve stenosis is a form of an acyanotic cardiac malformation with normal or diminished pulmonary blood flow. The atrial septum is usually intact; if not, the defect is usually in the form of a patent foramen ovale, although an actual atrial septal defect may coexist.

Presentation

The prevalence range of 0.07 to 0.19 reflects the use of echocardiography and diagnosis of milder forms of valvular stenosis. Morphologically, in the neonatal expression of critical pulmonary stenosis, the fused raphes extend from a central opening to the pulmonary artery wall (acommissural), creating an eccentric (rarely circular) hemodynamic orifice of varying diameter, depending on the extent of commissural fusion. No separate leaflets are present, and although angiographically they may appear thin, histologically they appear as disorganized myxomatous tissue throughout (479,480,481 and 482). Secondary changes occur in the right ventricle and pulmonary artery as a result of the profoundly afterloaded ventricle. The right ventricle hypertrophies, particularly the infundibular region, with encroachment on the size of the cavity. This may be quite extensive and in the neonate gives the appearance of true hypoplasia of the chamber. Few newborns, however, after effective relief of the valve obstruction, require additional sources of pulmonary blood flow, as the chamber both enlarges and becomes more compliant with time (483,484 and 485). Some infants, despite a prolonged course of prostaglandin, require some surgical maneuver to augment pulmonary blood flow, despite what is seemingly adequate relief of the outflow tract obstruction. This problem may reflect a poorly compliant ventricle, at times aggravated by a slightly restrictive tricuspid valve annulus, with right-to-left atrial shunting. The outflow portion of the ventricle, the infundibulum, is not displaced anteriorly as in Fallot's tetralogy. The tricuspid valve is usually well formed and competent, although right atrial enlargement can develop with significant tricuspid insufficiency secondary to right ventricular hypertension. In the absence of an intrinsic tricuspid valve anomaly (dysplasia of the leaflets, clefts, abnormal chordal attachments) this, too, resolves with relief of the obstruction. The tricuspid valve may be congenitally abnormal, especially in the neonatal expression of the disorder, although perhaps less severely disordered than in the patient with pulmonary atresia and intact ventricular septum (486). Poststenotic dilation of the main pulmonary trunk is the rule (*e*Fig. 30.0.16). Such enlargement can be seen at all stages of disease expression, from newborn through adult and pulmonary artery aneurysms, although they have been described rarely (487,488). There is disproportionate dilatation of the left pulmonary artery branch, reflecting the leftward orientation of the right ventricular outflow tract and the parallel takeoff of the left pulmonary artery from the main trunk. Calcification may occur within the pulmonary valve, but is exceptional in any patient but the adult with long-standing disease (489). The aortic arch is usually, but not invariably, left sided when pulmonary valve stenosis is present with an intact ventricular septum, in contrast to the situation in Fallot's tetralogy, in which a right-sided aortic arch is present in 30% of cases. Although the expression of pulmonary valve stenosis is usually but not invariably an isolated malformation, in its "typical" presentation, when the mechanism of right ventricular outflow obstruction is due to valve dysplasia, there is a greater incidence of associated cardiac and noncardiac malformations (e.g., Noonan's syndrome, Williams syndrome, and Alagille syndrome), although peripheral pulmonary arterial stenosis is a more prominent feature (490,491,492,493,494,495,496,497,498,499,500,501,502,503,504,505,506,507,508,509,510,511, 512,513,514 and 515) (*e*Fig. 30.0.17).

Café au lait spot. There is a flat localized hyperpigmentation that is uniformly light brown in the lower lip (*arrows*) that may be associated with neurofibromatosis, Albright syndrome, or pulmonary stenosis.

Leopard's syndrome. Figure shows a patient with Leopard's syndrome characterized by multiple basal cell nevi and broad facies. There is an association with pulmonic stenosis.

The dysplastic form of pulmonary valve stenosis occurs much less frequently (in approximately 20% of cases with pulmonary valve stenosis) than typical valve stenosis (497) (eFig. 30.0.17). In this setting, obstruction to right ventricular outflow reflects the reduced mobility of the thickened valve leaflets with the often associated hypoplasia of the valve annulus, supravalve tethering, a small or short main pulmonary artery, and, frequently, peripheral pulmonary artery stenosis. The three leaflets are distinct, composed of disorganized myxomatous tissue, and generally have little or no commissural fusion. The response to balloon valvotomy would suggest that in some patients a commissural element exists (511,512 and 513). Valve thickening generally involves the entire leaflet through to the attachments to the annulus. The expression of pulmonary valve stenosis in the neonate has the appearance of such dysplasia angiographically; however, medium-term studies after successful balloon dilation documented that the valve becomes pliant and then with time or spontaneously normalizes, or nearly so.

Perloff (478) reviewed the typical clinical, radiographic, electrocardiographic, and chocardiographic findings of typical pulmonary valvular stenosis. The systolic ejection murmur maximally audible in the pulmonary area, an intermittent systolic ejection click along the left sternal border, variable splitting of the second heart sound, with a reduction in intensity of the pulmonary closure sound consistent with more disease, are the usual auscultatory findings. Indeed, with progressive severity, the systolic murmur becomes louder, peaking later in systole, and with very severe disease the click may be inaudible, as is the pulmonary closure sound. In patients with severe disease and an associated interatrial communication, right-to-left atrial shunting may result in hypoxemia. The electrocardiogram usually reflects the severity, except in infants who have right ventricular hypoplasia (478). There is unanimity of opinion that balloon valvuloplasty is the therapy of choice (516,517,518,519,520,521,522,523,524,525,526,527,528,529,530,531,532,533,534,535,536,537,538, 539,540,541,542,543 and 544), and a number of technical aspects have been addressed to cross the severely stenotic neonatal valve and the application of multiple balloons in those with a large pulmonary valve annulus. Most recommend this approach in patients with pressure gradients of at least 40 mm Hg, especially in those with typical pulmonary valvular stenosis. There is perhaps less enthusiasm for valvuloplasty in those with dysplastic pulmonary valves because of the variable result. Nonetheless, we still advocate this approach for the patient with pulmonary valve dysplasia requiring intervention. One should be reminded of the association between pulmonary valve dysplasia, eccentric cardiomyopathy, and Noonan's syndrome (501,502,503,504 and 505).

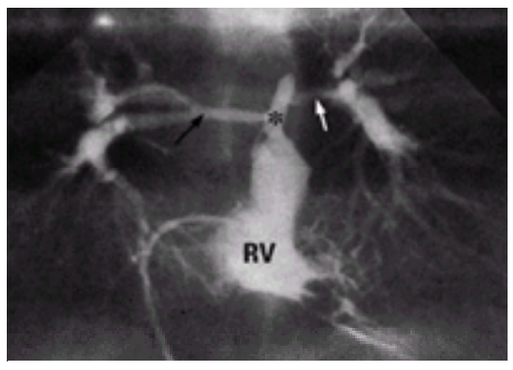
VIDEO

Video 30.6 Transesophageal echo of a patient with congenital pulmonary stenosis. Note the severe hypertrophy of the right ventricular outflow tract, causing infundibular pulmonary stenosis as well as valvular pulmonary stenosis. The pulmonic leaflets are thin and pliable; however, there is marked doming caused by tethering of the leaflet tips. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Pulmonary Arterial Stenosis

Abnormalities of pulmonary artery branching, caliber, and origin can occur in relative isolation or may reflect a component of rubella embryopathy, an internal stigmata of generalized dysmorphism, the Silver-Russell syndrome, cutis laxa, and the Williams or Alagille syndromes (eFig. 30.0.18), among others; it may reflect a component of a widespread vasculopathy or be an integral component of congenital cardiac anomalies, including tetralogy of Fallot, pulmonary atresia and ventricular septal defect, the hypogenetic right lung syndrome, the complex heart malformations associated with right atrial isomerism, and many others (545,546,547,548,549,550,551,552,553,554,555,556,557,558,559,560,561,562,563,564,565,566,567, 568,569,570,571,572,573,574,575,576,577,578,579,580,581,582,583,584,585 and 586). Isolated pulmonary artery stenosis or that associated with similar systemic vascular lesions can occur in the main pulmonary artery, at its bifurcation, and at the secondary or even more distal branch points of the pulmonary artery, or such arterial stenoses may be very severe and extensive (560). Isolated stenosis of the main pulmonary artery alone is uncommon, however. Such obstruction is usually seen as part of a generalized pulmonary vascular dysplasia associated with obstruction to the pulmonary valve or the right ventricular infundibulum. The most common site of pulmonary artery stenosis is at the point of bifurcation of the main pulmonary artery and its right and left branches. The stenosis involves the distal main pulmonary artery and then extends a variable distance along the right or left pulmonary artery branch or both. Peripheral pulmonary artery stenosis involving the branch points of the right or left pulmonary artery may occur alone or associated with more proximal stenosis. Two basic forms of obstructive malformations of the pulmonary arteries can be identified: a focal and a diffuse form. The focal form of pulmonary arterial stenosis consists of a discrete obstruction preceded by a normal-sized artery and followed by poststenotic dilatation. The more diffuse type is characterized by a small vessel that remains small distally, resembling hypoplasia, and is not amenable to surgical reconstruction by local resection. Increasing experience has accumulated involving patients with bilateral severe pulmonary hypoplasia associated with jaundice and hepatic ductular hypoplasia, the so-called Alagille syndrome (560,561,562,563,564,565,566,567,568,569,570,571,572 and 573). This syndrome is an autosomal dominant disorder characterized by chronic cholestasis, reflecting a paucity of intrahepatic bile ducts, typical facies, peripheral pulmonary artery stenoses, skeletal abnormalities, and ocular posterior embryotoxon. Pulmonary arterial stenoses may be particularly severe and diffuse in patients with this syndrome, although at

least one follow-up study suggested that most such peripheral pulmonary arterial stenoses are relatively mild. In any patient, the recognition of pulmonary arterial stenosis should raise the possibility of a more widespread vasculopathy, such as that associated with rubella, infantile hypercalcemia, cutis laxa, and Ehlers-Danlos syndrome, among others. Rodriguez and Riggs (582) assessed so-called physiologic peripheral pulmonary arterial stenosis in infancy. They found that patients with physiologic peripheral pulmonary arterial stenosis have mild underdevelopment of the pulmonary artery branches, with consequent increased flow velocity and turbulent flow.



***e*FIGURE 30.0.18** Bilateral pulmonary arterial stenoses with a small main pulmonary trunk (*asterisk*). Left (*white arrow*) and right (*black arrow*) branch pulmonary artery stenoses are indicated. RV, right ventricle. Aneurysms of the Pulmonary Arteries

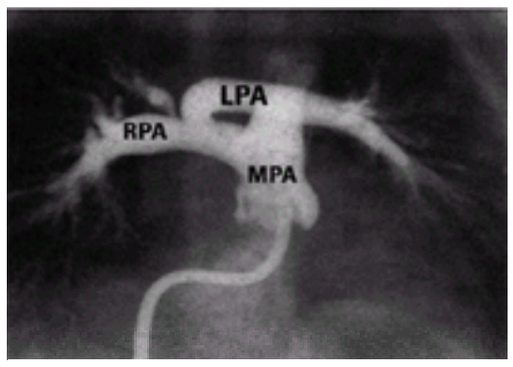
Aneurysms of the pulmonary arteries have been identified in patients with a wide range of systemic disorders, from those with Marfan syndrome to Behçet's syndrome (560,587,588,589,590,591,592,593,594,595,596,597,598,599 and 600). Pulmonary artery involvement in Marfan syndrome is far less common than the well-known aortic involvement. Aneurysms of the pulmonary arteries have been identified in those with Behçet's syndrome (a nonspecific vasculitis of unknown etiology of large and small arteries, veins, arterioles, venules, and capillaries of both the systemic and pulmonary circulations) as well as in those with mucoid vasculopathy. Pulmonary artery stenoses and aneurysms have been observed in those with Takayasu's arteritis, rheumatoid arthritis, and other systemic disease processes. Mycotic aneurysms of the pulmonary arteries have been amply recorded in those with intravenous substance abuse.

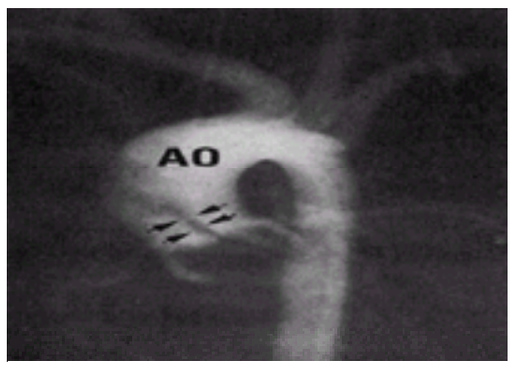
The clinical recognition of pulmonary arterial stenoses may be suggested by the presence of blowing systolic ejection murmurs conducting into the axillae and in the back. Neither the chest radiograph nor the electrocardiogram is specific for this diagnosis, although when arterial stenoses are severe, the electrocardiogram may show significant right ventricular hypertrophy. The echocardiogram may demonstrate a proximal arterial stenosis, and Doppler interrogation may provide some clue as to its or their hemodynamic significance. When the condition is unilateral, a pulmonary perfusion scan may demonstrate a significant perfusion imbalance. Selective pulmonary artery angiocardiography with craniocaudal tilt shows to advantage the pulmonary arteries, and such imaging defines whether the arterial stenosis or stenoses are diffuse, localized, and amenable to balloon angioplasty or intravascular stenting (559,560). Another important abnormality of the pulmonary arteries is the so-called pulmonary sling (*e*Fig. 30.0.19). In its errant course between the trachea and esophagus, it may cause severe bronchial compression and airway disease (559,560).



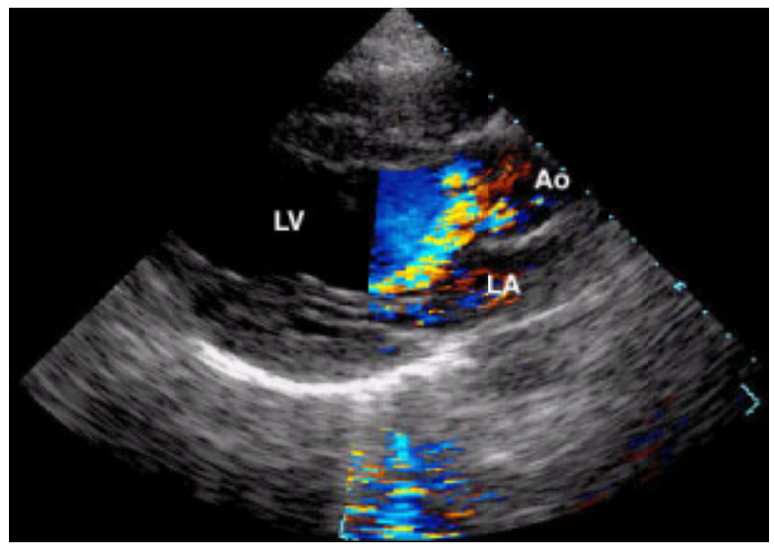
***e*FIGURE 30.0.19** The pulmonary sling results from the left pulmonary artery (LPA) originating from the right pulmonary artery (RPA), with an errant course between the trachea and the esophagus. MPA, main pulmonary artery. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

Congenital Aortic Valve Stenosis

It is plausible that the true prevalence of a bicuspid aortic valve in the infant and child is underestimated because of an absence of signs and symptoms. Hence, it is likely that a bicuspid aortic valve is one of the most common congenital cardiac conditions (*e*Fig. 30.0.20). This discussion, however, focuses on the unique problem of aortic stenosis that presents primarily in the neonate. For more information regarding the adolescent or adult, please refer to Chapter 22.



***e*FIGURE 30.0.20** Critical aortic stenosis with a doming aortic valve and a narrow jet (*arrows*) of nonopacified blood. AO, aorta. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)



Parasternal long-axis view (transthoracic echo) with color Doppler demonstrating the posteriorly directed aortic insufficiency caused by prolapse of the anterior leaflet of a bicuspid aortic valve. Note that the jet hits the anterior mitral leaflet.

Parasternal long-axis view of a prolapsing anterior cusp (right coronary cusp + left coronary cusp fusion) of a bicuspid aortic valve (the prolapsing leaflet is demonstrated by the short arrow). The posteriorly directed aortic insufficiency that is produced causes the posterior deformation of the anterior mitral leaflet (designated by the long arrow) as the aortic insufficiency jet hits this leaflet.

Congenital aortic stenosis that presents in the first months of life is a rare lesion and accounts for only approximately 3% of neonates presenting with significant congenital heart lesions. In this group, approximately four times more male infants present than female infants, and approximately 20% have associated lesions, including endocardial fibroelastosis, persistent spongy myocardium, mitral valve stenosis (valve and supravalve), mitral regurgitation, coarctation of the aorta, patent ductus arteriosus, and hypoplasia of the left ventricle. There is indeed a spectrum of disease that encompasses the hypoplastic left heart syndrome with overlap of patients who cannot sustain a biventricular repair (601). The critically ill neonate may present with severe stenosis or atresia of the aortic valve, which renders patency of the arterial duct with right-to-left flow crucial for survival.

The neonate with “isolated” aortic valve stenosis generally exhibits a morphology consisting of a bicuspid valve with fused raphe, a unicuspid valve, or a valve with no discernible valve tissue. The valve may be myxomatous or dysplastic with annular hypoplasia. Calcification is exceedingly rare in childhood, unlike in adulthood. Associated endocardial fibroelastosis is not uncommon, and neonates are often subdivided into those with good functioning hypertrophied ventricles and those with poorly contractile, dilated ventricles. Subendocardial myocardial fibrosis is common, and there is often poststenotic dilatation of the ascending aorta.

Most children with aortic valve stenosis are asymptomatic and present with a typical click and murmur in childhood, as previously described. The neonate with severe stenosis, however, presents early with cardiovascular collapse in the first days of life. In these neonates, poor feeding with tachypnea and diaphoresis precedes a rapid deterioration to medical or surgical emergency. There may be differential cyanosis with a lower saturation measured in the lower limbs as a result of the presence of right-to-left shunting at the ductal level, which may be further emphasized by the presence of a coarctation of the aorta or pulmonary hypertension. The liver is enlarged, and the peripheral pulses are poorly palpable. The precordium often demonstrates a right ventricular heave with no thrill. Auscultation typically finds a systolic ejection murmur at the right upper sternal border with a diminished aortic component. An aortic click is often not present in the neonate, depending on the severity of the valve leaflet dysplasia. In the desperately ill child who has an increasing metabolic acidosis as a result of poor systemic perfusion, a murmur may be absent, as there is little forward flow across the aortic valve in the situation of severe ventricular dysfunction.

The chest radiograph demonstrates cardiomegaly with pulmonary venous congestion. Electrocardiographic findings are often consistent with left ventricular hypertrophy in most cases and also may be associated with strain and evidence of subendocardial ischemia. One must be alert to the presence of endocardial fibroelastosis or sclerosis in the setting of a concurrent left bundle branch block pattern. Right ventricular predominance or hypertrophy occurs in the setting of a hypoplastic left ventricle but also may be associated with pulmonary hypertension secondary to left atrial hypertension resulting from ventricular diastolic dysfunction or

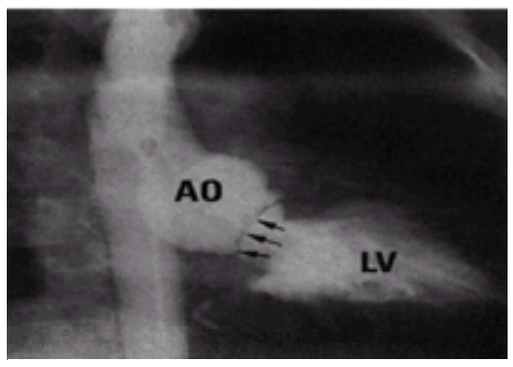
mitral valve disease.

The echocardiographic evaluation, including Doppler, reliably establishes the diagnosis (602,603,604,605,606,607,608 and 609). The aortic valve is often thickened and poorly mobile. Fusion of leaflets may be demonstrated, but this may be difficult in the severely dysplastic valve or unicommissural morphology. The annulus also may demonstrate hypoplasia. Increased echogenicity of the endocardium suggests the presence of fibroelastosis, and the global and segmental ventricular function can be assessed. Attention is often focused on distinguishing this entity from the hypoplastic left heart syndrome (60), especially when other anomalies of the left-sided structures coexist.

Prompt intervention is indicated in the neonate or child with symptomatic severe aortic valve stenosis, recognizing the difficulties in uniformly describing these patients. Patients who have less stenosis may have follow-up as outpatients, with the understanding that progression is usually the rule (610,611,612 and 613). It appears from studies of the natural history that the patient with a Doppler gradient greater than 80 mm Hg requires intervention, whereas the asymptomatic patient with a gradient less than 40 mm Hg can be safely observed. Indications for intervention in the group who is asymptomatic with a gradient between 50 and 80 mm Hg are less clear (613). The risk of sudden death in the population is usually related to severe disease; therefore, activity restriction is rarely indicated in the asymptomatic patient with a gradient less than 40 mm Hg. Naturally, antibiotic prophylaxis for potentially infective procedures is warranted. It is recognized that most patients with significant disease progress to aortic valve replacement later in life; however, palliation with open, closed, and transcatheter aortic valvuloplasty and valvotomy offers significant advantage to the growing infant and child. Surgical (604,614,615,616,617,618,619,620,621,622,623,624 and 625) and transcatheter (603,606,626,627,628,629,630,631,632,633,634,635 and 636) procedures result in similar relief of obstruction with equivalent incidence of postprocedure insufficiency and may delay the need for aortic valve replacement for several years. The method used to establish a reduction in the gradient is based more on institutional experience. Acute results in the neonate depend on associated conditions and the severity of ventricular dysfunction. Using the pulmonary valve to allow for growth of the aortic root is promising as an alternative, although long-term follow-up data are required in children and neonates before one considers this a primary option (625,637,638 and 639).

Left Ventricular Outflow Tract Obstruction

Obstruction to the left ventricular outlet can occur at a valvular level, a subvalvular or supravalvular level, or at more than one site (*e*Fig. 30.0.21). The fixed or discrete forms of subaortic obstruction have features of both congenital and acquired pathology, and many have some degrees of aortic-mitral separation, producing an intrinsically abnormal left ventricular outflow tract (640,641,642,643,644,645,646,647,648,649,650,651,652,653,654 and 655). This condition is rarely fibrous and discrete (646,647 and 648). The most commonly recognized complications of fixed subaortic stenosis include infective endocarditis, aortic regurgitation, and possible development of an inherent muscular obstruction. The incidence of aortic regurgitation is estimated to be as high as 50% in affected patients and is not static. Subaortic stenosis is a progressive condition, with worsening of the outflow tract pressure gradient over time (655); aortic regurgitation develops and progresses with time. At least two mechanisms have been implicated as causal to the aortic regurgitation. The probability of aortic incompetence at follow-up is significantly related to (a) older age at operation, (b) higher preoperative gradient, (c) cardiomegaly, and (d) surgical myomectomy. Early surgical intervention is likely to reduce acquired damage to the aortic valve, but this view is not universally supported (655). Aortic regurgitation may, in some patients, define the position of the obstructing subaortic fibromuscular tissue, a maneuver noted in cardiac angiography.



***e*FIGURE 30.0.21** So-called discrete, fixed-type, and short-segment subaortic stenosis (*arrows*) demonstrated by this right axial oblique left ventriculogram. AO, aorta; LV, left ventricle. Tissues derived from the membranous septum, tricuspid or mitral valve, accessory mitral valve, cysts of various composure, and cardiac tumor may produce left ventricular outflow tract obstruction. Posterior displacement of the infundibular septum is well recognized as perhaps the most frequent mechanism for subaortic stenosis in the patient with interruption of the aortic arch, and this produces a typical ventricular septal defect inferior to the displaced infundibular septum. An extensive literature documents the association between ventricular septal defect and subaortic stenosis (656,657,658,659,660,661 and 662). The morphologic bases for the subaortic stenosis are variable and may reflect posterior or caudal malalignment of the infundibular septum (as seen in the patient with interruption of the aortic arch or coarctation of the aorta); abnormal muscle bundles of the left ventricle in the patient with midtrabecular muscular ventricular septal defects; so-called fibrous type of subaortic stenosis associated with perimembranous ventricular septal defect and anomalous muscle bundle of the right ventricle; and subaortic stenosis reflecting tricuspid, mitral, or accessory tissue tags (656,657,658,659,660,661,662 and 663). It is often the ventricular septal defect or associated obstructive anomaly of the aortic arch that dominates the clinical picture in most of these patients. Indeed, in many patients, the subaortic stenosis seemingly develops on the substrate of a ventricular septal defect.

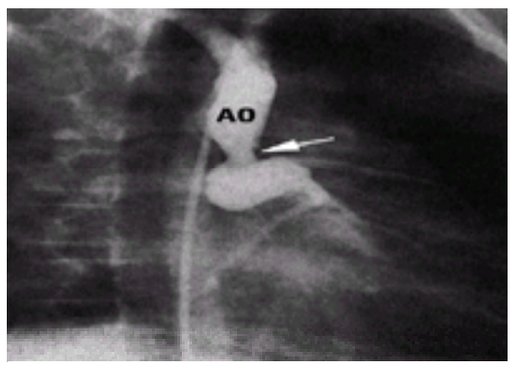
Ventricular Septal Defect, Subaortic Stenosis, and Divided Right Ventricle

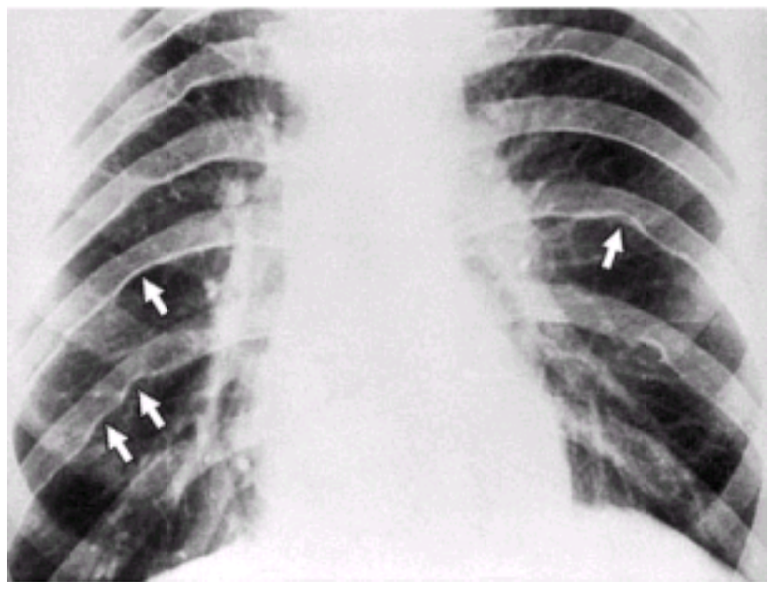
A well-known relationship in patients with a perimembranous ventricular septal defect, a right ventricular anomalous muscle bundle, and a fixed subaortic abnormality has been defined (664). In some patients, progression of a subaortic deformity initially produces no obstruction, and some years later causes severe left ventricular outflow tract obstruction after surgical closure of a ventricular septal defect with or without resection of anomalous muscle bundles of the right ventricle (664). For a discussion of supravalvular aortic stenosis (*e*Fig. 30.0.22), see the section Natural History of Congenital Heart Disease, earlier in this chapter.



***e*FIGURE 30.0.22** Supravalvular aortic stenosis in a patient with Williams syndrome. Note the important supravalvular narrowing (*arrow*). AO, aorta. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

Coarctation of the Aorta

Coarctation of the aorta is defined by a narrowing of the descending thoracic aorta, usually in the region of the ductus (or ligamentum) arteriosus. This narrowing is due to the presence of a shelf composed of thickened intima with an increased media that typically contains collagen, smooth muscle cells, and varying amounts of elastic tissue. In the neonate or small infant, ductal tissue composed of smooth muscle fibers that constrict with ductal closure may be present (665,666). The ductus arteriosus plays a pivotal role in the clinical presentation of an isolated lesion. Prevalence at birth ranges from 0.239 to 0.430 per 1,000 live births (667,668). A coarctation of the aorta may occur in isolation; however, it is often associated with intracardiac congenital heart disease, often resulting in decreased aortic blood flow (*e*Table 30.0.2).

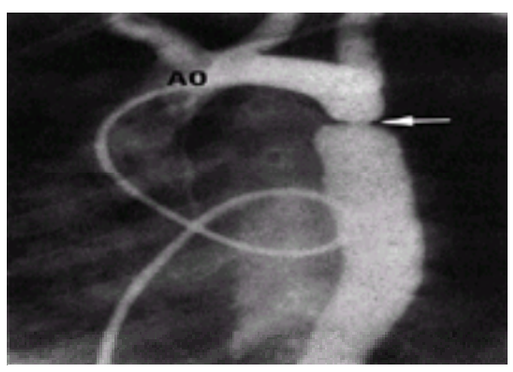


Chest x-ray in coarctation of the aorta. There is prominent rib notching (*white arrows*).

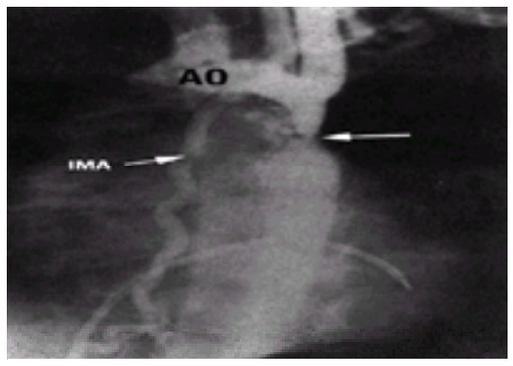
Video 30.14 Coarctation of aorta (oblique). A signal-void jet is visible in the proximal descending aorta due to a short-segment narrowing representing a coarctation. Left ventricular hypertrophy is also present. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

***e*TABLE 30.0.2** COARCTATION OF THE AORTA: ASSOCIATED ANOMALIES
Patent ductus arteriosus
Transverse aortic arch hypoplasia
Bicuspid aortic valve
Ventricular septal defect
Subaortic stenosis
Mitral valve anomalies
Positional anomalies of the great arteries (e.g., transposition)

The timing and type of clinical presentation vary in coarctation of the aorta, depending on the nature of the lesion with respect to the ductus arteriosus (*e*Fig. 30.0.23 and *e*Fig. 30.0.24). Consideration must be given to the possibility of Turner's syndrome in girls, as coarctation of the aorta represents the most common cardiovascular anomaly. In the so-called infantile-type isolated coarctation of the aorta, systemic blood flow is often dependent on the patency of the ductus arteriosus and may be affected by the status of the pulmonary vascular bed; thus, the presentation often evolves over the first week of life. Differential cyanosis may occur in the newborn as a result of the right-to-left flow of systemic venous blood from the right ventricle to the pulmonary artery and through the ductus arteriosus to supply the descending aorta (669). Restriction or closure of the ductus arteriosus can result in increased afterload, which, if severe, leads to profound left ventricular dysfunction, with circulatory collapse in the first week of life. Prostaglandin infusion to reestablish patency of the arterial duct can be life-saving. Typically, the affected neonate is pale and diaphoretic with a history of poor feeding and tachypnea. Pulses in the lower limbs are typically diminished or absent, and careful blood pressure measurements in all four limbs are mandatory, recognizing the care that must be taken in obtaining and interpreting neonatal blood pressure measurements (670,671 and 672). It is important to acknowledge that the femoral pulses may be normal early in the first week of life, as the ductus arteriosus usually is most restrictive at the pulmonary end, with diminished pulses present later as the aortic insertion of the ductus arteriosus becomes narrowed. In the setting of a persistently patent ductus arteriosus, diagnosis is indeed difficult. One must also be alerted to other more unusual causes of diminished femoral pulses in the neonate, including cerebral arteriovenous malformations, aortic thrombosis, or abdominal aortic coarctation. Auscultation often is related to associated defects; however, a gallop due to the presence of third and fourth heart sounds in the setting of a failing ventricle is not uncommon. Right ventricular hypertrophy results from the increased work in maintaining systemic flow and is evident on the scalar electrocardiogram with associated right-axis deviation and strain pattern. The chest radiograph may demonstrate cardiomegaly in the sick neonate, but is not diagnostic. Notably, the finding of rib notching is never present in the neonate.



***e*FIGURE 30.0.23** Severe coarctation of the aorta (AO) (*arrow*) demonstrated by aortography. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)



***e*FIGURE 30.0.24** Significant collaterals derived from the internal mammary artery (IMA) in a different patient with a severe coarctation of the aorta (AO) (*arrows*). (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

The older child or adult with a coarctation of the aorta presents differently. Often patients are asymptomatic with upper limb hypertension. Occasionally, some patients present with recurrent headache, nose bleeds, or lower limb claudication and weakness. Physical examination invariably includes differential blood pressure measurements, with diminished or absent femoral and pedal pulses underscoring the importance of palpating lower limb pulses in all patients with systemic hypertension (673). A short systolic murmur may be present over the anterior left precordium, radiating to the back, with continuous murmurs from collateral vessels in some patients over the superior left and right chest as well as the back. The electrocardiogram is often within normal limits for age but may demonstrate left ventricular hypertrophy. Rib notching due to collateral vessels may be noted in children most reliably over the age of 5 years with a characteristic “3” sign in many patients (674). It is possible to detect a coarctation of the aorta *in utero*, recognizing the need for meticulous serial aortic arch measurement and its known association with more complex congenital heart disease (21,675,676). First, laterality of the aortic arch is determined, followed by an assessment of the head and neck vessels and transverse arch. In the presence of a closed ductus arteriosus, there is a typical spectral pattern representing diastolic runoff with severe obstruction (677).

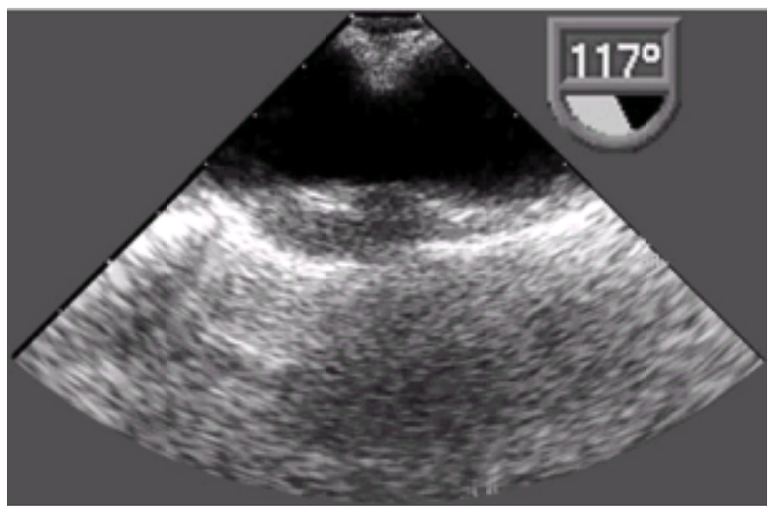
If echocardiography fails to delineate the anatomy completely, excellent images of the aortic arch can be obtained using MRI techniques (678,679). In general, invasive imaging using cineangiography or digital subtraction techniques as a diagnostic procedure is reserved for unusual situations. In addition to the coarctation, an assessment for the origin and course of the head and neck vessels, presence and extent of the collateral circulation, and the presence of aneurysmal dilatation of the aorta or subclavian vessels is important to planning intervention. A careful hemodynamic evaluation of the pressure gradient from proximal to distal descending thoracic aorta should distinguish the true lesion from a pseudocoarctation due to a tortuous course of the aorta distal to the transverse arch.



A still frame of a transesophageal echo demonstrating a coarctation of the aorta. Note the local narrowing of the aorta located at the junction of the distal arch and descending aorta. There was a 100–mm Hg pressure gradient across the coarctation as determined by continuous wave Doppler.

VIDEO

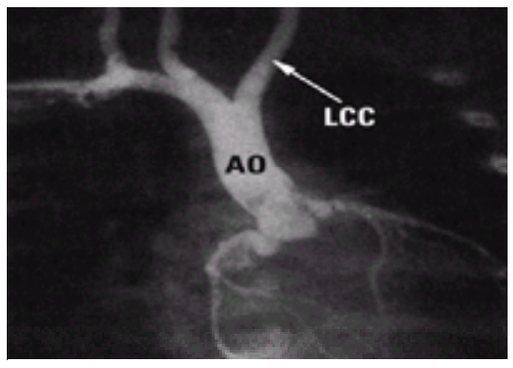
The outlook for neonates presenting with circulatory collapse is understandably dismal in the absence of intervention, initially with prostaglandin infusion to restore patency of the ductus arteriosus before more definitive therapy. Although surgical intervention has resulted in significant improvements in outcome, these patients remain at risk for premature atherosclerosis, late hypertension, and premature death, with age at operation reflecting an incremental risk factor (680,681,682 and 683).

Surgery for a “native” isolated coarctation of the aorta is directed to resecting the coarctation with either primary end-to-end anastomosis of the aorta or arch augmentation using a subclavian flap technique. An end-to-side augmentation of the transverse arch is used where significant hypoplasia is expected to compromise the postoperative course. In most situations, this is accomplished using a left posterolateral thoracotomy, but an anterior midline sternotomy may be used when associated lesions also are being addressed. Some surgeons prefer to augment the aorta with a Dacron patch arterioplasty, and rarely in long-segment lesions, an interposition graft is necessary. The hospital mortality in the current surgical era is low for neonates (2% to 10%), and results are even better for infants and older children (684,685,686,687,688,689,690 and 691). Postoperative problems include paradoxical systemic hypertension, abdominal pain, chylothorax, vocal cord paralysis, aneurysm formation, and rarely spinal cord ischemia, impaired left arm growth, or gangrene. Despite early intervention, there is some evidence of altered vascular reactivity, particularly in the upper limbs, which may predispose to hypertension, although the exact mechanism remains to be ascertained (680,683). Freedom from restenosis in early childhood in the current surgical era ranges from 81% to 96% for neonates and young infants (685,688); the risk of restenosis is less than 5% in the older patient (681).

Percutaneous transcatheter angioplasty of the so-called native or recurrent coarctation of the aorta also has been described, with acute results and long-term results similar to those of surgery (692,693,694,695,696,697,698,699,700,701,702,703 and 704). Concern arises with respect to the occurrence of aneurysms and the fate of the femoral artery used for the procedure. Results in neonates are not as encouraging as those in older children, with reintervention either in the catheterization laboratory or the surgical theater. Concern has been expressed regarding a potential for spinal cord compromise with surgery after angioplasty due to involution of protective collateral vessels, but this concern is not borne out by the literature (699). Complications include femoral artery thrombosis, aneurysm formation, thromboembolic cerebrovascular events, vessel perforation, and rarely aortic rupture. Life-long follow-up, ideally with periodic MRI, for growing aneurysms is mandatory, as is careful surveillance for restenosis. Whereas angioplasty remains most appropriate for the growing child, the development of extra-large stents offers an attractive alternative to surgery in selected patients (705,706,707 and 708).

Interruption of the Aortic Arch

Interruption of the aortic arch is an uncommon cardiovascular anomaly, accounting for less than 1.3% of critical congenital heart disease (709,710), characterized by the absence of anatomic continuity between the transverse aortic arch or isthmus and the descending thoracic aorta (711,712,713 and 714) (eFig. 30.0.25). This condition usually produces symptoms in the neonate coincident with constriction or closure of the arterial duct, although patients surviving to adulthood have been reported (715,716 and 717). Symptoms reflect a disordered circulation to that portion of the body supplied by the arterial duct before its functional closure. Interruption of the aortic arch should be distinguished anatomically from atresia of the aortic arch, where continuity between these segments is achieved by an imperforate fibrous strand of various lengths (although the hemodynamic and physiologic effects may be identical). This condition is usually not familial, but there is a well-known association between interruption of the aortic arch and DiGeorge syndrome; this syndrome is characterized by maldevelopment of the third and fourth pharyngeal pouches (i.e., the thymus and parathyroid glands) (718,719,720,721,722,723,724,725 and 726).



***e*FIGURE 30.0.25** Interruption of the aortic arch distal to the left common carotid artery (LCC) demonstrated by ascending aortography. AO, aorta. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

The initial classification for interruption of the aortic arch was proposed by Celoria and Patton (711) and was based on the site of the interruption: type A, distal to the left subclavian artery; type B, between the left common carotid artery and the left subclavian artery; and type C, between the innominate artery and the left common carotid artery. The last site of interruption is by far the least common. The classification of Celoria and Patton did not take into consideration patients with interruption and a right-sided aortic arch, nor did it mention the aberrant subclavian artery.

Commonly Associated Malformations

Interruption of the aortic arch rarely occurs in isolation. The most frequently associated cardiac lesions are a ventricular septal defect and a patent arterial duct. Considerable scrutiny has focused on the form of the ventricular septal defect. Although the ventricular septal defect may occupy any position within the ventricular septum, its morphology most commonly compromises flow to the ascending aorta during fetal life. The defect that so characterizes interruption of the aortic arch is the posterior malalignment of the infundibular septum, which occurs above the ventricular septal defect and below the aortic valve to encroach on the left ventricular outflow tract (714,715 and 716,727,728 and 729). The malalignment occurs as though the door of the infundibular septum is opened toward the left ventricular outflow tract. The so-called hinge of the door is along the ventriculoinfundibular fold when viewed from the right ventricle and along the aortic valve annulus when viewed from the left ventricle. The ventricular septal defect produced by this posterior malalignment of the infundibular septum is more commonly a muscular outlet defect and less frequently perimembranous. The ventricular septal defect in interruption of the aortic arch does not invariably involve posterior displacement of the infundibular septum. The doubly committed subarterial ventricular septal defect in the patient with interruption of the aortic arch can occur. In addition, a perimembranous confluent defect with aortic overriding and partial closure by tricuspid tissue was not uncommon in any large cohort of these patients. Tissue tags derived from the tricuspid valve and responsible for narrowing the ventricular septal defect may further compromise the left ventricular outflow tract, which is already reduced in size because of the aortic override.

Left Ventricular Outflow Tract Obstruction in Interruption of the Aortic Arch

Multiple mechanisms have been identified to produce left ventricular outflow tract obstruction in hearts with interruption of the aortic arch and concordant atrioventricular and ventriculoarterial connections (714,715 and 716,727,728,729,730 and 731). Those morphologic variables include the degree of development, malalignment, and deviation of the infundibular septum; the length of the subpulmonary infundibulum; overriding of one or the other of the arterial trunks; hypertrophy of the anterolateral muscle bundle; anteroseptal bulge or twist of the anterior interventricular septum; stenosis of the bicuspid aortic valve; or hypoplasia of the aortic valve annulus. The left ventricular outflow tract obstruction may be quite mild or severe, so severe in some patients that conventional biventricular repair is seemingly precluded.

Interruption of the Aortic Arch and DiGeorge Syndrome

There is a particular association between anomalies of the third and fourth pharyngeal pouch and interruption of the aortic arch, DiGeorge syndrome (718,719,720,721,722,723,724,725 and 726). Features typical of DiGeorge syndrome are hypocalcemia and defective thymic-mediated cellular immunity (725). Also common in these patients are anomalies of the face, palate, ears, and particular congenital heart malformations. The hypocalcemia and defective thymic-dependent cellular immunity reflect either absent or deficient thymic and parathyroid tissue. Interruption of the aortic arch, type B, is the major cardiac anomaly, and second in frequency is truncus arteriosus. When viewed from the perspective of interruption of the aortic arch, 68% had DiGeorge syndrome, as did 33% of the patients with truncus arteriosus. Microdeletion of chromosome 22 is quite common in patients with conotruncal abnormalities and between anomalies of the third and fourth pharyngeal pouch.

Clinical Features. With the normal postnatal changes in ductal structure and function, the portion of the systemic circulation requiring ductal patency becomes inadequate. Thus, in most instances, interruption of the aortic arch is a disorder of the neonate. The gravity of this disorder is illustrated by the observation that the

average age at death of these babies in Van Praagh's series was only 6 days; no sex predilection was found. Almost all these babies present with some respiratory distress, mild to severe cyanosis, varying degrees of congestive heart failure, and clinical evidence of low cardiac output. The amplitude of peripheral pulses may be reduced. In some infants in an agonal condition, all peripheral pulses are feeble. In others, the left brachial and radial pulses and the femoral pulses are substantially weaker in caliber than the right radial and brachial pulses, suggesting interruption proximal to the arch origin of the left subclavian artery. When both brachial pulses are relatively strong but the femoral pulses are weak or impalpable, one would suspect the level of obstruction to be distal to the left subclavian artery. In that situation, in which both arm and both leg pulses are weak while both carotid pulses are strong, one would suspect obstruction proximal to the left subclavian artery with aberrant origin of the right subclavian artery as the last arch branch. Strong right arm and right carotid pulses and weak left carotid, left arm, and both femoral pulses would localize the obstruction between the innominate artery and the left common carotid artery (type C interruption) with normal origin of the right subclavian artery. The cardiac examination often demonstrates a bulging left chest and a hyperdynamic left precordium with a prominent right ventricular impulse. The heart sounds are crisp, with the second sound closely split. A blowing systolic ejection murmur, grade 2 to 3/6, is audible along the left sternal edge. Conspicuous diastolic flow rumbles are uncommon in the neonate, but S_3 gallop rhythms are frequent. The liver shows a variable degree of enlargement, reflecting the severity of the congestive heart failure.

Diagnosis. Neither chest radiography nor electrocardiography is diagnostic of interruption of the aortic arch. The diagnosis of aortic arch obstruction has fallen into the care of the echocardiographers, and this diagnosis is usually easily established. Unlike aortic coarctation, interruption of the aortic arch is associated with significant intracardiac abnormalities in the form of ventricular septal defect(s), left ventricular outflow tract obstruction, and other complex malformations. Echocardiographic assessment should therefore address not only the morphology of the aortic arch but also the intracardiac anomalies that affect surgical management and outcome. Angiocardiography is rarely required to make the diagnosis of aortic arch interruption.

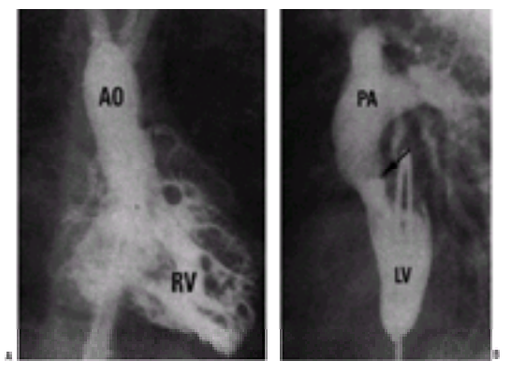
Medical Therapy. In any neonate in whom a severe obstructive anomaly of the aortic arch is considered likely, an E-type prostaglandin should be promptly administered intravenously (715,717,732). Attention should be paid to correcting any metabolic acidosis and to the maintenance of a satisfactory cardiac output. The judicious use of digoxin and potent diuretics is determined by the renal output and severity of congestive heart failure.

Surgical Therapy. Several major studies indicate that complete repair can be carried out with a mortality less than 10% to 15%, perhaps somewhat higher in those with severe subaortic stenosis (733,734,735,736,737 and 738). After repair, attention must be focused on the adequacy of the arch repair and on the development of left ventricular outflow tract obstruction (739).

Cyanotic Lesions

Transposition of the Great Arteries

The hallmark of transposition of the great arteries (740,741,742 and 743) is that the great arteries are placed across and originate from the inappropriate ventricle; thus, in the patient with atrial situs solitus or normal atrial arrangements and a concordant atrioventricular connection, the aorta originates from the morphologically right ventricle and the pulmonary artery from the morphologically left ventricle (744,745,746,747,748 and 749) (*e*Fig. 30.0.26). In the usual form of transposition of the great arteries, there is a well-formed subaortic infundibulum but no subpulmonary infundibulum, although other hearts with the abnormal or discordant ventriculoarterial connection of transposition have been described with bilateral infundibulum; bilaterally deficient infundibulum; or, rarely, just a subpulmonary infundibulum preventing mitral valve–pulmonary valve continuity (744,745,746,747,748,749,750 and 751). Whereas the most common spatial relationship between the great arteries in transposition is a rightward and anterior aorta, virtually any spatial relationship has been found, including the relatively uncommon posterior transposition (744,745,746,747,748,749,750,751,752,753,754 and 755).



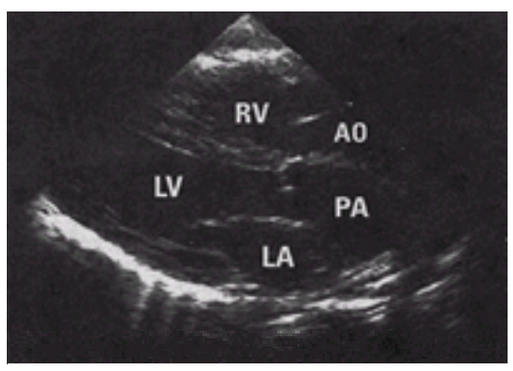
***e*FIGURE 30.0.26** Angiocardiography of complete transposition of the great arteries. **A:** The frontal right ventriculogram shows the discordantly connected transposed aorta (AO). **B:** The left ventriculogram shows the discordantly connected transposed pulmonary artery (PA) (*arrow*). LV, left ventricle; RV, right ventricle. (From Freedom RM, Mawson JB, Yoo S-J, et al. *Congenital heart disease: textbook of angiocardiography*. Armonk, NY: Futura Publishing, 1997, with permission.)

Prevalence

The prevalence of transposition of the great arteries is 0.2 per 1,000 live births, and approximately two-thirds are boys (756,757). Few major extracardiac anomalies are associated with transposition, and low birth weight is also uncommon.

Diagnosis

The clinical findings, chest radiographic findings, and electrocardiographic findings usually can make the diagnosis of complete transposition of the great arteries, but this diagnosis can be firmly established by two-dimensional echocardiography (740,743,758,759 and 760) (*e*Fig. 30.0.27). Diagnostic cardiac catheterization is rarely required in typical cases, although many institutions still perform aortography to define the anatomy of the coronary circulation (760,761) (*e*Fig. 30.0.28). The sites for mixing in transposition of the great arteries include the atrial septum, arterial duct, and ventricular septum. Because 65% to 75% of babies with transposition of the great arteries have an intact ventricular septum, it is not surprising that shortly after birth these babies become profoundly hypoxemic, coincident with ductal constriction and closure of the ovale foramen. For profoundly hypoxemic babies, institution of an E-type prostaglandin followed by balloon atrial septostomy should improve the state of arterial oxygenation (762,763,764,765,766 and 767).



***e*FIGURE 30.0.27** Transposition of the great arteries. Parasternal long-axis echocardiographic image of the great vessels in transposition of the great arteries. In contrast to the normal ventriculoarterial arrangement, the pulmonary and aortic roots align in the same two-dimensional plane, resulting in the typical appearance above in the setting of a discordant connection. Note that the aortic root lies anterior to the pulmonary valve. AO, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RV, right ventricle.

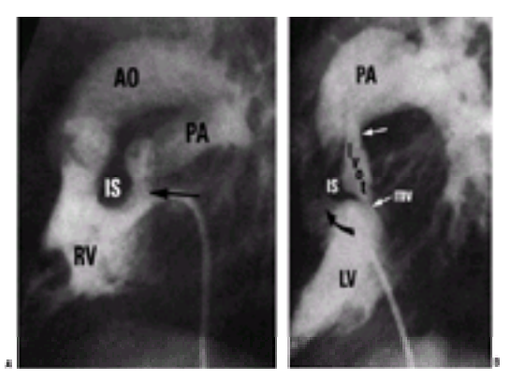
Surgical Therapy

A remarkable evolution in surgical therapy has occurred for the patient with complete transposition of the great arteries. In the long-term follow-up of large cohorts of patients who had undergone the atrial repair (after Senning or Mustard) for transposition, late right ventricular dysfunction, atrial rhythm disturbances reflecting damage to the sinoatrial node or its artery, and sudden death caused continuing concern because of ongoing attrition and morbidity (768,769,770,771,772,773,774,775,776 and 777). By the mid-1980s, the arterial switch procedure with coronary relocation was extended to the neonate (777,778,779,780,781,782 and 783). Today, in centers of excellence, the arterial switch operation can be carried out with a mortality less than 5% whether the ventricular septum is intact or in infants with an associated ventricular septal defect. Perhaps the risk for the arterial switch procedure is increased in infants with an intramural coronary artery or other uncommon coronary artery pattern. Thus, there has been increasing scrutiny on the echocardiographic and angiographic definition of the coronary artery anatomy in patients considered for the arterial switch repair. For infants presenting after the first month of life or in those with central nervous system hemorrhage or necrotizing enterocolitis or other medical or surgical conditions necessitating delay in the performance of the arterial switch procedure, Jonas and colleagues, of the Boston Children's group, championed the rapid two-stage arterial switch for transposition of the great arteries and intact ventricular septum beyond the neonatal period (784), which includes banding the pulmonary artery and placement of an arterial shunt to prepare the left ventricle by increasing its mass; the shunt is necessary to maintain a "reasonable" systemic arterial oxygen level. In the mid- and long-term follow-up of infants who undergo the arterial switch repair, some experience pulmonary artery stenoses, although this number has been reduced subsequent to the implementation of LeCompte's maneuver (785). Important supraaortic obstruction after the arterial switch operation has been uncommon. Although there have been comforting data supporting the growth of the coronary arterial anastomoses, more recent data provoke some concern in this regard.

In some patients with complex transposition, anatomy does not permit an arterial switch procedure. The most common of these is the group with a large malalignment ventricular septal defect and important left ventricular outflow tract obstruction (786,787,788,789,790 and 791) (*e*Fig. 30.0.29). In these patients, Rastelli's operation or the *reparation à l'étage ventriculaire* procedure can be used to achieve an anatomic repair. The left ventricle is tunneled through the ventricular septal defect to the aorta (the Rastelli concept); the main pulmonary trunk is divided or ligated as it exits the left ventricle, and continuity is achieved with a valved conduit. The *reparation à l'étage ventriculaire* procedure is similar, but the outlet septum is widely resected to permit a more direct pathway to the aorta from the left ventricle, and the main pulmonary trunk is connected directly to the right ventricle, thus avoiding the ongoing morbidity and need for reoperation when a conduit is used. These procedures usually are performed beyond infancy, and such patients may require palliation with balloon atrial septostomy and an arterial shunt.



***e*FIGURE 30.0.29** Transposition of the great arteries, ventricular septal defect, and left ventricular outflow tract obstruction (lvot). **A:** This lateral right ventriculogram shows the anterior aorta (AO), the smaller posterior pulmonary artery (PA), and the caudal displacement of the infundibular septum (IS), producing the lvot (*arrow*). **B:** This long axial left ventriculogram also demonstrates the posteriorly displaced IS, the ventricular septal defect (*black arrow*), and the long tunnel between the mitral valve (mv) and pulmonary valve (*white arrows*). LV, left ventricle; RV, right ventricle.

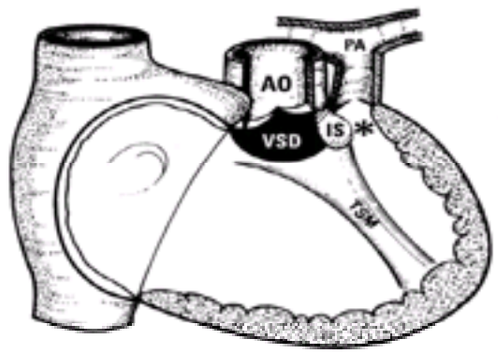
The Mustard or Senning forms of atrial repair still may be required for patients with a small ventricular septal defect and important pulmonary valvar stenosis. In both operations, the systemic venous return is diverted or baffled through the mitral valve into the left ventricle and then the pulmonary arteries, with the pulmonary venous return diverted to the tricuspid valve, the right ventricle, and the aorta. The long-term complications of these atrial repairs have been amply catalogued and reflect rhythm disturbances secondary to injury to the sinoatrial node or its artery, sudden death, and failure of the systemic ventricle, often accompanied by tricuspid regurgitation. In patients with a failing right ventricle, there has been some experience in converting them to anatomic repair (792,793,794 and 795). Most patients require preparation of the left ventricle by banding of the pulmonary trunk to increase the left ventricular mass. A few patients with a failing right ventricle have prepared the left ventricle by virtue of pulmonary hypertension (from pulmonary venous baffle obstruction) or from dynamic left ventricular outflow tract obstruction. In some patients with a failing right ventricle and important tricuspid regurgitation, banding of the pulmonary trunk to prepare the left ventricle by changing the geometry of the ventricular septum improves the tricuspid regurgitation (795).

Tetralogy of Fallot

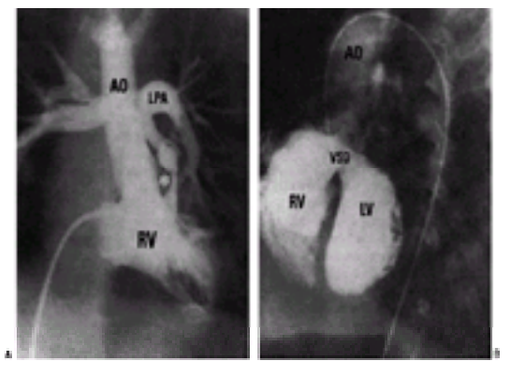
Considerable evolution has occurred in our understanding of what constitutes tetralogy of Fallot. Fallot, and those who translated his work, considered tetralogy as consisting of a ventricular septal defect, stenosis of the pulmonary outflow tract, an overriding aorta, and right ventricular myocardial hypertrophy, this last feature a natural consequence of the pulmonary outflow tract obstruction (796,797,798 and 799). The evolution in our understanding of the morphology is paralleled by those achievements in therapy: from palliation as the only form of therapy 50 years ago, to repair of this malformation at almost any age today (800,801,802,803,804,805,806,807,808,809,810,811 and 812). The most frequent segmental anatomy of tetralogy of Fallot is levocardia, atrial situs solitus, and concordant atrioventricular and ventriculoarterial connections. Tetralogy of Fallot in situs inversus totalis is uncommon (less than 5%), as is tetralogy of Fallot with isolated dextrocardia.

The morphologic findings of tetralogy of Fallot include pulmonary stenosis of a specific infundibular character, a ventricular septal defect located between the anterior and posterior limbs of the trabecular septal band overriding the aorta, and right ventricular hypertrophy (800,801,812,813,814 and 815). Right ventricular hypertrophy is progressive, reflecting the myocardial response to both right ventricular outflow tract obstruction and to the large nonrestrictive ventricular septal defect. Uniting these features is anterocephalad deviation of the infundibular outlet septum, and this malalignment or displacement of the infundibular septum is now considered the essence of tetralogy of Fallot (*e*Fig. 30.0.30). Indeed, in 1970, Van Praagh and colleagues suggested that tetralogy of Fallot is really a "monology" of Fallot resulting from this displaced infundibular or outlet septum and that in tetralogy the outlet septum is "too short, too narrow, and too shallow" (816,817 and 818). The leftward or septal end of the infundibular septum is displaced anteriorly, inserting in front of the left anterior division of the septal band rather than between its two divisions as in the normal heart. The rightward aspect of the infundibular septum is rotated anteriorly and passed anteriorly and inferiorly to reach the free wall of the right ventricle so that the infundibular septum and its parietal extension lie almost in a sagittal plane rather than the usual frontal plane (806). Others, although agreeing that tetralogy reflects this malalignment of the outlet septum, do not agree that invariably the outlet septum is hypoplastic (813). In many patients, this infundibular obstruction is aggravated by a hypoplastic pulmonary valvular annulus, pulmonary valve stenosis with a bicuspid valve with thickened cusps and fused commissures, anomalous muscle bundles, and varying degrees of hypoplasia of the main pulmonary trunk and its branches (*e*Fig. 30.0.31). The pulmonary arteries can exhibit considerable variability in caliber; they may be nonconfluent with one pulmonary artery originating from an arterial duct (819). Rarely, one pulmonary artery, usually the left, may originate from the ascending

aorta. The coronary arteries also may exhibit variation in aortic origin and epicardial course. The most important abnormality is origin of the anterior descending coronary artery from the right coronary artery (819). The left anterior descending coronary artery crosses the right ventricular outflow tract to descend in the anterior interventricular sulcus. In approximately 25% to 30%, the aortic arch is right-sided. Five to seven percent have multiple ventricular septal defects. A few patients with typical infundibular anatomy of tetralogy of Fallot have important ventricular hypoplasia.



***e*FIGURE 30.0.30** Diagram showing the essential "monology" of Fallot, posterior displacement of the infundibular septum (IS) producing a typical ventricular septal defect (VSD), and a narrowed pulmonary outflow tract (*asterisk*). AO, aorta; PA, pulmonary artery; TSM, trabecula septomarginalis.



***e*FIGURE 30.0.31** Tetralogy of Fallot. **A:** Right ventriculogram with cranial caudal angulation demonstrates right-to-left shunting to the aorta (AO) via the ventricular septal defect (VSD) and the narrowed (*asterisk*) right ventricular outflow tract. **B:** The VSD and overriding AO are demonstrated by this long axial oblique left ventriculogram. Prevalence

The diagnostic frequency for tetralogy of Fallot of 0.214 per 1,000 live births was provided by the New England Regional Infant Cardiac Program (820), and data from the more recently completed Baltimore-Washington Infant Study provided a prevalence of 0.262 per 1,000 live births (821). The Alberta Heritage Study indicated a liveborn prevalence of 0.184 per 1,000 live births (822) for tetralogy of Fallot.

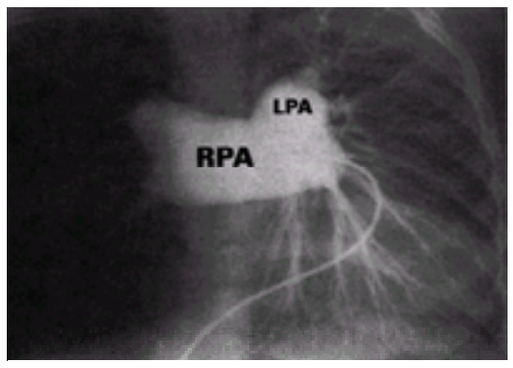
Clinical Course and Surgical Intervention

Untreated, only 10% of patients with tetralogy of Fallot survive to 10 years of age (823). Today, many centers prefer to carry out complete repair at any age, even in very young patients with small pulmonary arteries (805,806,807,808,809 and 810). The pulmonary arteries are small and thin-walled because they are underfilled (824). Most patients undergoing repair of tetralogy of Fallot require a transannular patch and thus have significant pulmonary regurgitation, which may have a long-term effect on the size and function of the right ventricle, and some may require pulmonary valve replacement. In these patients, it is always important to exclude important stenoses within the pulmonary arteries, whether acquired from a previously constructed surgical shunt or from ductal tissue in the wall of the pulmonary artery (825). Of the many morphologic considerations in the preoperative investigation of the patient with tetralogy of Fallot, it is imperative to define the epicardial course of the coronary arteries, showing whether a major coronary artery crosses the right ventricular outflow tract (819,826,827,828,829,830,831,832,833,834,835,836,837,838,839,840 and 841). Surgical repair of uncomplicated tetralogy of Fallot can be accomplished with a mortality less than 3% (804,806,807,809,820). Medical treatment with a beta-blocker should be considered only a short-term maneuver to treat a hypercyanotic spell, but should not forestall surgical therapy, whether primary repair or a palliative shunt.

In follow-up, these patients should be surveyed for the effect of chronic pulmonary regurgitation, residual pulmonary artery branch stenosis, a residual left-to-right shunt, rhythm disturbance, and aortic insufficiency. As for any cardiac condition with residual morphologic abnormalities, the patient must be protected against infective endocarditis at times of risk.

Variant of Tetralogy of Fallot with Absent Pulmonary Valve

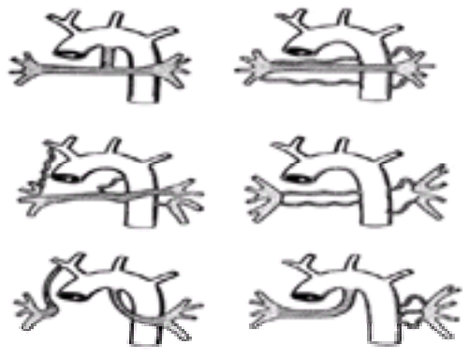
Variant of tetralogy of Fallot with absent pulmonary valve is rare, with a prevalence of approximately 0.0065 per 1,000 live births (842). Like other conotruncal abnormalities, there is an association with DiGeorge syndrome and deletion within chromosome 22, and most affected patients have the velocardial facial syndrome (843,844,845,846,847,848 and 849). Tetralogy of Fallot with absent pulmonary valve produces the substrate for varying degrees of right ventricular outflow tract obstruction, pulmonary regurgitation because of a pulmonary valve annulus completely devoid or nearly so of valvar issue, and right-to-left ventricular shunting at ventricular level because of a large ventricular septal defect resulting from anterior displacement of the infundibular septum, a finding considered characteristic of tetralogy of Fallot (850,851,852,853,854,855,856 and 857). What is so unusual about patients with tetralogy of Fallot and absent pulmonary valve is the aneurysmally dilated pulmonary arteries with their potential for compression of the major bronchi (*e*Fig. 30.0.32), potentially resulting in massively hyperinflated lungs and spontaneous pneumothorax. Patients with this syndrome also may have nonconfluent pulmonary arteries, with either a ductal origin or origin from the ascending aorta (858,859). Primary repair of the symptomatic infant with plication of the aneurysmal pulmonary arteries is preferred (860,861,862,863 and 864). Some of these infants may require lobectomy or subtotal lobectomy because of profound air trapping. In the preoperative management of the very ill infant with profound respiratory distress, it might be appropriate to keep the infant on his or her stomach (865).



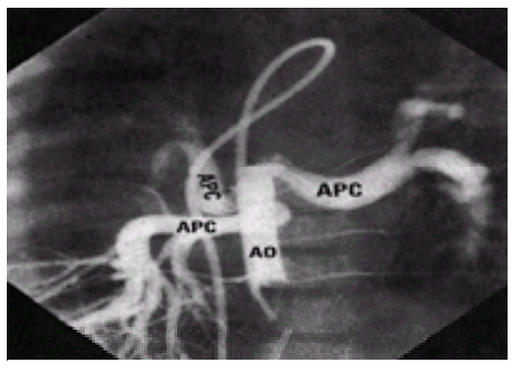
***e*FIGURE 30.0.32** The pulmonary arteries in the tetralogy of Fallot and absent pulmonary valve syndrome. Note the aneurysmally dilated pulmonary arteries. LPA, left pulmonary artery; RPA, right pulmonary artery.

Tetralogy of Fallot with Pulmonary Atresia

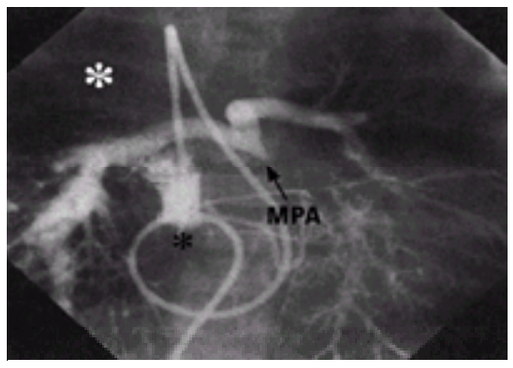
In hearts with tetralogy of Fallot and pulmonary atresia or pulmonary atresia and ventricular septal defect, fundamental to management and prognosis is the definition of pulmonary arterial supply (*e*Fig. 30.0.33, *e*Fig. 30.0.34, and *e*Fig. 30.0.35). For the most part, this is via the arterial duct or from collateral arteries originating directly or indirectly from the aorta (866,867,868,869,870,871,872,873,874,875,876 and 877). The surgical challenge rests with the ability to define, recruit, and rehabilitate the pulmonary arteries (877,878,879,880,881,882,883,884,885,886,887,888,889,890,891 and 892), achieved in part by resolution of the following questions: How is blood conducted into the lungs, and how does one define those sources of pulmonary blood supply to each of the bronchopulmonary segments (877,878,879,880 and 881) (*e*Fig. 30.0.34)? At this time, surgery should be eschewed because of the potential and reality for compromising the often fragile pulmonary circulation (893,894,895 and 896).



***e*FIGURE 30.0.33** Schematic diagram demonstrating some of the myriad variations in pulmonary arterial supply in the patient with pulmonary atresia and ventricular septal defect.



***e*FIGURE 30.0.34** Multiple large direct aortopulmonary collateral arteries (APCs) in a patient with pulmonary atresia and ventricular septal defect demonstrated by balloon occlusion aortography. AO, aorta.



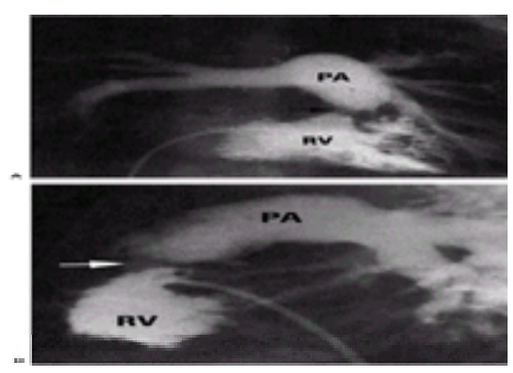
***e*FIGURE 30.0.35** Small confluent pulmonary arteries with the so-called seagull configuration demonstrated by balloon occlusion aortography. Note that the right upper lung field (*asterisk*) is not supplied from the true lung arteries. MPA, main pulmonary artery.

For the patient with tetralogy and pulmonary atresia, there is no “easy” surgical algorithm. Even the surgical management with confluent pulmonary arteries mediated by a solitary arterial duct remains contentious. Some would palliate the neonate or young infant with a modified Blalock-Taussig shunt until the patient reaches the age of 1 or 2 years and then carry out a complete repair. Others advocate a complete repair even in the neonate. The situation is even more complex for the patient with multiple sources of pulmonary blood flow. Many of these patients require unifocalization of the various sources of pulmonary blood flow, and the timing and methodologies remain both debatable and complex. Among any cohort of babies with complex pulmonary atresia and multiple sources of pulmonary blood supply, some sources will be precarious because of severe stenosis within the collateral, whereas in others the absence of any obstruction may promote pulmonary vascular obstruction in that segment of lung perfused by the “unprotected” collateral. Thus, in any given patient, some bronchopulmonary segments may be profoundly underperfused, and others are at risk for pulmonary vascular obstruction (878,879,881,897,898).

Clearly, however, for neonates presenting with profound hypoxemia, administration of an E-type prostanoid should by virtue of dilating a constricted arterial duct afford considerable improvement until the nature of the pulmonary blood supply is clarified by echocardiography or angiocardiography (878,879,881,899). Even in infants without an arterial duct, the prostanoid may provide improvement because of its pulmonary vasodilating effect.

Divided Right Ventricle and Ventricular Septal Defect

The most common etiology for division of the right ventricle is the so-called anomalous right ventricular muscle bundles (900,901,902,903,904,905 and 906) (*e*Fig. 30.0.36). There are, however, a variety of structures that may divide the right ventricle, including from tissue derived from perimembranous septum or septal leaflet of the tricuspid valve, the obstructive or imperforate form of Ebstein’s tricuspid valve deformity, accessory tricuspid valve, a windsock deformity of the tricuspid valve and contiguous tissue, muscular division within the right ventricle, neoplastic obstruction to the right ventricular outlet, hypertrophic obstructive cardiomyopathy, neurofibromatosis, or combinations of these (905,906).



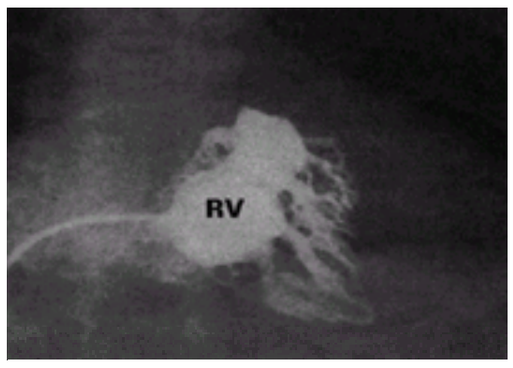
***e*FIGURE 30.0.36** Frontal **(A)** and lateral **(B)** right ventriculogram in a patient with anomalous muscle bundles (*arrow*) dividing the right ventricle (RV). PA, pulmonary artery.

The so-called double-chambered or divided right ventricle describes the conditions in which the morphologically right ventricle is divided or septated by muscular or fibrous structures (903). Most reported cases of the divided right ventricle are characterized by muscular obstruction, which usually but not invariably produces some degree of obstruction within and between the component parts of the right ventricle. Division of the right ventricle can occur at the junction between the inlet and trabecular components of the right ventricle or more distal at the level of the infundibulum. In a large cohort of patients with muscular division of the right ventricle, the most frequent associated abnormality is the perimembranous ventricular septal defect (900,903,907). When the ventricular septal defect is large and the right ventricular obstruction severe, the findings should be similar to the patient with tetralogy of Fallot. In some patients, however, the ventricular septal defect is only moderate in size, and spontaneous diminution in size of the defect may occur (905). If the muscular division of the right ventricle is particularly severe, profound right ventricular hypertrophy is a consequence of progressive diminution in the size of the ventricular septal defect and progression of the anomalous right ventricular muscles. It is important to remember the association between the perimembranous ventricular septal defect, muscular division of the right ventricle, and left ventricular outflow tract obstruction (905,906,907,908,909 and 910). In most patients, surgery can be accomplished with low risk (911).

Pulmonary Atresia and Intact Ventricular Septum

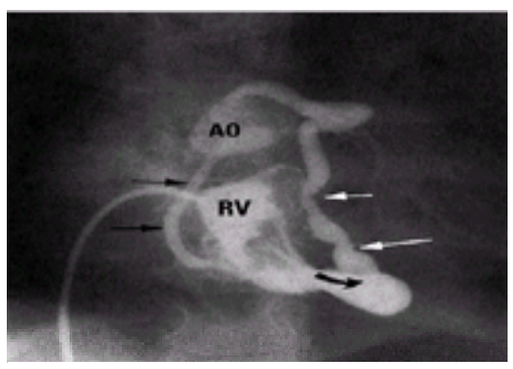
In its simplest definition, pulmonary atresia and intact ventricular septum constitute a disorder characterized by complete membranous and, in many patients, muscular obstruction to the right ventricular outlet (912,913,914,915,916,917,918,919,920,921,922 and 923). The pulmonary valve is imperforate, and in many patients right ventricular infundibular muscular atresia of variable extent or length is also present. The ventricular septum is intact (*e*Fig. 30.0.37). With rare exception, pulmonary blood flow in these patients is mediated by a patent arterial duct, and there is an obligatory right-to-left shunt at the atrial level (912). Rarely, the pulmonary arteries are nonconfluent, each mediated by its own arterial duct (924). Rarely, the only sources for pulmonary blood flow are direct aortopulmonary collaterals (925). Because the right ventricular outlet is blind, there is an obligatory right-to-left shunt at atrial level. As in the patient with tricuspid atresia, an atrial septal defect of some form is invariably present because of the obligatory right-to-left shunt at atrial level. In some infants, the atrial septal defect is restrictive at birth, and a balloon atrial septostomy

is necessary (912). In other patients, a seemingly adequate interatrial communication becomes restrictive with time.

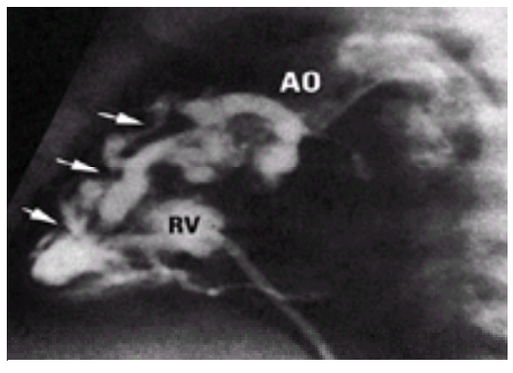


***e*FIGURE 30.0.37** Pulmonary atresia and intact ventricular septum with a well-formed tripartite right ventricle (RV).

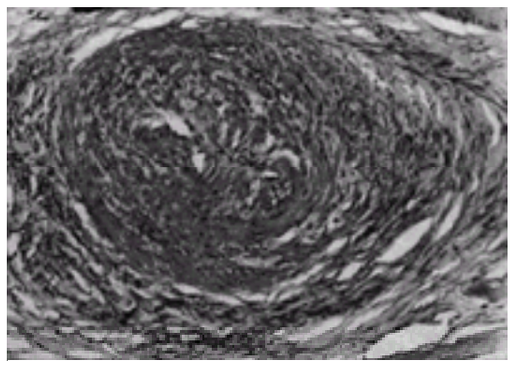
There is considerable heterogeneity. Some patients have a nearly normal-sized right ventricle and a blind pulmonary valve with only mild infundibular narrowing (*e*Fig. 30.0.37). Such patients are amenable to surgical pulmonary valvotomy or to radiofrequency catheter perforation of the valve (926). In other patients with pulmonary atresia and an intact ventricular septum, massive tricuspid regurgitation reflecting displacement or dysplasia of the tricuspid valve or even an unguarded tricuspid orifice results in extreme cardiomegaly and lung underdevelopment (927,928 and 929). These infants have a grossly disadvantaged right ventricle that is thinned, virtually devoid of normal myocardium that cannot generate systemic pressures (927,928). At the other end of the spectrum of this disorder are those patients with extreme tricuspid valve stenosis and hypoplasia, a hypertrophied and diminutive right ventricle that can generate systemic or suprasystemic right ventricular pressures (912) (*e*Fig. 30.0.38 and *e*Fig. 30.0.39). Many of these infants have ventriculocoronary connections with the potential for coronary arterial stenosis or interruption (930,931,932,933,934,935,936,937,938,939,940,941,942,943,944,945,946,947,948,949 and 950). Some infants in this group have a coronary circulation that is right ventricular dependent (*e*Fig. 30.0.40) (i.e., because of coronary arterial stenosis or interruption, coronary blood flow is mediated by right ventricular systole and blood entering the right ventricle) (930,934,935,937,938,939,940 and 941,943,944,945,946 and 947,949,950). In this situation, any maneuver that reduces the right ventricular systolic pressure or prevents blood from entering the right ventricle (thromboexclusion of the right ventricle) can unmask the egregious nature of the coronary circulation, resulting in myocardial ischemia, infarction, or death (951).



***e*FIGURE 30.0.38** Pulmonary atresia and intact ventricular septum with a unipartite right ventricle (RV), extensive ventriculocoronary connections (*curved black arrow*) to both ventricles with luminal irregularities. Note the retrograde flow from the coronary arteries to the aorta (AO). The straight black arrows point to the right coronary artery; the white arrows note the anterior descending coronary artery.



***e*FIGURE 30.0.39** Multiple levels of coronary artery stenosis and interruption (*arrows*) in this patient with pulmonary atresia and intact ventricular septum and a right ventricular (RV)–dependent coronary circulation. AO, aorta.



***e*FIGURE 30.0.40** The nearly complete occlusive coronary artery pathology in a patient with pulmonary atresia, intact ventricular septum, and a right ventricular–dependent coronary circulation.

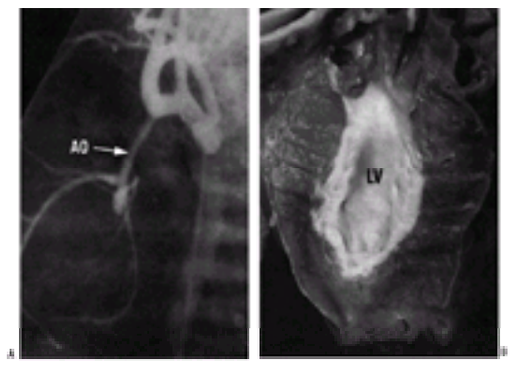
Pulmonary atresia and intact ventricular septum constitute an uncommon form of congenitally malformed heart, accounting for only approximately 3% of newborns with serious congenital heart disease (952) and a prevalence of 0.083 per 1,000 live births (953). In a survey of cyanotic neonates with congenital heart disease, this disorder ranks third after transposition of the great arteries and pulmonary atresia and ventricular septal defect (954). Fetal echocardiography provides a unique window to study the later phases of the fetal heart and to define specific types of heart predisposed to fetal death. There is increasing evidence that fetuses with florid tricuspid regurgitation may not fare well (955,956,957,958,959 and 960). Such fetuses are known to develop right-sided heart failure with pleural and pericardial effusions, ascites, pulmonary hypoplasia, and fetal death. Thus, fetal loss might be anticipated in a specific subset of patients with pulmonary atresia, intact ventricular septum, extremely severe tricuspid regurgitation, and a low-pressure right ventricle.

With the profound heterogeneity in the form of hearts with pulmonary atresia and intact ventricular septum, many of whom have a profoundly abnormal coronary

circulation, the surgical algorithms are complex. Because pulmonary blood flow is duct dependent, until a stable source of pulmonary blood flow is established, an E-type prostaglandin must be given. The diagnosis of pulmonary atresia and intact ventricular septum is usually easily established by cross-sectional echocardiography (961,962 and 963), but in those with the hypertensive and hypertrophied right ventricle, it is usually necessary to perform a cardiac catheterization to define the nature of the coronary circulation (912,920,922,923,930,935,936,937,938 and 939,964,965 and 966). Thus, some infants are amenable to right ventricular outflow tract reconstruction; others are amenable to some form of pulmonary valvotomy, but an arterial shunt is necessary to maintain a satisfactory systemic arterial oxygenation. Only 30% to 35% were alive at 15 to 20 years (967,968 and 969). We reported the results of the Fontan operation in these patients, including a group with a right ventricular–dependent coronary circulation (970). For infants with massive tricuspid regurgitation and a grossly disadvantaged right ventricle, the novel approach of Starnes of converting these patients to tricuspid atresia might salvage some (971).

Hypoplastic Left Heart Syndrome

Hearts with the usual forms of hypoplastic left heart syndrome are usually left-sided; the usual atrial arrangement (solitus) is present, and the atrioventricular and ventriculoarterial connections are concordant, although various expressions of the hypoplastic left heart syndrome have been identified in patients with right or left atrial isomerism. Hearts with the usual forms of hypoplastic left heart syndrome exhibit aortic atresia or severe stenosis, mitral atresia or severe stenosis, and often profound left ventricular hypoplasia with variable left ventricular endocardial fibroelastosis (eFig. 30.0.41). The interatrial communication is represented by a flap of the foramen ovale, but in 20% of patients with the hypoplastic left heart syndrome, the foramen ovale is prematurely sealed. Such infants are extremely hypoxemic, and many exhibit some degree of pulmonary lymphangiectasia. Once considered uncommon, a coarctation of the aorta is probably identified in 70% to 80%. Rarely, aortic arch interruption coexists with aortic atresia. In these uncommon patients, blood to the ascending aorta is conducted either from a right-sided arterial duct, an aortopulmonary fenestration, or via fifth aortic arch. The aortic arch is usually left-sided, and an arterial duct supports the entire systemic circulation in those infants with the usual expression of the hypoplastic left heart syndrome. With ductal closure, systemic output, including coronary blood flow, rapidly becomes inadequate, and a relentless metabolic acidosis results, culminating in death. Prevalence ranges from 0.164 to 0.267 per 1,000 live births (972,973).



***e*FIGURE 30.0.41 A:** Diminutive aorta (AO) and aortic atresia demonstrated by retrograde aortography in this duct-dependent condition. **B:** Small left ventricle (LV) with severe endocardial sclerosis.

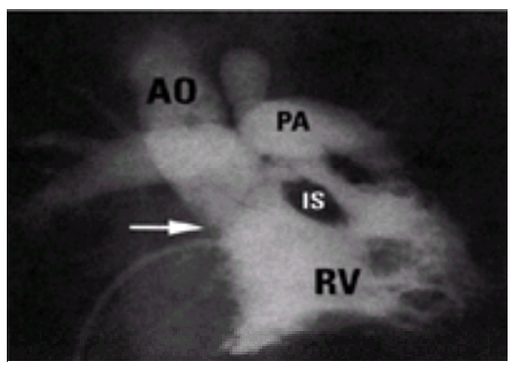
Treatment

The mainstay of medical therapy for hypoplastic left heart syndrome is the administration of an E-type prostaglandin to promote and maintain patency of the arterial duct and correction of metabolic acidosis (971,972,973,974,975 and 976). Many of these infants are better cared for ventilated and paralyzed. Supplemental oxygen should be administered judiciously because of the precarious balance between the systemic and pulmonary circulations. Enhancement of pulmonary blood flow could promote a “steal” from the systemic circulation, leading to myocardial insufficiency and death. Diagnosis is rapidly established by cross-sectional echocardiography, and cardiac catheterization is rarely required. Some infants with the hypoplastic left heart syndrome are extremely hypoxemic, reflecting premature closure of the ovale foramen (974,975).

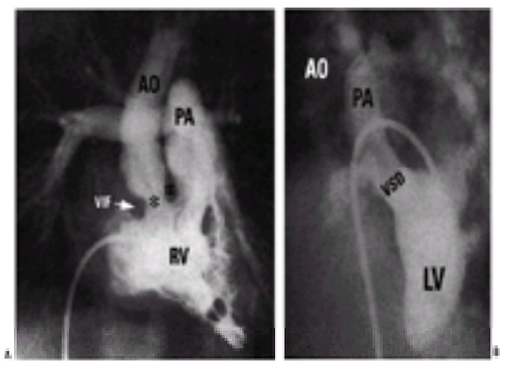
Hypoplastic left heart syndrome was once considered inoperable, but now two major forms of active intervention are available: staged surgical therapy as pioneered by Norwood, concluding in a Fontan operation (977,978,979,980,981,982,983,984,985 and 986), and cardiac transplantation (987,988,989,990 and 991). The initial operation consists of a wide atrial septectomy, reconstruction of the often diminutive ascending aorta with connection from the main pulmonary trunk and augmentation of the aortic isthmus to treat the often present coarctation of the aorta, and a 3.0- to 3.5-mm modified Blalock-Taussig shunt to the distal confluent pulmonary arteries. The point of disconnection of the distal pulmonary arteries is widely patched to avoid unilateral obstruction. Although in some centers this initial form of palliation can be achieved with a mortality of between 10% and 15%, the mortality in most centers is considerably higher. Between the first and second stage, unfortunately, some infants die; the causes of death include shunt occlusion, infection, adverse central nervous system events, and presumed dysrhythmia. The second stage usually is carried out when the infant is 3 to 9 months of age, which takes the form of a bidirectional cavopulmonary shunt with repair of any pulmonary artery stenosis and an atrial septectomy if necessary. Some patients also may require a tricuspid valve annuloplasty at this time. The “final” operation is a Fontan-type operation, usually a fenestrated lateral tunnel or extracardiac Fontan. The bidirectional cavopulmonary connection has a mortality of approximately 5%, and for patients meeting Fontan’s criteria, a Fontan-type operation can be carried out with a mortality less than or equal to 5%. The Loma Linda group has had extensive experience with transplantation as primary therapy for the hypoplastic left heart syndrome (987,988,989,990 and 991). They report a 25% pretransplant mortality, a 10% operative mortality, and 1- and 7-year survivals of 84% and 72%, respectively (42,43).

Double-Outlet Right Ventricle

DORV is a condition in which more than one-half of each great artery is connected to the morphologically right ventricle (992,993,994,995,996,997,998,999,1000,1001,1002 and 1003) (*e*Fig. 30.0.42 and *e*Fig. 30.0.43). In the uncommon situations in which the ventricular septum is intact, there is no difficulty in determining that both great arteries originate from the morphologically right ventricle; but usually there is a ventricular septal defect, and there may be difficulty in assigning the ventriculoarterial connection. DORV reflects considerable heterogeneity, with a wide range of spatial relationships between the great arteries; considerable variation in the location of the ventricular septal defect; pulmonary or aortic outflow tract obstruction; varying degrees of ventricular hypoplasia; and important abnormalities of the atrioventricular junction. Indeed, for some patients with significant ventricular hypoplasia or major straddling of an atrioventricular valve or a ventricular septal defect that is remote from either great artery, a one-ventricle or Fontan-type repair is considered. For those patients with a subaortic ventricular septal defect and no pulmonary outflow tract obstruction, presentation is similar to a patient with a large and nonrestrictive ventricular septal defect, and most are amenable to primary repair. The patient with the tetralogy type of DORV has a clinical presentation and course similar to that of the patient with tetralogy of Fallot (*e*Fig. 30.0.42). Most patients are amenable to primary repair, although some prefer palliation with a systemic-to-pulmonary artery shunt for small infants. The arterial switch operation with coronary artery relocation is the preferred operation for the patient with DORV with subpulmonary ventricular septal defect or the Taussig-Bing form of DORV, although some are treated by an intraventricular repair (*e*Fig. 30.0.43). Patients with DORV and subpulmonary ventricular septal defect or the Taussig-Bing form of DORV are likely to have right ventricular subaortic obstruction; some may have an associated obstructive anomaly of the aortic arch.



***e*FIGURE 30.0.42** Double-outlet right ventricle (RV) of the tetralogy-type with side-by-side great arteries and a narrowed subpulmonary outflow tract demonstrated by this frontal right ventriculogram. Arrow points to the level of the aortic valve. AO, aorta; IS, infundibular septum; PA, pulmonary artery.



***e*FIGURE 30.0.43 A:** Double-outlet right ventricle (RV) of the Taussig-Bing form with side-by-side great arteries and a narrowed subaortic outflow tract (*asterisk*) demonstrated by this frontal right ventriculogram. **B:** This left long axial oblique left ventriculogram demonstrates the subpulmonary ventricular septal defect (VSD) in this patient previously palliated by pulmonary artery (PA) banding. AO, aorta; LV, left ventricle; RV, right ventricle; VIF, ventricular infundibular fold.

Diagnosis and Treatment

Prevalence of DORV is low: 0.03 to 0.06 per 1,000 live births (1004,1005). The considerable heterogeneity in cardiac morphology embraced by the designation *DORV* is reflected in various clinical presentations as well. Thus, no single clinical feature, electrocardiogram, or chest radiograph is diagnostic of this condition. The echocardiogram certainly can establish the diagnosis of DORV and can define the important associated abnormalities as well. For most patients considered for either a biventricular repair and for all considered for a one-ventricle or Fontan-type repair, cardiac catheterization with angiocardiography is required (1006). The categorization of DORV by the relative position of the ventricular septal defect has been integrated into common usage, but this approach is physiologic, not anatomic (*e*Table 30.0.3).

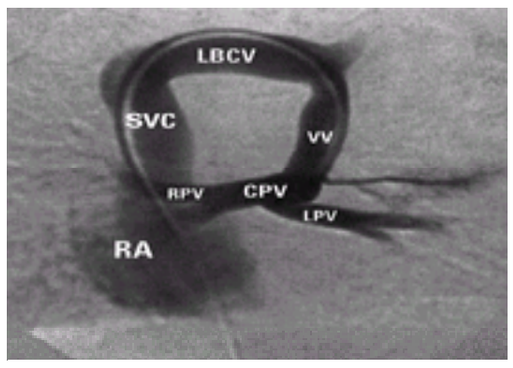
***e*TABLE 30.0.3** TYPES OF DOUBLE-OUTLET RIGHT VENTRICLE
Subaortic ventricular septal defect
Subpulmonary ventricular septal defect
Juxtaarterial or subarterial ventricular septal defect
Remote ventricular septal defect

One can provide general guidelines for the treatment of patients with the generic type of DORV as follows (996,997,998,999,1000,1001,1002 and 1003,1006):

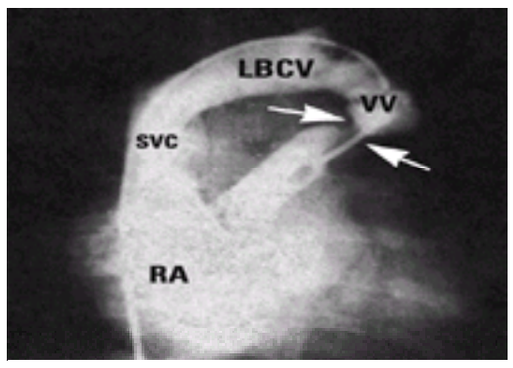
- DORV, large ventricular septal defect, and no pulmonary outflow tract obstruction: primary repair.
- DORV of the tetralogy type: Some would palliate in infancy, with repair beyond age 1 to 2 years; others would carry out a primary repair when the patient is symptomatic.
- DORV with subpulmonary ventricular septal defect, or DORV of the Taussig-Bing form: The two primary surgical considerations are (a) the arterial switch operation with coronary artery relocation with closure of the ventricular septal defect and (b) an intraventricular repair.
- DORV with so-called remote ventricular septal defect or complex DORV with ventricular hypoplasia or major straddling of an atrioventricular valve: Consider a one-ventricle-type repair.

Total Anomalous Pulmonary Venous Connections

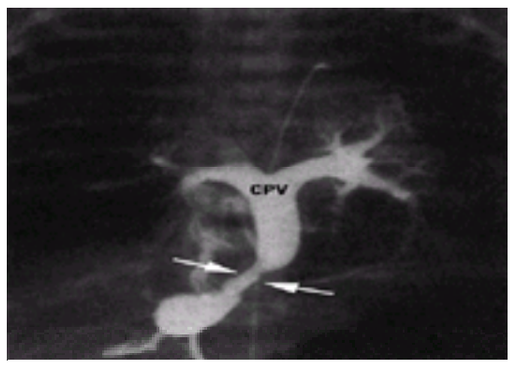
TAPVC is characterized by connection of all the pulmonary veins to one or more systemic veins and the right atrium or to the coronary sinus (1007,1008,1009,1010,1011,1012,1013,1014,1015,1016,1017 and 1018) (*e*Fig. 30.0.44, *e*Fig. 30.0.45, and *e*Fig. 30.0.46). *e*Table 30.0.4 provides a commonly used classification of TAPVC.



***e*FIGURE 30.0.44** Total anomalous pulmonary venous return, supracardiac type, with a vertical vein (VV) connecting to the left brachiocephalic vein (LBCV). CPV, common pulmonary vein; LPV, left pulmonary vein; RA, right atrium; RPV, right pulmonary vein; SVC, superior vena cava.



***e*FIGURE 30.0.45** The vertical vein (VV) is narrowed (*arrows*) in its course through the anatomic vise. LBCV, left brachiocephalic vein; RA, right atrium; SVC, superior vena cava.



***e*FIGURE 30.0.46** Infradiaphragmatic total anomalous pulmonary venous connections to the portal system, with narrowing in its course (*arrows*). CPV, common pulmonary vein.

***e*TABLE 30.0.4** CLASSIFICATION OF TOTAL ANOMALOUS PULMONARY VENOUS CONNECTIONS

Coronary sinus
Left atrium (failure of complete incorporation of common pulmonary vein)
Infradiaphragmatic
Inferior vena cava
Ductus venosus
Portal vein
Left gastric vein
Mixed
To more than one site

The most serious clinical manifestation of TAPVC is severe obstruction (1011,1012,1014,1016,1018,1019,1020,1021,1022,1023,1024,1025,1026,1027,1028,1029,1030, 1031,1032,1033 and 1034), which results when the common pulmonary vein connects below the diaphragm to the ductus venosus or to the portal vein (*e*Fig. 30.0.46). Severe obstruction also has been documented with the supracardiac type, especially the form connecting to the brachiocephalic vein via a vertical vein. In this form, the ascending common pulmonary vein is obstructed in its course in the anatomic vise: the left pulmonary artery and the left mainstem bronchus (1014,1016,1017) (*e*Fig. 30.0.45). Rarely, pulmonary venous connections are obstructed in their connection to the coronary sinus. Perhaps the most severe form of obstructed TAPVC occurs when both right- and left-sided pulmonary veins form a confluence behind the heart, but an ascending or descending pulmonary vein has not formed or is atretic (1020,1021,1022,1023,1024,1025,1026,1027,1028,1029,1030,1031,1032,1033 and 1034). The obstructed form of TAPVC is characterized by progressive hypoxemia, a small heart, and intense pulmonary edema, sometimes accompanied by pulmonary lymphangiectasia (1024). In patients with so-called unobstructed TAPVC, most patients present in the first months of life, occasionally earlier, with findings of congestive heart failure and mild hypoxemia. Rarely, the patient with unobstructed TAPVC presents late, such as the patient with a large secundum atrial septal defect. The so-called “snowman” appearance in the supracardiac form of TAPVC to the brachiocephalic vein mediated by a vertical vein is rarely appreciated in the first months of life (1009,1010,1011 and 1012,1014,1016).

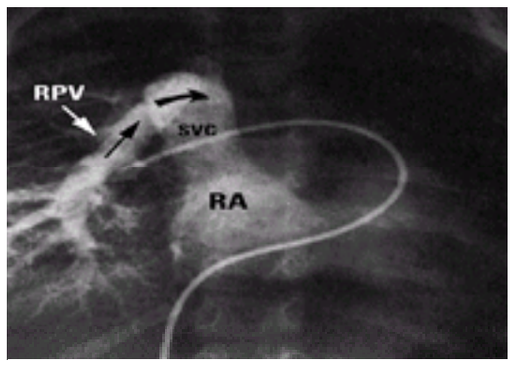
Diagnosis and Therapy

The diagnosis is readily made clinically and from cross-sectional echocardiography. Cardiac angiography is rarely required in typical forms of TAPVC, but it may be required in those patients with complex mixed or double drainage. Judicious use of digoxin and diuretics with ventilation are important preoperative maneuvers, with mechanical ventilation often being important in infants with severely obstructed total anomalous pulmonary venous return.

The treatment of choice is surgical repair; there is little to be gained by delay. The confluence of pulmonary veins behind the left atrium is the surgeon’s friend, and reanastomosis of the confluence to the posterior wall of the left atrium can be accomplished with a low surgical mortality (1014,1018). Some patients have come back with postoperative pulmonary venous obstruction, and surgical salvage in these patients has been disappointing (1014).

Partial Anomalous Pulmonary Venous Connections

One or more pulmonary veins may connect anomalously to a systemic vein, right atrium, or coronary sinus, with most pulmonary veins connecting to the left atrium (1035,1036,1037,1038,1039,1040,1041 and 1042) (*e*Fig. 30.0.47). The clinical findings, especially when there is an associated atrioventricular septal defect, are similar to the patient with a large uncomplicated atrioventricular septal defect, and repair usually can be deferred until the patient is 1 year of age or older. Occasionally, partial anomalous pulmonary venous return is identified in the patient with an intact atrial septum. The second heart sound may split and move normally, and the decision to intervene surgically is predicated on how many veins connect to the right side of the heart.



***e*FIGURE 30.0.47** Partial anomalous pulmonary venous connections of the right middle pulmonary vein (RPV) to the right superior caval vein (SVC). RA, right atrium.

Cor Triatriatum or Subdivided Left Atrium

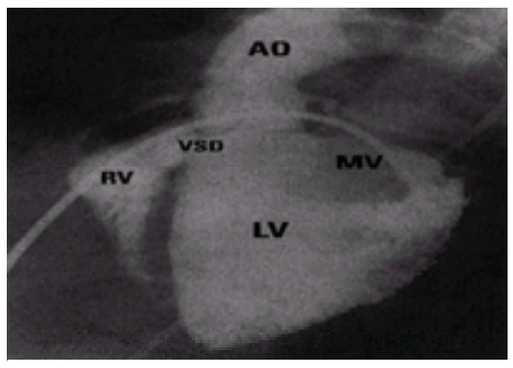
This uncommon congenital abnormality is characterized by a membrane dividing the left atrium into a superior chamber receiving the pulmonary veins and an inferior chamber receiving the left atrial appendage and mitral inflow (1043,1044,1045,1046,1047,1048,1049,1050,1051,1052,1053,1054 and 1055). The atrial septum may be intact, or an interatrial communication may be identified between the superior chamber and the right atrium, or inferior chamber and the right atrium. Rarely presenting in isolation in the newborn, cor triatriatum may present with pulmonary hypertension and pulmonary edema in infants as young as 1 to 2 months, and this disorder has been recognized in the adult as well. The clinical presentation depends on the size of the orifice of the dividing membrane and on any associated cardiac malformation. The severity of the pulmonary venous obstruction may be masked by the presence of associated complex congenital heart disease with important pulmonary outflow tract obstruction. The diagnosis is readily established by cross-sectional echocardiography, and surgical excision is the therapy of choice. Most data support the finding that reoperation is rarely necessary.

Congenital Pulmonary Vein Stenosis or Atresia

Congenital pulmonary vein stenosis and atresia are uncommon conditions. Congenital stenosis of all four pulmonary veins is considerably more complex than its designation implies, and often the process of pulmonary vein stenosis is diffuse with hypoplasia of the pulmonary veins (1056,1057,1058,1059,1060,1061,1062,1063,1064,1065,1066,1067,1068,1069 and 1070). This condition only rarely involves a discrete obstruction at the left atrial pulmonary vein connection; thus, surgical results for most patients are disappointing, with early initial improvement followed by recurrence of the stenosis, progressive pulmonary venous obstruction, pulmonary hypertension, and death. Congenital pulmonary vein atresia is usually unilateral (1071,1072,1073,1074 and 1075). By redistributing pulmonary blood flow to the unaffected side, unilateral pulmonary vein atresia may be reasonably well tolerated considering the ventilation-perfusion mismatch.

Tricuspid Atresia

The classic expression of tricuspid atresia is an absent right-sided atrioventricular connection (1076,1077,1078,1079,1080,1081,1082,1083,1084,1085,1086,1087,1088,1089,1090 and 1091). Atrioventricular sulcus tissue is interposed between the floor of the right atrium and the ventricular mass, preventing any potential connection with the rudimentary right ventricle. Indeed, the floor of the right atrium is potentially in communication with the left ventricle, not the right (1085,1086). The right ventricle is usually quite small, lacking its inlet component (*e*Fig. 30.0.48). An atrial septal defect of some form is invariably present because of the obligatory right-to-left shunt at the atrial level. In some infants the atrial septal defect is very restrictive at birth, and a balloon atrial septostomy is necessary. In other patients, a seemingly adequate interatrial communication becomes restrictive with time. The ventriculoarterial connection may be concordant or normal, discordant or transposed. Rarely, there is a double outlet from the rudimentary right ventricle or left ventricle; a common arterial trunk has also been described. The original classification of tricuspid atresia is further subdivided in these patients by the character of the pulmonary blood flow: reduced, normal, or increased (1090,1091).



***e*FIGURE 30.0.48** Typical right ventricular hypoplasia in a patient with tricuspid atresia. AO, aorta; LV, left ventricle; MV, mitral valve; RV, right ventricle; VSD, ventricular septal defect.

Tricuspid atresia is an uncommon form of congenital heart disease, clearly less frequent than transposition of the great arteries, tetralogy of Fallot, or truncus arteriosus. Prevalence ranges between 0.039 and 0.051 per 1,000 live births (1092,1093 and 1094). Familial instances of tricuspid atresia have been reported (1095,1096). Seven percent of babies with tricuspid atresia in the New England Regional Infant Cardiac Program had birth weights less than 2.0 kg, and 13% were considered to have severe extracardiac anomalies (1095).

The diagnosis of typical tricuspid atresia can be suspected in a cyanotic infant with reduced pulmonary markings on the chest radiograph and a systolic ejection murmur whose electrocardiogram demonstrates left-axis deviation, right atrial enlargement, and left ventricular hypertrophy with a paucity of right ventricular forces (1097). Beyond echocardiography, cardiac catheterization is rarely required, but such investigation may be required before the performance of a bidirectional cavopulmonary connection and then again before the Fontan procedure.

The life history of patients with tricuspid atresia and indeed a wide range of congenitally malformed hearts was forever altered by the signal contribution of Fontan and Baudet, when they partitioned and thus separated the atria and constructed an atriopulmonary connection (1098). These maneuvers effectively separated the systemic venous from the pulmonary venous circulations, and blood is conducted into the lungs without the benefit of ventricular contribution. The Fontan operation or one of its many modifications can be performed today in patients with tricuspid atresia meeting certain criteria, with a surgical mortality less than 5%; effective long-term palliation is achieved in many patients (1099,1100,1101 and 1102). An occasional patient with tricuspid atresia may survive into the third or fourth decade of life with a palliative shunt, but most are not so fortunate (1103,1104 and 1105). In long-term series before the Fontan operation, creation of a surgical shunt greatly improved (to 50%) the chance of survival to 15 years (1106). In the current era, 45% meet and successfully undergo the Fontan operation, with most deaths occurring in patients with tricuspid atresia and pulmonary atresia, and thus diminutive pulmonary arteries, or in patients with tricuspid atresia and transposition of the great arteries, with many in this latter group particularly predisposed to developing subaortic stenosis (1107,1108). Of the patients who survived to a Fontan procedure but were excluded from consideration, the more common factors leading to exclusion included ventricular dysfunction, severe distortion of pulmonary arteries from previous shunts, mitral regurgitation, and severe myocardial hypertrophy (1095,1107,1108,1109,1110,1111,1112,1113,1114,1115 and 1116). The classic Fontan criteria are listed in *e*Table 30.0.5 (1117).

***e*TABLE 30.0.5** CRITERIA FOR THE FONTAN OPERATION
Normal sinus rhythm
Normal caval and pulmonary venous connections
Normal pulmonary vascular resistance, with a mean pulmonary artery pressure <15–20 mm Hg
No significant pulmonary artery branch stenosis that would preclude surgical repair
Pulmonary artery to aortic ratio >0.75
“Normal” ventricular function
No regurgitation of the systemic atrioventricular valve
Normal diastolic ventricular function
Optimal minimal age: uncertain, but when anatomy and hemodynamics are ideal, probably 2–4 yr; until relatively recently, a minimum age of 4 yr was advocated

These criteria continue to evolve and today the Fontan operation is often performed in children aged 2 to 3 years or younger (1118,1119,1120,1121,1122 and 1123). Variations in caval anatomy can be addressed by the staging maneuver of a bidirectional cavopulmonary connection or bilateral bidirectional cavopulmonary connections. It is less important that the Fontan operation be carried out in patients with normal sinus rhythm, although one would not want to carry this out or indeed any operation if the patient is in a tachycardia. We have learned that myocardial hypertrophy is a risk factor for a poor outcome at Fontan’s operation (1095,1109,1110,1111,1112,1113,1114,1115 and 1116). Such myocardial hypertrophy was identified frequently in patients with a discordant ventriculoarterial connection and increased pulmonary blood flow treated by banding of the pulmonary trunk. Today, palliative pulmonary artery banding is eschewed, and these patients are treated with a Norwood-like approach. At 3 to 9 months of age, these patients are staged with a bidirectional cavopulmonary connection (1124,1125,1126,1127,1128,1129,1130,1131,1132 and 1133). Any pulmonary arterial stenosis or restrictive atrial septal defect also can be addressed at this time with the Fontan operation, whether a lateral tunnel or extracardiac, with or without a fenestration, at approximately 2 years of age.

The strategy for any patient with tricuspid atresia is to preserve the myocardial matrix, its structure and function, as well as the integrity of the pulmonary arteries and to optimize the pulmonary hemodynamics to allow patients to survive to and meet the criteria for a Fontan-type operation with a favorable outcome. Thus, for the patient with tricuspid atresia, concordant ventriculoarterial connections, and severe pulmonary outflow tract obstruction requiring palliation in the first days or weeks of life, we would perform a modified right-sided Blalock-Taussig shunt. When the patient is 3 to 9 months old, the right-sided Blalock-Taussig shunt would be closed and a bidirectional cavopulmonary connection performed, with completion of the Fontan operation at 18 to 24 months of age. Today, in most centers, a Fontan operation can be accomplished with a surgical mortality less than 5%.

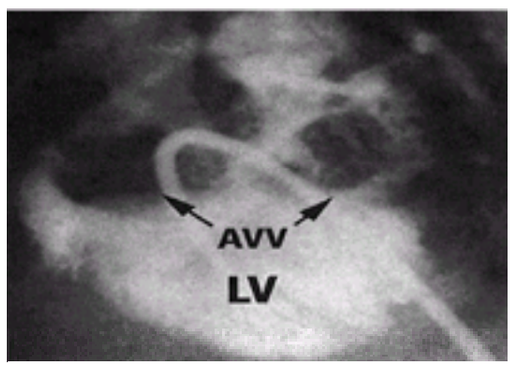
Finally, most life tables constructed from patients surviving a Fontan operation demonstrate ongoing attrition with morbidity as well (1134,1135,1136,1137,1138,1139,1140,1141,1142,1143,1144,1145,1146,1147,1148,1149,1150,1151, 1152,1153,1154,1155,1156,1157,1158,1159,1160,1161,1162,1163,1164 and 1165). *e*Table 30.0.6 lists some of the sequelae of the Fontan operation.

***e*TABLE 30.0.6** SEQUELAE OF THE FONTAN OPERATION
Right atrial enlargement for those treated with a right atrium–pulmonary artery connection

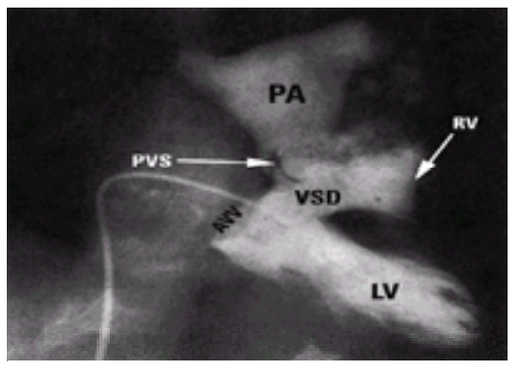
Enlargement of the coronary sinus for those in whom the coronary sinus was left on the systemic venous side of the circulation
Distention of the hepatic veins
Cirrhosis
Thrombosis of the right atrium or lateral tunnel
Obstruction of foreign material contributing to atriopulmonary, lateral tunnel, or extracardiac connection
Development of systemic venous collaterals with the potential for systemic vein–pulmonary vein or left atrial connection
Atrial arrhythmias
Surgically created Wolff-Parkinson-White syndrome
Right-to-left shunting at atrial level
Cerebrovascular accidents
Systemic ventricular outlet obstruction
Atrioventricular valve regurgitation
Ventricular dysfunction
Development of pulmonary arteriovenous fistulae
Protein-losing enteropathy
Plastic bronchitis

Double-Inlet Ventricle

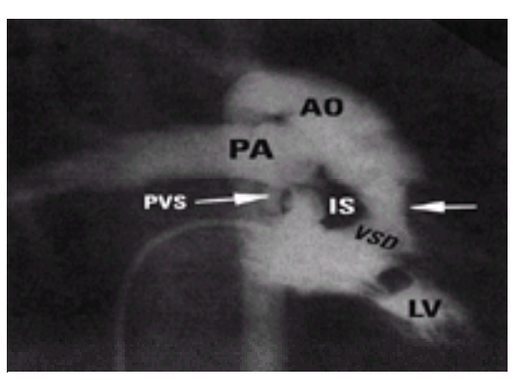
A group of complex congenital heart malformations characterized by connection of both atrioventricular valves to one ventricle are often designated as a double-inlet ventricle or single ventricle (1166,1167,1168,1169,1170,1171,1172,1173,1174,1175,1176,1177 and 1178) (*e*Fig. 30.0.49, *e*Fig. 30.0.50, and *e*Fig. 30.0.51). Most patients with a double-inlet left ventricle, all patients with a double inlet to a morphologically right or indeterminate ventricle, and all those with an absent atrioventricular connection are not candidates for a biventricular repair, but they are potential candidates for a one-ventricle or Fontan-type repair. This challenge is “tested” by the change in form and function known to occur in these hearts and vascular systems (1176,1179,1180,1181,1182,1183,1184 and 1185).



***e*FIGURE 30.0.49** Double-inlet left ventricle (LV) in a patient demonstrated by hepatoclavicular left ventriculogram. Both atrioventricular valves (AVVs) connect to the dominant LV.

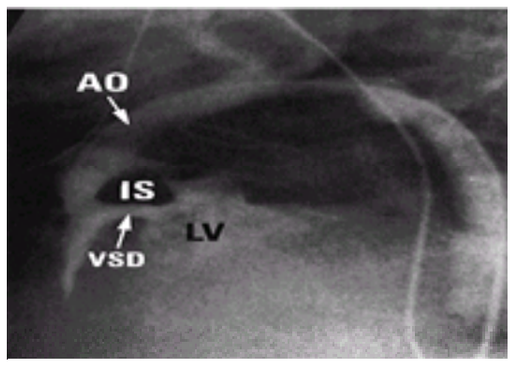


***e*FIGURE 30.0.50** Double-inlet left ventricle (LV), a left-sided rudimentary right ventricle (RV), and discordant ventriculoarterial connections. Note the excellent-caliber main pulmonary artery (PA) and pulmonary valve stenosis (PVS). AVV, atrioventricular valve; VSD, ventricular septal defect.



***e*FIGURE 30.0.51** Another patient with double-inlet left ventricle (LV), a left-sided rudimentary right ventricle, discordant ventriculoarterial connections, and pulmonary valve stenosis (PVS). The subaortic infundibulum is mildly narrowed as well (*arrow*). AO, aorta; IS, infundibular septum; PA, pulmonary artery; VSD, ventricular septal defect.

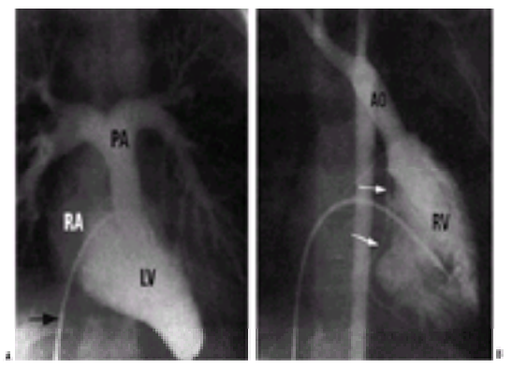
Most patients with a double-inlet ventricle have a dominant ventricle of left ventricular morphology receiving both atrioventricular valves, a left-sided rudimentary right ventricle, and transposed or discordantly connected great arteries (*e*Fig. 30.0.50, *e*Fig. 30.0.51, and *e*Fig. 30.0.52). Many have valvar or subvalvar pulmonary stenosis, but some have torrential pulmonary blood flow and pulmonary artery hypertension. The strategies to preserve the functional integrity of the myocardium, to avoid ventricular hypertrophy, and to preserve the anatomy and hemodynamics of the pulmonary vascular bed are fully discussed elsewhere. Indeed, the once common strategy of banding the pulmonary trunk in patients with no pulmonary outflow tract obstruction and excessive pulmonary blood flow and pulmonary artery hypertension is largely eschewed to avoid myocardial hypertrophy, a risk factor for those considered for the Fontan operation (1186,1187,1188,1189,1190 and 1191), although some still advocate banding with a rapid conversion to a bidirectional cavopulmonary connection and a proximal pulmonary artery aortic connection (1192,1193). The current surgical results for the Fontan procedure for most patients with double-inlet ventricle or for those patients with more complex anomalies of the atrioventricular junction, although quite good, do not reflect the reality that many patients do not survive to a Fontan procedure or are excluded from consideration because they do not meet the criteria (1194,1195,1196,1197 and 1198).



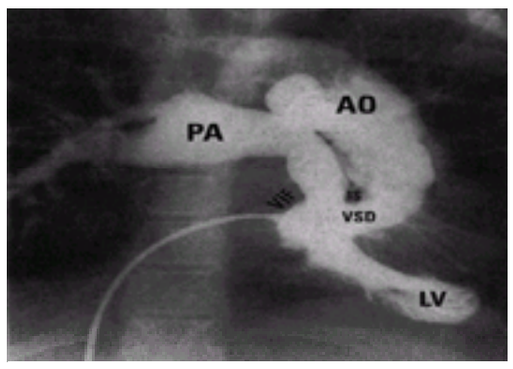
***e*FIGURE 30.0.52** Severe subaortic stenosis in this patient with a univentricular atrioventricular connection, discordant ventriculoarterial connections, and a small ventricular septal defect (VSD). Note the enlarged infundibular septum (IS). AO, aorta; LV, left ventricle.

Congenitally Corrected Transposition of the Great Arteries

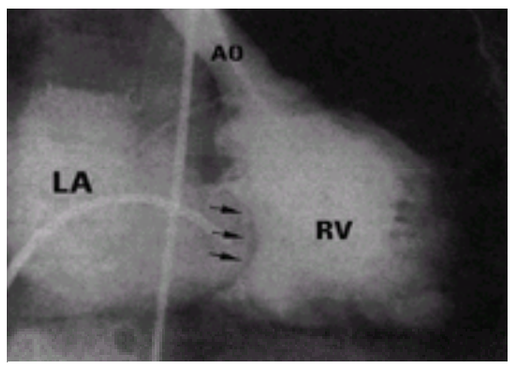
Congenitally corrected transposition of the great arteries is an uncommon cardiac anomaly that, despite its designation as congenitally corrected, rarely occurs in isolation and thus should not be considered "corrected" (1199,1200,1201,1202,1203,1204,1205,1206,1207,1208,1209,1210 and 1211). This condition is characterized by atrioventricular and ventriculoarterial discordance (*e*Fig. 30.0.53). In the patient with normal or solitus atrial arrangement, the systemic venous return connects with the morphologically right atrium. This atrium is connected by a mitral valve with the morphologically left ventricle, which in turn supports a discordantly connected transposed pulmonary artery (*e*Fig. 30.0.53). There is mitral valve–pulmonary valve fibrous continuity, indicative of a poorly defined subpulmonary infundibulum. The left atrium receiving the pulmonary veins connects through a tricuspid valve with its normal septal attachments with the morphologically right ventricle, which in turn supports a transposed aorta. The aortic valve is anterior and to the left of the pulmonary valve; a subaortic infundibulum is well developed, promoting discontinuity between the tricuspid and aortic valves. The effects of ventricular inversion are potentially corrected by the associated transposition of the great arteries, but in reality, most patients with so-called congenitally corrected transposition of the great arteries have abnormalities singularly or in combination involving the ventricular septum, the left ventricular or pulmonary outflow tract, and the morphologically tricuspid valve (1199,1200,1201,1202,1203,1204,1205,1206,1207,1208,1209,1210 and 1211) (*e*Fig. 30.0.54 and *e*Fig. 30.0.55). The specialized conduction tissue in the patient with atrioventricular and ventriculoarterial discordance has received considerable and appropriate attention because of the striking difference in the position of the atrioventricular node and penetrating bundle, with the important surgical and natural history implications (1212,1213,1214,1215,1216,1217,1218,1219 and 1220). The prevalence of this condition ranges from 0.60% to 0.95% (1221,1222,1223,1224 and 1225).



***e*FIGURE 30.0.53** Atrioventricular and ventriculoarterial discordance. **A:** This frontal left ventriculogram shows the double discordance with the right artery (RA) connected to the left ventricle (LV) and LV-to–pulmonary artery (PA) connection. The arrow points to the catheter in the inferior vena cava. **B:** This frontal right ventriculogram shows the levopositioned discordantly connected aorta (AO). Arrows note the coronary artery in the left-sided atrioventricular groove. RV, right ventricle.



***e*FIGURE 30.0.54** Double discordance, ventricular septal defect (VSD), and left ventricular outflow tract obstruction shown in this frontal left ventriculogram. AO, aorta; IS, infundibular septum; LV, left ventricle; PA, pulmonary artery; VIF, ventricular infundibular fold.



***e*FIGURE 30.0.55** Double discordance and severe left atrioventricular valve (*arrows*) regurgitation shown by this frontal right ventriculogram. AO, aorta; LA, left atrium; RV, right ventricle.

The heart position and its apex may be normal (levocardia) or in the midline (mesocardia), but in approximately 20% of patients with congenitally corrected transposition of the great arteries, the cardiac apex is predominantly right-sided (i.e., dextrocardia). The atrial situs is solitus in approximately 92% to 95% of patients; an inverse atrial situs was recorded in 5% to 8%. The most commonly associated anomalies in patients with congenitally corrected transposition of the great arteries include (a) ventricular septal defect, (b) pulmonary outflow tract obstruction, (c) dysplasia and displacement of the left or systemic atrioventricular valve, or (d) combinations of these associated lesions (1199,1200,1201,1202,1203,1204,1205,1206,1207,1208,1209,1210 and 1211) (*e*Table 30.0.7). Furthermore, intrinsic to hearts exhibiting atrioventricular discordance is a particularly fragile specialized conduction system. It is the unusual disposition of the conduction tissue that predisposes patients with atrioventricular discordance to spontaneous heart block, occurring in approximately 4% of patients with this condition per year (1226).

***e*TABLE 30.0.7** COMMONLY ASSOCIATED MALFORMATIONS IN HEARTS WITH CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES
Systemic (tricuspid) atrioventricular valve regurgitation
Abnormal atrioventricular conduction tissue
Left ventricular outflow tract obstruction
Ventricular septal defect

Even in patients with congenitally corrected transposition of the great arteries without major associated abnormalities, spontaneous onset complete heart block is always a hazard.

Diagnosis and Therapy

The clinical findings in patients with congenitally corrected transposition of the great arteries have been amply reviewed elsewhere (1199,1200,1201,1202,1203,1204 and 1205,1209,1210 and 1211,1225). For many patients with this disorder, the clinical suspicion of this diagnosis is readily confirmed by cross-sectional echocardiography and angiocardiography (1201,1202,1204,1209,1210 and 1211).

Congenitally malformed hearts are well known to change in form and function, particularly patients with congenitally corrected transposition of the great arteries. There are considerable data showing that progressive regurgitation of the morphologically tricuspid valve, the systemic atrioventricular valve, is well known in these patients (1201,1202,1204,1209,1210,1227,1228,1229 and 1230). This change in the function of the morphologically tricuspid valve has been observed before reparative surgery, after repair. In addition, the function of the morphologically right ventricle, the systemic ventricle, demonstrates in many of these patients progressive deterioration regardless of whether major associated anomalies are present (1229,1230,1231,1232 and 1233). Thus, it is not surprising that many ask, Can the morphologically right ventricle function as the systemic right ventricle in the long term? Although some individuals with congenitally corrected transposition of the great arteries survive into the seventh or eighth decades of life, the natural or modified history of many patients is clouded by the reality of progressive regurgitation of the systemic atrioventricular valve, deterioration of the systemic and morphologically right ventricle, or both (1201,1202,1204,1209,1210,1227,1228,1229,1230,1231,1232,1233,1234,1235 and 1236).

Surgical Intervention

Until the past few years, conventional surgery included (a) closure of the ventricular septal defect, (b) closure of the ventricular septal defect and interposition of a conduit between the morphologically left ventricle and pulmonary artery in those with ventricular septal defect and tunnel-form left ventricular outflow tract obstruction, (c) replacement of the severely regurgitant tricuspid valve, or (d) some combination of these (1208). Concerns about the function and progressive deterioration of both the morphologically tricuspid valve and right ventricle led to the novel surgical approach of a double-switch procedure (1237,1238,1239,1240,1241,1242 and 1243). When this extensive surgery is successful, the morphologically right ventricle faces a lower afterload, the pulmonary circulation, and improvement in both the function of the tricuspid valve and right ventricle may be anticipated. The double-switch operation takes two major forms: (a) In patients who do not have important pulmonary outflow tract obstruction, an atrial switch of the Senning or Mustard type and a classic arterial switch are performed; (b) in patients with important pulmonary outflow tract obstruction and a perimembranous outlet ventricular septal defect, an atrial switch of the Senning or Mustard type and a “ventricular” switch are performed. The morphologically left ventricle is tunneled through the ventricular septal defect to the aorta (the Rastelli concept); the main pulmonary trunk is divided or ligated, and continuity between the morphologically right ventricle and pulmonary artery is usually achieved with a valved conduit. Finally, because of the significant heterogeneity in hearts with atrioventricular and ventriculoarterial discordance, surgical intervention must be individualized.

Right Atrial Isomerism

A group of patients exists in whom it is difficult, if not impossible, to assign visceral situs because the abdominal viscera are not lateralized, or at least are incompletely lateralized (1244,1245,1246,1247,1248,1249,1250,1251,1252,1253,1254,1255,1256,1257,1258,1259,1260,1261, 1262,1263 and 1264) (*e*Fig. 30.0.3, *e*Fig. 30.0.4, and *e*Fig. 30.0.5). Such patients are considered to have visceral heterotaxia (from the Greek words *heteros*, other than, and *taxis*, arrangement; i.e., other than the normal arrangement). The liver is more symmetric than normal, and the bowel is not fixed in the normal way (1250,1251,1252 and 1253). In these same patients, the thoracic contents also often have a degree of symmetry, with both major bronchi having the appearance of a right mainstem bronchus (so-called bilateral eparterial bronchi) or left mainstem bronchus (so-called hyparterial bronchi) (1245,1247,1253,1255). Frequently, each of the lungs is trilobed in patients with bilateral eparterial bronchi, resembling the right lung, and bilobed and like the left lung in patients with hyparterial bronchi, although lobation is considerably more variable in this setting than the character of the bronchi. In patients with incomplete lateralization of visceral and thoracic contents, the atrial appendages are also not clearly lateralized, and in many of these patients both atrial appendages look like a morphologically right atrial appendage or a morphologically left atrial appendage, thus the designation by some of *atrial isomerism* to characterize these hearts. In 1955, Ivemark (1244) helped to define those complex cardiac malformations associated with splenic agenesis, indeed establishing the concept of the splenic agenesis or asplenia syndrome (1249).

It has also long been appreciated that the syndrome of so-called visceral heterotaxia includes severe and characteristic malformations of the heart, frequently but not invariably associated with malformations of the spleen (i.e., asplenia and polysplenia among others) (1244,1245,1246,1247,1248,1249,1250,1251,1252,1253,1254,1255,1256,1257,1258,1259,1260,1261, 1262,1263 and 1264). In patients with either right or left atrial isomerism, but particularly right, visceral heterotaxy or abnormal lateralization has been and still is a clinical marker of the splenic syndromes. Common to most of these patients is nonfixation of the gastrointestinal tract, varying degrees of malrotation, and not uncommonly an annular pancreas. In a survey of patients with asplenia, one-fourth had anomalies of the genitourinary system. A major concern to patients with polysplenia is the known association with extrahepatic biliary atresia and a short pancreas as well (1265,1266,1267,1268,1269,1270,1271,1272 and 1273). Indeed, up to 25% of babies with biliary atresia bear associated malformations that most often cluster in the polysplenia syndrome. Among patients with visceroatrial heterotaxia, definition of splenic function or hypofunction must be ascertained so that prophylaxis against overwhelming infection can be instituted (1274,1275,1276 and 1277).

Complex cardiac malformations should be anticipated in patients with visceroatrial heterotaxia, especially those with right atrial isomerism and asplenia. There is considerable literature defining the range of the cardiac malformations in the cardiosplenic isomerism syndromes and in the noncardiac malformations as well (1244,1246,1248,1249,1253,1256,1260,1262,1263,1278). The prostaglandin challenge is particularly helpful in this assessment. Abnormalities of systemic venous connections are particularly frequent.

Diagnosis and Treatment

One can suspect the diagnosis of visceroatrial heterotaxia and complex heart malformations in any cyanotic infant in whom the visceral situs is uncertain from a plain chest radiograph, in a cyanotic infant with discordancy between heart position and apparent visceral situs, in an infant whose echocardiogram suggests abnormal juxtaposition of the abdominal inferior caval vein and aorta, in an infant with azygous continuation of the inferior caval vein, or in any infant who has complex congenital heart disease in which the echocardiogram defines the spectrum of heart malformations listed previously, or in whom the echocardiogram suggests atrial appendages of like morphology and appearance (1278,1279,1280,1281,1282,1283,1284,1285,1286,1287,1288,1289,1290,1291,1292,1293,1294,1295, 1296 and 1297). The appearance of normal visceral lateralization on a chest radiograph (i.e., left-sided gastric bubble and right-sided hepatic shadow) does not exclude the consideration of right or left atrial isomerism. A leftward and superior P-wave axis is particularly common in patients who have left atrial isomerism and abnormal formation of the sinoatrial node.

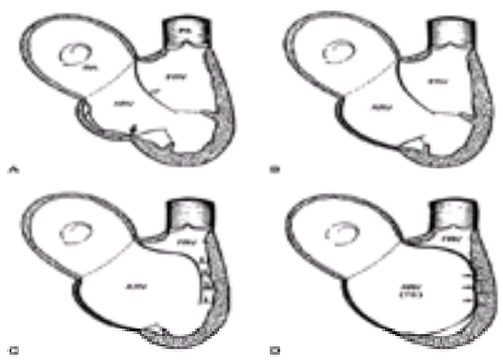
Whereas an increasing number of reports have documented surgical successes in patients with right atrial isomerism, most address only patients undergoing a one-ventricle type of repair. Long-term survival in this group is improved, with 44% alive at 5 years (1298,1299). Thus, despite some surgical successes with a Fontan-type repair or, less commonly, a biventricular repair, overall survival is poor, reflecting the egregious nature of the complex heart malformations.

Other Conditions

Ebstein’s Anomaly of the Tricuspid Valve

This is an uncommon (prevalence of 0.5% to 1.0% of congenital heart disease) congenital abnormality of the tricuspid valve that is characterized by variable degrees of displacement and dysplasia of the mural and septal leaflets of the tricuspid valve (1300,1301,1302,1303,1304,1305,1306,1307,1308,1309,1310,1311,1312,1313,1314,1315,1316,1317, 1318,1319,1320,1321,1322,1323,1324 and 1325). Such displacement and dysplasia of the tricuspid valve may be mild, and patients have survived to the seventh and eight decades of life. At the other end of the spectrum are the fetuses with florid tricuspid regurgitation developing severe hydrops with an intrauterine death. Some newborns with extreme tricuspid regurgitation may present with profound hypoxemia and no forward flow from the right ventricle to the pulmonary artery, and the clinical dilemma posed by these newborns is to determine whether the pulmonary atresia is functional or organic. These infants often have gigantic hearts virtually obscuring both lung fields. The right ventricle of this particular group of infants is severely disadvantaged, being profoundly thinned and devoid of right ventricular musculature, especially in the so-called atrialized zone of the right ventricle, that portion of the right ventricle between the right atrioventricular valve and the displaced tricuspid valve. Other expressions of Ebstein’s anomaly of the

tricuspid valve include those with so-called linear distal attachments posing obstruction to pulmonary blood flow (eFig. 30.0.56). The most severe expression of distal attachments is the imperforate form of Ebstein's anomaly, producing an uncommon form of tricuspid atresia.

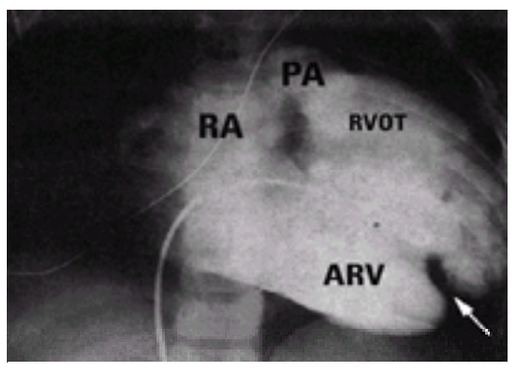


***e*FIGURE 30.0.56** Diagram showing Ebstein's anomaly of the tricuspid valve and distal linear attachments. **A:** Moderate displacement of septal and posterior leaflets (*closed arrow*) with mobile anterior leaflet (*open arrow*). **B:** Marked displacement of septal and posterior leaflets with mobile anterior leaflet. **C:** Nonmobile anterior leaflet with chordal tethering (*arrows*) to ventricle. **D:** Severely stenotic or imperforate Ebstein's anomaly (*arrows*). ARV, atrialized right ventricle; FRV, functional right ventricle; PA, pulmonary artery; RA, right atrium; TS, tricuspid sac.

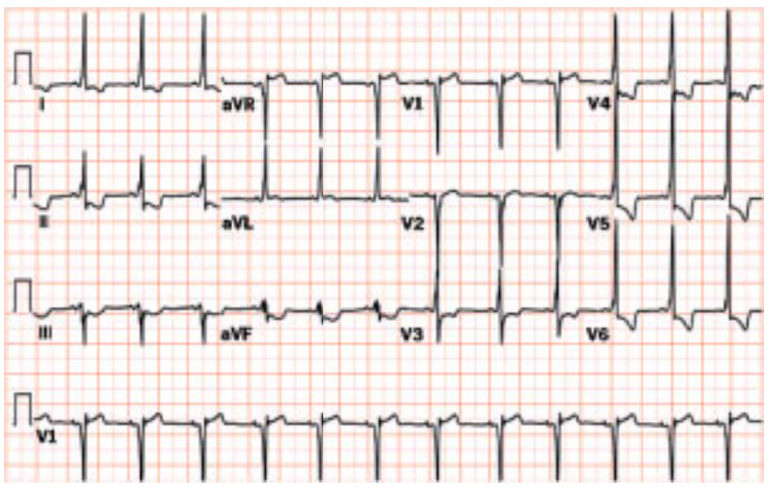
The most common associated anomaly in patients with Ebstein's anomaly is the secundum atrial septal defect, although many forms of congenitally malformed hearts have been found in association with Ebstein's anomaly, including tetralogy of Fallot, atrioventricular septal defect, ventricular septal defect, pulmonary stenosis, and atresia (1315,1316 and 1317). In addition, left ventricular myocardial abnormalities and mitral valve prolapse may confound the clinical course and management of patients with this disorder (1316,1317).

Diagnosis

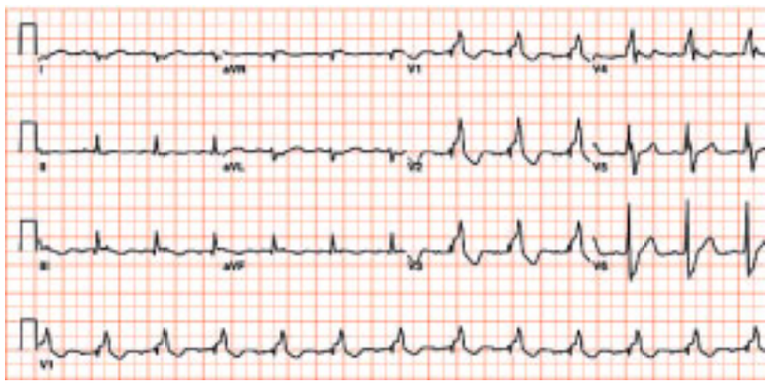
The diagnosis of Ebstein's anomaly of the tricuspid valve should be considered in any patient with tricuspid regurgitation, and especially those with evidence of preexcitation (1326). The findings of a patient with a murmur of tricuspid regurgitation, a triple or quadruple rhythm with multiple clicks, with or without cyanosis, is presumptive of this diagnosis. The heart size varies from only mildly enlarged to severe heart enlargement (eFig. 30.0.57). Echocardiography is nearly always definitive.



***e*FIGURE 30.0.57** Right ventricular angiogram showing a notch of the displaced tricuspid valve (*arrow*) on the diaphragmatic surface of the right ventricle, typical of Ebstein's anomaly of the tricuspid valve. ARV, atrialized right ventricle; PA, pulmonary artery; RA, right atrium; RVOT, right ventricular outflow tract.

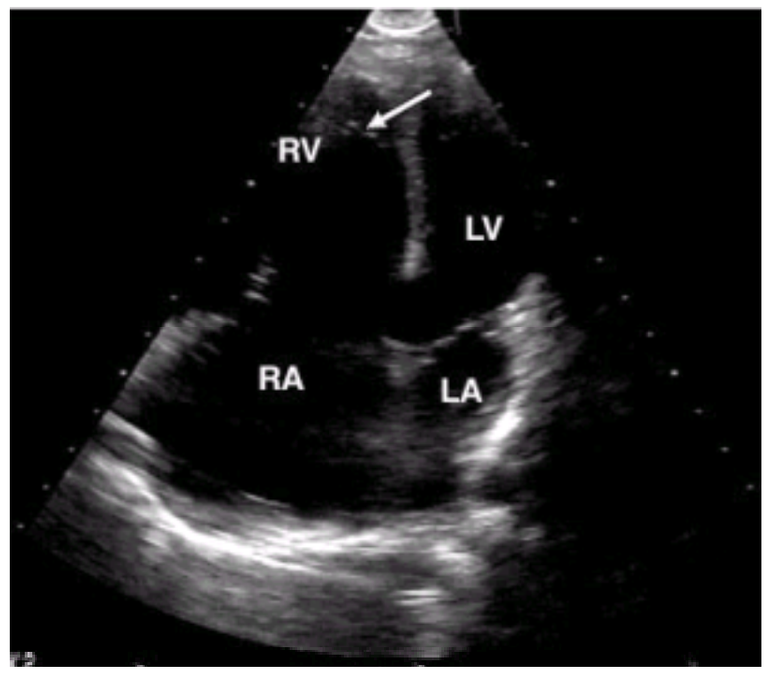


Wolff-Parkinson-White syndrome. Eleven-year-old patient with manifest preexcitation consistent with Wolff-Parkinson-White.

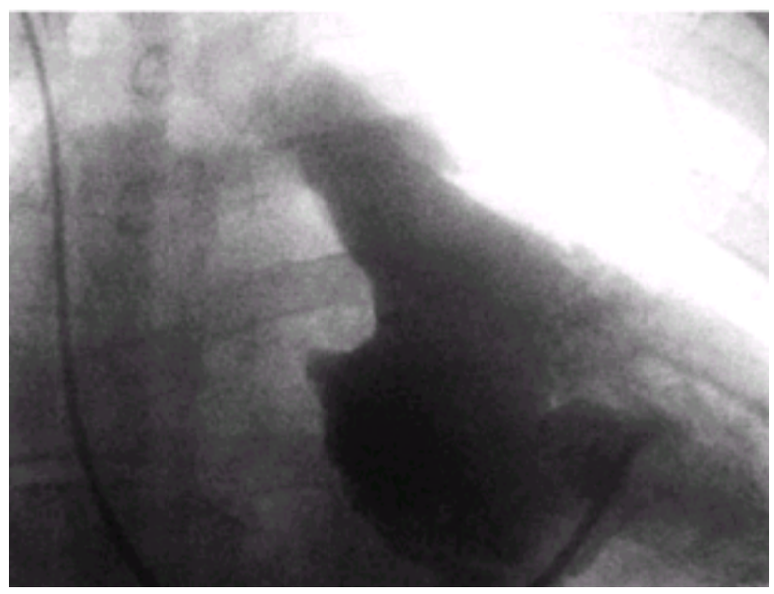


A 47-year-old male patient with Ebstein's anomaly.

A 19-year-old male patient with Ebstein's anomaly.



Ebstein's anomaly of the tricuspid valve. Note marked apical displacement of the tricuspid leaflets, especially the septal leaflet. The arrow designates the septal leaflet of the tricuspid valve.

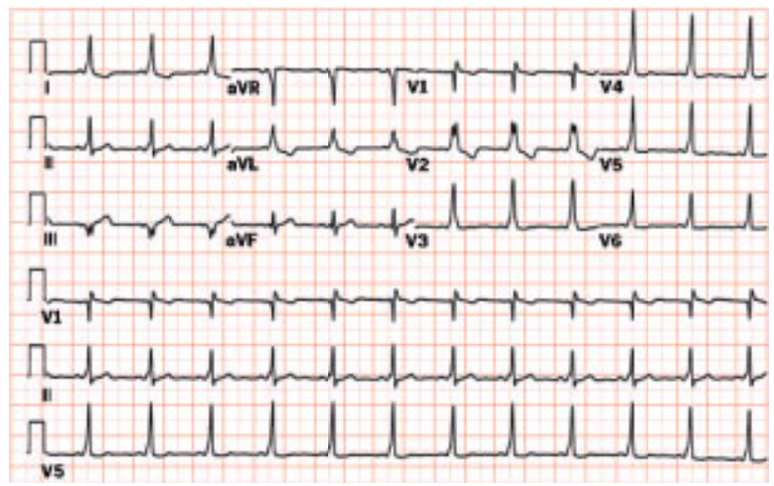


Epstein's anomaly. Right anterior oblique projection of a right ventriculogram demonstrating Epstein's anomaly.

Prognosis

For infants with gigantic hearts and functional or organic pulmonary atresia, the outlook is poor (1327), although some demonstrate spontaneous improvement coincident with maturation of the pulmonary vascular bed. The significant predictors of mortality in a bivariate analysis include the presence of functional or organic pulmonary atresia, increased displacement of the tricuspid valve and more severe tricuspid regurgitation, larger atrioventricular septal defect, and reduced left ventricular function (1327).

Wolff-Parkinson-White syndrome, type B, is particularly well known to be associated with Ebstein's anomaly of the tricuspid valve and to complicate its course (1326). For infants who die in the newborn or neonatal period with hypoxemia and congestive heart failure, results of either tricuspid valvuloplasty or tricuspid valve replacement have been dismal, likely reflecting the severe impact of this disorder on the right ventricular myocardium (1311,1316,1317). Cardiac replacement is certainly one alternative, as is the novel approach taken by Starnes and associates of closing the tricuspid valve, placing an arterial shunt and thus putting the patient on a one-ventricle repair tract (1328). Fortunately, probably less than 20% to 30% of patients with Ebstein's malformation of the tricuspid valve require surgery in the first decade of life; surgery is well tolerated in older patients (1329).



Wolff-Parkinson-White syndrome. Note short PR interval with classic delta wave due to accessory pathway conduction.

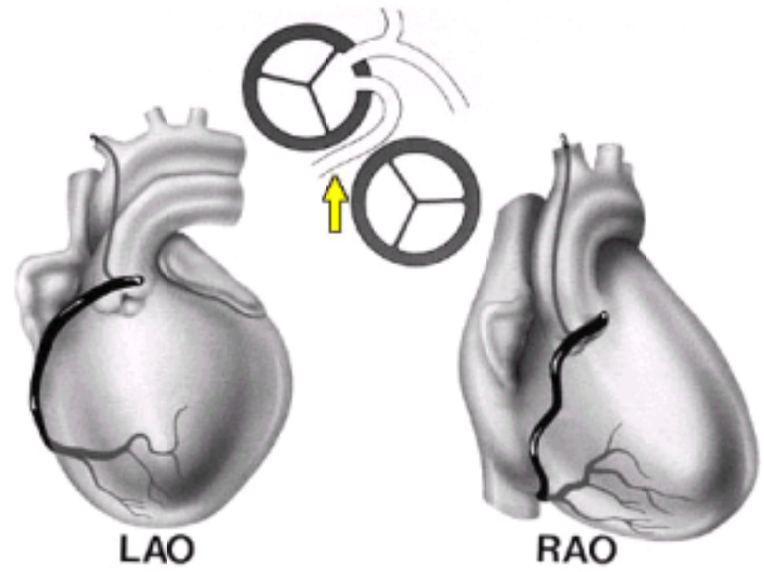
Congenital Anomalies of the Coronary Arteries

It is important to recognize that anomalies of the coronary arterial circulation may coexist with other congenital heart anomalies and may have significant implications in planning surgical intervention (*e*Table 30.0.8). Therefore, a complete evaluation of the preoperative patient includes an assessment of the origin and distribution of the coronary arteries. Because of its usual presentation in infancy, anomalous origin of the left coronary artery from the main pulmonary artery deserves more extensive comment.

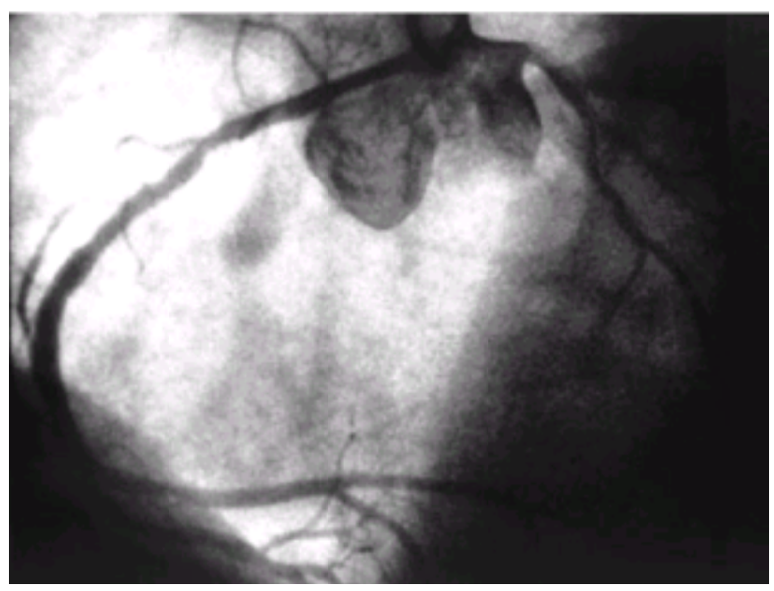
***e*TABLE 30.0.8** CONGENITAL ANOMALIES OF THE CORONARY ARTERIES

Coronary arterial ostia	High origin of coronary artery
Position	Both coronaries arise from the same sinus of Valsalva
	Common ostial origin, closely related above a commissure
	Acute angular origin of a coronary artery
	Single coronary artery
	Absent proximal connection of the coronary artery
Number	Separate origin of the artery to the conus
	Separate origin of the circumflex
Single coronary artery	Several variations in origin, course, and distribution exist

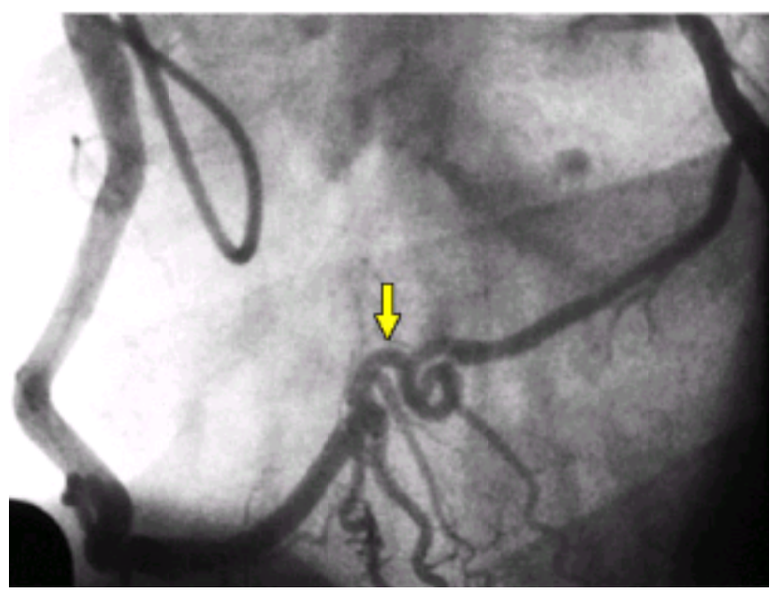
Stenosis or atresia of the ostium	
Anomalous origin of the coronary arteries from the main pulmonary artery	Left or, more rarely, right system
Abnormal origin and distribution of epicardial branches	For example, origin of the circumflex from the right coronary artery Left coronary artery coursing between the great vessels
Coronary artery fistulae	To the cardiac chambers, coronary sinus, superior vena cava, or pulmonary arteries Most connect to right-sided chambers
Obstructive lesions	Mural left anterior descending coronary artery associated with sudden death Obstructive lesions seen in association with pulmonary atresia and intact ventricular septum with fistulous connections
Aneurysms	Congenital aneurysms occur; however, Kawasaki's disease most common acquired condition



Anomalous origin of the right coronary artery. In the left panel, the left anterior oblique projection shows the right coronary artery originating from the left sinus of Valsalva. The course of the right coronary artery passes between the aorta and pulmonary artery (*yellow arrow*). In the right panel the right anterior oblique projection of this same anomalous coronary artery is illustrated.



Angiogram showing anomalous origin of the right coronary artery. In this left anterior oblique cranial projection the right coronary artery originates from the left sinus of Valsalva and passes between the aorta and pulmonary artery.



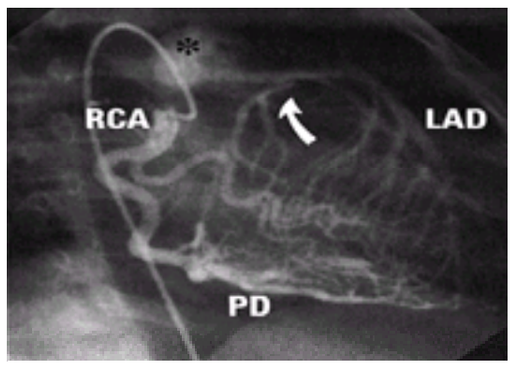
Anomalous connection of right coronary artery to left circumflex artery. This anomaly is known as the Miller connection, as shown in this shallow left anterior oblique projection (*yellow arrow*).

Video 30.24 Anomalous origin of the right coronary artery from the left coronary sinus. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery

Anomalous origin of a coronary artery from the pulmonary artery, a rare anomaly, usually involves the left coronary artery, but it also has been noted to occur with the right system, rarely both (eFig. 30.0.58). Early in neonatal life the distribution of the anomalous vessel is perfused with the lower saturated blood of the mixed venous (pulmonary artery) return; however, this occurs at relatively higher pressures as a result of the higher pulmonary pressures in the newborn period. As the pressure in the pulmonary arterial system falls, the perfusion pressure to the anomalous coronary artery also falls, and myocardial perfusion relies heavily on collateral vessels from the right coronary artery system. If extensive, the collateral flow can result in steal from the coronary to the pulmonary circulation and a left-to-right shunt. The effect of this process on myocardial perfusion and function is varied and can result in one of several clinical presentations. Usually, the infant is brought to medical attention within the first 4 months of life with angina-like symptoms [ashen color (especially after feeding), tachypnea, diaphoresis, failure to thrive] or severe ischemic cardiomyopathy. A murmur of mitral insufficiency may also be present because of ischemic papillary muscle dysfunction and annular dilatation. The chest radiograph typically demonstrates pulmonary venous congestion with cardiomegaly, and the electrocardiogram suggests anterolateral myocardial infarction (1330). It can be

difficult to distinguish this presentation from that of acute myocarditis or cardiomyopathy from another cause. Echocardiography with pulsed and color flow Doppler establishes the diagnosis in most instances; however, transesophageal echocardiography and cardiac catheterization with aortography and selective coronary angiography can be of assistance (1331,1332,1333,1334,1335 and 1336). A careful assessment of the origin of the coronary arteries must accompany the complete investigation of any patient presenting, particularly in infancy, with dilated myocardial dysfunction. Selective angiography also serves to assess the nature of the collateral circulation as well as the status of myocardial perfusion.



***e*FIGURE 30.0.58** Anomalous left coronary artery originating from the main pulmonary trunk. Selective right coronary artery (RCA) injection with filling of the posterior descending coronary artery (PD) and then the left anterior descending coronary artery (LAD), which connects to the pulmonary trunk (*asterisk*). The arrow points to the collateral connection to the LAD.

Older infants and children may present with a murmur of mitral insufficiency, and those with well-developed collateral circulation may present late with a continuous murmur (1337). Some instances have been detected unexpectedly at postmortem examination in an adult with no history of coronary anomaly who suddenly collapsed.

Surgical treatment of this condition has evolved over time. Most institutions favor the maintenance of a two-coronary system for myocardial perfusion, and so the previously popular ligation of the coronary artery at the origin from the pulmonary artery to minimize the steal phenomenon has fallen out of favor (1338,1339). A two-coronary system is preserved by a variety of techniques, including the creation of an aortopulmonary tunnel, reimplantation, and ligation with saphenous or arterial coronary bypass (1340,1341,1342,1343,1344 and 1345). Although results of this approach have been gratifying, concern remains with respect to persistent problems in myocardial perfusion in follow-up (1346,1347).

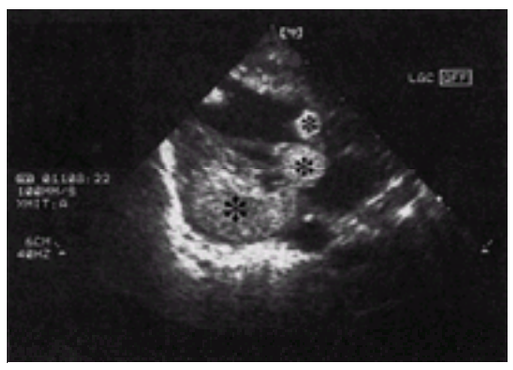
The diagnosis of anomalous left coronary artery from the pulmonary artery often can be made on the basis of typical clinical, electrocardiographic, and radiographic findings and confirmed by echocardiography (1348). Retrograde aortography or selective right coronary arteriography may be needed in some cases to establish this diagnosis firmly (1349,1350).

Cardiac Tumors

Cardiac tumors in the pediatric population are extremely uncommon, and the most common type of tumor in the neonate and young infant is extremely uncommon in the adult and vice versa (1351,1352,1353,1354,1355,1356,1357,1358,1359,1360,1361,1362,1363,1364,1365,1366,1367,1368, 1369,1370,1371,1372,1373,1374,1375,1376,1377,1378,1379,1380,1381,1382,1383,1384,1385,1386, 1387,1388,1389,1390,1391,1392,1393,1394,1395,1396,1397,1398,1399,1400, 1401,1402,1403,1404 and 1405).

Rhabdomyoma

The most common intracardiac tumor of the neonate is the rhabdomyoma, followed by the cardiac fibroma (1351,1356,1358,1360,1382,1384,1389,1390,1391,1392,1393,1394,1395,1396,1397,1398,1399,1400, 1401,1402 and 1403). Cardiac rhabdomyoma is often associated with tuberous sclerosis (1351,1353,1355,1356,1357 and 1358,1361,1362,1367,1371,1378,1380,1383,1392,1395,1403) (*e*Fig. 30.0.59). The tuberous sclerosis complex is an autosomal dominant disorder with a high mutation rate, affecting the brain, heart, skin, kidneys, and other organs. These histologically benign tumors consist of vacuolated cells resembling spider cells and contain glycogen. The cardiac rhabdomyoma tends to be multiple and to involve the intraventricular septum and the walls of the heart; it appears to be filling defects in the cavities of both ventricles, with a special predilection to involving the left ventricular outflow tract. These tumors may be strategically placed to interfere with cardiac filling, and tumors approximating the right atrioventricular junction have simulated tricuspid atresia, and those obstructing the mitral valve have simulated mitral atresia and the hypoplastic left heart syndrome and have produced severe myocardial ischemia. Subaortic stenosis has been a fairly common finding in the infant with cardiac rhabdomyomata, with pedunculated tumors in the subaortic vestibule. Superior or inferior caval vein obstruction is well recognized in the infant with cardiac rhabdomyoma. Patients with cardiac rhabdomyomas may present with almost any type of atrial or ventricular dysrhythmia, including preexcitation (1372,1378,1391,1392). Fetal dysrhythmias or hydrops may be the presenting features in some patients with cardiac rhabdomyoma. Cardiac rhabdomyomas are often diagnosed in the first year of life, and there is increasing experience with fetal diagnosis of these tumors. Another association of the cardiac rhabdomyoma is with the basal cell nevus syndrome (1404).



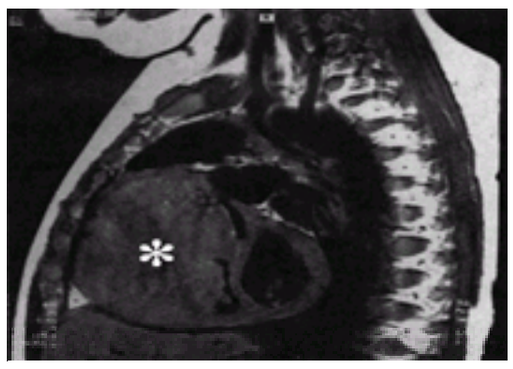
***e*FIGURE 30.0.59** Multiple cardiac rhabdomyoma (*asterisks*) in a newborn with tuberous sclerosis.

One of the peculiar aspects of these tumors is the observation of spontaneous regression (1353,1355,1364,1368,1374,1375 and 1376,1379,1380 and 1381,1395,1396,1400,1401,1403). Thus, surgery is recommended only for patients with severe hemodynamic compromise or refractory dysrhythmias. Even with regression of cardiac rhabdomyomas, a substantial number of patients are still disadvantaged by cerebral involvement.

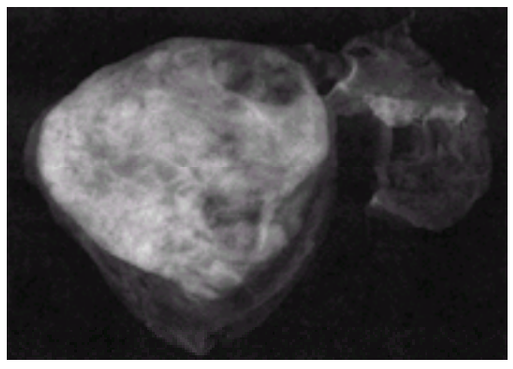
Cardiac Fibroma

The cardiac fibroma is second in frequency after the cardiac rhabdomyoma in infancy and childhood (1406,1407,1408,1409,1410,1411,1412,1413,1414,1415,1416,1417,1418,1419,1420,1421,1422, 1423,1424,1425,1426 and 1427) (*e*Fig. 30.0.60 and *e*Fig. 30.0.61). The mean age at diagnosis is 13 years, ranging from 1 day to 56 years. More than one-third of the patients were younger than 1 year at diagnosis. This tumor, usually solitary, most often involves the left ventricular free wall or septum. Involvement of the right ventricular free wall and cavity is less frequent. The cardiac fibroma is not encapsulated, and its tissue blends or merges with normal myocardium. Noninvasive assessment by MRI usually can differentiate between fibroma and rhabdomyoma. This tumor is benign, but continued slow growth may cause conduction defects, may spread to the ventricular free wall, and may result in atrioventricular valve inflow or arterial outflow tract obstruction. Cardiac fibroma has presented in the neonate as severe congestive heart failure. Rarely, this tumor may simulate cyanotic heart disease in the newborn because of septal and right ventricular involvement, promoting right-to-left shunting at atrial level. Spontaneous regression of the type seen in the patient with cardiac rhabdomyoma has not been observed in the patient with cardiac fibroma, and operative intervention is usually required. Ventricular tachycardia and an abnormal cardiac silhouette on chest radiography in the infant and child may be considered presumptive evidence of a cardiac fibroma (1412). Even less

common are intrapericardial teratoma (1428,1429,1430,1431 and 1432) and myxoma (1433,1434,1435,1436,1437,1438,1439,1440,1441 and 1442).



***e*FIGURE 30.0.60** A huge cardiac fibroma (*asterisk*) is demonstrated by this magnetic resonance imaging study.



***e*FIGURE 30.0.61** Huge cardiac fibroma from an infant who successfully underwent cardiac transplantation.

Congenital Abnormalities of the Mitral Valve Producing Stenosis or Regurgitation

Previous sections have described the mitral valve abnormalities associated with rheumatic heart disease and prolapse, with and without associated disease states involving connective tissues. This section focuses primarily on congenital mitral valve conditions, excluding prolapse.

Congenital Mitral Stenosis

Obstruction to mitral valve flow can occur at the supravalvar level, annular level, free valve margin, and at the tensor apparatus or papillary muscle level. Typically, the mitral valve demonstrates thickened rolled-valve leaflet edges with short thick chordae and papillary muscles that are hypoplastic and close to one another. When the papillary muscles fuse, the so-called parachute mitral valve is formed. Typically, the abnormalities coexist with other left-sided lesions, including obstructive abnormalities of the left ventricular outflow tract and coarctation of the aorta. Leaflet and chordae dysplasia also may result in coaptation abnormalities that lead to valvar regurgitation. Approximately 40% of patients in an autopsy series had truly hypoplastic valves with little leaflet and chordal dysplasia. This type of abnormality was most commonly associated with severe left ventricular outflow tract abnormalities (1443). At the other end of the spectrum is the perforate but severely dysplastic valve associated with the hypoplastic left heart syndrome with a diminutive annulus and leaflets, diminutive or absent chordae, and papillary muscles that are incorporated into the fibroelastic scar of the ventricle.

The supramitral ring consists of a fibrous tissue that arises above the leaflets of the mitral valve but, in contrast to the membrane of cor triatriatum, remains below the level of the orifice of the left atrial appendage. The classic description by Shone et al. (1444) of the ring occurred as a complex with a parachute mitral valve, subaortic stenosis, and coarctation of the aorta. In the parachute mitral valve, the anterolateral papillary muscle is usually absent and has a common insertion of thick shortened chordae.

The timing of clinical presentation depends on the presence of associated lesions and the degree of obstruction to left ventricular inflow. This condition may have a profound effect on the nutritional status and growth of the patient. Other congestive symptoms include tachypnea, diaphoresis, poor feeding, cough, and frequent respiratory infections. Severe obstruction manifests with poor systemic perfusion and an active right ventricular heave resulting from elevated pulmonary artery pressures secondary to left atrial hypertension. An opening snap is rarely heard, as the leaflets are often severely dysplastic. Frequently, the pulmonary component of the second heart sound is more intense, and there is a mid-diastolic murmur with presystolic accentuation in the setting of sinus rhythm.

In all instances, the electrocardiogram usually exhibits left atrial enlargement, with right ventricular hypertrophy indicating significant pulmonary hypertension. The left ventricular voltages may be reduced as a result of concurrent left ventricular hypoplasia. Echocardiography often provides the mainstay of diagnosis both in two-dimensional assessment of the anatomy and in the functional assessment of severity, recognizing that many previously described indices have not been validated in children (1445,1446,1447,1448 and 1449).

Medical management consists of decreasing pulmonary congestion and attention given to nutrition, infection, atrial arrhythmias, and embolic phenomena. If unresponsive to medical management, surgery is directed at primarily preserving native valve function while preserving its integrity. Repair of the native valve often is focused on modifying the annulus, leaflets, or chordae (1450,1451,1452,1453,1454,1455,1456,1457 and 1458). Papillary muscles are subject to commissurotomy and fenestration. If a double orifice exists that is adequate, it is best not to incise the bridging tissues. Supramitral rings are generally excised, taking care to avoid the circumflex coronary artery. The role of balloon valvotomy in the child with congenital stenosis is controversial, with some centers reporting good palliation; however, the results are less satisfying than procedures undertaken for rheumatic disease (1459,1460,1461,1462 and 1463). Transesophageal echocardiography is mandatory before proceeding with left atrial catheterization (1464). Mitral valve replacement is best undertaken after the age of 3 years with a mechanical valve as opposed to a bioprosthetic appliance (1465,1466). Difficulties exist in anticoagulation, especially in the setting of a changing diet with varying amounts of vitamin K.

Congenital Mitral Valve Regurgitation

Congenital mitral regurgitation is particularly uncommon (1467). In the morphologic assessment of the congenitally regurgitant mitral valve, virtually all aspects of the mitral valve, including abnormalities of the free valve margin, chordal apparatus, and papillary muscles, have been identified in the etiology of the regurgitation (1468,1469,1470,1471,1472,1473,1474,1475,1476,1477,1478,1479,1480,1481,1482,1483,1484,1485,1486,1487,1488,1489,1490,1491,1492,1493,1494,1495,1496,1497,1498,1499,1500,1501,1502,1503,1504,1505,1506,1507,1508,1509,1510,1511,1512,1513,1514,1515,1516,1517,1518,1519,1520 and 1521). Such abnormalities include dysplasia of the valve, double-orifice deficient leaflet tissue, isolated anterior cleft of the mitral valve, polyvalvular disease, displacement of the mitral valve of the Ebstein type, and the so-called anomalous mitral arcade. Mitral regurgitation can occur in the newborn period, reflecting a disordered transitional circulation (i.e., transient myocardial ischemia of the newborn) (1503,1504 and 1505). Papillary muscle ischemia and infarction in the infant with critically severe aortic stenosis have been well described (1521). Mitral regurgitation also has been identified in the newborn infant with myocarditis as well as other primary endomyocardial disorders. Usually, beyond the newborn period, infants with anomalous left coronary artery originating from the pulmonary artery or with atresia of the left coronary artery ostium and inadequate coronary artery collateralization develop papillary muscle ischemia or frank infarction with resultant mitral regurgitation. Mitral regurgitation has been observed in patients with coarctation of the aorta, representing either functional impairment of the left ventricle or congenital abnormalities of the mitral valve. In the infantile presentation of Marfan syndrome and severe mitral regurgitation, the mitral valve may exhibit features of dysplasia as well as prolapse. Mitral regurgitation can occur in the patient with Kawasaki's disorder, infective endocarditis, following trauma, and in the patient with chronic anemia.

The so-called anomalous mitral arcade (1484), which is responsible for this lesion, is characterized by connection of left ventricular papillary muscles to the anterior mitral leaflet, either directly or through the interposition of unusually short chordae (1485,1486,1487,1488,1489 and 1490). Enlarged thickened papillary muscles in

close approximation to the free valve margin of the mitral valve contribute to subvalvular obstruction. Although the anomalous mitral arcade is considered a disorder of the pediatric age group, it has been recognized in the adult (1488).

Among the causes of the congenital mitral regurgitation is the isolated cleft of the anterior leaflet of the mitral valve (1491,1492,1493,1494,1495,1496,1497,1498,1499,1500 and 1501). This disorder is quite different from the so-called cleft left atrioventricular valve in the patient with an atrioventricular septal defect (1499). The isolated cleft of the anterior mitral leaflet is characterized by a cleft dividing the anterior leaflet of the mitral valve into two portions with a normally positioned mitral annulus and intact atrioventricular muscular and membranous septum. This deformity of the mitral valve is an uncommon cause of congenital mitral regurgitation, but it has been identified in patients with ventricular septal defect, tetralogy of Fallot, tricuspid atresia, and others.

Double-orifice mitral valve is a condition in which two complete orifices are supported by their own tension apparatus (1502) and should be distinguished from a simple fenestration of a valve leaflet not supported by its own tension apparatus. The basic morphology is either central division into two orifices of equal size by a bridge of leaflet tissue or presence of an accessory orifice at a commissure or in a leaflet. The double-orifice mitral valve is a well-known morphologic finding in the patient with an atrioventricular septal defect, but a number of cases of double-orifice mitral valve have been documented in patients with normal atrioventricular septa. This condition does not invariably result in a regurgitant valve, although severe regurgitation in the setting of a double-orifice mitral valve has been observed in the pediatric patient as well as in the adult in the seventh decade of life.

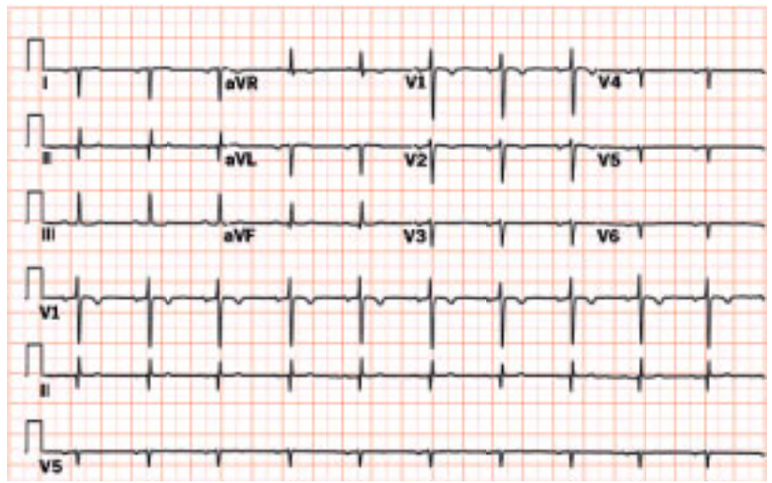
Congenital Pericardial Defect

A congenital defect of the pericardium represents defective formation of the pleuropericardial membrane and may involve the entire pericardium, the left-sided aspect of the pericardium, or the right pericardium (1522,1523,1524,1525,1526,1527,1528,1529,1530,1531,1532,1533,1534,1535,1536,1537,1538,1539, 1540 and 1541). Defects of the left pericardium are most commonly involved, but complete and small right-sided defects are well described (1529,1535). Incomplete formation of the septum transversum is believed to be responsible for a diaphragmatic defect. Partial absence of the left pericardium may be suspected clinically in the child or adult because of chest pain and an unusual cardiac silhouette observed on the plain chest radiograph. In patients with partial absence of the left pericardium, either the cardiac ventricles or the left atrial appendage may protrude or herniate through the pleuropericardial defect, leading in some patients to chest pain or syncope; in others, strangulation of the ventricles or left atrial appendage may lead to death. Herniation or protrusion of the right lung into the pericardial cavity may obstruct the right superior cava vein. Herniation of the omentum into the pericardial cavity occurs when there is a diaphragmatic pericardial defect and a defect in the diaphragm.

All these defects are uncommon, and we are aware of only a few instances of symptomatic right- or left-sided pericardial defect being recognized in the neonate. The chest radiograph in the older child may provide a clue as to the presence of a left-sided defect, and diagnosis may be confirmed by cross-sectional echocardiography and contrast-enhanced computed tomography or MRI (1524,1526,1532,1534,1535 and 1536,1538,1540,1541). In symptomatic patients, surgical attention, including treatment by thoracoscopic pericardiectomy, is required to close or widely open the pleuropericardial defect.

Dextrocardia, Situs Inversus, and Kartagener's Syndrome

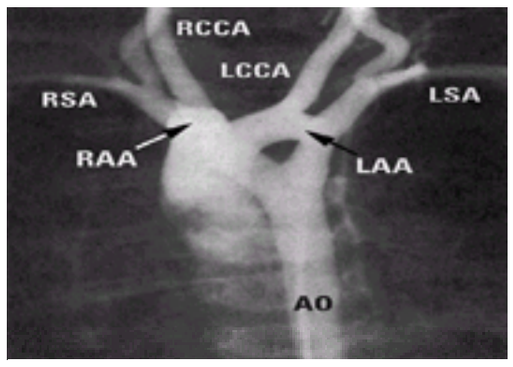
Kartagener's syndrome is the syndrome of dextrocardia with situs inversus totalis, sinusitis, and bronchiectasis (1542,1543,1544,1545,1546,1547,1548,1549,1550,1551,1552,1553,1554,1555,1556 and 1557). The respiratory difficulties, including recurrent middle ear infections, in this syndrome result from hypomotility or immotility of the tracheobronchial cilia. The basic defect is lack of ciliary dynein (1544,1545,1546,1547,1548,1549,1550 and 1551). Male subjects with this disorder are usually infertile, and the absence of dynein in the sperm tails accounts for spermatic immotility (1547,1553). Although it is uncommon to establish this diagnosis in the neonate, in at least one neonate the diagnosis of primary ciliary dyskinesia was confirmed by both ultrastructural and functional investigations (1553). The immotile cilia syndrome was suspected in this patient because of respiratory distress, situs inversus, abnormal nasal discharge, and hyperinflated chest radiograph. Others also have made this diagnosis in the neonate and young infant. In the older patient with Kartagener's syndrome, end-stage bronchiectasis has been treated by heart-lung or double-lung transplantation (1555,1556 and 1557).



Dextrocardia. Notable findings include a positive R wave in aVR and counterclockwise rotation in the precordial leads.

Vascular Rings

There are a wide variety of aortic arch anomalies and related conditions, some of which cause vascular rings (*e*Fig. 30.0.62). Vascular rings and slings usually present with respiratory distress in the neonate or infant. Because of respiratory distress, difficulty swallowing, and wheezing, they may present in older children or remain clinically silent, being discovered only as an incidental finding. The true vascular ring comprises a complete encirclement of the trachea and esophagus. A number of entities cause incomplete encirclement, including the pulmonary sling. When sufficient compression of the trachea and esophagus exists, symptoms are present; however, when the compression is mild, symptoms may be absent. Dysphagia tends to be a problem only after solid foods are introduced. The most common of these anomalies are well documented in the literature (1558,1559,1560,1561,1562,1563,1564,1565,1566,1567,1568 and 1569), as are the imaging findings. Cross-sectional imaging, particularly MRI and echocardiography, have supplanted cardiac catheterization and angiography as the modalities of choice to supplement the chest radiograph and esophagogram in the investigation of uncomplicated patients. Vascular rings represent approximately 1% to 2% of cases of isolated congenital heart malformations (1566,1567 and 1568). Additionally, they may be found in association with other malformations, particularly tetralogy of Fallot, in which some 10% of those having a right aortic arch have an aberrant left subclavian artery with a patent arterial duct or ligamentum completing the ring (1568,1569).

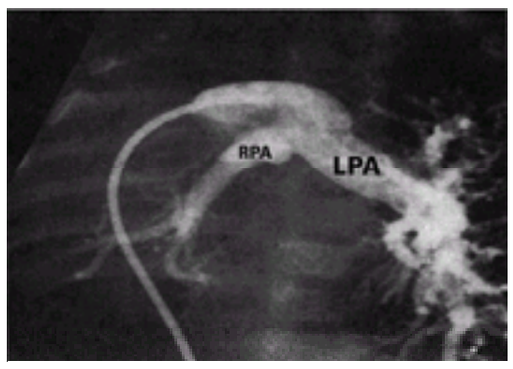


***e*FIGURE 30.0.62** Vascular ring in patient with both right and left arches widely patent. AO, aorta; LAA, left aortic arch; LCCA, left common carotid artery; LSA, left subclavian artery; RAA, right aortic arch; RCCA, right common carotid artery; RSA, right subclavian artery.

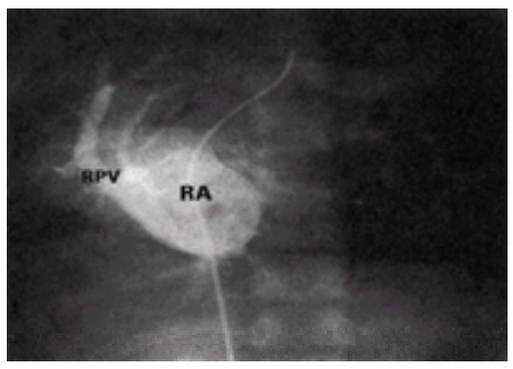
Scimitar Syndrome

Scimitar syndrome derives its name from the radiographic appearance of the anomalously draining right pulmonary veins, which, in their connection to and intraparenchymal course to the inferior vena cava, suggest the appearance of a scimitar (1570,1571,1572 and 1573) (*e*Fig. 30.0.63, *e*Fig. 30.0.64, and *e*Fig. 30.0.65).

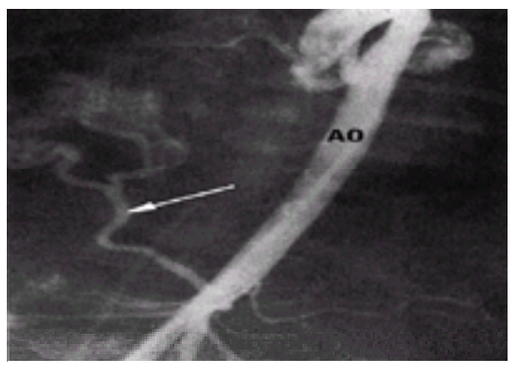
Also termed the *hypogenetic right lung syndrome*, these patients usually have some degree of hypoplasia of the right pulmonary artery and right lung, anomalous connection of the right pulmonary veins to the inferior vena cava or the caval-atrial junction, and an aberrant systemic artery from the descending thoracic aorta supplying a portion of the right lung (1570,1571,1572,1573,1574,1575,1576,1577,1578,1579,1580,1581,1582,1583,1584,1585,1586,1587 and 1588) (*e*Fig. 30.0.63, *e*Fig. 30.0.64, and *e*Fig. 30.0.65). Not infrequently, there is sequestration as well. The heart is often in the right chest, reflecting the right pulmonary artery hypoplasia. Some patients who have this syndrome may present in infancy, reflecting a large anomalous systemic artery or severe anomalies of the pulmonary veins (1573,1578,1580,1582,1583,1584,1585,1586,1587 and 1588). Other patients present in childhood with recurrent chest infection, sometimes progressing to bronchiectasis. Surgical repair seldom results in normal blood flow to the right lung, but should abolish the left-to-right shunt. We have found that postoperative pulmonary venous obstruction is prevalent, especially in the infant (1571).



***e*FIGURE 30.0.63** Hypogenetic right lung or scimitar syndrome. Note the smaller right pulmonary artery (RPA). LPA, left pulmonary artery.



***e*FIGURE 30.0.64** In this patient with the scimitar syndrome, note the anomalously connected right pulmonary veins (RPV). RA, right atrium.



***e*FIGURE 30.0.65** In this patient with the scimitar syndrome, note the anomalous systemic artery (*arrow*) originating from the descending aorta (AO) and coursing into the right lung.

CONTROVERSIES AND PERSONAL PERSPECTIVES

To look into the future for the diagnosis and treatment of congenital heart disease, one must observe the lessons from the past. The themes and variations present in the anatomy and physiology are subject to interpretation analogous to that of the conductor expressing the nuances of a symphony. Added to this is the influence of local experience and expertise as they relate to peer-reviewed evidence. Indeed, perusal of the published literature in clinical congenital heart disease rarely exceeds the levels of case report, case series (either retrospective or prospective), or retrospective case controls. The terms *double-blind*, *placebo-controlled*, and *randomized* do not find their way into the titles and methods of the clinical literature. The lack of large cohorts of patients in general does not allow the power for most investigators to suggest more than a trend in the difference between observations to support an argument. Acceptance of the null hypothesis is rarely valid given the limitations of sample size inherent in most publications. We are often compelled, therefore, to manage problems based on consensus or expert opinion, neither of which is particularly stringent in this era of attempting to define evidenced-based plans for care. A valid argument is not the equivalent of truth. As management protocols move through the continuum described by the nouvelle to that of the established or the discarded, one must be ever vigilant in assessing the nature of the evidence, whether by induction or deduction.

One does not have to look much beyond the present to find controversies in management. Many of our own current perspectives have been presented in the preceding pages. Contrary opinion can be found repeatedly in many aspects of diagnosis and management. We have witnessed a trend to neonatal correction of congenital heart problems. Whereas mortality statistics are often compared, the challenge will be to answer the questions of morbidity. For instance, there is a paucity of literature comparing the neurodevelopmental outcome of neonatal patients undergoing elective bypass repair with those repaired later, after years of cyanosis; however, few would consider a randomized trial today in this setting. We made a major move to designating the arterial switch as the operation of choice for patients with transposed great vessels and an intact ventricular septum, and yet there is no long-term follow-up of the arterial switch patient to suggest that there is not a steep increase in hazard function due to problems with the coronary circulation over time. Once beta-blockers were considered absolutely contraindicated in the patient with ventricular dysfunction, but are now receiving attention as a powerful addition to the pharmacologic management of patients with end-stage ventricular dysfunction and congenital heart disease. Acute myocarditis is still the subject of ongoing controversy in establishing the diagnosis and determining optimal treatment. Natural and unnatural history data continue to be debated when considering the optimal timing of cardiac replacement therapy. A well-known example is the patient with the hypoplastic left heart syndrome. Some believe that cardiac transplantation is the best palliative strategy, whereas others contend that the best option is that of palliative surgery in staged sequences in an effort to defer transplantation to later years. The relative shortage of donor grafts and improvements in immunotherapy foreshadow the ongoing debate regarding the merits of xenograft transplantation, and opportunities of fetal diagnosis spark further discussion of outcomes and challenge us to be consistent in our consideration of the potential for differences in standards of care. The list goes on.

The patient and family are not only interested in whether the child will survive, but increasingly we are called on to comment on the child's future. Practical issues dictate that we must strive to reach decisions with patients and families to use the best of incomplete information and experience in an uncompromising ethic of truly caring for the child. We have journeyed a long way this century and clearly have a long way to go as we travel through the next millennium.

FUTURE DIRECTIONS

The discipline of clinical pediatric cardiovascular medicine has evolved in less than a century from a meticulous pathologic description of morphology to a dynamic interaction of molecular biology, embryology, clinical application of anatomy and physiology, diagnostic imaging, and medical and surgical intervention. The advent of

advances in ultrasound technology and the development of computerized tomography and MRI have resulted in a move toward less invasive preoperative imaging and hemodynamic assessment. The catheterization laboratory has evolved from being primarily a diagnostic to an ever-increasing therapeutic resource. Issues in genetics and fetal medicine have resulted in new considerations and challenges in embryology and its application to the developing fetus. Indeed, fetal therapeutic intervention using the skills of surgeons, obstetricians, and cardiologists is no longer a dream of the future; instead, it is a present reality. Importantly, a description of the natural history of congenital heart diseases now should reflect the prenatal development as well as the postnatal progression and should include the outcome of intervention.

As already noted, the importance of a recognizable and practically applicable denominator remains one of the great challenges in the description of the management and progress of patients with congenital heart disease that occurs in isolation and with other defects in growth and development. Given the diversity of lesions, the challenge is in finding meaningful cohorts of patients for description, as few patients have identical disease. The result is an exciting creative application of a changing technology. This technologic imperative, however, must be guided by a responsibility for critical evaluation of its clinical utility. Malformations can be repaired and palliated with increasing success, as evidenced by the growing and changing face of the practice of adult congenital heart disease. In cases in which this is not possible, the heart can be mechanically supported and replaced, again with increasing success. Although we strive to define evidence to guide our practice, experience remains central to management, particularly in the setting of complex issues. To be truly successful, we must continue to care for and define not only where the child has been, but also what the child will become.

THE FUTURE

The challenges are many for the patient with congenital heart disease and those caring for these patients. From maximizing care for the child and adult with congenital heart disease, to defining insurability for the adult with congenital heart disease, to defining care givers for the adult with congenital heart disease or the “aftermath” of congenital heart surgery, these are but some of the obvious challenges. For many patients with complex heart malformations, much has been accomplished, but there are still patients who die before, or fail to meet the criteria for, the Fontan operation or other surgical interventions. Patients undergoing the Fontan operation, double switch, or others are probably just the “tip of the iceberg.” Considerable emphasis should focus on the denominator, not just the numerator. Outcomes must be measured in more sophisticated, meaningful ways. Neurodevelopmental outcome and strategies—both peri- and postoperative—must be designed and used to preserve the integrity of cerebral function. To address the root of the problem, there must be reallocation of resources—human as well as fiscal—to define the causation of congenital heart disease. The application of molecular genetics and ongoing definition of the human genome will likely redefine the issues of those caring for the patient with congenital heart disease.

OVERVIEW

At the time of adulthood, native anatomy, physiology, and operative status converge to determine prognosis and surgical and medical management considerations. For common simple shunt lesions or single obstructive lesions of the right or left ventricular outflow tracts, early intervention for significant disease leads to optimal long-term results. When patients with complex lesions unoperated or palliated reach adulthood, physiologic repair may be feasible. The decision to proceed depends on the reversibility of deleterious physiology and the possibility of preventing further deterioration. The long-term complications of palliative shunts are pertinent, particularly for the first generation of patients who have undergone surgery. When physiologic repair has taken place, issues of concern in long-term follow-up include hemodynamic and arrhythmic complications and reoperation.

Adolescents and adults with congenital heart disease (CHD) are optimally cared for in specialized centers staffed by medical and pediatric cardiologists or cardiologists trained and committed to the care of adults with CHD as well as cardiac surgeons with skill in congenital heart surgery. These facilities should have easy access to specialists including those in cardiac anesthesia, obstetrics and gynecology, pulmonary disease, hematology, neurology, psychiatry, and genetic counseling.

The purpose of this chapter is to provide an overview of the issues that will be of major concern for physicians who are given the responsibility of following these patients as adults. We discuss a framework for clinical assessment and management at the time of presentation in adulthood. The role of invasive and noninvasive diagnostic modalities is reviewed. A problem-oriented discussion of the unoperated and operated lesions most likely to be encountered in this patient population is provided. Specialized issues pertinent to this population as a whole, such as Eisenmenger's syndrome, the medical management of cyanosis, endocarditis prophylaxis, exercise recommendations, pregnancy, and psychosocial issues, are summarized.

GLOSSARY

Complex lesions: A combination of lesions, the most common patterns of which, seen in adults, are described in this chapter.

Cyanosis: A blue discoloration of the mucous membranes resulting from an increase in the amount of reduced hemoglobin. Central cyanosis occurs when the circulation is mixed secondary to a right-to-left shunting. Cyanosis can be observed in unoperated and palliated patients with native cyanotic lesions.

Eisenmenger's complex: A term referring to flow reversal across a ventricular septal defect when pulmonary vascular resistance exceeds systemic levels.

Eisenmenger's physiology: A term used to designate the physiologic response in a broader category of lesions in which a right-to-left shunt occurs in response to an elevation in pulmonary vascular resistance.

Eisenmenger's syndrome: A term applied to common clinical features shared by patients with Eisenmenger's physiology. These findings in combination with the absence of left-to-right shunting make the patient inoperable.

Native lesions: The anatomic lesions at birth.

Palliative interventions: Increase or decrease pulmonary blood flow while a mixed circulation and cyanosis persist. Palliative surgical shunts aimed at increasing pulmonary blood flow are summarized in Table 31.1.

Palliative surgical shunts	
Systemic venous-to-pulmonary artery shunts	
Classic Glenn	SVC to right PA
Bidirectional Glenn	SVC to right and left PA
Bilateral Glenn	Right and left SVC to right and left PA
Systemic arterial-to-pulmonary artery shunts	
Classic Blalock-Taussig	Subclavian artery to PA
Modified Blalock-Taussig	Subclavian artery to PA (prosthetic graft)
Pott's anastomosis	Descending aorta to left PA
Waterston's shunt	Ascending aorta to right PA

PA, pulmonary artery; SVC, superior vena cava.
Adapted from Marelli AJ, Mullen M. Congenital heart disease onward into adulthood. *Baillieres Pediatr* 1996;4:192.

TABLE 31.1 SURGICAL PALLIATION OF CONGENITAL HEART LESIONS

Physiologic repair: A term applied to procedures that result in total or near total anatomic and physiologic separation of the pulmonary and systemic circulations in complex cyanotic lesions. These patients are typically acyanotic.

Simple lesions: Shunt lesions or obstructive lesions of the right or left ventricular outflow tract that occur in isolation.

HISTORICAL PERSPECTIVE AND EPIDEMIOLOGY

Over the past four decades, the convergence of major advances in pediatric and medical cardiology as well as cardiovascular surgery has resulted in the survival of an increasingly large number of patients with complex structural heart lesions. Table 31.2 provides a historical perspective of primary operations for major disease categories. This chronologic listing of surgical interventions and their dates of introduction provides a basis for predicting the sequential rise in expected survival for patients with specific diseases.

1955	Tetralogy of Fallot
1959	Senning atrial baffle in TGA
1964	Mustard atrial baffle in TGA

TABLE 31.2 SURGICAL REPAIR OF COMPLEX CONGENITAL HEART LESIONS

Congenital cardiac malformations occur at a rate of 8 per 1,000 live births, corresponding to approximately 32,000 infants with newly diagnosed CHD each year in the United States. An estimated 20% die within the first year from life-threatening conditions, a substantial decrease from the reported 40% in the late 1960s (1). An approximate 80% of the first-year survivors live to reach adulthood in the current era (2,3 and 4). Coincident with improved survival in the neonatal and early childhood years, these numbers continue to grow with prevalence rates of adults with CHD in the United States estimated to be an approximate 800,000 (5).

PRESENTATION IN ADULTHOOD

The management of the young adult with CHD requires the clinician, at the end of his or her assessment, to determine the native anatomy, the surgical anatomy, the patient's physiology, and operative candidacy (Fig. 31.1) (6).

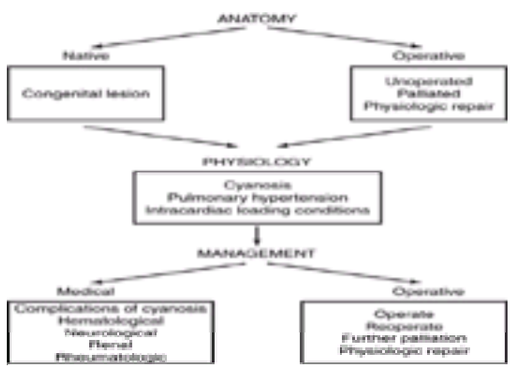

FIGURE 31.1 The goals of complete clinical assessment are to define anatomy and physiology to determine appropriate management. (From Marelli AJ. Congenital heart disease in adults. In: Goldman L, Bennett J. *Cecil's textbook of medicine*. Philadelphia: WB Saunders, 1999, with permission.)

Understanding the details of the native and surgical anatomy is the cornerstone of appropriate management. Information obtained from objective diagnostic tests should complement that obtained from review of all previous available records. Reconsideration of the findings is imperative in delivering proper care, as the management of CHD has changed significantly over the last thirty years.

Determination of the *physiology* includes two components. The first relates to the presence or absence of cyanosis, the medical complications that ensue, and the assessment of the pulmonary vascular bed. The second relates to the loading conditions of the cardiac chambers. Congenital heart lesions are classified as cyanotic or acyanotic (7). The presence or absence of pulmonary hypertension, with or without an increase in pulmonary vascular resistance, depends on the quantity and source of pulmonary blood flow. If forward flow from the right side of the heart is insufficient, native collaterals, surgical shunts, or both provide alternate sources of pulmonary blood flow. An increased volume load to the heart can result from intracardiac shunting or valvular regurgitation. An increase in pressure afterload can result from native or acquired stenosis of either outflow tracts or high pulmonary or systemic vascular resistance. It is the interaction between the pulmonary vascular bed and the heart that determines the patient's physiology.

Palliative interventions are defined as those operations that serve to either increase or decrease pulmonary blood flow while allowing a mixed circulation and cyanosis to persist. Palliative surgical shunts aimed at increasing pulmonary blood flow are summarized in Table 31.1. Systemic arterial-to-pulmonary artery shunts may result in a significant improvement in saturation levels but at the price of high levels of pulmonary blood flow and direct exposure of the pulmonary vascular bed to the high pressures of the systemic circulation (8). The possible long-term complications of these shunts include pulmonary hypertension, pulmonary artery stenosis, and volume overload of the ventricle receiving pulmonary venous return, making further surgical intervention more difficult or impossible. This is particularly true of large central shunts, the Pott's shunt, and Waterston's anastomosis. Well-sized Blalock-Taussig shunts can result in more controlled pulmonary flow, but may stenose over time and distort the pulmonary artery anatomy (9). These considerations provide the rationale for the current widespread use of systemic venous-to-pulmonary arterial shunts resulting in acceptable saturations with more balanced pulmonary blood flow and a lower transpulmonary pressure gradient (10). Surgical *pulmonary artery banding* is a palliative measure aimed at decreasing pulmonary blood flow and protecting the pulmonary vascular bed against direct exposure to systemic pressures. The pulmonary band is usually placed above the valve and below the pulmonary artery bifurcation. This procedure has been performed in patients with a ventricular septal defect (VSD) large enough to significantly increase pulmonary blood flow in the presence or absence of other complex lesions. In long-term follow-up, two issues are of concern. The first relates to distortion of the pulmonary artery trunk or at the bifurcation, with or without migration of the band. This can preclude or complicate adequate late repair, requiring reconstruction of the proximal pulmonary vascular bed. The second complication of the band has been observed in a subgroup of patients having a univentricular heart and transposition of the great arteries with a potentially or truly restrictive VSD. It has been suggested that banding the pulmonary trunk stimulates myocardial hypertrophy, promoting spontaneous reduction in the size of the bulboventricular foramen, leading to secondary subaortic stenosis. The surgical management of this is associated with a high mortality (11).

Physiologic repair is a term applied to procedures that result in total or near total anatomic, physiologic, or both anatomic and physiologic separation of the pulmonary and systemic circulations. Examples include repair of tetralogy of Fallot (TOF), the Senning's or Mustard's operation for transposition of the great arteries, and the Fontan operation for the single ventricle. Although an attempt is made to approximate normal physiology, long-term complications relating to prosthetic materials, valves, and conduits, as well as ventricular dysfunction, require careful and continued follow-up. These are discussed, where applicable, in the context of specific

lesions.

DIAGNOSTIC TECHNIQUES: APPROACH, STRENGTHS, AND LIMITATIONS

Adequate use of the diagnostic tools assists in the determination of the anatomy, physiology, and operative status of the adult patient. A complete clinical assessment is essential and includes 12-lead electrocardiography, chest radiography, and baseline oxygen saturation. Serial use of these tests, Holter monitoring, and cardiorespiratory exercise testing are tailored to the individual patient. In this section, we describe the use of noninvasive imaging and cardiac catheterization as it pertains to adults with CHD.

Transthoracic Echocardiography

Two-dimensional and Doppler echocardiography is the cornerstone of imaging for diagnosis and follow-up of congenital lesions. The principle of segmental analysis of anatomy and hemodynamics underlies the echocardiographic examination of CHD in patients of all ages. The segmental approach to congenital cardiac disease (12) refers to sequential diagnosis of the major cardiac segments in a venous-to-arterial sequence, consistent with the development of the heart. Native and surgical anatomy is therefore described from inflow to outflow in keeping with the concept of a circulation in series.

The three major cardiac segments consist of the visceroatrial segment, the ventricles, and the great arteries. The two major connecting segments are the atrioventricular junction and the ventriculoarterial junction. Because the visceral and atrial situs are usually concordant with one another, the viscera and the atria are considered as one segment. A segmental approach in echocardiographic diagnosis is performed by examining the viscera, systemic and pulmonary venous return, atria, atrioventricular junction, ventricular arrangement, and great arteries. Starting with extracardiac structures and going to intracardiac structures, and within the heart, going from chamber and great vessel arrangement to valvular function, a complete diagnostic examination is performed. The diagnosis of complex disease is derived from the information obtained at each segment. Each segment is therefore a building block. The sum of these parts constitutes the final diagnosis. For complete assessment of the patient with CHD, this principle should be respected if not in the sequence of image acquisition, then in the analysis and synthesis of information.

The number of ventricles, their relative size, and arrangement influence two key factors of the patient's natural history: (a) whether the patient is a candidate for biventricular repair, and (b) which of the two morphologic ventricles is subaortic and therefore performs systemic work. Assessment of ventricular function is crucial and yet difficult. Geometric assumptions necessary to quantitate ventricular function limit the ability to accurately measure morphologic right ventricular and distorted single-ventricular contractility. Right ventricular pressure inferred from the velocity of a tricuspid regurgitation should be cross-checked from a measured pressure gradient between both ventricles in the event of a restrictive VSD and with knowledge of systemic blood pressure measured simultaneously. In the absence of obstruction to right ventricular outflow, this pressure reflects that in the pulmonary vascular bed. On the other hand, a gradient across the right ventricular outflow tract can be used to approximate pulmonary artery pressure when the right ventricular pressure has otherwise been estimated based on a tricuspid regurgitation or properly aligned VSD jet. When conotruncal anatomy is difficult to image from standard parasternal views, off-axis views can be used in experienced laboratories to maximize determination of pressure gradients in native outflow or conduit stenosis. Distal pulmonary anatomy beyond the pulmonary artery branches is a notoriously difficult area. In the absence of pulmonary hypertension, when right ventricular pressure is elevated, and there is no stenosis of the proximal right ventricular outflow tract, other diagnostic modalities should be used to examine the distal pulmonary artery branches. The aortic arch, isthmus, and descending aorta can also be difficult to image in the adult. Erroneous pressure-gradient measurements in patients with coarctation of the aorta can result from stenosis in series or from pressure recovery secondary to long tubular segments (13). Native and surgical pulmonary artery shunts can be interrogated to determine patency. When the systemic pressure is known, it may be possible to infer pulmonary artery pressure from a pressure gradient measurement aligned with a systemic arterial to pulmonary artery shunt.

Accurate assessment of complex congenital anatomy results from a careful interactive diagnostic search, which becomes progressively more specific and focused as the examination proceeds. This is particularly important during a patient's first examination, as echocardiography becomes the key to the future clinical and surgical management. In adults and older children in whom acoustic windows are more challenging, information can be maximized by adhering to three precautions: referring the patient to an echocardiographer who is familiar with congenital heart lesions and technically versatile with adults, providing as much information on the patient's history ahead of time, and referring the patient to the same laboratory for sequential examinations.

Complete spatial understanding of complex congenital lesions can be challenged by the limitations of two-dimensional echocardiography. Three-dimensional reconstruction of images acquired transthoracically offers unique imaging perspectives, more closely approximating surgical anatomy and optimizing surgical planning (14,15). Improved accuracy and spatial resolution of suboptimal data sets as well as the ability to quantitate cardiac function (16) are broadening the application of three-dimensional echocardiography (17).

Transesophageal Echocardiography

The transesophageal echocardiographic (TEE) examination is particularly useful in adults to maximize image acquisition when transthoracic acoustic windows are poor (18). TEE is routinely used to clarify and detail intracardiac anatomy when transthoracic echocardiography is problematic. By comparison with transthoracic imaging, TEE provides additional anatomic information for specific posterior and anterior congenital lesions. Anomalous pulmonary venous connections (19) and atrial septal defects (ASDs), in particular those of the sinus venosus type (20), and atrial septal aneurysms can be detected transthoracically but are best imaged using a combination of horizontal and vertical transesophageal planes. Integrity of atrial baffles and Fontan connections can sometimes only be inferred from abnormal flow patterns, using transthoracic imaging in adolescents and adults. Obstruction due to thrombus or progressive narrowing can clearly be seen using TEE. Assessment of complex atrioventricular anatomy and function can be enhanced using posterior acoustic windows. For central pulmonary vascular architecture, subaortic and supraaortic lesions, as well as ventriculoarterial conduit function, specific sites of obstruction can be clearly delineated with vertical transesophageal views. Proximal coronary artery anomalies and coronary fistulas at their point of exit and entry can be easily imaged using transesophageal views. Using transthoracic echocardiography, a patent ductus arteriosus (PDA) can be inferred from a turbulent flow pattern seen at the origin of the left pulmonary artery. In adolescents and adults, however, often the duct cannot be directly visualized. TEE can be used to confirm the diagnosis and exclude the presence of endarteritis (21). Palliative shunt anastomosis can be imaged and interrogated using a combination of transesophageal views. Difficulty in properly aligning the Doppler signal parallel to the shunt can hinder the ability to make a definitive diagnosis of an obstructed shunt. Aortic coarctation can be diagnosed using multiple transesophageal views, but accurate multilevel measurements of the arch and descending aorta often require the use of other complementary examinations.

Intraprocedural TEE has become increasingly important. Intraoperative TEE is used as an adjunct to complex intracardiac repair. In pediatric series, intraoperative TEE has been shown to affect surgical management of complex congenital lesions in up to 20% of cases (22,23). TEE is being routinely used during interventional catheter-guided atrial septal device closure (24) and coarctoplasty. Atrial baffle dilations can be guided using TEE. In addition, the electrophysiologist can be helped in guiding ablation catheters through the heart when abnormal native or surgical anatomy results in a distortion of the usual landmarks. This can be particularly useful for ablation therapy in patients with right-sided Ebstein's anomaly and congenitally corrected transposition of the great arteries, after Mustard's procedure for complete transposition of the great vessels and after the Fontan operation (18).

Magnetic Resonance Imaging and Computed Tomography

These imaging modalities are available in specialized centers and can be used as adjuncts to cardiac ultrasound and angiography. Magnetic resonance imaging (MRI) and ultrafast computed tomography (CT) can be particularly useful for detailed assessment of the aorta, branch pulmonary arteries, systemic-to-pulmonary artery shunts, and anomalous systemic venous connections (25,26). For patients with TOF repair, MRI is particularly useful to clarify anatomy and function of the pulmonary arteries and right ventricle (27). Judicious use of complementary noninvasive tools to elucidate anatomy allows a more focused application of cardiac catheterization.

Diagnostic Cardiac Catheterization

There are three principal indications for diagnostic studies most commonly performed before surgical or catheter-based intervention. These include assessment of pulmonary vascular bed, clarification of anatomy, and coronary angiography in patients over the age of 40 years. The study usually includes a aturation run for shunt calculations, right and left pressure measurements as needed, cardiac output measurements, and appropriate biplane cine angiographic views. Shunt quantification can usually be inferred from secondary chamber enlargement using noninvasive imaging. In instances in which an atrial or ventricular level shunt is of borderline significance or in which chamber enlargement is secondary to concomitant primary regurgitant lesions, pulmonary to systemic flow ratios should be directly measured. In assessing the pulmonary vascular bed, cardiac catheterization is indicated when there exists doubt as to the etiology and potential reversibility of pulmonary vascular disease (28). Morphometric analysis of lung biopsy specimens and pulmonary wedge angiography can be used to quantify pulmonary vascular obstructive correlating obliterative vascular changes with hemodynamic abnormalities in the pulmonary circulation (29).

The etiology of unexplained pulmonary hypertension in patients with complex CHD can vary. Patients with repaired TOF may have right ventricular hypertension due to proximal or distal pulmonary artery stenosis. Pulmonary hypertension itself is rare. Pulmonary vascular disease can be seen in the setting of a previous large arterial-to-pulmonary artery shunt. Unoperated patients with complex tetralogy (pulmonary atresia with VSD) have extensive aortopulmonary collaterals. Determination

of resistance and delineation of the exact source of collaterals is indicated when unifocalization procedures are contemplated. In patients who have undergone Mustard's or Senning's repair for complete transposition of the great arteries, pulmonary venous baffle obstruction should be sought as a reversible cause of unexplained pulmonary hypertension. In the unoperated patient with single ventricle physiology, Fontan candidacy necessitates a detailed assessment of pulmonary vascular resistance and proximal and distal pulmonary artery anatomy. After Fontan repair, systemic venous congestion may indicate obstruction or thrombosis at the pulmonary artery anastomotic site. In the absence of an atrial level residual shunt across the cavopulmonary anastomosis in a patient with Fontan repair or Glenn's shunt, increasing cyanosis may be secondary to pulmonary arterial venous fistulae. After the Fontan procedure, the occurrence of a new harsh mid-systolic murmur in a patient with previous pulmonary artery banding should prompt a search for the latent development of bulboventricular subaortic obstruction.

INTERVENTIONAL CARDIAC CATHETERIZATION

Intercirculatory Shunts

The Rashkind foam-covered, double-umbrella device, the Bard clamshell septal umbrella, button devices, coil embolization, and the Amplatzer device have all been used for nonsurgical closure of PDAs measuring 7.0 to 12.5 mm (30,31,32,33 and 34).

A large experience has been gained using the Rashkind PDA occluder device. In a multicenter series, there were no procedure-related mortalities in over 600 cases in the trials conducted in the early 1990s. Complications including device embolization were seen in 2% of patients, and residual shunts occurred in less than 8% of the patients. Most residual shunts were detected only by echocardiography with no audible murmur (35,36). Using the Rashkind device, closure of the ductus arteriosus can be accomplished safely and effectively in adult patients with or without calcification of the duct (37). Coil embolization of a duct can be accomplished using one or more coils, particularly for PDAs measuring less than 7 mm. Residual shunts occur in less than 3% of patients and at 3-year follow-up there is no evidence of delayed coil migration, thromboembolism, or endocarditis (38). The use of the Amplatzer duct occluder has made it possible to close larger ducts measuring up to 12.5 mm in adults with a less than 0.5% residual shunt rate at 12 months (39). In the largest series, there was no evidence of thromboembolism, and spontaneous device embolization was seen in 2 of a total of 252 patients (39,40).

Successful device closure of ASDs and patent foramen ovale (41) can be performed using transcatheter techniques with a variety of devices with data reported on over 1,000 patients. Experience has been obtained with the ASDOS device (42), the buttoned device (43), the Angel Wings Das device (44), the Cardio-Seal implant (48), and, most recently, the Amplatzer device (45,46,47 and 48), which has been used to close ASDs measuring up to 3.5 cm in stretched diameter.

Complete occlusion rates for ASDs are variable from one device to another and improve over time with follow-up of individual devices. Residual shunt rates have been reported in as little as 10% of patients at 24 hours (48) or as much as 30% of patients at 1 year (42). Complete occlusion rates have been achieved in 98% of patients by 3 months using the Amplatzer device (46,47). Structural and clinical complication rates are variable and reported with all devices. Embolization, entrapment of adjacent structures, arm fracture necessitating transcatheter or surgical removal of the device, thromboembolic complications (49), and heart block have been observed in less than 10% of patients in most series. Direct comparison of transcatheter and surgical ASD closure reported with the Amplatzer device (50) underscores that in centers where expertise is available, adequate patient selection for interventional closure of ASDs (51) can lead to good results with less morbidity and a decreased hospital stay.

There are reports of catheter closure of VSDs in adults (52,53). Success rates are higher for congenital VSDs than for post–myocardial infarct VSDs, in which damaged tissue does not lend itself to secure device closure. Coil embolization has been used to occlude bronchial collateral arteries before and after repair of TOF with pulmonary atresia (54) and to occlude Blalock-Taussig shunts (55). Transcatheter closure has also been used to close residual postoperative interatrial communications after the Fontan procedure (56), atrial baffle leak after Mustard's procedure (57), and coronary artery fistulas (58,59).

Right and Left Ventricular Outflow Tract Obstruction

Pulmonary angioplasty is the procedure of choice for adults with congenital pulmonary valve stenosis (60). Long-term follow-up data of nearly 10 years demonstrates persistent resolution of the dynamic component of sub–pulmonary stenosis and no restenosis at the valvar level even for severe pulmonary stenosis (61,62). Pulmonary regurgitation is noted in an approximate 10% of patients and improves over time. Stents have been used in adults to relieve right ventricular pulmonary artery conduit obstruction (63) and peripheral pulmonary artery stenosis (64). The clinical usefulness of stents in the pulmonary arteries is particularly important in postoperative patients with TOF and truncus arteriosus with small pulmonary arteries. These patients may have peripheral pulmonary stenosis with severe pulmonary regurgitation after surgical repair. Stent placement with reduction in pulmonary artery pressure may reduce the amount of pulmonary regurgitation, decrease right ventricular dilatation and tricuspid regurgitation, and improve right ventricular function.

Balloon aortic valvuloplasty is recognized as the treatment of choice for children with congenital nonrheumatic stenosis in whom delaying the need for aortic valve replacement confers a therapeutic advantage. Aortic valvuloplasty has been described in adolescents and young adult patients. Reported success rates are as high as 89% with a 55% reduction in the mean peak-to-peak gradient after dilation, follow-up residual gradients of less than 55 mm Hg, and only mild to moderate aortic regurgitation after the procedure (65). This experience contrasts with that in older patients in whom the high incidence of early restenosis in the presence of acquired calcification of the aortic valve makes surgical intervention the procedure of choice.

Aortic coarctation can safely and effectively be treated with balloon dilation with or without stent implantation, particularly for adult patients with recoarctation after surgical repair (66,67). Incomplete relief is observed in 25% of patients with recoarctation versus 19% of patients with native coarctation (66). Restenosis remains a concern and appears to occur more frequently in children with native coarctation. The incidence of incomplete relief and restenosis is decreased in adolescents and adults with endovascular stent implantation (68). Aortic aneurysm formation is reported in 7% to 17% of adult patients (68,69), and aortic rupture occurs rarely. Percutaneous coarctoplasty is contraindicated in those with transverse arch hypoplasia.

LONG-TERM FOLLOW-UP AND MANAGEMENT OF THE MOST COMMON SPECIFIC LESIONS

A problem-oriented approach to the lesions most commonly encountered in this patient population, based on observations across the age groups (70), is provided. The patients presenting to adult cardiologists are a mixed population of operated and unoperated patients, the relative proportion of which will continue to vary, based on evolving therapeutic trends in pediatric cardiology. The discussion pertinent to each lesion is divided into three parts. Prevalence and Anatomy provides epidemiologic information and reviews the anatomy necessary to understand diagnostic categories. Outcome describes the clinical course and complications of the operated or unoperated patients, based on the pathophysiology of the lesion. Management provides a problem-oriented discussion of issues related to choice of medical or surgical therapy and surveillance of the patient presenting as an adult.

Isolated Shunt Lesions

Shunts at the atrial, ventricular, and great artery levels are some of the most commonly encountered lesions in children and adults. Hemodynamic complications of significant shunts relate to volume overload and chamber dilation of the primary chambers receiving the excess left-to-right shunt: the right side of the heart for patients with ASD and the left side of the heart for patients with VSD and PDA. Secondary complications result from valvular dysfunction and damage to the pulmonary vascular bed. The size and duration of the shunt determine the natural history and therefore the indications for closure. The degree of shunting is always a function not only of the size of the communication, but also a function of its location on biventricular compliance, the pulmonary and systemic vascular resistances, or both. Hemodynamic sequelae of shunts are typically clinically apparent or can be expected to occur when pulmonary-to-systemic flow ratios exceed 1.5 to 1.0; hence, the designation of a "significant shunt." It should be noted, however, that the diagnostic method used influences the clinical detectability of abnormal findings. For example, assessment of a mildly enlarged right ventricle may be variable between the physical examination, chest roentgenology, and cardiac ultrasound. Uncertainty about the physiologic significance of a borderline shunt can be minimized by integrating serial determinations from multiple clinically relevant diagnostic sources, rather than making management decisions based strictly on a calculated shunt value. Clinical decision making takes into consideration the patient's age, symptoms, and direct and indirect diagnostic information reflecting intracardiac and pulmonary hemodynamics.

Atrial Septal Defects

Prevalence and Anatomy

The ostium secundum ASD is reported to account for 7% of all congenital lesions and is twice as prevalent in female patients (71) (*e*Fig. 31.1.1 and *e*Fig. 31.1.2). Defects of the atrial septum constitute 30% to 40% of CHD seen in adults (70). The secundum ASD occurs as a result of an enlarged foramen ovale, an excessive resorption of the septum primum, or inadequate growth of the septum secundum (*e*Fig. 31.1.3). Abnormal development of the endocardial cushions results in a variety of atrioventricular canal defects, the most common of which consists of an atrial defect in the ostium primum location, typically accompanied by a cleft mitral valve (*e*Fig. 31.1.4). The sinus venosus defect of the superior vena caval type accounts for 2% to 3% of all interatrial communications. It is located posterior to the fossa

ovalis at the junction of the superior vena cava and right atrium and is generally associated with an anomalous connection of the right-sided pulmonary veins. Less commonly, interatrial communications can be seen at the site of the coronary sinus, typically associated with an anomalous left superior vena cava (72). Although most cases of ASD occur sporadically, there is a reported genetic anomaly associated with a range of skeletal anomalies of the upper extremities (73).

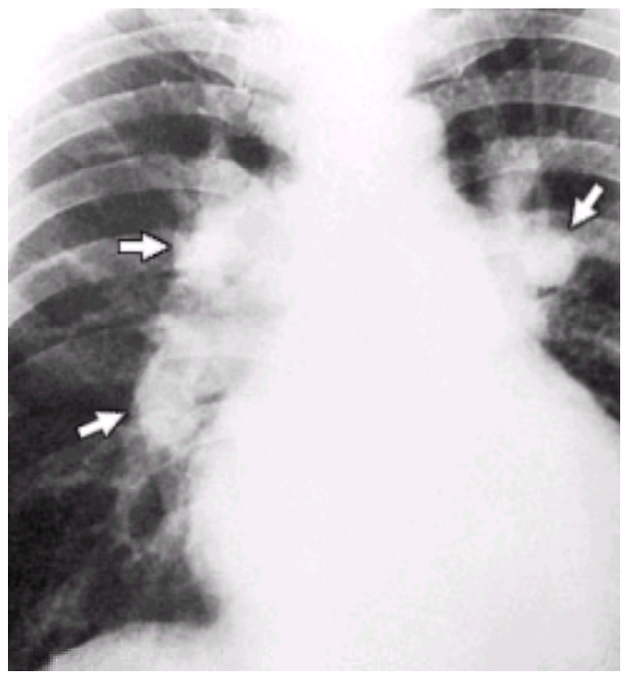
Video 31.3 A modified transthoracic view demonstrating the tricuspid valve of a patient with an endocardial cushion defect including a primum atrial septal defect and cleft mitral valve. The septal leaflet of the tricuspid valve is characteristically tethered, forming a septal aneurysm, decreasing the size of a ventricular septal defect or completely closing the ventricular septal defect, which is part of the endocardial cushion defect. (The septal leaflet of the tricuspid valve is located towards the left of the

screen.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Chest x-ray in atrial septal defect. There is plethora of the pulmonary vasculature with prominent main pulmonary arteries (*white arrows*).

Outcome

Right atrial and right ventricular dilatation occurs as a function of shunt size and may become accelerated as systemic hypertension and coronary artery disease modify left ventricular compliance, favoring left-to-right shunting. The unoperated history of secundum atrial defects has been well studied. Although most patients are minimally symptomatic in the first three decades, more than 70% become impaired by the fifth decade, and annual mortality increases to 10% in the sixth decade (74). Complications include pulmonary hypertension, right-sided heart failure, atrial fibrillation or flutter, and stroke (75). Symptoms include exercise intolerance, dyspnea on exertion, fatigue, palpitations, and syncope. Mitral valve disease and left ventricular dysfunction are unusual in the young, but the incidence is as high as 15% in patients over age 50 (76).

The overall incidence of pulmonary hypertension, defined either as a mean pulmonary artery pressure greater than 20 mm Hg or a systolic pulmonary artery pressure greater than 50 mm Hg, occurs in 15% to 20% of patients with ASD (77,78). Pulmonary hypertension is unusual before age 20 but is seen in 50% of patients above age 40 (78,79). The elevation in pulmonary pressure occurs on account of increased pulmonary blood flow. Eisenmenger's disease with pulmonary vascular obstructive disease and reverse shunting is a late and rare complication of isolated secundum ASD, reported in 5% to 10% of patients, and more commonly in female subjects (77,80).

Management

The goal of management in patients with ASD is to prevent death, right-sided heart failure, atrial arrhythmia, and pulmonary hypertension (see the section Outcome for a description of complications). ASD closure may be achieved percutaneously (see previous discussion) or surgically. Uncomplicated secundum ASDs may be closed surgically in children and adults with minimal operative mortality, in the range of 1% to 3% (75) or less. The long-term prevention of death and complications is best achieved when ASD is closed before age 25 and when the systolic pressure in the main pulmonary artery measured at cardiac catheterization is less than 40 mm Hg. This results in a long-term mortality that is similar to age- and sex-matched control populations (75). Closure after age 40 in symptomatic patients with significant shunts improves survival, prevents deterioration in functional capacity (81), and improves exercise tolerance (82) when compared with patients treated medically. In contrast, surgical closure after age 40 does not reduce the risk of nonfatal cardiovascular complications, including supraventricular arrhythmias and cerebrovascular events (75,81). Age greater than 60 is not a contraindication to ASD closure in the presence of a significant shunt because up to 80% of patients show evidence of symptomatic improvement (83). ASD closure in asymptomatic patients with significant shunts between age 25 and 40 years is controversial (84), but is associated with a reduced incidence of atrial arrhythmia (85) and is undertaken in many centers with the expectation that long-term symptomatic deterioration is preventable (86).

Preoperative pulmonary artery pressure and the presence or absence of pulmonary vascular disease are important predictors of successful surgical outcome (75,80). Patients with a total pulmonary vascular resistance of less than 7 Wood units show improvement in New York Heart Association (NYHA) class, regression of symptoms, radiographic evidence of pulmonary artery enlargement, and electrocardiographic evidence of right ventricular hypertrophy, while a pulmonary vascular resistance greater than 15 Wood units is associated with a high surgical mortality (80). If pulmonary artery pressure, pulmonary vascular resistance, or both are greater than two-thirds systemic, there should be a net left-to-right shunt of at least 1.5:1.0 or evidence of reversibility during reactive pulmonary vascular reactivity studies before proceeding to surgical repair (87).

Patients who have had surgical closure of an uncomplicated ASD before age 25 have a favorable prognosis. Patients who are older at the time of repair require variable supervision depending on the presence and degree of preoperative and postoperative medical complications. Atrial fibrillation or flutter is more prevalent as the age of operation increases (85) and is present in up to 50% to 60% of patients over the age of 40, regardless of surgical status. In 60% to 70% of patients with preoperative arrhythmias, the rhythm persists postoperatively (75), particularly if surgery is undertaken after the age of 40 years (85). Ten percent to 25% of patients may develop new-onset atrial arrhythmias in spite of operation (75,81). Thromboembolic events including transient ischemic attacks or stroke are also observed in 5% to 10% of patients on long-term follow-up, regardless of surgical status (75,81). Atrial arrhythmias may be better tolerated postoperatively and should be managed with conventional therapy, including anticoagulants. Depending on the preoperative status, continued surveillance and conventional medical management of pulmonary hypertension and ventricular dysfunction in addition to acquired cardiac disease are necessary.

Ventricular Septal Defect

P> **Prevalence and Anatomy**

The isolated VSD is the most common congenital defect seen in the pediatric population (88). For anatomic classification (89), the interventricular septum can be divided into four regions. Defects of the membranous septum or infracristal VSDs, located in the left ventricular outflow beneath the aortic valve, account for up to 80% of VSDs. The membranous septum itself is small and is located posterior to the conal septum, below the crista supraventricularis. These VSDs typically show a variable degree of extension into the inlet or outlet septum, hence their designation as *perimembranous*. Infundibular defects or supracristal outlet VSDs occur in the conal septum above the crista supraventricularis and below the pulmonary valve. Inlet defects are identified at the crux of the heart between the tricuspid and mitral valves and are usually associated with other anomalies of the atrioventricular canal. Defects of the trabecular or muscular septum can be multiple and occur distal to the septal attachment of the tricuspid valve and toward the apex.

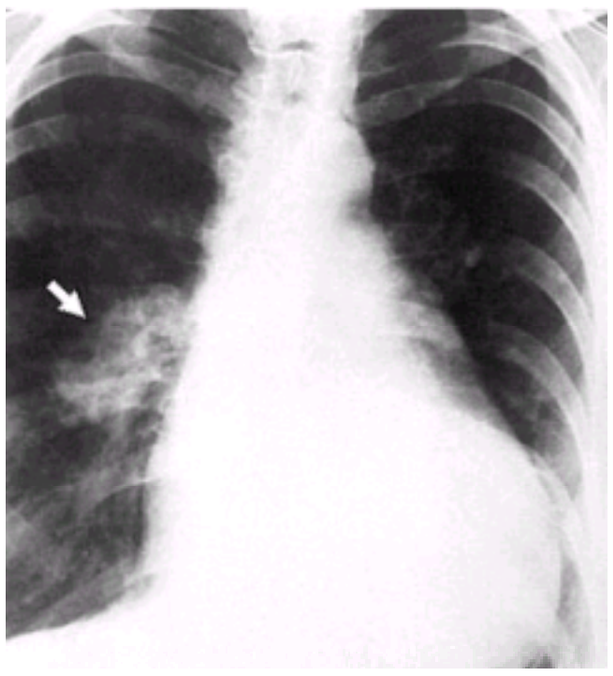
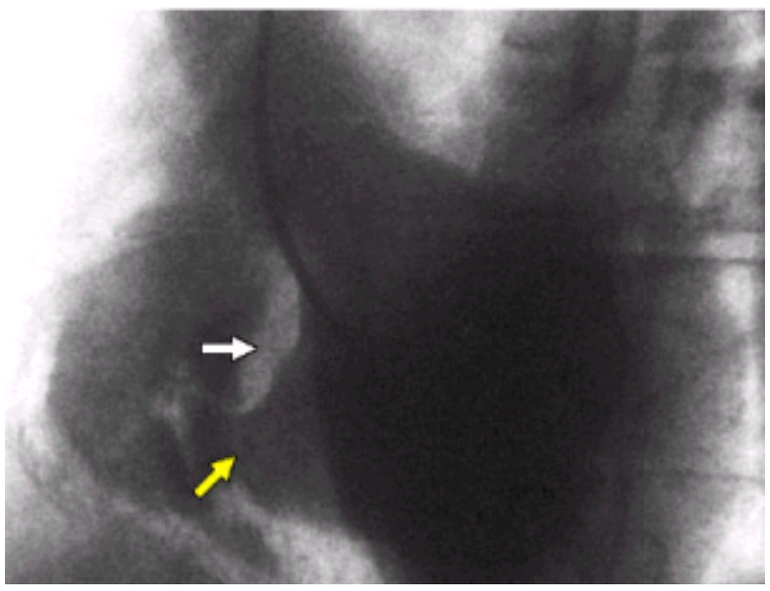
Video 31.4 Hepatoclavicular view (left anterior oblique, 60; cranial, 45) of a membranous ventricular septal defect in a 16-year-old male patient. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Chest x-ray in patient with a congenital ventricular septal defect. There is fullness in the hilum secondary to an enlarged pulmonary artery (*white arrow*).



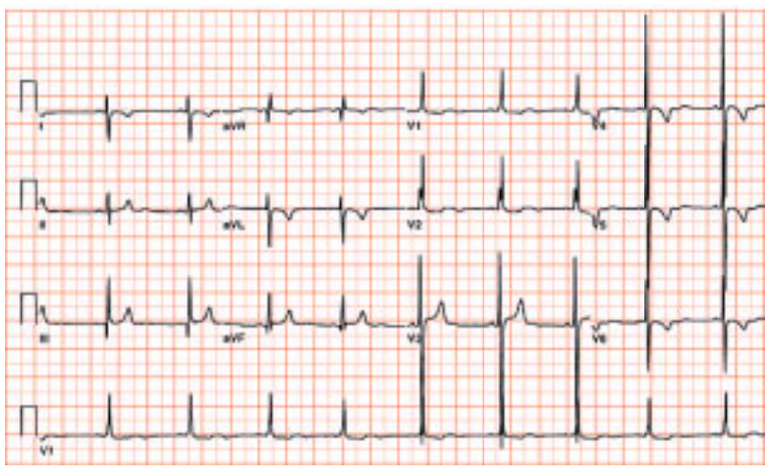
Muscular ventricular septal defect. This left anterior oblique left ventriculogram demonstrates the presence of a muscular ventricular septal defect (*yellow arrow*) with opacification of the right ventricular cavity and pulmonary outflow tract. The ventricular septum (*white arrow*) is seen to divide the right and left ventricular chambers.

Outcome

The clinical course of VSDs depends on the size of the defect and the pulmonary vascular bed, both of which can change with time. Unlike ASDs, spontaneous closure of VSDs can occur and do so as a function of native defect size, anatomy, and patient age. Approximately one-half of all VSDs are small (90) and up to 75% of those close spontaneously (89). Five percent to 10% of moderate or even large VSDs may also undergo some degree of spontaneous closure (91). Trabecular muscular septal defects may close more frequently than perimembranous defects, whereas closure of outlet defects is least common (92,93). The highest closure rates are observed in the first year of life. Ninety percent of VSDs destined to close have done so by age 10, whereas spontaneous closure in adult life is unusual but reported (91).

The physiologic severity of VSDs takes into account the pulmonary-to-systemic flow ratios (Qp:Qs), the main pulmonary artery pressure (MPAP), and the ratio of pulmonary-to-systemic vascular resistance (Rp:Rs). VSDs can be classified based on the criteria used in the First Natural History Study of Congenital Heart Defects (NHS-1) (90). Patients in group I have trivial or mild shunts with a Qp:Qs ratio of less than 1.5 and a mean MPAP of less than 20 mm Hg. Patients in group II have moderate defects with a Qp:Qs ratio of greater than 1.2, a mean MPAP greater than or equal to 20 mm Hg but an Rp:Rs ratio of less than 0.2. Patients in group III have severe defects with an MPAP greater than or equal to 20 mm Hg and an Rp:Rs ratio between 0.2 and 0.7. Patients in group IV have Eisenmenger's physiology with a systemic or near systemic MPAP, a pulmonary vascular resistance that is greater than two-thirds systemic resistance, and a right-to-left shunt or a left-to-right shunt with a Qp:Qs of less than 1.2.

Minimal or mild defects can be expected to cause no significant physiologic abnormality. A moderate or severe defect causes volume loading of the left side of the heart. Left atrial and ventricular dilatation occurs as a function of the degree of left-to-right shunting. Shunting across the ventricular septum occurs predominantly during systole when left ventricular pressure exceeds that on the right. The first intracardiac chamber to sustain a significant diastolic filling abnormality is the left atrium. With moderate or severe defects, the right side of the heart becomes secondarily affected as a function of the increase in pulmonary pressure. Note that this is in contrast to shunting at the atrial level where the right atrium and ventricle tolerate both primary volume and secondary pressure loading. An approximate 10% (90) of patients with VSDs develop Eisenmenger's complex (94), typically during the first decade (95), when pulmonary vascular resistance rises progressively to exceed systemic levels, resulting in shunt reversal. The majority of patients with Eisenmenger's physiology are said to have nonrestrictive defects. By definition this means that there is no resistance to flow at the level of the defect per se. Typically, the defect is as large as the aorta, pressures in both ventricles are equal, and the degree of shunting is determined by the ratio of pulmonary to vascular resistances. This has two major implications: The first is that the pulmonary vascular bed is exposed directly to systemic pressures in the left ventricle, resulting in an accelerated increase in pulmonary pressure and resistance; the second is that, likewise, the right ventricle is directly exposed to pressure overload early in life. In the simplest terms, a *restrictive* VSD is one through which there exists a systolic pressure gradient between both ventricles in the absence of right ventricular outflow tract obstruction. In physiologic terms this is useful insofar as it indicates that there is a resistance to left-to-right shunting at the ventricular septal level and that the size of the defect is less than that of the aorta. It follows that in terms of physiologic severity a "restrictive" defect is often trivial, mild, or moderate, but can also be severe as long as the pressure between both ventricles has not equalized.



A 16-year-old male patient with biventricular hypertrophy secondary to ventricular septal defect and Eisenmenger's syndrome.

Management

For patients with VSD, management issues vary depending on the shunt size as manifested by volume overload of the left side of the heart and the presence or absence of pulmonary hypertension (see the section Outcome for a description of complications). The NHS-1 enrolled 1,280 patients with VSD from 1958 to 1969 (91). The overall 25-year survival rate for all patients managed with medical or surgical therapy is 87%, with mortality increasing with the severity of the VSD (90). Adult presentation is most frequently that of a small restrictive VSD, native or postsurgical, or that of a large unoperated VSD with Eisenmenger's complex (70).

Patients with Eisenmenger's complex can survive into the fourth decade (91). The focus of management for patients with Eisenmenger's complex centers around the medical complications of cyanosis. These include death due to intracardiac or pulmonary complications, prevention of infective endocarditis, and systemic complications related to the neurologic, hematologic, and renal systems. These issues are discussed in this chapter as part of a discussion of the medical complications of cyanosis applicable to all patients with Eisenmenger's syndrome.

Excluding those with Eisenmenger's physiology, the majority of unoperated patients have a small VSD and therefore have a favorable long-term prognosis (90). Late results after operative closure of isolated VSDs show residual patency in up to 20% of cases (96) but with only a 5% incidence of need for reoperation, indicating that most residual surgical defects are small (90). For patients with small residual defects, native or surgical management revolves around endocarditis prophylaxis and complications related to secondary valvular anomalies. Perimembranous defects may regress in size through aneurysm formation by engaging part of the septal tricuspid leaflet, resulting in secondary tricuspid insufficiency (97). Prolapse of the right or noncoronary cusp results in acquired aortic valve disease in approximately 2% of patients, regardless of surgical status (90). This occurs most frequently with subarterial outlet VSDs, but also with perimembranous and inlet defects (98). The surgical management of this group of patients is controversial and needs to take into account the location of the VSD, the degree of aortic regurgitation, and the patient's age (99,100). Hence, for a substrate of patients with small VSDs, the potential for progressive valvular insufficiency necessitates careful consideration and follow-up even after the defect is closed.

Patients with moderate pulmonary hypertension and operated or unoperated VSD require particular consideration. Fifteen percent of patients who had a large VSD in infancy or childhood, surgically closed when pulmonary vascular resistance was normal, are found to have indirect evidence of pulmonary hypertension on long-term follow-up, even in the absence of a residual shunt (90). These may represent a substrate of patients in whom factors responsible for triggering the development of pulmonary vascular disease are already engaged at time of VSD closure. When a VSD is present and appears small but the pulmonary pressure is moderately elevated, the left heart is enlarged, or both, there may have been partial closure of the VSD, either through a spontaneous reduction in size or through surgical intervention. One of two hemodynamic scenarios is possible: Either the pulmonary hypertension is "residual" from a previous large shunt and is not related to current shunt size or there is a significant moderate residual shunt, the closure of which may be beneficial (87,90). If surgical closure is contemplated and pulmonary artery pressure, pulmonary vascular resistance, or both are greater than two-thirds systemic, there should be a net left-to-right shunt of at least 1.5:1.0 or evidence of reversibility during pulmonary vascular reactivity studies before proceeding to surgical repair (87).

Sudden cardiac death after surgical repair of VSD occurs in 2% of patients (90,96). The etiology is unclear, and it remains surprising that even patients with small VSDs may be at risk for sudden cardiac death (90). It is reasonable, however, to consider age at operation and the presence of pulmonary hypertension as possible contributing factors. Abnormal myocardium long exposed to volume or pressure overload or both, with or without surgical scar, is likely to provide the substrate for arrhythmias and heart block. Rhythm disturbances after surgical closure of VSDs include tachyarrhythmias and conduction disturbances (90,96,101). Right bundle branch block is reported to occur in 30% to 60% of patients and appears independent of whether the VSD was repaired through an atrial or ventricular incision (90,96,101). Right bundle branch block with left-axis deviation is seen in 3% to 15% of patients (96,101). First-degree atrioventricular block occurs in approximately 10% of patients and the incidence of complete heart block on long-term follow-up is 1% to 3% (96,101). On 12-lead electrocardiography, couplets are observed in 18% of patients, while nonsustained ventricular tachycardia occurs in 5% of patients. Arrhythmia management should be symptom directed, with particular attention paid to reversible hemodynamic factors. Unexplained syncope is usually an indication for an electrophysiology study when Holter monitoring is unrevealing, and there are no exercise-induced arrhythmias.

Patent Ductus Arteriosus

Prevalence and Anatomy

The estimated incidence of the isolated PDA is 1 in 2,000 or approximately 10% of all congenital cardiac lesions at birth, with a female predominance (102). The ductus arteriosus connects the descending aorta to the main pulmonary trunk with the pulmonary arterial end found immediately to the left of the bifurcation of the pulmonary trunk near the origin of the left pulmonary artery. The aortic end is found just distal to the origin of the left subclavian artery. Normal postnatal closure results in fibrosis and degenerative changes in the ductal lumen, leaving in its place the residual ligamentum arteriosus, which can become part of a vascular ring (103,104).

Constriction of the ductus arteriosus starts at the pulmonary end of the ductus and proceeds toward the aorta. Hence, the observed conical shape of a patent duct with narrowing at the pulmonary arterial end and a dilated ampulla at the aortic end is seen in 65% of cases (105). Other ductal shapes include a short duct with narrowing at its aortic insertion, a tubular duct without constriction, a channel with multiple constrictions, or a long duct with an unusual shape (105). Progressive dilatation of the aortic end with aneurysm formation has also been observed (106).

The fetal ductus is derived from the sixth aortic arch as are the right and left pulmonary arteries. The fetal duct is therefore a direct extension of the pulmonary artery but enters the aortic isthmus at a sharp angle. Not surprisingly, when the duct persists, significant calcification of the aortic ductal end can be observed (102,107).

Outcome

A small PDA is one in which there is continuous flow throughout the cardiac cycle without left-sided heart dilatation and without pulmonary hypertension. Patients with a small PDA, although protected from hemodynamic complications of a significant left-to-right shunt, remain at risk for infectious endarteritis, which usually occurs on the pulmonary side of the duct. Early natural history studies in patients with clinically detectable shunts document a risk of endocarditis of 0.45% per year after the second decade and death from endocarditis accounting for up to one-third of total reported mortality (108). These ominous figures have led to widespread acceptance of ductal closure as a safe therapeutic alternative, even in patients with small shunts. The advent of echocardiography, highly sensitive for the detection of small shunts, has led to the concept of the clinically "silent duct," that is to say, a shunt that is not audible on clinical examination but is present on Doppler interrogation of the pulmonary artery (109,110). Although this remains controversial, these patients do not appear to be at risk for endocarditis (110).

A patent duct is of moderate or large size but still restrictive when there is a left-to-right shunt throughout systole and a variable duration of diastole. Left atrial or ventricular dilatation, or both, as well as pulmonary hypertension, varies with the quantity of left-to-right shunting as well as with the secondary effects on the pulmonary vascular bed. An unoperated moderate or large persistent ductus is associated with a high morbidity and mortality in the first year of life (108). If unoperated after the first year, most children become asymptomatic for the first two decades (108). In the second and third decades symptoms include the onset of dyspnea secondary to enlargement of the left side of the heart (108), palpitations secondary to atrial arrhythmias, and exercise intolerance (107). Morbidity occurs on account of heart failure, pulmonary hypertension, and endarteritis. By the fourth decade, mortality rises to 3% to 4% per year (108). One-third of patients die by age 40 and two-thirds by age 60 (108).

Five percent of patients with an isolated PDA develop Eisenmenger's physiology with systemic or suprasystemic pulmonary pressures (102). The resulting right-to-left shunt from pulmonary artery to descending aorta can result in oxygen saturations, which are decreased in the lower extremities compared with those in the upper extremities.

Management

Most of the patients with moderate or large PDA have undergone ductal ligation in infancy (see the section Outcome for a description of complications). Typically, these patients have had the lesion repaired early enough that few sequelae can be expected to occur. If the clinical examination, electrocardiography, and chest radiography results are normal, surveillance requirements are minimal.

Adult patients with a PDA but without an audible murmur may come from one of two groups: those with Eisenmenger's physiology and irreversible pulmonary vascular obstructive disease, or those with a fortuitously discovered PDA on echocardiography. The management of patients with Eisenmenger's disease is as outlined for patients with VSD and Eisenmenger's physiology and is described later in this chapter (see Eisenmenger's Syndrome). Based on the observation that endocarditis has been documented in conjunction with an audible murmur, the current consensus is that the presence of a silent duct does not warrant closure unless endarteritis has occurred (87).

In all other patients, in the presence of a PDA with an audible murmur, the combined risk of endarteritis, left-sided heart failure, and late mortality provides the rationale for shunt closure (87). Between 1951 and 1984, 117 patients were seen at The Cleveland Clinic with a diagnosis of isolated PDA (107). Although the majority of patients was in NYHA class I or II on initial presentation, significantly higher mortality was found in the nonsurgical patient group. After a mean follow-up of 18 years,

mortality occurred in 39% of the nonsurgical compared with 7% of the surgical group. Sixty percent of the patients who underwent ductal ligation reported symptomatic improvement compared with 19% of patients without ductal closure (107). These findings underscore the poor outcome of unoperated patients, even in the absence of significant symptoms at the time of presentation. If pulmonary artery pressure, pulmonary vascular resistance, or both are greater than two-thirds systemic, there should be a net left-to-right shunt of at least 1.5:1.0 or evidence of reversibility during pulmonary vascular reactivity studies before proceeding with PDA occlusion (87).

Options for ductal repair include surgical closure and transcatheter methods. Reported operative mortality varies from 0% to 8% (111,112,113 and 114). Calcification of the aortic end of the ductus and excessive bleeding if pulmonary hypertension is present may complicate the surgical approach and lead to incomplete ductal closure in adults (111,113). As described previously, transcatheter device closure or coil occlusion is considered the procedure of choice for PDA closure in adults (30,32,33 and 34,40,87).

Obstructive Lesions of the Right and Left Ventricular Outflow Tracts

The focus of the discussion that follows is on the most common single obstructive lesions of the pulmonary and aortic valves and aortic coarctation. Other anatomic variants are defined and referenced in the Prevalence and Anatomy section for each lesion. Obstructive lesions of the outflow tract are complicated by the secondary effects of pressure overload in the chamber proximal to the obstruction. In the presence of significant lesions, the inability to increase systemic or pulmonary blood flow in the face of a fixed obstruction, exercise intolerance, inadequate myocardial perfusion, ventricular arrhythmias, and sudden death requires monitoring, activity restriction, and timely intervention. Although recommendations for intervention are based on peak-to-peak gradients measured at cardiac catheterization, serial echocardiographic Doppler measurements can be used to assess initial disease and screen for significant changes in severity with the knowledge that cardiac catheterization–derived peak gradients correlate best with mean gradients obtained by echo-Doppler (115).

Pulmonary Stenosis

Prevalence and Anatomy

Obstruction of the right ventricular outflow tract can occur at the level of the pulmonary valve, below, or above it, either in the main pulmonary artery trunk or at one or both of its branches. These lesions as a group represent a spectrum of unoperated and postoperative anomalies and are some of the most commonly encountered in the adult with congenital disease.

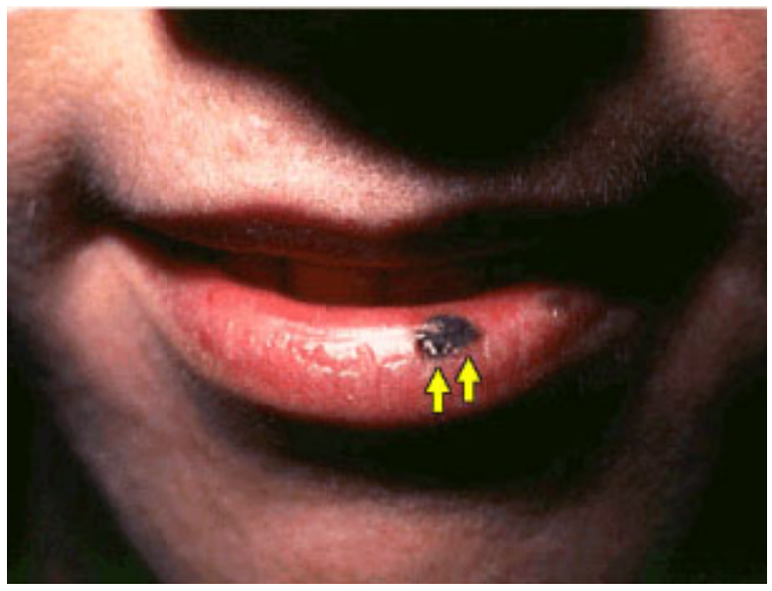
VIDEO

Video 31.5 Transesophageal echo of a patient with congenital pulmonary stenosis. Note the severe hypertrophy of the right ventricular outflow tract, causing infundibular pulmonary stenosis as well as valvular pulmonary stenosis. The pulmonic leaflets are thin and pliable; however, there is marked doming caused by tethering of the leaflet tips. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Isolated congenital valvar pulmonary stenosis is a common lesion reported to occur in 10% of all patients with CHD (116). The normal adult pulmonary orifice is approximately 2 cm per m^2. When stenosis of the valve occurs, fusion of the leaflets results in a narrow orifice seen at the top of a doming valve. There is a variable degree of thickening and calcification in older patients. A bicuspid pulmonary valve is seen in 20% of autopsied cases of pulmonary stenosis. In the majority of remaining cases, the valve is trileaflet. In 10% of these, the valve is dysplastic. The obstruction is not due to fusion but rather to myxomatous changes and severe thickening (117).

Pulmonary atresia with intact ventricular septum is a complex cyanotic lesion seen in newborns and infants, the physiology of which is governed by the variable degree of right ventricular hypoplasia and the presence of an abnormal coronary circulation (118). At the current time, these patients, operated on or not, are rarely encountered as adults. Pulmonary atresia with nonrestrictive VSD is a complex cyanotic lesion that can be seen in unoperated or operated adult patients. This is discussed in this chapter in conjunction with the TOF.

Supravalvar and branch pulmonary artery stenoses constitute important and common complications of the patient with TOF and are discussed with other complex lesions (see Complex Lesions). Residual supravalvar pulmonary stenosis can be encountered in patients who have had palliative pulmonary artery banding to decrease pulmonary blood flow in the presence of an isolated large VSD or other complex cyanotic lesions discussed in this chapter. Distortion of the main pulmonary artery trunk or the origins of the right and left pulmonary arteries can occur in up to 25% of cases (119). Congenital branch pulmonary artery stenosis can occur in isolation, in association with valvar pulmonary stenosis, with shunt lesions, or in association with a variety of syndromes. Patients with Noonan's syndrome—in addition to having a characteristic phenotypic facial appearance, short stature, and webbed neck—may have a dysplastic pulmonary valve and hypertrophic cardiomyopathy of the left ventricle in addition to peripheral pulmonary artery stenosis (116). Supravalvar pulmonary stenosis can occur with supravalvar aortic stenosis in association with the William's elfin facies syndrome (120).



Café au lait spot. There is a flat localized hyperpigmentation that is uniformly light brown in the lower lip (*arrows*) that may be associated with neurofibromatosis, Albright syndrome, or pulmonary stenosis.

Leopard's syndrome. Figure shows a patient with Leopard's syndrome characterized by multiple basal cell nevi and broad facies. There is an association with pulmonic stenosis.

Primary infundibular stenosis with intact ventricular septum can result from a fibrous band at the infundibulum (117). Right ventricular obstruction can also be due to the presence of anomalous muscle bundles that divide the right ventricle into two chambers; a high-pressure chamber below the hypertrophied muscle bundles and a low-pressure chamber above the bundles and below the valve. Hence the designation *double-chambered right ventricle*. The clinical features vary depending on the presence or absence of concomitant valvar pulmonary stenosis or a VSD, which typically communicates with the high-pressure chamber (121).

Outcome

Twenty-five-year survival is 96% of 586 patients with valvar pulmonary stenosis enrolled in the NHS-1 (122). Of the original cohort, 331 patients were followed for 16 to 29 years and enrolled in the NHS-2 (122). Poorest survival occurred in patients who had severe pulmonary stenosis on admission to the study. In patients with moderate pulmonary stenosis, with peak systolic gradients between 50 and 80 mm Hg at catheterization, survival was excellent, regardless of the choice of medical or surgical management. One-third to two-thirds of patients had echo-Doppler or clinical evidence of pulmonary insufficiency, the incidence of which was higher in surgically treated patients. Bacterial endocarditis, complex ventricular arrhythmias, and progression of the severity of the gradient was rare in those managed medically. Overall, the majority of patients had an excellent clinical status.

Management

For patients with pulmonary stenosis, indications for intervention should be tailored to symptoms, subjective and objective exercise tolerance, and the presence or absence of syncope and arrhythmias (see the section Outcome for a description of complications). Data from the NHS-1 and NHS-2 have been used to support recommendations for the management of valvar pulmonary stenosis (87,122). Intervention is usually indicated for severe lesions, defined as peak pulmonary gradients of greater than 80 mm Hg obtained on cardiac catheterization. Intervention is also indicated in patients with gradients greater than or equal to 50 mm Hg and symptoms. Conservative management is indicated for mild stenosis, defined as a gradient of less than 40 mm Hg. Unlimited athletic participation is allowed for asymptomatic patients with a peak echo-Doppler gradient of less than 50 mm Hg in patients with pulmonary stenosis (123).

The advent of balloon valvuloplasty for pulmonary valve obstruction has facilitated the decision to intervene in young patients, in whom the prospect of delaying or avoiding surgery with or without valve replacement is attractive (see previous discussion). Surgical valvulotomy remains a viable and safe alternative when valvuloplasty is not possible (124).

Aortic Stenosis

Prevalence and Anatomy

Stenosis of the left ventricular outflow tract can occur at, below, or above the aortic valve. Aortic coarctation is discussed later in this chapter (see Aortic Coarctation). Other forms of supravalvar aortic stenosis are seen in the context of William's elfin facies syndrome (120). Discrete subaortic stenosis accounts for 10% of all cases of congenital aortic stenosis and typically consists of a diaphragm or fibrous ring around the left ventricular outflow tract (eFig. 31.1.5) (125,126 and 127).

Subaortic stenosis. This right anterior oblique left ventriculogram demonstrates the presence of a stenosis in the left ventricular outflow tract (*yellow arrow*) just below the level of the aortic valve (*red arrow*).

The normal aortic valve has three cusps and commissures. Variations in the number and size of aortic cusps are well described (128). When the aortic valve is unicuspid, a single commissure is most commonly observed. The commissural unicuspid aortic valve accounts for the majority of cases of severe aortic stenosis in infants. Quadricuspid valves can be functionally normal or insufficient as is observed in truncus arteriosus. These valves are rarely stenotic. Congenital valvar aortic stenosis due to a bicuspid aortic valve is one of the most common congenital anomalies and accounts for up to one-half of all operated cases of aortic stenosis in adults (128) (eFig. 31.1.6). In patients with bicuspid aortic valve, associated dilatation of the aortic root with or without aneurysm occurs secondary to changes in the media of the aortic wall (129) and can occur out of proportion to the hemodynamic lesion (130,131).

Outcome

The estimated overall 25-year survival for patients with valvar aortic stenosis is 85% (132). Based on data obtained in 457 patients from the NHS-1 and NHS-2, those patients with initial peak cardiac catheterization gradients of less than 50 mm Hg at entry have a long-term survival of over 90% compared with those with gradients of greater than or equal to 50 mm Hg whose equivalent survival rates are 80%. Over one-half the deaths were sudden or unexpected. Forty percent of the patients required a reintervention or a first intervention if the initial decision was medical management. Twelve percent of patients treated surgically had complex ventricular arrhythmia on follow-up. Three percent of the original cohort had bacterial endocarditis. Only one-third of patients were in excellent clinical status on long-term follow-up (132). These findings are in sharp contrast to the favorable operated and unoperated history of patients with pulmonary stenosis; hence the difference in recommended threshold for intervention.

Management

For patients with aortic stenosis acquired as children, indications for intervention should be tailored to absolute gradients as well as symptoms (see the section Outcome for a description of complications). Data from the NHS-1 and NHS-2 can be used to support recommendations for the management of valvar aortic stenosis (87,132,133). Conservative management is generally indicated only for mild stenosis, defined as a peak cardiac catheterization gradient of less than 25 mm Hg, although close supervision is required because 20% of these patients are expected to require an intervention during long-term follow-up. The significant incidence of death during exercise in patients with severe aortic stenosis (134) underscores the need for close supervision and serial assessment for progression of disease. This is well reflected in the contrast between recommended exercise parameters for patients with pulmonic and aortic valve disease (123). Unlimited athletic participation is only allowed for asymptomatic patients with a peak echo-Doppler gradient of less than 20 mm Hg, and for patients with aortic stenosis, only if there are normal electrocardiogram and exercise test results. For patients in whom moderate or severe aortic stenosis is acquired during adulthood, indications for intervention are similar to those described for patients with other forms of acquired aortic valve disease described in Chapter 22.

In the absence of significant aortic insufficiency, transcatheter aortic valvotomy can be achieved successfully in children, although results are less uniform and less predictable than with pulmonary valvotomy (135). In young adults, aortic valvuloplasty can be considered as described previously. Calcification limits the procedural

success, prompting consideration of well-established surgical alternatives described elsewhere in this text.

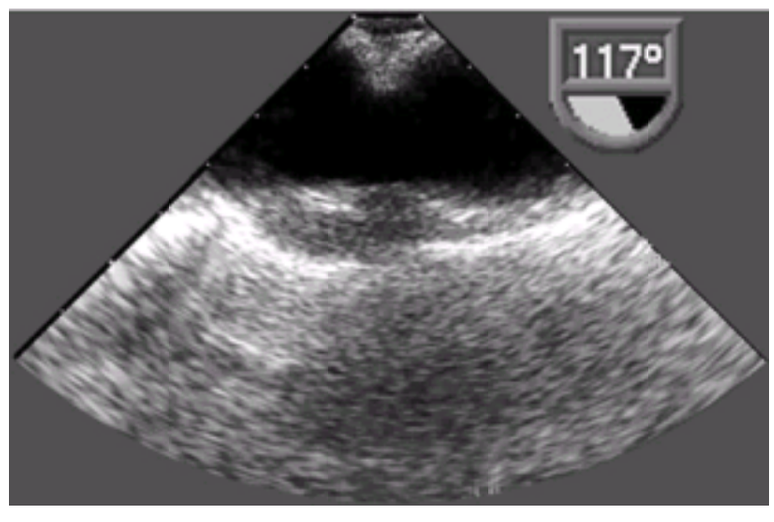
In patients with fixed fibromuscular subaortic stenosis, aortic regurgitation occurs in over 50% of cases (126) as the jet damages one or more of the leaflets of an otherwise normal valve. For these patients, surgical closure is indicated with resting gradients greater than 50 mm Hg, particularly in the presence of more than mild aortic insufficiency to prevent further deterioration of the valve (87,136).

Aortic Coarctation

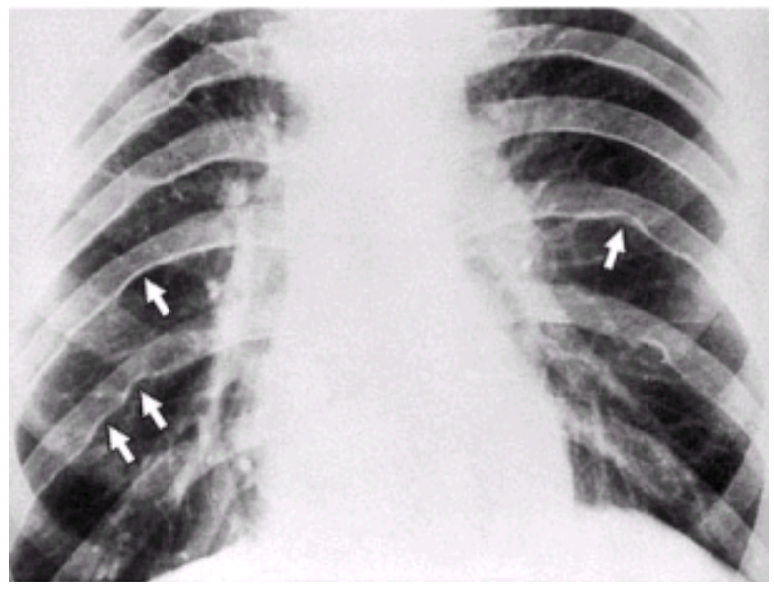
Prevalence and Anatomy

Aortic coarctation is a common congenital lesion in the infant population (137) in whom the presentation can be that of a severe low output state. In adolescents and adults, the diagnosis should always be sought in the event of unexplained hypertension of the upper extremities. The anatomy of coarctation (138) typically consists of a constriction just distal to the left subclavian at the site of the aortic ductal attachment or its residual ligamentum arteriosum. Less commonly, the coarctation ridge lies proximal to the left subclavian, giving rise to a differential blood pressure in the upper extremities. When aortic coarctation is diagnosed, careful assessment is made of the mitral inflow and the aortic outflow in its entirety for assessment of associated lesions. A bicuspid aortic valve is the most common coexisting anomaly, but obstruction above or below the valve as well as malformations of the mitral valve apparatus should not be missed. The coexistence of a VSD or a PDA is well documented (138). The transverse arch should be carefully examined for tubular hypoplasia. *Pseudocoarctation* refers to buckling or kinking of the aortic arch without the presence of a significant gradient (138,139).

Video 31.12 Coarctation of aorta (oblique). A signal-void jet is visible in the proximal descending aorta due to a short-segment narrowing representing a coarctation. Left ventricular hypertrophy is also present. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



A still frame of a transesophageal echo demonstrating a coarctation of the aorta. Note the local narrowing of the aorta located at the junction of the distal arch and descending aorta. There was a 100–mm Hg pressure gradient across the coarctation as determined by continuous wave Doppler.



Chest x-ray in coarctation of the aorta. There is prominent rib notching (*white arrows*).

Outcome

Complications of aortic coarctation include secondary left ventricular hypertrophy, systemic hypertension, heart failure, aortic dissection, premature coronary disease, and cerebrovascular complications (138,140). With untreated coarctation a mean survival of 35 years with a 75% mortality by age 50 years can be expected (140).

In a long-term study from the Mayo Clinic of over 500 patients who underwent coarctation repair, estimated survival at 30 years is 76 (141). Outcome after repair is closely related to the age at operation, with long-term survivorship maximized when surgery is performed before age 10 (141,142). Fifty percent of patients who received repairs after age 40 have residual hypertension, whereas those who underwent surgery between the ages of 1 and 5 have a less than 10% prevalence of hypertension on long-term follow-up (142). Not surprisingly, for those who have required surgery before the age of 1, the incidence of residual systemic hypertension is higher, reflecting the severity of neonatal coarctation syndrome (142). Even in the absence of systolic hypertension at rest after successful coarctectomy, an abnormal hypertensive response to exercise and a persistently elevated left ventricular mass have been documented (143,144). Cerebral vascular complications, myocardial infarction, and aortic dissection can occur in 2% to 6% of patients (142). After the age of 40, heart failure becomes increasingly frequent in the presence of unoperated coarctation and may persist after coarctation repair (142).

Management

Intervention in patients with coarctation or recoarctation should be performed with gradients greater than 50 mm Hg documented by cardiac catheterization (145) (see the section Outcome for a description of complications). For patients with gradients above 20 mm Hg, the occurrence of symptoms, systemic hypertension, or both warrant consideration for intervention (87).

Surgical intervention is well established (141). Surgery is more hazardous in adults than in children. When patients of all ages are considered, perioperative death rates are 3% (141) or less. The incidence of paraplegia due to spinal cord injury is less than 1% and the preferred surgical approach is resection with end-to-end anastomosis of the descending aorta (119). This approach has the advantage of removing the site of cystic medial necrosis, which has been observed at the site of coarctation, thereby decreasing susceptibility to aneurysm formation and dissection (146). Recoarctation is least common when an end-to-end anastomosis is performed, but the prevalence varies from 11% requiring a reoperation (141) to as high as 30%, depending on the age of repair and the surgical approach used (147). Latent development of coronary artery disease (141) and systemic hypertension (147) require lifelong monitoring (142).

Percutaneous coarctoplasty is being increasingly used as an alternative to surgical intervention (see Interventional Cardiac Catheterization). It is the treatment of

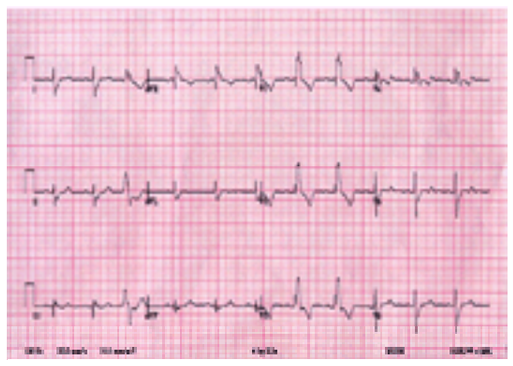
choice for focal recoarctation in adult patients who are previously operated. For adults with native coarctation, the choice of surgery or percutaneous coarctoplasty depends on the coarctation anatomy, the presence or absence of associated anomalies, as well as local expertise (87,148).

Complex Lesions

Tetralogy of Fallot

Prevalence and Anatomy

TOF is the most common cyanotic malformation (137) and was the first complex cyanotic lesion to be surgically repaired, as reported by Lillehei in 1955 (149). Hence, it is not surprising that repaired TOF accounts for one the most common lesions seen in adults with congenital cardiac anomalies (eFig. 31.1.7 and eFig. 31.1.8).



***e*FIGURE 31.1.7** Twelve-lead electrocardiogram of an adult patient with tetralogy of Fallot repair. Note the complete right bundle branch block and the ventricular ectopic beat.

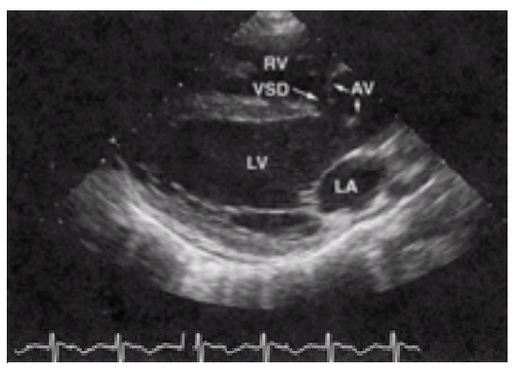
Note the mid-systolic ejection murmur probably related to right ventricular outflow tract obstruction. Left lower sternal border. (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The core lesion is an underdeveloped subpulmonary infundibulum (150), which is superiorly and anteriorly displaced, resulting in the well-known tetrad: pulmonary stenosis, VSD, aortic override, and right ventricular hypertrophy (eFig. 31.1.9). The term *pulmonary stenosis* in this context seems deceptively benign. The nature, degree, and site of right ventricular outflow obstruction represents the spectrum of severity seen with this lesion. This includes malformations of the subvalvar and valvar areas, distal pulmonary artery stenosis, and pulmonary artery hypoplasia. Hence, the right ventricular outflow tract is the seat of the most difficult preoperative and postoperative management issues. The following remarks are confined to TOF without pulmonary atresia.



***e*FIGURE 31.1.9** Parasternal long-axis echocardiographic view of an unoperated patient with tetralogy of Fallot showing the overriding aorta and perimembranous ventricular septal defect (VSD). AV, aortic valve; LA, left atrium; LV, left ventricle; RV, right ventricle.

Outcome

Published data, on approximately 1,500 patients with complete TOF repair followed for at least 10 years, show 90% to 95% survivorship with good functional results (151,152,153 and 154). Overall 35-year survival rates are maintained at 85% (154,155), but mortality increases after 25-year follow-up (155). The best results are obtained when repair is performed before age 5 (154), thereby providing the rationale for current trends in complete early repair, avoiding the use of palliative surgical shunts (155,156). In patients who have not benefited from early repair, total correction in adulthood is possible with a low mortality and a favorable long-term follow-up (155,157). Residual pulmonary stenosis, proximal or distal, with a right ventricular pressure greater than half systemic has been reported in up to 25% of patients (152,158). Some degree of pulmonary insufficiency is common, particularly if a patch has been inserted at the level of the pulmonary valve or if there has been a pulmonary valvotomy. An approximate 12% of patients undergo pulmonary valve replacement (159). Residual VSDs can be found in up to 20% of patients, but significant shunts are less common (154,158). The most common electrocardiographic finding after TOF repair appears to be the most benign: the complete right bundle branch block. This is seen on follow-up 12-lead electrocardiography in 80% to 90% (152). Even in the presence of a left anterior hemiblock, the prognosis for

these patients is favorable (152,160). Sinus node dysfunction, atrial fibrillation or flutter, and nonsustained ventricular tachycardia are seen in approximately 20% to 40% of patients (161). The reported incidence of sudden death in patients after TOF repair is approximately 5% (162), with an increase in yearly incidence with duration of follow-up (155).

Management

Long-term management in the patient with TOF is focused on maximizing right ventricular function, the need for surgical or percutaneous intervention, and arrhythmia therapy (see the section Outcome for a description of complications). An unoperated or palliated adult with TOF should be considered for full repair. Candidacy for repair depends on the pulmonary vascular bed in a patient who has been palliated and on biventricular function in a patient who is unoperated. Indications for reoperation in a patient who has undergone physiologic repair most commonly include recurrent stenosis in the right ventricular outflow tract if the right ventricular pressure is greater than two-thirds systemic or if residual pulmonary stenosis occurs in combination with significant pulmonary regurgitation (87). Other indications include the presence of a significant residual VSD or significant aortic regurgitation. The indication for pulmonary valve replacement in a patient with asymptomatic significant pulmonary insufficiency remains controversial (159), but surgery is recommended when progressive right ventricular dilatation and dysfunction occur, particularly in the presence of significant arrhythmia.

Hemodynamic complications coexist with arrhythmias. The most contentious is the well-named *ectopic* ventricular beat, poorly understood and difficult to manage. Ventricular arrhythmias can be detected on a 12-lead electrocardiogram in 10% of patients, during an exercise test in 40% of patients, and during 24-hour Holter monitoring in 40% to 60% of patients (160,163). Although symptomatic patients with atrial or ventricular arrhythmia should be treated with antiarrhythmic therapy, it is not recommended to attempt suppression of ventricular ectopy in those who are without symptoms (164).

On 12-lead electrocardiography, a QRS duration of more than 180 ms correlates with right ventricular size, sustained monomorphic ventricular tachycardia, and sudden cardiac death (165,166). In addition to sustained ventricular tachycardia, severe right ventricular systolic hypertension (152,163) and significant pulmonary regurgitation (165) have both been implicated in sudden cardiac death, which is reported in up to 5% of patients after TOF repair (162). The presence of ventricular arrhythmia in combination with right ventricular pressure or volume overload conspires to increase the risk of sudden death more than either one alone, and therefore in the presence of either, the other should always be sought.

Monitoring of arrhythmias may be undertaken using 24-hour Holter monitoring and exercise testing every 1 to 2 years. Underlying hemodynamics, using two-dimensional and Doppler echocardiography, should be carefully and serially reassessed, particularly in the event of a change in frequency or complexity of ventricular ectopy. A reversible cause for a new-onset ventricular arrhythmia such as a rise in right ventricular pressure or a change in right ventricular function should not be missed. There is no role for routine electrophysiologic testing in the prevention of sudden death, but patients with unexplained syncope should be referred for detailed assessment in specialized centers. In addition to surgical or percutaneous intervention aimed at improving significant hemodynamic lesions, antiarrhythmic therapy, pacemakers, and implantable defibrillators may be indicated.

Pulmonary Atresia with Ventricular Septal Defect

Prevalence and Anatomy

TOF with pulmonary atresia or pulmonary atresia with ventricular septal defect (PA-VSD) is a complex form of TOF. As the name indicates, the right ventricular outflow tract is completely atretic, with pulmonary blood flow being derived from aortic-to-pulmonary collaterals. This group of patients is of interest to the adult cardiologist because unoperated adult survival is well documented (167).

Outcome

Survival depends on the adequacy of pulmonary blood flow derived from systemic collaterals. Unoperated PA-VSD exhibits a bimodal mortality pattern. The majority of unoperated patients with inadequate aortic-to-pulmonary blood flow dies in infancy or childhood. A small percentage survive to adulthood because of adequate but not excessive aortic-to-pulmonary circulation, but one-third of all unoperated adult survivors and close to one-half of those who remain unoperated die at a mean age of 33 (167). Morbidity in the unoperated adult survivor relates mainly to heart failure and aortic regurgitation (167).

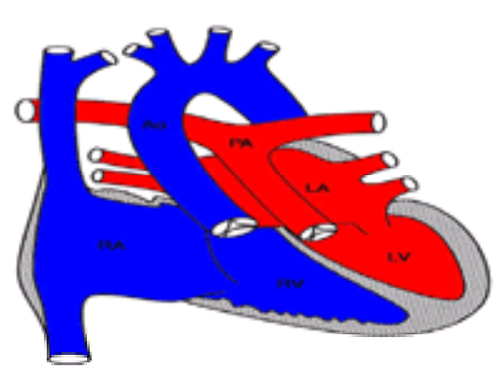
Management

Staged reconstructive operations are now performed on a broad range of patients with PA-VSD, but long-term results of complex surgical management remain uncertain. Of adult survivors, two-thirds may be eligible for physiologic repair with low postoperative mortality and seemingly favorable outcome (167). Whether complex unifocalization techniques are destined to provide the best long-term follow-up remains to be seen, but consideration should be given to surgical management in specialized centers where expertise is available.

Complete Transposition of the Great Arteries

Prevalence and Anatomy

The following remarks are confined to simple complete transposition of the great arteries, defined anatomically as atrioventricular concordance with ventriculoarterial discordance, in the absence of tricuspid or mitral atresia or univentricular heart. In this variant of the transposition complexes, the aorta is most often anterior and rightward (dextroposed), with respect to the pulmonary artery. Hence the designation D-*transposition* of the great arteries (eFig. 31.1.10). This lesion constitutes the second most common cyanotic lesion (137) and, in its surgically corrected form, accounts for an important group of operated adult survivors.



***e*FIGURE 31.1.10** Schematic illustration of complete transposition of the great arteries with S,D,D segmental anatomy. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

The chronologic evolution of surgical treatment for D-transposition of the great arteries is shown in Table 31.2. This exemplifies the progress achieved in congenital cardiac surgery and demonstrates how surgical strategies determine anticipated clinical profiles. The current issues of major concern in the late follow-up of these patients reflect the application of repair at the atrial (Senning's and Mustard's atrial baffles as described below) and ventricular levels (168). Over the course of the next two decades we will see a different set of complications related to the primary neonatal arterial switch operation with its formidable coronary translocations (169).

Outcome

The native physiology is such that at birth, the pulmonary and systemic circulations occur in parallel instead of in series, with effective pulmonary blood flow being dependent on intracardiac shunting. Not surprisingly, without treatment mortality is 90% in the first year of life (170). At the present time the problems of major concern are the ones associated with the atrial switch. These procedures are designed to reroute systemic and pulmonary venous return so that deoxygenated blood can be directed to the pulmonary artery and oxygenated blood to the aorta. This is accomplished by using native atrial tissue in Senning's operation (171) or pericardial tissue

with or without prosthetic material in Mustard's operation (172) to create an intraatrial baffle. "Repair" is accomplished, but at the cost of the morphologic right ventricle remaining in the subaortic position to perform lifelong systemic work.

Of an approximate 1,200 patients followed, on whom long-term published data are available, survival estimates average 75% at 15 years and 67% to 76% at 20 years (173,174 and 175). Although 90% of patients deny subjective limitation in daily life (175), right ventricular dysfunction can be documented in asymptomatic patients, at rest in over 30%, and during exercise in up to 60% of those tested at approximately 10 years' follow-up (176,177). Tricuspid regurgitation is present in 40% of patients with or without right ventricular dysfunction (178). Compounding the hemodynamic complications of systemic right ventricular dysfunction, the extensive atrial surgery results in a progressive decline in the prevalence of sinus rhythm with sinus bradycardia, nodal rhythms, and heart block occurring with increased frequency (173,175). At 20-year follow-up, less than one-half the patients are in sinus rhythm (175). Late atrial flutter or fibrillation occurs in 20% of patients (179). The late occurrence of atrial flutter is an important predictor of poor outcome and may precede the accelerated decline in right ventricular dysfunction (175,180). The incidence of sudden cardiac death varies from 2% to 3% (173) to as high as 16% (175). The etiology of sudden death is poorly understood, but it is likely to be multifactorial and related to poor right ventricular hemodynamics in combination with bradyarrhythmias and tachyarrhythmias (175).

Management

In patients who have undergone Senning's or Mustard's operation arrhythmia management, systemic right ventricular dysfunction, and the need for reoperation constitute the key issues in long-term follow-up (see the section Outcome for a description of complications). Reoperation is performed in an approximate 20% of patients (181). The indications relate to baffle leak or obstruction, significant systemic tricuspid regurgitation, progressive left ventricular outflow tract obstruction, or rarely pulmonary venous obstruction (181).

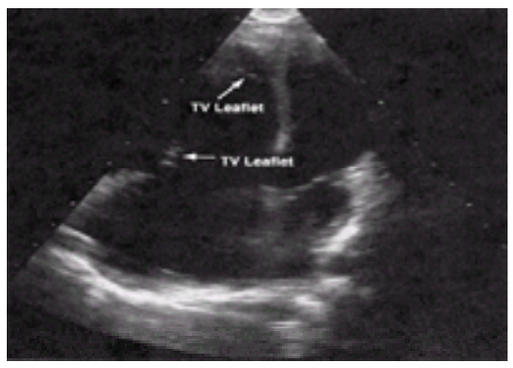
Long-term follow-up reveals an increasing incidence of bradyarrhythmias and supraventricular tachyarrhythmias. Surveillance of arrhythmias should include Holter monitoring and exercise testing at regular intervals. Every attempt should be made to maintain the patient in sinus rhythm, using electrical cardioversion, medical therapy, or both. Pacemaker insertion should be considered in patients with symptomatic bradyarrhythmias. Transvenous pacing with fixation in the morphologic left ventricle (subpulmonary) may be required with or without antitachycardia pacing. Baffle integrity should always be verified to rule out obstruction or leak possibly giving rise to paradoxical emboli. Epicardial pacing is an alternative when ventricular access is hampered by small venous baffle channels. Referral for electrophysiologic studies should be considered in the event of unexplained syncope or arrhythmias unresponsive to medical therapy. Radiofrequency catheter ablation of supraventricular tachycardias can be performed in experienced specialized centers (182). The concurrent monitoring of hemodynamics is crucial. New arrhythmias should always prompt a search for a change in ventricular function or progressive atrioventricular valvar regurgitation requiring tricuspid valve replacement or repair. Trials are ongoing to examine if afterload reduction with angiotensin-converting enzyme inhibitors or receptor blockers may improve systemic right ventricular dysfunction.

For patients with unmanageable systemic right ventricular failure, atrial baffle takedown with a late arterial switch operation has been attempted as an alternative to heart transplantation (183,184,185 and 186). At the current time, mortality for this procedure is high, and much remains to be learned before this can be recommended. The problems delineated previously provide the rationale for the widespread application of the arterial switch operation whereby the left ventricle is reinstated to perform its destined systemic function, and the mismatch between morphology and function is restored. For the arterial switch operation, center-specific series are now emerging with encouraging results (187). Cumulative 15-year survival is over 85% and is expected to increase as improved early mortality makes an impact. The most common complication is neopulmonary stenosis, and thus far, arrhythmias and coronary complications are infrequent (187).

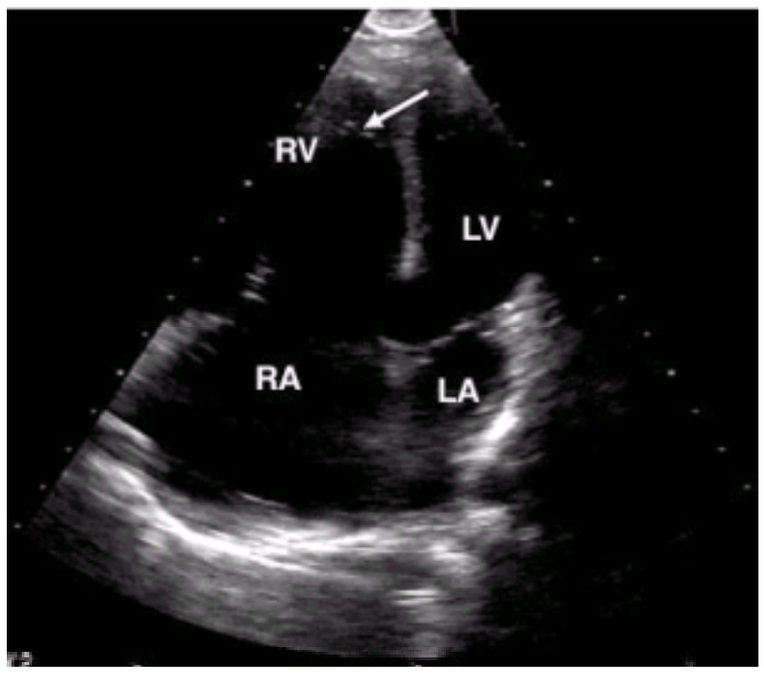
Right-Sided Ebstein's Anomaly

Prevalence and Anatomy

Transthoracic two-dimensional echocardiography has become the method of choice for diagnosing Ebstein's anomaly. The most sensitive echocardiographic feature is distal septal tricuspid leaflet displacement of greater than 8 mm per m^2 (indexed to body surface area). Measurements can be made from the tricuspid valve annulus at the crux (*e*Fig. 31.1.11) (188). In right-sided Ebstein's anomaly of the tricuspid valve, the right side of the heart consists of three anatomic components including the right atrium proper, the functional right ventricle (true right ventricle), and the atrialized portion of the right ventricle between the two. The displaced tricuspid valve lies between the atrialized right ventricle and the true right ventricle. The atrialized right ventricle is anatomically and electrically right ventricle, but functionally right atrium. It generates a ventricular QRS but an atrial pressure pulse (189). Hence, it fills while it contracts. There is a wide spectrum of severity of the lesion, based on degree of tricuspid leaflet tethering, the relative proportion of atrialized and true right ventricle, and the presence or absence of right ventricular outflow tract obstruction. These variations account for differences in clinical presentation. The most common associated cardiac defect is a secundum ASD or patent foramen ovale reported in over 50% of patients (190).



***e*FIGURE 31.1.11** Four-chamber echocardiographic view showing apical displacement of septal tricuspid (TV) leaflet in a patient with Ebstein's anomaly.

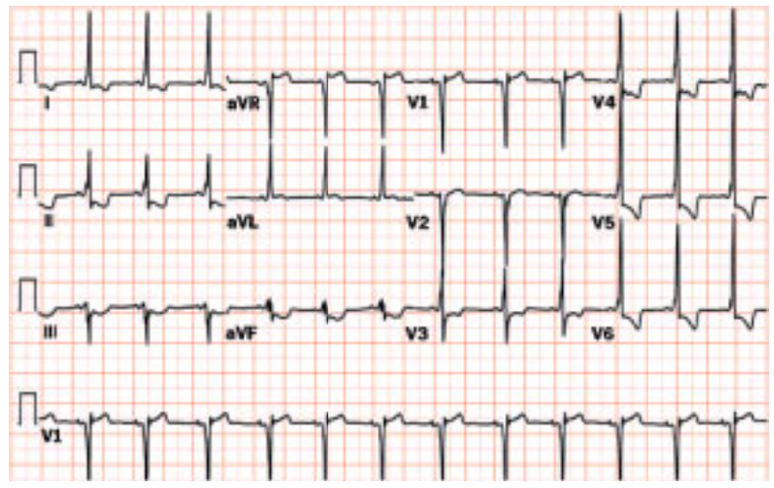


Ebstein's anomaly of the tricuspid valve. Note marked apical displacement of the tricuspid leaflets, especially the septal leaflet. The arrow designates the septal leaflet of the tricuspid valve.

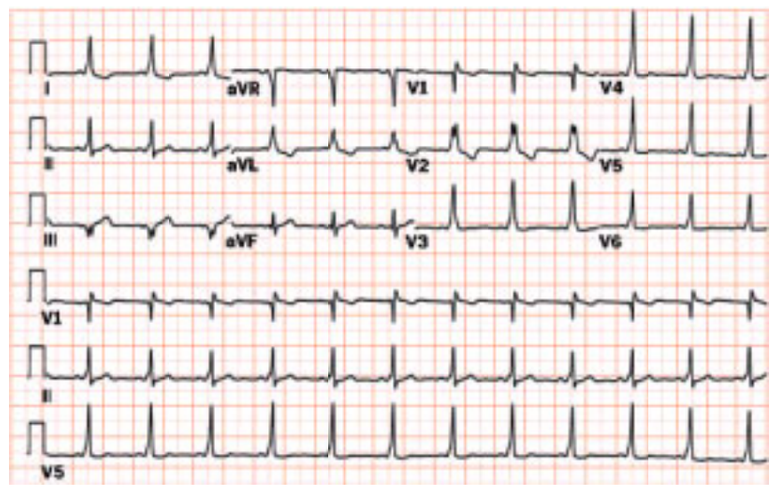
Outcome

Ebstein's anomaly diagnosed in the neonatal period and in infancy has a poor prognosis, with mortality of 30% to 40% in the first decade. When patients of all ages are

taken together, the predicted mortality is approximately 50% by the fourth or fifth decade (191,192). Clinical factors that have been shown to predict poor outcome include infancy at the time of diagnosis, NYHA class III or IV, oxygen saturation of less than 90%, and cardiothoracic index of greater than or equal to 0.65 (191,192 and 193). Cardiomegaly at the expense of the right atrium and atrialized right ventricle are indicators of poor outcome (191). Preexcitation by 12-lead electrocardiography occurs in 20% of patients (191). Supraventricular tachyarrhythmias, including reentrant supraventricular tachycardia, atrial fibrillation, and atrial flutter, occur in 30% to 40% of patients and constitute the most common presentation in adolescents and adults (191,192). The role of arrhythmias in the etiology of sudden death, reported in 3% to 4% of patients (191), remains unclear.



Wolff-Parkinson-White syndrome. Eleven-year-old patient with manifest preexcitation consistent with Wolff-Parkinson-White.



Wolff-Parkinson-White syndrome. Note short PR interval with classic delta wave due to accessory pathway conduction.

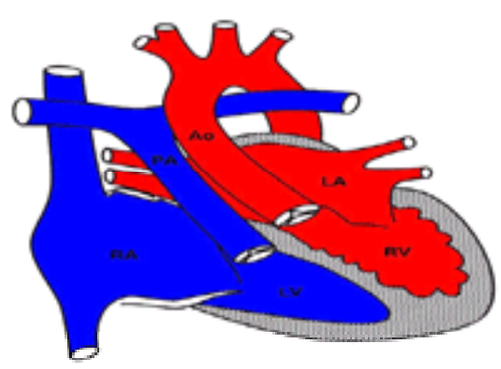
Management

In patients with Ebstein's anomaly, the indications for surgery are deterioration in functional class, progressive cardiomegaly or tricuspid regurgitation, and worsening cyanosis (87) (see the section Outcome for a description of complications). For surgical purposes, Carpentier has distinguished four types of Ebstein's anomalies emphasizing the mobility of the anterior leaflet of the tricuspid valve (type A and B) or its restricted motion (type B and C) as well as the variable degree of the septal leaflet displacement and the variable size and function of the atrialized right ventricle and the true right ventricle (194). Surgical options used in patients with Ebstein's anomaly include tricuspid valve replacement (195) or repair (194,196,197 and 198) of the tricuspid valve and closure of the atrial septal defect. Preservation of the native tricuspid valve and feasibility of tricuspid valvuloplasty depend on the size and mobility of the tricuspid leaflet used to construct a unicuspid right atrioventricular valve (194,196,197 and 198). Although early reports were associated with a mortality of 25% (193), more recent reports have shown early and late mortality of 3% to 14% with (195) or without (194,199) tricuspid valve replacement. In patients with high-risk preoperative anatomy the inclusion of a bidirectional cavopulmonary shunt decreases operative mortality (200). Addition of the Maze procedure in experienced centers is expected to reduce the incidence of atrial arrhythmias (201).

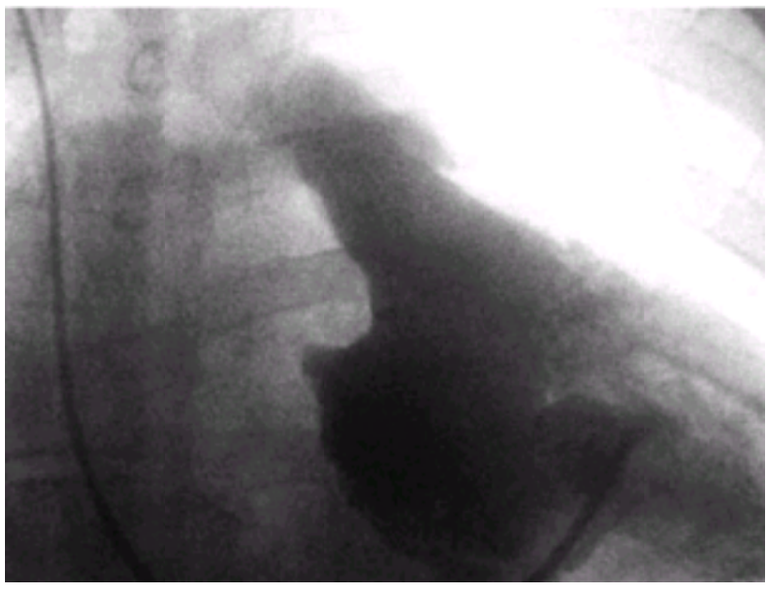
Congenitally Corrected Transposition of the Great Arteries

Prevalence and Anatomy

Congenitally corrected transposition of the great arteries is a condition in which, although the great arteries are transposed, the ventricles are also inverted. There is visceral situs solitus, atrial situs solitus, ventricular inversion (L ventricular loop), and most commonly the aorta is anterior and leftward, hence the designation S,L,L segmental anatomy (*e*Fig. 31.1.12). There is atrioventricular discordance as well as ventriculoarterial discordance. The occurrence of this double discordance has two important implications. First, the systemic and pulmonary circulations are in series, as is the case in the normal cardiopulmonary circulation, and therefore, in the absence of a shunt, the patient is acyanotic; the condition is thus "congenitally corrected." Second, the morphologic right ventricle and tricuspid valve are aligned with the aorta and perform lifelong systemic work. It follows that, although this lesion has been reported in only 1% to 2% of pathologic series of congenital lesions, the presentation of a seemingly well unoperated adult is not uncommon for adult cardiologists. The physiology is determined by the presence of accompanying lesions, which occur in isolation or in various combinations in 20% to 90% of patients. These include a perimembranous VSD, pulmonary stenosis, and Ebstein's malformation of the tricuspid valve (202,203). The presence of left-sided Ebstein's anomaly can occur with or without left-sided accessory bypass tracts between the left atrium and systemic right ventricle, thereby predisposing the patient to preexcitation and reentrant tachycardias (202). The coronary anatomy tends to be uniform, with the left coronary artery supplying the morphologic left ventricle and the dominant right coronary artery arising from the left sinus, supplying the morphologic right ventricle (204).



***e*FIGURE 31.1.12** Schematic illustration of congenitally corrected transposition of the great arteries with S,L,L segmental anatomy. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.



Epstein's anomaly. Right anterior oblique projection of a right ventriculogram demonstrating Epstein's anomaly.

Outcome

The patient's presentation and clinical outcome are determined by the presence or absence of associated lesions, systemic morphologic right ventricle dysfunction, atrioventricular valve regurgitation, and rhythm disturbances. Patients with congenitally corrected transposition of the great arteries and no other associated defects can remain free of symptoms until the sixth decade, at which time significant atrioventricular valve regurgitation, heart failure, and supraventricular arrhythmias occur in over 50% of patients (205). Survival rates at 20 years are strongly influenced by the presence of significant (systemic) tricuspid regurgitation, which affects the course of right ventricular function (206). Complete heart block is reported in 10% to 40% of patients (203,205,207) and develops at a rate of 2% per year. In the presence of associated lesions requiring palliative or definitive surgical repair, mortality increases and survivorship diminishes significantly (203). When adults are considered as a group, at least 30% to 50% of patients are likely to require surgery over the course of follow-up (203,207).

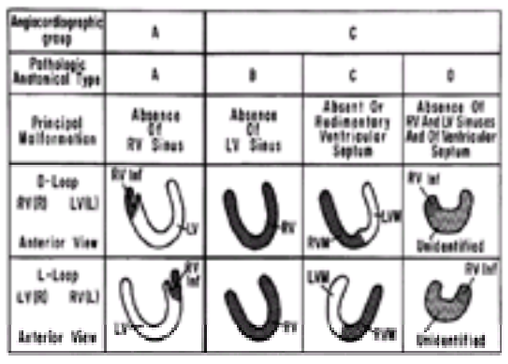
Management

In patients with congenitally corrected transposition of the great arteries, management issues relate to maintenance of systemic right ventricular function, treatment of heart block, and surgical correction of residual or associated lesions (see the section Outcome for a description of complications). Trials are ongoing to determine the effectiveness of afterload reduction in improving ventricular performance. Indications for surgery fall into one of three categories: pacemaker insertion, correction of associated VSD or pulmonary stenosis, and atrioventricular valve replacement or repair. Permanent pacing is usually required in the presence of complete heart block. DDD pacing is preferable to maximize ventricular filling in a systemic morphologic right ventricle. Surgical ablation of accessory pathways sometimes occurs fortuitously or with surgical intervention on the tricuspid valve. In the presence of a shunt, transvenous pacing is contraindicated because of the risk of paradoxical emboli. A VSD should be closed when the shunt is significant. Intervention or reintervention for pulmonary stenosis should be considered when the left ventricular outflow tract gradient exceeds 60 to 70 mm Hg. For uncomplicated congenitally corrected transposition of the great arteries, the timing of surgical intervention for atrioventricular valvular regurgitation remains controversial but should be considered in patients with moderate atrioventricular valve regurgitation in the face of worsening systemic right ventricular function. Early and late surgical mortality appears related to progressive ventricular failure. Postoperative survivorship correlates with a preoperative ventricular ejection fraction (208). A poor outcome occurs when preoperative ejection fraction is less than 40% to 45% (208).

Univentricular Heart and Tricuspid Atresia

Prevalence and Anatomy

Complex lesions such as single ventricle and tricuspid atresia account for less than 2.5% of all CHD (240), but operated adult survivors are becoming increasingly common (5). The terms *single ventricle*, *common ventricle*, and *univentricular heart* have been used interchangeably to indicate a condition in which one ventricular chamber receives both the tricuspid and mitral valves, hence the accurate designation *double-inlet ventricle*. Patients with a single ventricle can be categorized based on two principal findings: the morphology of the ventricle and the presence or absence of an outlet chamber giving rise to one or both great arteries. In the majority of cases, the single ventricle is of the morphologic left ventricular type with a univentricular heart of the right ventricular type accounting for 10% to 25% of all cases (210). Least commonly, the ventricular morphology is indeterminate. Most commonly, an outlet chamber is present and is found in the anterosuperior position, either to the right (D-loop or noninverted) or left (L-loop or inverted) (eFig. 31.1.13, type A). In the majority of cases, the ventriculoarterial connection is discordant, with the aorta arising from the outflow chamber (eFig. 31.1.14). Obstruction of one of the great arteries is frequent (210).



***e*FIGURE 31.1.13** Classification of univentricular heart. LV, left ventricle; LVM, left ventricular muscle; RV, right ventricle; RVM, right ventricular muscle.

***e*FIGURE 31.1.14** Angiogram of univentricular heart.

Tricuspid atresia has been classified into eight basic categories (eTable 31.2.1) (211). Patients with associated pulmonary atresia (types 1A and 2A) rarely survive infancy unless they have a persistent PDA or have a palliative surgical shunt. Patients with pulmonic stenosis (types 1B, 2B, and 3A) account for 70% of all patients with tricuspid atresia and constitute the most common anatomy associated with adult survival (212).

***e*TABLE 31.2.1** CLASSIFICATION OF TRICUSPID ATRESIA
Type 1: Normally related great arteries (69%)
Pulmonary atresia
Pulmonary stenosis and ventricular septal defect
Large ventricular septal defect without pulmonary stenosis
Type 2: D-Transposition of the great arteries (27%)
Pulmonary atresia
Pulmonary stenosis and ventricular septal defect
Large ventricular septal defect without pulmonary stenosis
Type 3: L-Transposition of the great arteries (3%)
Pulmonary stenosis
Subaortic stenosis

Outcome

Long-term follow-up of unoperated and palliated patients with univentricular heart has been studied (213,214). Of 83 unoperated patients (242), type A single ventricle anatomy was observed in 81% and type C in 19%. Fourteen years after diagnosis, when most patients were in their late teens and late twenties, 50% of the patients with type A univentricular heart had died at an approximate annual death rate of 5%. Sixteen years after diagnosis, only 30% of the patients with type A anatomy were alive. Type C anatomy had a poorer prognosis. Only 50% of these patients were alive 4 years after diagnosis. Long-term follow-up of 84 palliated patients with univentricular heart was also examined (214). Mean age at diagnosis was 10 years, with a mean follow-up of 5 years. Palliative procedures included systemic-to-pulmonary-artery shunts alone in 43, pulmonary artery banding in 15, and a combination of procedures in 26. At the end of the observed follow-up period at a mean age of only 15 years, close to one-third of patients had died. The outcome of patients who have undergone the Fontan operation is described in the next section.

Management

Patients with univentricular heart and tricuspid atresia require a detailed evaluation with noninvasive and invasive imaging techniques. Two-dimensional echocardiography and Doppler interrogation as well as MRI are used to determine ventricular and atrioventricular valve function, pulmonary artery pressure and resistance, and pulmonary anatomy. When biventricular repair is not feasible, patients may benefit from further palliation with a Glenn's shunt or may be eligible for the Fontan operation.

In both instances, a direct anastomosis is performed between the systemic venous and pulmonary circulations. The Glenn's anastomosis diverts part of the systemic venous return to the lungs, whereas the Fontan procedure and its variants divert the entire systemic venous circulation to the pulmonary vascular bed. Both are done with the goal of improving oxygenation and loading conditions of the systemic ventricle. Partial volume unloading of the single ventricle can be achieved with a bidirectional Glenn's anastomosis (215). Cavopulmonary shunts confer long-term benefit to ventricular function when compared with aortopulmonary shunts (216). Actuarial survival with Glenn's shunt is 84% and 66% at 10 and 20 years, respectively (10).

Fontan Operation

Since its first application in patients with tricuspid atresia in 1972, the Fontan procedure has undergone multiple modifications, resulting in improved surgical technique and expanded criteria for surgical candidacy. In its most recent anatomic variants, direct anastomosis between the systemic venous and the pulmonary circulations is achieved by bypassing the systemic venous ventricle (modified Fontan) or both the systemic venous atrium and ventricle (total cavopulmonary anastomosis) with or without a fenestration (217,218). In the absence of a pulsatile subpulmonary chamber, pulmonary pressures must necessarily be low. In the presence of a fenestration, the established communication between the Fontan conduit and the atrial cavity allows "decompression" of the pulmonary pressures maximizing flow through the pulmonary vascular bed. The goals of the Fontan operation are threefold: relief of cyanosis, maximal reduction of volume loading of the systemic ventricle, and maintenance of appropriate cardiac output. For optimal results, a successful Fontan operation requires preserved ventricular function, minimal atrioventricular valve regurgitation, unobstructed anastomosis between the systemic veins and the pulmonary arteries, as well as a low pulmonary vascular resistance.

The Fontan operation can be successfully performed in selected adults with a low operative mortality and favorable intermediate-term results (219,220). The Mayo Clinic reported a large series of 121 patients over 18 years who had the Fontan procedure (219). This included 34 patients with tricuspid atresia, 38 patients with double-inlet left ventricle, and 49 patients with complex malformation, such as double-inlet right ventricle, associated with asplenia and heterotaxy syndromes. The operative mortality in adults from 1988 to 1992 was 10%. During the same time period, the operative mortality for children less than 17 years of age was not significantly different at 7%, confirming that older age at the time of intervention is not an independent marker of poor outcome (219,220 and 221). When patients of all ages are considered together, examining a cohort of subjects operated before 1985, 5- to 10-year survival varies from 60% to 70%. Late deaths are due to reoperation (220), arrhythmia, ventricular failure, and protein-losing enteropathy.

At 5- to 10-year follow-up, 80% or more of Fontan survivors are in NYHA functional class I or II (220,221 and 222). Successful pregnancy has been reported in a small number of patients after the Fontan operation (223). Despite the fact that most patients report good subjective aerobic functional capacity, objective measures of exercise tolerance are impaired. The heart-rate response to exercise is blunted (221), and ventricular ejection fraction increases little in response to exercise (221). Other parameters of abnormal cardiopulmonary response include lower maximum workload, lower aerobic threshold (221), a decreased maximum oxygen uptake, and a restrictive pattern in lung function when compared with normal (224). In addition, decreased ventilatory threshold, increased physiologic dead space, and ventilation-perfusion mismatch have been reported (221,225).

The incidence of atrial arrhythmia varies between 20% and 40% of patients 10 years after the Fontan operation (226). The occurrence of new atrial arrhythmias should motivate a search for hemodynamic complications such as worsening of atrioventricular valvular function or obstruction of Fontan anastomosis with or without thrombus (227). Important predictors of supraventricular tachyarrhythmias after surgery are related more to abnormalities of the atrioventricular valve and age at operation rather than to the anatomic variant of Fontan procedure (228). Atrial flutter and fibrillation are poorly tolerated and should be treated aggressively with overdrive pacing or DC cardioversion combined with appropriate antiarrhythmic medication (226). When atrial arrhythmias are refractory to medical therapy, Fontan revision with cryoablation may be considered (229). Long-term anticoagulation with coumadin should be instituted. There are a significant number of adult patients who develop late sinus bradycardia. For symptomatic bradycardia, permanent atrial pacing is required. As many as 10% of long-term survivors may require permanent pacing for sinus node dysfunction or atrioventricular block (226).

Protein-losing enteropathy is a serious complication of the Fontan procedure occurring in 4% to 10% of Fontan patients during early or late follow-up (230,231). In conditions predisposing to systemic venous congestion, it is postulated that chronic elevation in superior vena cava pressures may lead to impaired lymphatic drainage with enteric protein loss and secondary hypoproteinemia. Clinical findings include peripheral edema, ascites, pleural effusions, and elevated right atrial pressures. When other causes of hypoproteinemia have been excluded, the diagnosis is made by quantifying gastrointestinal protein loss using $alpha_1$-antitrypsin clearance or ^{51}chromium-labeled albumin. Medical therapy includes the use of diuretics, afterload reduction, and protein infusions. Surgical or interventional therapy uses a wide variety of procedures aimed at optimizing Fontan hemodynamics. Conversion of the Fontan operation to a bidirectional Glenn's shunt or heart transplantation may be necessary. Overall prognosis is poor, with an approximate 50% survival at 5 years (230).

The prevention and management of thromboembolic complications of the Fontan procedure remain controversial (232). The prevalence of intracardiac thrombosis is as high as 30% when transesophageal echocardiography is used for diagnosis (233). Patients may or may not be symptomatic, and the risk of thromboembolism does not appear to be clearly modified by the type of Fontan anastomosis (234). At the current time anticoagulation with coumadin is recommended in the presence of arrhythmias in patients with a Fontan fenestration and when evidence of stasis is seen on echocardiographic examination.

The Fontan operation and its evolution illustrate some fascinating surgical concepts that have challenged our understanding of the subpulmonary circulation. Because palliated survival with single-ventricle physiology is possible, performing the Fontan operation in adult life may be appropriate and should be considered in individual cases. The two issues to be determined are, first, is it feasible, and, second, is it beneficial? As described in this chapter, the Fontan operation can be performed in properly selected adults with acceptable operative mortality and encouraging results. The question as to whether the Fontan operation *should* be performed on an adult is more controversial. The rationale for doing so is twofold: prevention of progressive ventricular deterioration and the alleviation of cyanosis. On the other hand, what more do we achieve with the Fontan procedure in an adult? Is quality of life improved? Which complications are easier to live with? The answers to these questions are still controversial, but when appropriate, they should always be asked with respect to the individual patient. The final decision should be made in centers of expertise where experience, knowledge, and skill maximize the clinical outcome.

EISENMENGER'S SYNDROME

Definition

The designation *Eisenmenger's syndrome* is not synonymous with pulmonary hypertension in a cyanotic patient with CHD. The term is reserved for patients in whom, in the presence of pulmonary vascular obstructive disease, pulmonary vascular resistance is fixed and irreversible. These findings in combination with the absence of left-to-right shunting make the patient inoperable in terms of physiologic repair or further palliation. It then becomes useful to designate the patient's physiology and its consequences as Eisenmenger's syndrome. The focus of management and therapy of chronic cyanotic heart disease is described.

Outcome and Cardiovascular Management

Survival into the seventh decade is rare but has been documented in Eisenmenger's patients (235,236) and is determined by the underlying cardiac condition and the medical complications of cyanosis. Mortality is high, and up to two-thirds of the deaths are sudden and unexpected. The etiology of sudden cardiac death remains poorly defined (235,236 and 237). Multiple factors including arrhythmias have been described. Symptomatic arrhythmia should be treated with individualized antiarrhythmic therapy depending on the presence or absence of ventricular dysfunction. An implantable defibrillator should be considered in patients with syncope and documented concurrent ventricular arrhythmia. The decision to use anticoagulants in patients with cyanosis is complicated by the presence of bleeding diathesis. Patients with atrial fibrillation should receive warfarin therapy with judicious monitoring of international normalized ratio levels.

MANAGEMENT OF CYANOTIC PATIENTS

Cyanosis is seen when persistent venous-to-arterial mixing results in hypoxemia. When cyanosis is not relieved, chronic hypoxemia and erythrocytosis result in systemic complications that require continued surveillance. Medical complications of cyanosis (238) are observed in unoperated or palliated adult patients with CHD. Hematologic, neurologic, renal, and rheumatic complications (236) and their management (239) are well described. Hematologic management is described here.

Hematologic complications (240) of chronic hypoxemia include erythrocytosis, iron deficiency, and bleeding diathesis. Erythrocytosis is different from polycythemia, which is the result of an increase in cellular mass not only of red cells, but also of white cells and platelets. Symptoms of hyperviscosity include headaches, faintness, dizziness, fatigue, altered mentation, visual disturbances, paresthesias, tinnitus, and myalgias. Patients with compensated erythrocytosis establish equilibrium hematocrit at higher levels in an iron-replete state with minimal symptoms. Patients with decompensated erythrocytosis manifest unstable rising hematocrit levels and experience severe hyperviscosity symptoms. In the iron-replete state, moderate to severe hyperviscosity symptoms may occur, typically when hematocrit levels are in excess of 65%.

Iron deficiency (241) is a common finding in cyanotic adult patients occurring because of inappropriate phlebotomy or excessive bleeding. Although normochromic erythrocytosis is not usually symptomatic at hematocrit levels of less than 65%, iron deficiency may manifest as symptoms similar to hyperviscosity at hematocrits well below 65%. If iron deficiency anemia is confirmed, careful iron replacement with 325 mg of ferrous sulfate or 65 mg of supplemental iron should be prescribed until an increase in hematocrit is detected, typically within 1 week. A significant and rapid increase in hematocrit is undesirable as it may exacerbate hyperviscosity symptoms, leading to phlebotomy, which can in turn worsen the iron deficiency (240).

Hemostatic abnormalities (240) have been documented in cyanotic patients with erythrocytosis and can occur in up to 20% of patients. In a minority of patients, hemoptysis or postoperative bleeding can be life-threatening. An elevated prothrombin and partial thromboplastin time, decreased levels of various coagulation factors, in addition to thrombocytopenia, and platelet disorders have been described (242,243). The management of bleeding diathesis is determined by the clinical circumstance, the severity, and the abnormal hemostatic parameters. Aspirin, heparin, and coumadin should be avoided unless indicated for chronic atrial fibrillation or in the presence of a mechanical prosthetic valve. Platelet transfusions, fresh frozen plasma, vitamin K, and cryoprecipitate and desmopressin can be used to treat severe bleeding.

Pulmonary thrombosis *in situ* and pulmonary hemorrhage have been described in up to 30% of patients with Eisenmenger's VSD who have CT scans of the chest (236,244). Typically, *in situ* thrombosis presents in a patient with a rapid clinical decline associated with progressive hypoxemia, marking the terminal stage of the disease. The tendency to form laminated thrombus in calcified, aneurysmal proximal pulmonary arteries is poorly understood. Currently, no benefit has been observed with the use of oral, intravenous, or intrapulmonary anticoagulants or from an attempt at pulmonary endarterectomy. The risk of bleeding and the potential for massive pulmonary hemorrhage continue to appear to outweigh the benefits of anticoagulation.

Neurologic complications (245), including cerebral hemorrhage, can occur secondary to hemostatic defects and can be seen after inappropriate use of anticoagulant therapy. Patients with right-to-left shunts may be at risk for paradoxical cerebral emboli. Focal brain injury may provide a nidus for brain abscess if bacteremia supervenes. Attention should be paid to the use of air filters in peripheral intravenous lines to avoid paradoxical emboli through a right-to-left shunt. Cyanotic adults are not at risk for cerebral arterial thrombosis (245). The occurrence of cerebrovascular accidents secondary to cerebral venous thrombosis in children (246,247) does not justify the presumed risk of cerebral arterial thrombosis in adults.

Phlebotomy is indicated under two sets of circumstances: for patients symptomatic of hyperviscosity in a nondehydrated state, most commonly when hematocrit levels exceed 65; and in asymptomatic patients with hematocrit levels greater than 65 before surgery to minimize postoperative bleeding. If symptoms occur with hematocrits of less than 65, evidence of iron deficiency should be sought. When indicated, removal of 500 mL of blood over 30 to 45 minutes followed by quantitative volume replacement with normal saline or dextran can be performed. Symptom control can be achieved with the removal of less than 2 L of blood and sometimes with as little as 250 mL. The procedure may be repeated every 24 hours until improvement occurs. An attempt should be made to achieve symptom control with the smallest quantity of blood removal to avoid iron deficiency. Prophylactic phlebotomy has no place in the prevention of cerebral arterial thrombosis (245,248).

Renal dysfunction (236,249) can manifest as proteinuria, hyperuricemia, or renal failure. Increased blood viscosity from erythrocytosis with or without iron deficiency in combination with arteriolar vasoconstriction can lead to renal hypoperfusion with progressive glomerulosclerosis. Hyperuricemia is common and is thought to be due mainly to the decreased reabsorption of uric acid rather than to overproduction from erythrocytosis. Urate nephropathy, uric acid nephrolithiasis, and gouty arthritis are rare but may occur. Gallstones composed of calcium bilirubinate and consequent cholecystitis occur with increased frequency in adults, adolescents, and children (244). Hydration before procedures involving contrast media should be prescribed to avoid renal dysfunction.

Rheumatologic complications include gout and hypertrophic osteoarthropathy, which is thought to be responsible for the arthralgias affecting up to one-third of patients (236,244). In patients with right-to-left shunting, megakaryocytes released from the bone marrow bypass the lung, escaping fragmentation. Their entrapment in systemic arterioles and capillaries induces the release of platelet-derived growth factor, promoting local cell proliferation. Digital clubbing and new osseous formation with periostitis occur, giving rise to symptoms of arthralgia. Asymptomatic hyperuricemia should not be treated. Long-term therapy aimed at lowering uric acid levels has not been shown to prevent renal disease or gout. Symptomatic hyperuricemia and gouty arthritis can be treated as necessary with colchicine, probenecid, sulfinpyrazone, or allopurinol. Nonsteroidal antiinflammatory drugs should be avoided to prevent hemostatic anomalies (244).

The use of angiotensin-converting enzyme inhibitors in patients with cyanotic CHD (250) is controversial and should therefore not be routinely used in cyanotic patients. Afterload reduction may, on the one hand, increase cardiac output and improve oxygen delivery, but on the other hand, lower systemic vascular resistance may increase right-to-left shunting with worsening cyanosis.

The results of cardiac transplantation in properly selected patients with CHD, with and without previous palliative surgery, have improved both in terms of hospital and medium-term mortality (251). Lung transplantation (single or double) (252) with intracardiac repair can be effective in reducing pulmonary hypertension. Long-term complications relate to those of obliterative bronchiolitis and to a variable course in right ventricular recovery, with or without the development of dynamic subpulmonary obstruction after the procedure.

SPECIALIZED ISSUES

Issues Pertinent to Patients Undergoing Noncardiac Surgery

Patients with acyanotic congenital lesions require routine intraoperative and postoperative care for noncardiac procedures. The intracardiac hemodynamics and arrhythmic complications are determined by the native and surgical anatomy. In patients with intracardiac shunts who are cyanotic or acyanotic, the risk of paradoxical embolization is increased (253). To avoid the introduction of air or particles into peripheral or central venous catheters, filters should be placed in intravenous lines, with care taken to avoid the introduction of air or bubbles (256). Other issues of concern include difficulties in venous and arterial access, appropriate volume and airway management, prevention of hemostatic anomalies as described previously, and precautionary measures in the administration of anesthesia (254,256,257 and 258). Because hemostatic defects correlate with the severity of hypoxemia and the degree of erythrocytosis, reduction in erythrocyte mass results in improved hemostasis

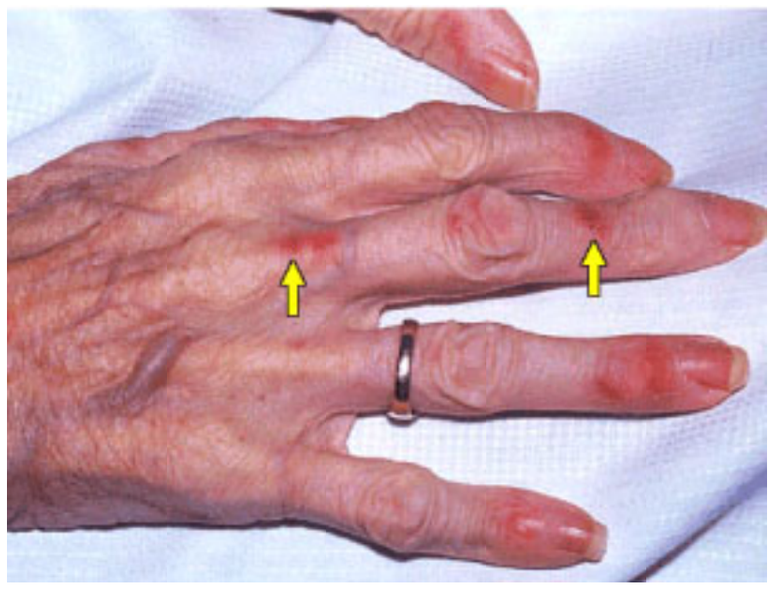
(255). Cyanotic patients undergoing surgery should have prophylactic phlebotomy if the hematocrit is greater than 65 to minimize bleeding.

Noncardiac surgery in patients with Eisenmenger's syndrome is associated with a 5% to 10% mortality even for minor procedures (259). In patients with pulmonary vascular disease (256) management includes the prevention of dehydration and hypovolemia. Large fluctuations in systemic vascular resistance should be avoided. Systemic hypotension can lead to an increase in the right-to-left shunt with a decrease in pulmonary blood flow. Hypercapnia and hypoxia are also hazardous, in that they stimulate an increase in pulmonary vascular resistance. Close monitoring of intravascular blood volume and cautious use of systemic vasodilators, including regional anesthesia, are mandatory. The usefulness and risks of using a pulmonary artery catheter during and after the procedure in patients with pulmonary hypertension are controversial (257). Airway management can be complicated by an enlarged pulmonary artery with resulting chronic compression of the left main stem bronchus or the right middle lobe bronchus and recurrent atelectasis, pneumonia, or localized emphysema (258). An enlarged hypertensive pulmonary artery trunk can also compress the recurrent laryngeal nerve, resulting in chronic hoarseness (258). Previous surgery may have resulted in injury to the phrenic nerve with subsequent development of diaphragmatic palsy (256). Patients with cyanotic CHD tend to have increased ventilation with normal P_{CO_2}. Scoliosis occurs with a frequency reported to be as high as 19% (258). Although the degree of scoliosis is not always severe enough to impair pulmonary function, restrictive airway obstruction is well recognized (258).

Anesthesia care of patients with congenital disease requires precautionary measures (256,257). Epidural anesthesia has been used successfully in patients with pulmonary vascular disease, but local anesthetic needs to be given slowly. Of major concern is the period of anesthetic induction. It is critical in patients with elevated pulmonary artery pressure that they not become hypotensive during induction. Volume expanders and drugs such as epinephrine and levarterenol (Levophed) need to be available to be sure that systemic vascular resistance and arterial pressure are maintained.

Endocarditis

Prolonged survival of patients with complex CHD has resulted in a population at increased risk for developing infective endocarditis in unoperated and operated patients (260). Infection most commonly affects sites of turbulent blood flow (260) on the low-pressure side of gradients. Such sites include restrictive VSDs, PDA, the cleft mitral valve, aortic coarctation (most often at the site of an associated bicuspid aortic valve), and prosthetic shunts, valves, and conduits in the postoperative patient (261). These lesions may occur in combination in complex operated cyanotic heart disease. The risk of endocarditis associated with isolated low-pressure lesions in the right side of the heart is low in both simple and complex lesions (260).



Septic emboli from infective endocarditis (*arrows*).

Janeway lesions of endocarditis. There are hemorrhages with nodular character at the fingertips (*arrows*).

Osler nodes. There are tender nodules on the toe pads (*arrows*) secondary to infective endocarditis.

Splinter hemorrhages. Linear hemorrhages on the fingertips of a patient with infective endocarditis.

Current recommendations for the prevention of bacterial endocarditis apply to most congenital heart lesions with the exception of the isolated secundum ASD, the surgically repaired atrial and ventricular or ductal shunt without residual shunt beyond 6 months after repair. These guidelines should be used for dental, oral, or respiratory procedures (262).

Pregnancy

The reported genetic transmission of maternal CHD to offspring varies from 4% (264) to as high as 16% (267). The conditions that result in the greatest risk to the mother and fetus include Eisenmenger's syndrome, severe pulmonary hypertension, severe left ventricular outflow tract obstruction, Marfan's syndrome with an enlarged aortic root, and heart failure resulting in NYHA class III or IV. Pregnancy in patients with Eisenmenger's syndrome is associated with mortality of up to 50% (268,269). Pregnancy in cyanotic CHD that excludes Eisenmenger's reaction results in a 3% incidence of maternal cardiovascular complications and a near 40% incidence of prematurity (264). These data support the recommendation that pregnancy should be avoided in patients with Eisenmenger's syndrome (87). When women with operated or unoperated CHD are studied as a group, live birth rates are 80% (270). In women after successful coarctation repair, in the presence of an arm-to-leg blood pressure gradient of less than 20 mm Hg, the incidence of preeclampsia is not increased (271). For patients with complex lesions, individual series have reported a total of nearly 250 pregnancies with no maternal mortality (272,273,274 and 275). Successful pregnancies have been reported in patients following surgically repaired transposition of the great arteries (265,272); congenitally corrected transposition of the great arteries (273); Ebstein's anomaly (266,274); and the Fontan operation (275). Although small individual series are encouraging, complication rates remain significant even when close follow-up is undertaken in specialized centers. These patients should always be referred to experienced facilities when pregnancy is being considered.

Prepartum assessment includes a thorough cardiovascular evaluation of the mother and the fetus (277). The efficacy and ease of each method of contraception will need to be weighed against risks to the mother, the efficacy and ease of the method itself, and the risk of pregnancy, should it occur (276). The more pregnancy is contraindicated, the more fail-safe the method chosen should be. Barrier methods are usually safe to the woman, but have pregnancy prevention failure rates in the range of 10% to 20%. The intrauterine device has a failure rate of approximately 4%, but is a potential source of infection. Hormonal suppression of ovulation is associated with failure rates of less than 3%, but may lead to thromboembolism and should be avoided in patients with right-to-left shunts. Male or female sterilizations are most efficacious, with failure rates of less than 1%, but they are also more definitive and difficult psychologically. Intrapartum and postpartum management of the mother requires surveillance of changes in cardiac status, including the development of hypertension, heart failure, or arrhythmias; aggravation of the underlying condition; management of anticoagulation therapy; and endocarditis prophylaxis at the time of delivery. Anticoagulant therapy is an important part of stroke prevention in patients with mechanical valves and needs to be carefully continued during pregnancy. Warfarin embryopathy can be a serious complication of therapy to the offspring, particularly during the first trimester (278). Anticoagulation can be achieved with heparin, which does not cross the placenta. Recommendations with respect to specific anticoagulation during pregnancy are controversial (279) and are based on the regional experience and discussions with the patient. Although antibiotics are frequently administered, the American Heart Association guidelines do not recommend endocarditis prophylaxis for uncomplicated vaginal delivery (262).

Exercise

The goals of exercise evaluation are to assess functional results of therapeutic interventions and provide guidelines for athletic participation. Patients with residual hemodynamic lesions or unrepaired congenital cardiac anomalies should be evaluated on an annual basis with physical examination, electrocardiography, and cardiac ultrasound if indicated. Pertinent additional tests may include Holter monitoring and exercise testing. Attention should be directed to the detection of pulmonary hypertension, arrhythmias, myocardial dysfunction, and symptoms including exercise-induced syncope, chest pain, or dizziness. A series of guidelines have been proposed for major groups of congenital heart defects, including shunt lesions, obstructive lesions, and unrepaired and repaired defects (123). These are summarized in Table 31.3.

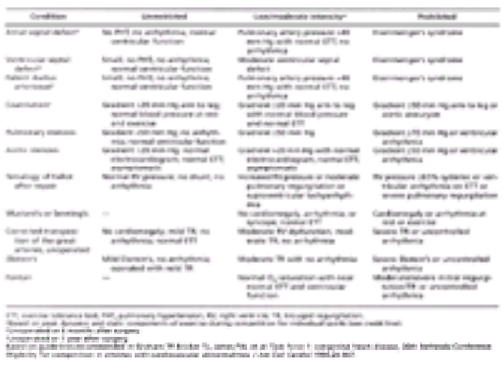


TABLE 31.3 EXERCISE RECOMMENDATIONS IN ADULTS WITH CONGENITAL HEART DISEASE

Psychosocial Issues

In addition to physical defects, mental retardation syndromes and long-term neurologic consequences of cyanotic heart disease or cardiac surgery may be present in the young adult with CHD (263). In comparison with peers, young adults with CHD may choose a more dependent lifestyle with significant involvement of parents or other family members (280).

CONTROVERSIES AND PERSONAL PERSPECTIVES

This subspecialty of cardiology is in its infancy. There are more questions than answers. To date, for an individual patient, the most controversial question has been to operate or not to operate? As surgical data accumulate, the consensus favors surgery. However, the same procedure in an infant and in an adult results in an operation with a different outcome, and can we use data generated in high-volume centers to make decisions about individual patients around the world? In the neonate and infant, current surgical strategy aims at intervening early enough to prevent exposure to deleterious physiology. In the adult, lifelong exposure to abnormal hemodynamics may offset the benefits of anatomic correction. On the other hand, a firm understanding of patient's anatomy may permit interventions that were previously not feasible. For both infants and adults, when physiologic repair has taken place, many issues of concern in long-term follow-up continue to exist, as described in this chapter. Right ventricular function and dysfunction take many forms in the numerous variants of CHD. Response to right ventricular remodeling and its prevention is undetermined. The right ventricle as a culprit for sudden cardiac death is atypical for adult cardiologists. The prevention of thromboembolic complications in a right-sided cardiopulmonary circulation without a subpulmonary ventricle is difficult. The organization of health care delivery for this group of patients remains our biggest challenge. Recommendations have been thoroughly laid out at the 32nd Bethesda conference (281,282). Their implementation remains variable. The

importance of appropriate referral cannot be overemphasized. Even in patients with simple lesions, the decisions can be complex. Those with adequate training and experience are best suited to make management decisions that take into account the patient's needs and the reality of the medical environment where these needs can be met.

THE FUTURE

A new landscape in CHD care has been created in a way that would have been difficult to envisage a mere 50 years ago. The concepts of surgical palliation and repair evolved sequentially in progressively younger and younger patients. At the current time, our youngest patients are rapidly growing in numbers. They are most likely to have been operated and reoperated. The first intervention may have occurred as early as 24 hours of age. The efforts of pediatric cardiologists and congenital heart surgeons have resulted in one of the most rewarding achievements of twentieth-century medicine. The trends witnessed since the 1950s are shaping our direction as we engage the twenty-first century. We want these patients to stay alive as long and as *well* as possible, defying anatomy and physiology as we know it. They continuously bring us back to the reality of persistent, changing, and growing medical and surgical problems. Ultimately, these adults should be framing the pediatric perspective. What we need for this young specialty are data. We need to quantify where we are, rather than describe it. We need national and international databases. We need randomized trials. This should be given priority in parallel with the molecular biology that will enable prevention in the fetus and perhaps the embryo. We encourage our readers to understand the principles that govern current thinking so as to be equipped to follow the direction of a specialty in evolution. The big picture appears promising. We are watching. The color of the future is coming to light as it unfolds.
