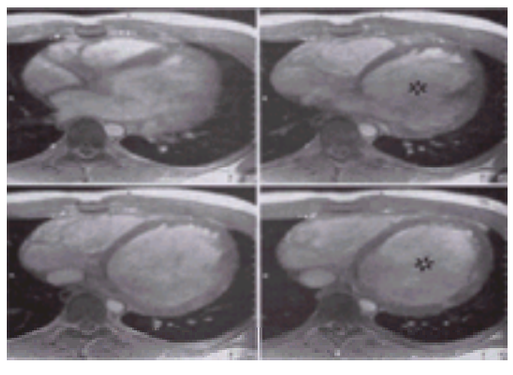
Nonischemic myocardial disease (CM) is represented by the group of diseases in which the dominant feature is pathology of the myocardium unrelated to ischemic, hypertensive, congenital, valvular, or pericardial diseases. Of the variety of schemes that have been proposed for classifying the CMs, the following categorization is helpful: (a) dilated CM causing ventricular dilatation, contractile dysfunction; (b) hypertrophic CM associated with inappropriate hypertrophy of the LV, often with asymmetric septal involvement and usually with preserved contractile function, despite frequent regional impairment; (c) restrictive CM characterized by impaired diastolic filling; and (d) RV CM causing dilatation and regionally or globally impaired contractility of the RV related to dysplasia, with partial to total replacement of the myocardium by variable amounts of adipose and fibrosis tissue.

Dilated Cardiomyopathy

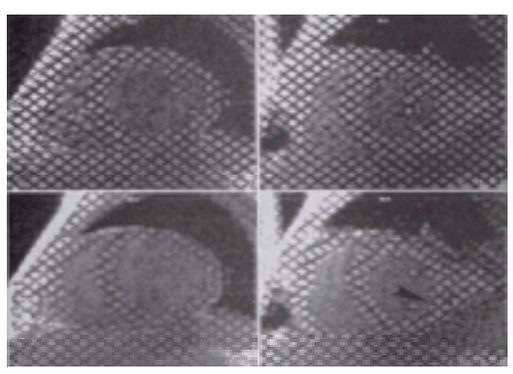
MRI can readily define the abnormally enlarged cavity size and globally depressed function (eFig. 54.12.1) of the LV and RV in cases of dilated CM (70,235). In contrast to healthy subjects, patients with dilated CM fail to demonstrate a gradient of progressively increasing systolic wall thickening from base to apex and have significantly decreased EF on cine (83,236), although improvement in LVEF from afterload reduction by angiotensin-converting enzyme inhibitor therapy has been demonstrated (237). The effects of such therapy on diastolic dysfunction have also been assessed using cine in patients suffering from dilated CM with and without MR; analysis of LV time-volume curves revealed improvements in both peak filling rate to end diastolic volume ratios and EF in the group without, but not in the group with, mitral regurgitation (238).



***e*FIGURE 54.12.1** Dilated cardiomyopathy (cine; transaxial). Marked enlargement of the left ventricle cavity (*asterisks*) is shown.

End systolic LV wall stress determined from cine has been determined to be abnormally elevated in patients with dilated CM, and inversely proportional to regional EF (239). In patients with dilated CM, significant increase in peak systolic wall stress, compared with normal values, has also been demonstrated (83). However, decreased end systolic wall stress following afterload reduction by angiotensin-converting enzyme inhibitor therapy has been shown using cine (237).

Myocardial tagging has been used in the assessment of the mechanical effects of surgical ventricular remodeling (eFig. 54.12.2) for treatment of LV failure; reshaping of the LV wall and improvement in contraction with surgery has been demonstrated.



***e*FIGURE 54.12.2** Ventricular remodeling surgery for dilated cardiomyopathy (spatial modulation of magnetization; short axis). From preremodeling (*left*) to the postremodeling (*right*), improvement in grid deformation from end diastole (*above*) to end systole (*below*) is noted in all left ventricle wall regions, except at the myectomy site (*arrowhead*); this indicates improved myocardial systolic function from the procedure.

Hypertrophic Cardiomyopathy

Various patterns of LV hypertrophy in hypertrophic CM (Fig. 54.13) have been defined using MRI (240). Unfortunately, S-E signal characteristics of the myocardium in hypertrophic CM have not been shown to differ from those found in healthy subjects or in patients with physiologic LV hypertrophy (241). Pathophysiologic characteristics associated with hypertrophic CM have also been demonstrated with MRI; in the setting of this condition, cine has been used to evaluate asymmetric LV systolic wall thickening, subaortic poststenotic flow related to systolic anterior motion of the anterior mitral leaflet, and related mitral regurgitation (Fig. 54.14 and eFig. 54.14.1) (242,243).

Video 54.6 Subaortic poststenotic flow in hypertrophic cardiomyopathy (long-axis). Asymmetric hypertrophy is noted, resulting in dynamic narrowing of the left ventricular outflow tract with a signal-void jet in the subaortic region. In addition, a signal-void jet in the left atrium is also seen, representing mitral regurgitation due to systolic anterior motion of the anterior leaflet of the mitral valve. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

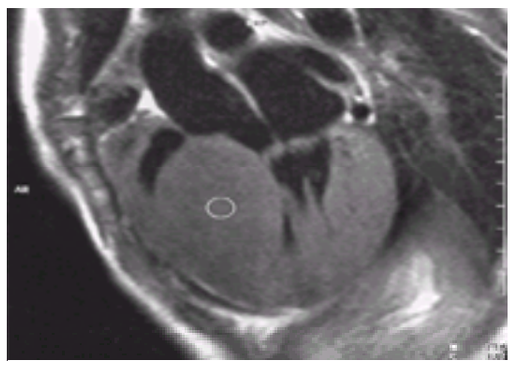


FIGURE 54.13 Left ventricular hypertrophy in hypertrophic cardiomyopathy (T1-weighted spin-echo; left ventricle outflow tract). Severe hypertrophy of the left ventricle wall, especially in the interventricular septum (*open circle*), is demonstrated.

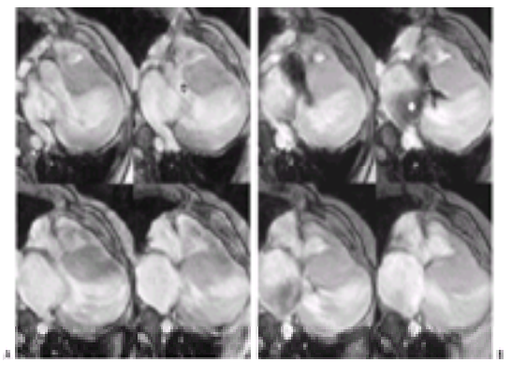

FIGURE 54.14 Subaortic poststenotic flow in hypertrophic cardiomyopathy (cine; horizontal long axis). On adjacent end diastolic images **(A)**, asymmetric left ventricle hypertrophy is noted; it results in fixed narrowing of the left ventricle outflow tract (*asterisk*). Because of systolic anterior motion of the anterior mitral leaflet in mid-systole **(B)**, abnormal subaortic signal void (*open circle*), representing stenosis, and left atrial signal void (*closed circle*), representing mitral regurgitation, develop.

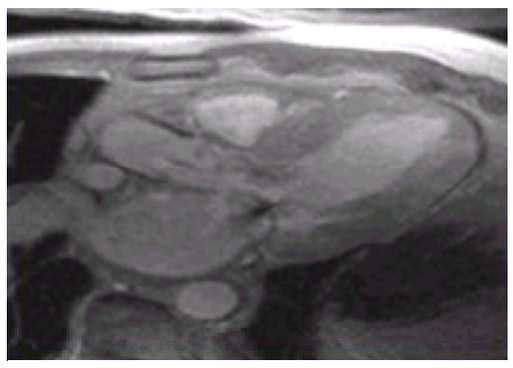

***e*FIGURE 54.14.1** Subaortic poststenotic flow in hypertrophic cardiomyopathy (long axis). Asymmetric hypertrophy is noted, resulting in dynamic narrowing of the left ventricle outflow tract with a signal-void jet in the subaortic region. In addition, a signal-void jet in the left atrium is also seen, representing mitral regurgitation caused by systolic anterior motion of the anterior leaflet of the mitral valve.

Pronounced heterogeneous reductions in circumferential, longitudinal, and 3-D shortening, with the septal impairment exceeding the free-wall impairment, have been described in hypertrophic CM using MRI (Fig. 54.15) (244,245). Accentuated heterogeneity in strain rate, increasing in diastole, has also been demonstrated in hypertrophic CM (246). The degree of contractile dysfunction has been correlated with both its abnormal geometry (e.g., flattened to negative septal curvature) (247) and the severity of internal histopathology (i.e., myocardial fibrosis and myofiber disarray) (248). Using cine to evaluate RV time-volume curves in hypertrophic CM, abnormally depressed peak-filling rates and filling fractions have been demonstrated; these changes suggested diastolic dysfunction from associated restrictive physiology (249). Contrast-enhanced ultrafast has been used to study cases of hypertrophic CM; decreased diastolic first-pass enhancement of the septal myocardium correlated with increased amounts of characteristic histopathology (e.g., intramyocardial small vessel narrowing) (250).

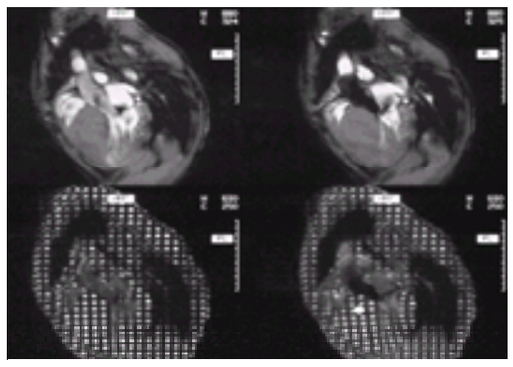

FIGURE 54.15 Regional variation in myocardial function in hypertrophic cardiomyopathy (cine and spatial modulation of magnetization; left ventricle outflow tract). With morphologic and hemodynamic abnormalities demonstrated on end diastolic cine (*above, left*) and end systolic cine (*above, right*) images, corresponding myocardial spin-tagging images (*below*) provide information about regional left ventricle function. Minimal deformation of the grid in the interventricular septum (*closed circle*), compared with the free wall, indicates its markedly impaired systolic mechanics.

Restrictive Cardiomyopathy

In cases of diastolic dysfunction caused by restrictive CM, rather than constrictive pericarditis, MRI is valuable in demonstrating the absence of abnormal pericardial thickening in the presence of indirect findings of impaired ventricular filling (e.g., dilatation of the inferior vena cava and right atrium) (251). MRI of cardiac amyloidosis (Fig. 54.16), a classic cause of restrictive physiology, has revealed increased thickness of the LV wall without cavity dilatation (252). Similar anatomic findings, in combination with slightly increased myocardial signal intensity, have been observed in some deposition diseases (e.g., Fabry's disease) resulting in diastolic dysfunction (253). However, for the most part, the myocardium of restrictive CM has normal MRI properties (e.g., T2) (254). There are notable exceptions in the setting of hemochromatosis: Prominent susceptibility-related loss of signal within the myocardium caused by iron deposition, especially on G-E images, has been demonstrated (255). Sarcoid heart disease, another potential cause of restrictive CM, is manifested on MRI in its acute inflammatory phase as discrete areas of high intensity that are associated with increased wall thickness within the LV septal and free wall myocardium (256) and chronically as focal areas of pronounced wall

thinning, possibly with aneurysm formation, in the same LV wall regions (eFig. 54.16.1).

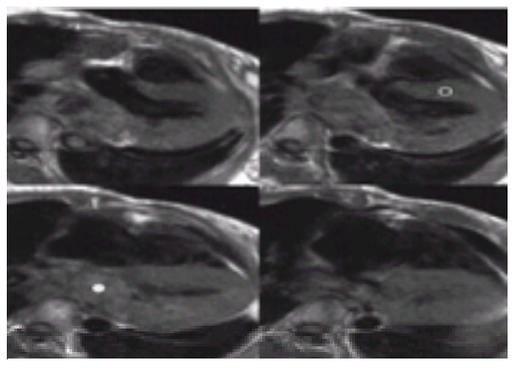

FIGURE 54.16 Cardiac amyloidosis (T1-weighted spin-echo; horizontal long axis). Generalized increase in left ventricle wall thickness (*open circle*), caused by protein deposition, is noted. Restrictive physiology is suggested by the presence of abnormal flow signal in the dilated left atrial cavity (*closed circle*).

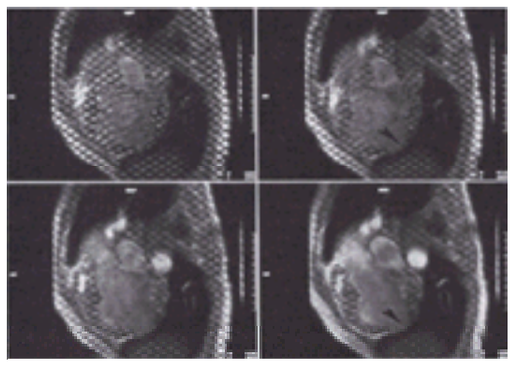

***e*FIGURE 54.16.1** Chronic sarcoid heart disease (spatial modulation of magnetization; left ventricle outflow tract). A focal area of pronounced wall thinning, impaired systolic function, and early aneurysm formation (*arrowheads*) is demonstrated in the distal left ventricle free wall region on the sequential spin-tagging images.

An abnormally delayed pattern of ventricular filling caused by diastolic dysfunction associated with restrictive CM can be evaluated qualitatively or quantitatively using cine (257). In the initial stages of restrictive CM, sluggish early ventricular filling is noted with or without mild impairment of systolic function; late restrictive CM, on the other hand, is characterized by rapid early, but abruptly terminated late filling of the ventricles (as in constrictive pericarditis) and with significantly impaired systolic emptying of the ventricles (unlike constrictive pericarditis). Velocity mapping of ventricular myocardium has been used to demonstrate reduction in mean peak early diastolic velocity related to LV stiffening with aging (258).

By measuring the rate of flow across the tricuspid and mitral annuli in diastole, velocity mapping has been proposed as a method for assessing diastolic dysfunction, as found in restrictive CM (259). Using velocity mapping, abnormal flow patterns in the superior vena cava have been demonstrated in restrictive CM; a progressively decreasing ratio of peak flow in systole relative to that in diastole is found with worsening restrictive physiology, but such ratios do not differentiate restrictive CM from constrictive pericarditis (260).

Right Ventricular Cardiomyopathy

Along with dilatation of the cavity of the RV, thinning of its wall in regions of fibrosis (Fig. 54.17) and increased signal intensity in regions of replacement of its myocardium with fat (eFig. 54.17.1) have been well demonstrated in advanced cases of RV CM (arrhythmogenic RV dysplasia) using MRI (261,262). Greater reduction in RVEF and more pronounced structural and histologic changes in the RV, including evidence of fatty replacement of the myocardium, have been more often demonstrated in the setting of RV CM than with inducible ventricular tachycardia (263). Regional wall motion abnormalities, compatible with milder focal dysplasia, have been observed using cine in patients with the diagnosis of idiopathic RV outflow tract tachycardia (eFig. 54.17.2) (264).

Video 54.7 Arrhythmogenic right ventricular dysplasia (transaxial). Thinning the right ventricular wall with dyskinesia of the right ventricular free wall during systole is due to fibrous replacement of the myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

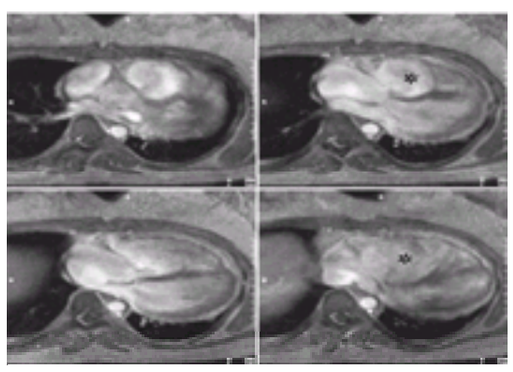

FIGURE 54.17 Arrhythmogenic right ventricle dysplasia (cine; transaxial). Marked dilatation of the cavity of the right ventricle (*asterisks*) and thinning of its wall in regions of fibrosis is shown on adjacent images.

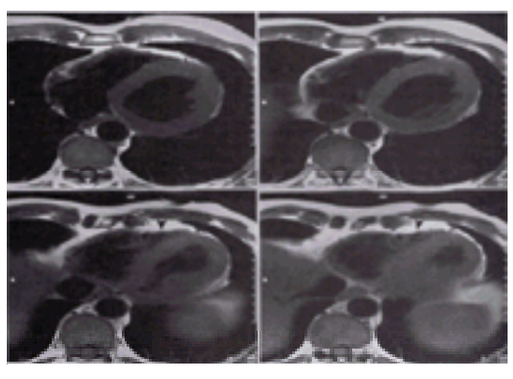
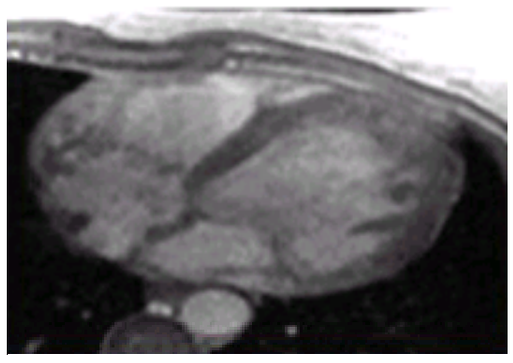


***e*FIGURE 54.17.1** Right ventricle dysplasia with fatty replacement of the myocardium (T1-weighted spin-echo; transaxial). Increased signal intensity in the anterior right ventricle wall (*arrowheads*) near the interventricular septum indicates replacement of its myocardium with fat.



***e*FIGURE 54.17.2** Arrhythmogenic right ventricle dysplasia (transaxial). Thinning of the right ventricle wall, with dyskinesia of the right ventricle free wall during systole, is caused by fibrous replacement of the myocardium.

Pericardial Disease

To an acute injury, the pericardial sac responds with one of the following reactions: (a) congestion; (b) increased exudation of fluid into the sac; (c) exudation of both fibrin and acute inflammatory cells into the sac; or (d) a combination of these reactions (the composition of the pericardial fluid that results depends on the cause of pericardial insult). Pericarditis, an inflammation of the pericardial surfaces, has many infectious and noninfectious causes.

Effusion and Tamponade

The normal pericardium and the contained physiologic fluid appear on MRI as only a thin (usually 2 mm or less) curvilinear line situated between the epicardial and pericardial fat. MRI has an advantage over CT in differentiating a small pericardial effusion from pericardial thickening because different acquisition schemes may be employed in MRI to appreciate and characterize fluid (265).

Simple pericardial effusions are visualized on S-E MRI as low-intensity regions between the cardiac surface with its epicardial fat and the outwardly displaced pericardial fat (265,266). Because of cardiac motion, the signal intensity from simple pericardial effusions is less than that from simple pleural effusions (265,266 and 267). Although characterized by low signal intensity on T1-weighted images, its signal intensity may increase on T2-weighted images; this is particularly true of the most dependent portions of the pericardial effusion. Whereas simple pericardial effusions produce high signal intensity on G-E MRI and when imaged with cine, they demonstrate mobility and changing distribution during the cardiac cycle (267) (Fig. 54.18).

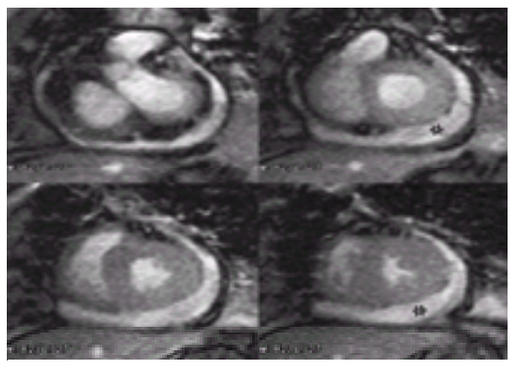


FIGURE 54.18 Simple pericardial effusion (cine, short axis). The bright appearance of the fluid (*asterisks*) separating the epicardial surfaces of the cardiac chambers from the dark-appearing pericardium indicates its simple nature.

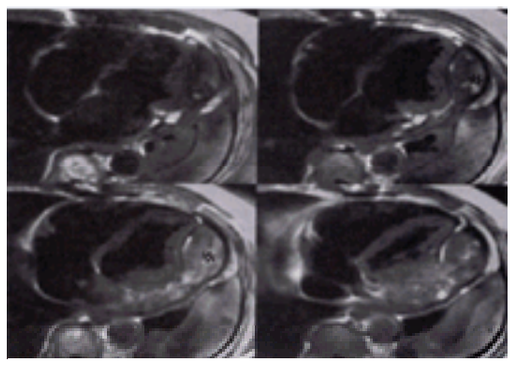
Assessment of the distribution and general size of a simple pericardial effusion using MRI has shown good overall correlation with that by 2-D echo (266). However, when fluid volume has been quantitated by both techniques, the pericardial effusion has tended to measure larger by MRI (268). In fact, MRI has been shown to detect small pericardial effusions not visualized by echo, and to be better for detecting fluid located superiorly in the aortic pericardial reflection or superior pericardial recess, medially at the border of the right atrium, and posteriorly at the LV apex (266,268).

Because of T1 shortening from their high protein or cell content, complex pericardial effusions typically exhibit greater signal intensity than simple pericardial effusions on T1-weighted S-E MRI (266,267). Thus, on S-E MRI, regions of moderately increased signal within complex effusions probably represent exudate made relatively immobile by fibrinous material that has adhered to the pericardium. With exudative pericardial effusions, both the pericardium and pericardial adhesions may have greater signal intensities than a normal pericardium (266,269).

Hemopericardium and pericardial hematoma can generally be distinguished from other types of effusions because of the high, at times extremely intense, signal of the paramagnetic blood products on S-E MRI (266). However, these hemorrhagic pericardial effusions often contain areas of both medium and high signal intensity, reflecting the variable age of the bloody material (*e*Fig. 54.18.1) (266,269). Although hemorrhagic effusions have been shown to have significantly greater effusion-to-myocardial signal intensity ratios than nonhemorrhagic effusions on T1-weighted S-E MRI, differences in hematocrit are not reliably appreciated (270).



***e*FIGURE 54.18.1** Hemopericardium (T1-weighted spin-echo; horizontal long axis). A lobular intrapericardial mass lesion (*asterisk*) compressing the left ventricle free wall represents a pericardial hematoma; its variable internal signal intensity results from blood breakdown products.

MRI appears to be superior to echo in defining the nature and extent of processes causing clinical signs of cardiac chamber compromise from hemopericardium (265,269); compression of the cardiac chambers by hematoma indicates pericardial tamponade (267).

Pericarditis and Constriction

The low intensity of the pericardium on S-E MRI is explained partly by the presence of a phase discontinuity artifact. The shearing action between the visceral and parietal pericardium presumably results in a large local velocity variation, causing a reduction in signal intensity in the voxels spanning the pericardium (271). Absence of the low-intensity pericardial line on S-E MRI implies that the normal transpericardial shearing motion is also absent in that region (269). This change is caused by primary or secondary abnormalities of the pericardium (e.g., inflammatory disease).

Because MRI provides excellent direct visualization of the pericardium, it can readily define the presence and extent of pericardial thickening. Measuring pericardial thickness is of great value in the diagnosis of constrictive pericarditis; however, the presence of pericardial thickening does not indicate constriction. Pericardial thickening has been noted on MRI in several other clinical settings (e.g., after cardiac surgery) (266). Both pericardial thickening and effusion have been demonstrated in the setting of uremic or infectious pericarditis; because of inflammatory changes associated with both of these conditions, the pericardial signal is generally increased on S-E MRI, and adhesions between the irregularly thickened visceral and parietal pericardium may be detected (Fig. 54.19). Nevertheless, MRI can be used effectively in the differentiation between constrictive pericarditis and restrictive CM (266,269,272), both of which may result in similar clinical presentations; although restrictive CM could demonstrate pericardial effusion, it would not generally reveal significant pericardial thickening.

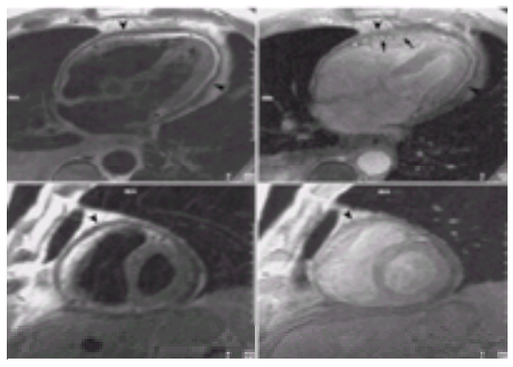


FIGURE 54.19 Pericarditis (subacute tuberculosis) (T1-weighted, spin-echo, and cine; horizontal long axis and short axis). Well shown on both the dark-blood **(left)** and bright-blood **(right)** images is the abnormally thickened pericardium (*arrowheads*) encasing the cardiac chambers, especially the ventricles, which appear compressed. The high concentration of small epicardial vessels along the right ventricular wall (*arrows*) is consistent with its inflammatory stage.

Although in constrictive pericarditis, increased thickness of the pericardium is evident on MRI (251,266,269,272), the associated conical or tubular narrowing of the generally nonhypertrophied ventricles, resulting from compression and confinement by the thick pericardium, is more specific for the diagnosis (Fig. 54.20). Secondary changes, such as atrial enlargement, systemic vein dilatation, hepatomegaly, ascites, and occasionally pleural effusion, may also be noted on MRI. When found in association with the appropriate clinical syndrome, these abnormal anatomic findings are strongly supportive of the diagnosis of constrictive pericarditis, with 93% accuracy documented (251). Unfortunately, MRI has not been able to differentiate reliably between fibrous tissue and calcification and, consequently, is of limited value compared with CT in the evaluation of calcification of the pericardium in the setting of calcific pericarditis (265).

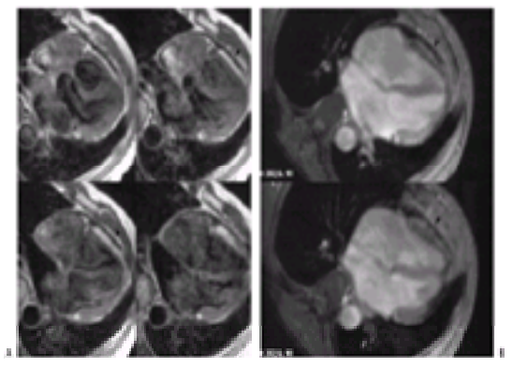

FIGURE 54.20 Constrictive pericarditis (T1-weighted, spin-echo, and cine; horizontal long axis). Constrictive pericarditis is manifested at adjacent levels on spin-echo **(A)** and cine **(B)** images by a thickened fibrotic and calcified pericardium (*arrowheads*), conical compression of the ventricles, biatrial dilatation, and abnormal intracardiac flow signal caused by diastolic dysfunction.

Cases of constrictive pericarditis may be evaluated functionally with MRI. Absolute and relative systolic wall thickening of the LV, measured with multiphasic S-E MRI, have not been found to be significantly different from that in normal volunteers (79). Cine is more useful than S-E techniques in functionally evaluating cases of diastolic dysfunction and in defining qualitatively or quantitatively the specific pathophysiologic abnormalities associated with constrictive pericarditis (63,267). Because of the higher temporal resolution provided with this technique, the abrupt limitation of late diastolic filling of the ventricles because of the abnormally thickened and confining pericardium in constrictive pericarditis is distinguishable from the delayed diastolic filling patterns of the ventricles caused by restrictive CM in the absence of significant pericardial thickening.

Using velocity mapping, abnormal flow patterns in the superior vena cava have been demonstrated in cases of constrictive pericarditis (260); improvement in diastolic return with pericardial stripping can be documented. In both healthy subjects and patients with right-sided disease, systemic venous flow measured without respiratory gating closely resembles its flow at end expiration (96).

Aortic Disease

Complete and timely imaging of the thoracic aorta is essential in that some disease entities are potentially life threatening and require prompt surgical intervention. The best surgical approach will be based on a complete depiction and understanding of the anatomy, which necessarily includes the thoracic aortic configuration and caliber, aortic wall characteristics, arch vessel origins, and descriptions of the aortic valve and the paraaortic structures.

MRI is now assuming an increasing and distinct role in furthering the evaluation and diagnosis of diseases of the thoracic aorta (273). In fact, the majority of CV MRI studies are currently performed for the evaluation of thoracic aortic disease (17). The ability of MRI to noninvasively depict abnormalities in anatomy or physiology in the thoracic aorta in multiple oblique planes or 3-D makes it ideally suited for initial diagnosis, monitoring during medical therapy, and postoperative assessment (273,274 and 275). Other parameters that are important to address in the evaluation of patients with thoracic aortic disease (e.g., origin of the coronary arteries) can also be evaluated effectively with MRI.

In addition, MRI provides a highly specific and sensitive method for detecting postoperative complications from thoracic aortic surgery (57,276,277). These complications include periprosthetic valve leak, graft infection, extension or development of dissection, rupture, or aneurysmal expansion.

Aneurysm

Accurate identification of the size, location, and extent of a thoracic aortic aneurysm is essential for management, preoperative planning, and follow-up; large aneurysms of the thoracic aorta should be surgically corrected because of the increased risk of spontaneous rupture when the diameter exceeds 5 cm. Thoracic aortic

aneurysms are categorized as being either true aneurysms, meaning that all three mural layers of the aortic wall are involved, or as pseudoaneurysms, in which there has been a break in the intima, and possibly media, leaving only the remaining wall to contain the intraaortic blood pool. These forms of aneurysm are characteristically represented by fusiform (i.e., circumferential enlargement of the involved segment) or saccular (i.e., asymmetric or focal outpouching of the involved segment) dilatations, respectively. The saccular configuration connotes a less stable condition than the other configuration. These characteristics of a thoracic aortic aneurysm can be easily delineated with MRI for planning of therapy or for clinical monitoring (273,276). In addition, because of the abilities of MRI to depict the configuration and associated mural changes, it is critical in differentiating the various etiologies of thoracic aortic aneurysms (278).

On MRI, atherosclerotic aneurysms may be found in any portion of the thoracic aorta and are characterized by fusiform enlargement, usually over long segments (Fig. 54.21). The aortic wall is thickened and irregular, secondary to atherosclerotic plaque (279). Mural calcification is common and is manifested by areas of focal signal absence on both S-E and cine, although it is better seen on CT. Intraluminal thrombus also is common and may be difficult to distinguish from atherosclerotic plaque, although thrombus usually has a smooth internal border as opposed to atherosclerosis, which typically is irregular (273,276). In atherosclerotic aneurysms involving the ascending portion, the sinotubular junction and aortic valve function usually are preserved—important characteristics appreciated on MRI.

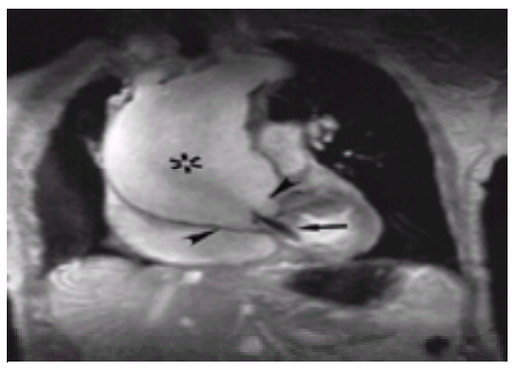

FIGURE 54.21 Atherosclerotic aneurysm (cine; oblique-coronal). Despite marked dilatation of the ascending aorta (*asterisk*), there is preservation of the sinotubular junction (*arrowheads*). Aortic regurgitation is also seen (*arrow*).

Aortic aneurysms that may occur secondary to aortic valvular disease are also characterized by relative preservation of the aortic root and sinotubular junction on MRI (273,276). In cases of AS, the aneurysmal dilation usually is limited to the midascending aorta where the poststenotic flow effects are most prominent (226). In AR, aneurysmal dilation of the thoracic aorta typically involves the ascending aorta but extends into the transverse arch because of the “water hammer” effect and, in long-standing cases, also may involve the descending thoracic aorta; often there is slight effacement of the sinotubular junction and dilatation of the aortic root in primary AR because of their relationship (228).

Equally important in the case of aneurysms involving the ascending aorta is the appreciation of annuloaortic ectasia that leads to characteristic “onion bulb” dilatation of the proximal ascending aorta and sinuses of Valsalva from pronounced effacement of the sinotubular junction (eFig. 54.11.1 and Fig. 54.22) (273,276). Indicating cystic medial necrosis, detection of annuloaortic ectasia on MRI connotes a worsened prognosis; Marfan syndrome and other connective tissue disorders characteristically result in weakening of the aortic wall, as a result of cystic medial necrosis. Typically, the associated dilation of the aortic root leads to suboptimal coaptation of the aortic valve cusps as the aortic annulus dilates and ultimately to significant AR. More serious and potentially ominous complications include ascending aortic dissection, rupture, or both (280).

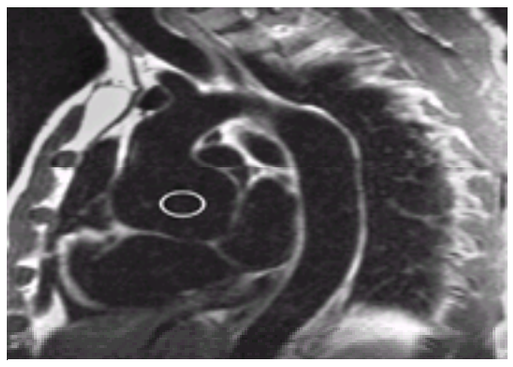

FIGURE 54.22 Annuloaortic ectasia of the aortic root (T1-weighted, spin-echo; left anterior oblique). An “onion-bulb” dilatation of the proximal ascending aorta and sinuses of Valsalva (*open circle*), associated with pronounced effacement of the sinotubular junction, is noted.

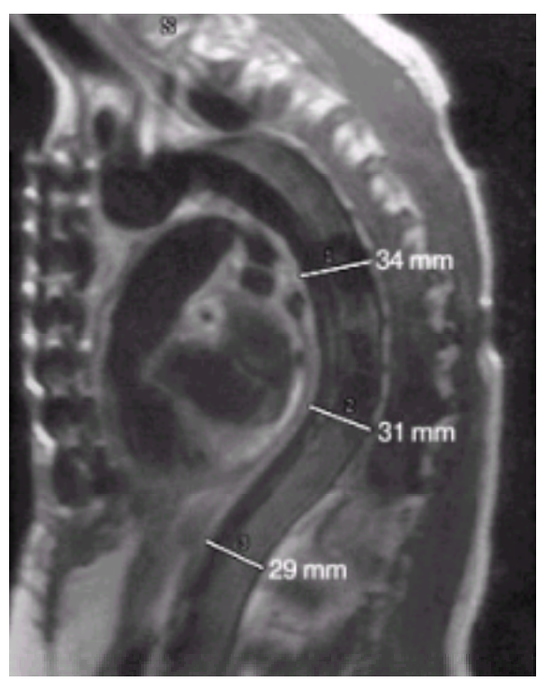

Magnetic resonance scan of the thoracic aorta in Marfan syndrome. There is dilation of the descending aorta with an average diameter of approximately 3 cm.

Another configuration of thoracic aortic aneurysms that is important to identify on MRI is saccular dilatation from a mycotic or pseudoaneurysm. Mycotic aneurysms result from weakening of the aortic wall by infection (278), although pseudoaneurysms typically are caused by trauma (e.g., automobile accidents) and occur most commonly at the level of the ligamentum arteriosum or after surgery at anastomotic or cannulation sites (Fig. 54.23) (281).

FIGURE 54.23 Aortic pseudoaneurysm (magnetic resonance angiography surface reconstruction). A saccular outpouching (*asterisk*) from the undersurface of the aortic arch communicates with the aortic lumen through a narrow neck (*arrow*), indicating disruption of the layers of the aortic wall.

Dissection

Dissections are classified according to either the Stanford or DeBakey systems. The important distinction to be made clinically is whether the dissection flap involves the ascending aorta with or without transverse arch involvement (Stanford A; DeBakey I and II) (eFig. 54.23.1) or both the distal arch beyond the left subclavian artery origin and the descending aorta (Stanford B; DeBakey III) (eFig. 54.23.2). This distinction is important because the involvement of the ascending aortic is associated with a higher mortality and generally requires urgent surgical repair.

VIDEO

Video 54.8 Aortic dissection (left anterior oblique). Type A dissection of the aorta is manifested on the cine image loop by a mobile intimal flap extending from the mid-ascending aorta to the descending thoracic aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

Video 54.9 Aortic dissection (left anterior oblique). Type B dissection of the aorta extending distally from the isthmus, just after the left subclavian artery, to the abdominal aorta. A communication between the true and false lumen is seen in the proximal portion of the descending aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

***e*FIGURE 54.23.1** Aortic dissection (left anterior oblique). Type A dissection of the aorta is manifested on the cine image loop by a mobile intimal flap extending from the mid-ascending aorta to the descending thoracic aorta.

***e*FIGURE 54.23.2** Aortic dissection (left anterior oblique). Type B dissection of the aorta extending distally from the isthmus, just after the left subclavian artery, to the abdominal aorta. A communication between the true and false lumen is seen in the proximal portion of the descending aorta.

MRI is a highly sensitive and specific technique for the detection of aortic dissection that has proven to be superior to conventional angiography, CT, and transthoracic echo (282). It also has been compared with transesophageal echo; both techniques have demonstrated a similar high sensitivity (e.g., 98% to 100%), but MRI has a significantly higher specificity (e.g., 98% to 100%) than transesophageal echo (e.g., 68% to 77%) in high-risk populations (282). The advantages of MRI include an ability to evaluate not just the intravascular space and walls of the aorta, but also the extravascular space, which may yield further information, particularly in regard to more serious complications of aortic dissection (273). Nonetheless, most agree that transesophageal echo—because of its portability, speed, and ability to image in real time—is the preferred method of evaluation in the subset of unstable patients, such as those in the emergency room and intensive care settings.

The goals of MRI in aortic dissections, both acute and chronic, are to identify the intimal flap, its extent, orientation, and involvement with aortic arch branch vessels and coronary arteries, the location of entry and reentry tears of the intima, and to assess for areas of flow and thrombus within the false channel (273). In addition, potential complications such as pleural effusion, pericardial tamponade, and AR must be assessed.

Whether by S-E or cine imaging, aortic dissection is characterized by the inwardly displaced intraluminal intimal flap, surrounded by rapid flow within the true channel and usually slower flow, with or without thrombus formation in the false channel (Fig. 54.24) (273,282,283). Both primary and secondary tears of the intimal flap may be difficult to identify on the static images unless they are relatively large. Dynamic flow-based images (i.e., cine, SPAMM, or velocity mapping) are useful adjuncts to identify these sites of flow between the true and false channels and to observe the frequently dynamic motion of the intimal flap (eFig. 54.24.1) (273,284).

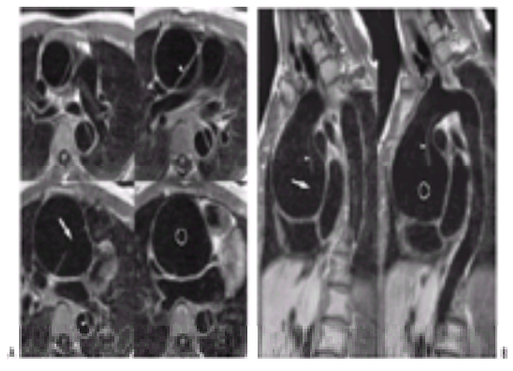

FIGURE 54.24 Aortic dissection (T1-weighted spin-echo; transaxial and left anterior oblique). Type A dissection of the aorta is manifested on representative transaxial **(A)** and oblique **(B)** images by the inwardly displaced intimal flap (*arrowheads*), extending from the dilated aortic root (*open circle*) to the descending thoracic aorta, and a large proximal intimal tear (*arrows*).

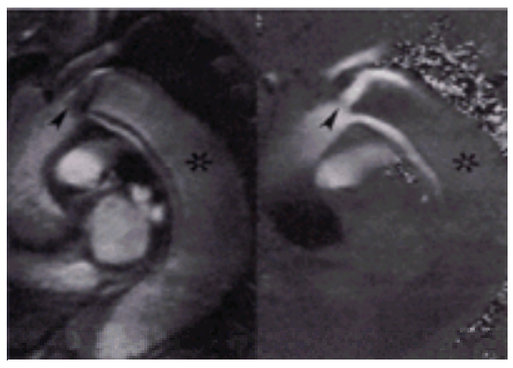

***e*FIGURE 54.24.1** Dynamic flow-based imaging of aortic dissection (cine and velocity mapping; left anterior oblique). The blood-flow patterns of this type B dissection of the aorta are manifested on systolic cine (*left*) and velocity mapping (*right*) images by rapid nonrestrictive flow through the large primary intimal tear (*arrowheads*) beyond the left subclavian artery and slower blood flow in the false channel (*asterisks*).

The patterns of flow within each channel can be further qualitatively or quantitatively assessed with these MRI techniques for the purposes of planning surgical repairs or interventional procedures (e.g., fenestration) in which the adequacy of blood supply to vital organs is often an issue (284). Velocity mapping, in particular, may identify retrograde patterns of flow within the false channel that may potentiate retrograde extension of a simple type B dissection into the arch and ascending aorta.

A common hurdle is the distinction between a thrombosed false channel within a chronic dissection from an intraluminal thrombus adherent to the wall of an aneurysm. These are not always possible to differentiate, as a chronic intraluminal thrombus may neoepithelialize, giving the appearance of an intimal flap overlying the chronic thrombus (273,284). Signs that have been reported to be more consistent with a diagnosis of thrombosed false channel associated with dissection are a compressed or eccentric patent channel and extensive thrombus with associated wall thickening over a length greater than 7 cm; these signs are easily appreciated on MRI (284).

The entity of noncommunicating dissecting intramural hematoma is being detected with increasing frequency with the development of tomographic imaging, including MRI. Technically, this may be described as dissection of the aortic wall without intimal rupture or tear; the etiology is unknown, but presumably is related to a weakening of the media. Clinically, the presentation is almost always similar to that of aortic dissection; the diagnosis of an intramural hematoma is entertained, once communicating aortic dissection has been excluded. On MRI designed to exclude communicating aortic dissection, an intramural hematoma is identified as a smooth crescentic to circumferential area of thickened aortic wall without evidence of blood flow in the false channel (e.g., velocity-dependent phase changes on velocity mapping or displacement of saturation bands on SPAMM) (284,285 and 286). Depending on the age of the hematoma, the area of thickening may be isointense or hyperintense relative to skeletal muscle on S-E MRI; the signal intensity is relatively isointense in the acute phase, and then becomes greatest in the subacute stages (Fig. 54.25) (286). If intramural bleeding stops, the intramural hematoma resolves with decreasing thickness and returns to S-E isointensity in the more chronic stages.

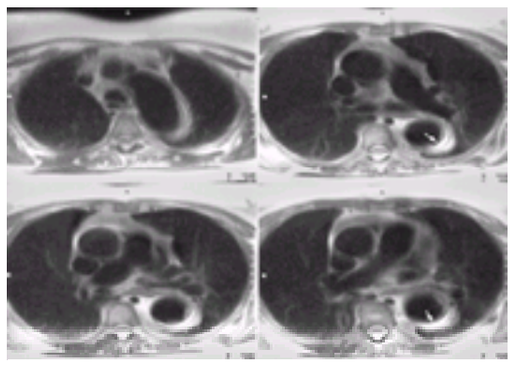

FIGURE 54.25 Intramural hematoma of the thoracic aorta (T1-weighted spin-echo; transaxial). A smooth crescentic collection within the wall of the descending thoracic aorta (*arrows*) indicates an intramural hematoma; its extremely bright signal intensity indicates its subacute nature.

At present, there is only limited knowledge regarding the natural course of an intramural hematoma. However, complete resolution or evolution to dissection have been demonstrated on MRI (285,286). Involvement of the ascending aorta by intramural hematoma has been shown to predispose the development of communicating aortic dissection in most cases; rebleeding before development of communicating dissection has been detected based on S-E intensity changes (285,286).

Atherosclerosis

The first attempt at MRI of atherosclerotic plaque involved the use of postmortem specimens of excised peripheral artery (287); good correlation between the morphology of the plaques on MRI and on histology was demonstrated. Atherosclerotic lesions were seen as vessel wall thickening with overall intermediate signal intensity, except in areas of calcium and lipids, where there were focally decreased and increased signal, respectively (287). Since these early studies, images obtained with more advanced MRI protocols in experimental models have proved to be useful in identifying various wall components in atheromatous artery samples on the basis of chemical composition, molecular motion, diffusion, physical state, or water content (288). These differences may be particularly important in determining the contributing factors related to plaque rupture, which depend strongly on the presence of soft lipid and collagenous fibers (289). Some studies using image processing have also shown that it may be possible to identify and quantify the types of materials present in atherosclerotic plaque (290,291).

High-resolution MRI has shown excellent contrast between fatty plaque components (i.e., foam cells, loose necrosis, and cholesterol) and solid components; signal loss in images was seen at locations where calcium existed (288,289). Experimental work has shown the potential of MRI to demonstrate (a) the variable nature of the collagen cap with underlying lipid-rich regions in more vulnerable plaques; (b) anatomic response of the atherosclerotic plaque to *in vitro* angioplasty; (c) the relationship between the nature of the lipids inside atheromatous plaques and the severity of vessel obstruction; and (d) “aging” changes of thrombi.

In the clinical setting, MRI currently has the capability of routinely providing valuable information regarding the patency of the arterial lumen, as well as the status of the arterial wall in patients with atherosclerotic vascular disease (40). Atherosclerotic lesions in humans consist of eccentric or concentric mural thickening with luminal narrowing and discrete plaques protruding into the vessel lumen. Although early studies using standard S-E techniques yielded promising results, limitations in

detecting calcified plaques by MRI were revealed (292).

Good accuracy of MRA for depicting peripheral stenoses and occlusions has been demonstrated clinically (60,293). However, because minor luminal irregularities, ulcers, or aneurysms may all lead to significant local turbulence and resultant intraluminal signal loss in the absence of an angiographically significant narrowing, an imperfect concordance between MRI and conventional forms of angiography may result. Nevertheless, measurements of the degree of stenosis on projectional MRA images have been shown to correlate reasonably well with conventional angiographic techniques (294). However, there are limitations that potentially interfere with clinical characterization of adjacent atherosclerotic plaques.

A penetrating atherosclerotic ulcer is an MRI-detectable entity, occupying an as yet uncertain place in the spectrum of aortic atherosclerotic disease (279). It usually appears as a shallow, wide-necked ulceration of an atheroma that extends through the intima to disrupt the underlying media; the mid- and distal descending aorta are the most common sites.

Pulmonary Artery Disease

Few options have been available for diagnosing disease of the pulmonary artery. The gold standard for diagnosis has been pulmonary artery catheterization with or without angiography. MRI has many unique capabilities that make it preferable to other noninvasive imaging methods and to angiography for the evaluation of some abnormalities of the pulmonary artery system. Aside from depicting intrinsic pulmonary artery disease, MRI is an ideal imaging method for evaluating the secondary effects of adjacent extravascular disease.

Pulmonary Emboli

Because all therapies for pulmonary emboli (PE) pose significant risks, an accurate diagnosis of such disease is mandatory before the initiation of treatment. For the diagnosis of PE, there has been no single noninvasive and accurate imaging procedure. Imaging by ventilation-perfusion scintigraphy is safe, but accurate interpretation in the presence of lung disease or cardiac conditions is reduced. Consequently, many individuals with suspected PE ultimately come to angiography because of diagnostic evaluations.

Because of the signal void of normally flowing blood, thrombus within a pulmonary artery can usually be readily discerned on systolic S-E images; the intensity of thrombus is variable, depending on its age. Because cases of pulmonary artery hypertension (PAH) are often present with symptoms requiring evaluation for suspected PE, and because abnormal systolic intravascular signal may also be caused by slow blood flow in PAH, the need for differentiation of thrombus from slow blood flow in MRI is common. This can be accomplished by noting that, unlike slow blood flow, a thrombus from PE demonstrates no even-echo rephasing on multiple S-E images, and no change in distribution on multiphasic images (295,296). Although it can be used to demonstrate a thrombus in a larger pulmonary artery, it is unlikely that S-E MRI can at the current time be considered reliable for the evaluation of PE beyond the level of a segmental pulmonary artery (296). Phase-display imaging may also be useful in detecting the phase changes related to slowly flowing blood and the absence of such phase changes related to a fixed thrombus.

Cine and SPAMM are adjuncts to S-E imaging, which potentially increase the diagnostic yield and capabilities for characterization of PE (296,297 and 298). In general, an intravascular thrombus from PE is manifested by a fixed area of signal void or preservation of saturation band patterns, respectively, which can be differentiated from the appearance of the surrounding flowing blood (Fig. 54.26). A complicating factor in thrombus detection would be slow blood flow caused by pulmonary artery obstruction by the thrombus or from superimposed PAH because of slow blood flow (296,297). PE diagnosed by cine has been shown to correspond to the locations of angiographic abnormalities and mismatched ventilation-perfusion defects on scintigraphy and has been able to assess the age of the embolic mass (299).

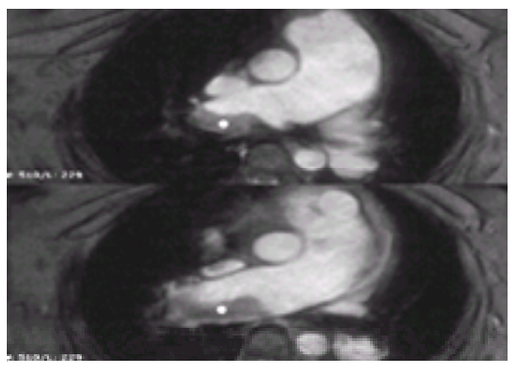

FIGURE 54.26 Intravascular thrombus from pulmonary emboli (cine; transaxial). Adjacent levels both demonstrate a fixed lobular area of relative signal void (*closed circles*), surrounded by flow enhancement, in the right central pulmonary artery; it represents pulmonary emboli.

Although some potential to identify the age of the thrombotic material within a pulmonary artery by MRI has been realized, it is more practically used for monitoring resolution of clotting during anticoagulation therapy. MRA techniques have created pleasing images of the branching pulmonary artery system, and the capability of reliably demonstrating PE is now being done (300).

Pulmonary Hypertension

The ability of S-E MRI to distinguish normally flowing from slowly flowing blood and slowly flowing blood from fixed intravascular lesions (e.g., thrombus caused by PE) indicates its value as an alternative to catheterization in assessing PAH. The increased risk of catheterization plus angiography for the diagnosis or exclusion of PE in cases of PAH has also emphasized the potential of MRI for this purpose.

Initially, the primary use of S-E MRI in evaluation of PAH was the description of secondary changes (301). Anatomic findings include RV hypertrophy in proportion to the pulmonary artery pressures; reversal of septal curvature when pulmonary artery pressures approximate systemic pressures; and pulmonary artery dilatation (Fig. 54.27).

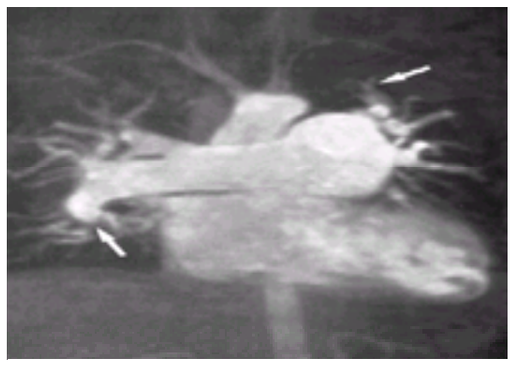

FIGURE 54.27 Pulmonary artery (PA) dilatation of pulmonary artery hypertension (contrast-enhanced three-dimensional magnetic resonance angiography; coronal). Marked dilatation of the main PA and each central PA is noted. Beyond the hilar regions, rapid tapering of PA branch caliber (*arrows*) is indicative of pulmonary artery hypertension.

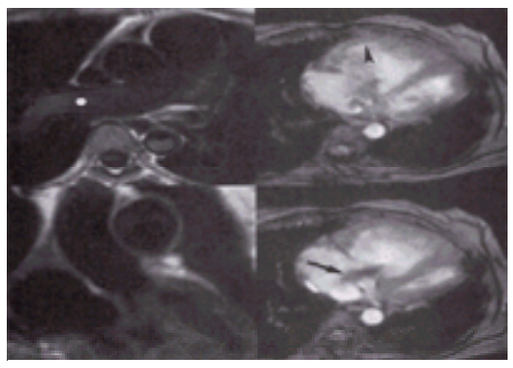
In PAH, substantial elevation in pulmonary vascular resistance and dilatation of the pulmonary artery system result in diminished velocity of blood flow; the intensity of such abnormal intravascular signal has a direct linear relationship with the amount of pulmonary vascular resistance, showing the ability of S-E MRI to provide information about the severity of PAH (302). Combined use of multiple S-E and multiphasic techniques permits further description of the characteristic pulmonary artery

signal patterns typically found in the setting of PAH (eFig. 54.27.1) (295). Because of the presence of even-echo rephasing, as well as its fluctuating distribution during the cardiac cycle, abnormal intravascular signal from slow blood flow can be distinguished from that of intraluminal thrombus or tumor (295,303). Phase-display and cine images can also be used to properly identify abnormal intravascular signal from slowly flowing blood in PAH, through demonstration of velocity-dependent phase changes and saturation-related diffuse intermediate signal loss, respectively (296,297).



***e*FIGURE 54.27.1** Secondary effects of pulmonary artery hypertension (T1-weighted spin-echo and cine; transaxial and coronal). Because of pulmonary artery hypertension, pulmonary artery dilatation with slow flow signal (*closed circle*) is seen. Right ventricular dilatation, associated with flattening of the interventricular septum, is noted; hypertrophy of the right ventricle wall (*arrowhead*) is also demonstrated. Last, tricuspid regurgitation (*arrow*) is evident.

Pulmonary artery distensibility has been studied with S-E MRI in healthy subjects and in patients with PAH; distensibility was found to be significantly reduced in cases with PAH (304). When velocity mapping of the pulmonary artery flow was performed, all cases of PAH had totally irregular antegrade flow in systole with large velocity variations across the vessel lumen. PAH was also associated with abnormally slow net forward flow, but with earlier velocity peaking than in healthy subjects; abnormally large retrograde flow was noted in systole and diastole in PAH.

The multipotentiality of MRI is clearly evident in the assessment of patients undergoing evaluation for possible lung transplantation or for monitoring following this surgery. Improved RV function and enhanced pulmonary artery flow n transplanted lungs have been shown (305,306).

Thrombi and Masses

MRI has proved to be extremely valuable in assessing mass lesions located in the cardiac chambers or myocardium or adjacent to the heart in the pericardium, mediastinum, or lung (307). S-E MRI images provide excellent anatomic detail, sufficient for assessment of the extent of such lesions, indicating their site of origin, as well as the secondary effects on adjacent structures. Cine may provide additional information concerning their movement relative to the cardiac chambers; this insight may provide a better appreciation of sites of attachment and influence on myocardial and valve function (267). This anatomic and functional information has an important role in planning therapy for thrombi and cardiac masses (308).

MRI has been shown to outperform echo in demonstrating the presence, location (i.e., paracardiac vs. intramural vs. intracavitary), and extent of mass lesions (308,309). In a significant proportion of cases referred from echo to MRI for evaluation of a suspected cardiac mass lesion, the presence of a lesion is excluded by MRI (309). Thus, MRI can be used effectively in combination with echo to increase the certainty of diagnosis and plan therapy (267).

In addition to providing important morphologic data, MRI has the potential to assess the tissue composition of mass lesions. As is true elsewhere in the body, the use of both T1- and T2-weighted S-E images allows for some general degree of tissue characterization (308,311). Because lipomatous tissues have a uniquely short T1 and their signal intensity resembles that of subcutaneous fat on S-E imaging, cardiac lipomas have a relatively high signal intensity on T1-weighted images and a moderate signal intensity on T2-weighed images (267,310). Cystic cardiac lesions typically have long T1 and T2 relaxation times, resulting in a low signal intensity on T1-weighted images and a high signal intensity on T2-weighted images (266,307,310). Most soft-tissue cardiac tumors have T1 and T2 relaxation times that are much shorter than those of cystic fluid, yet T1 and T2 are long enough to produce a relatively low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (267,307).

Like tumors elsewhere in the body, cardiac tumors have increased water content, resulting in prolongation of T1 and T2 relaxation times (267). The effects of edema in the surrounding tissue may make the distinction between the tumor and the surrounding tissues difficult. In addition, the presence of hemorrhage or necrosis within a tumor may alter its appearance. To complicate matters further, dense fibrous tissue and areas of calcification, possibly resulting from therapy, produce a low signal intensity on T1- or T2-weighted images because of a relative paucity of mobile protons.

Gd-DTPA accumulates in tumors more than in myocardium, improving detection and anatomic delineation of cardiac tumors (267,311). Enhancement helps to distinguish neoplasms from nonvascular masses, because the tumor must have a capillary blood supply to accumulate the extracellular contrast agent. However, similar to other organ systems, cardiac neoplasms show variable degrees of enhancement, and the kinetics are not specific for benignancy or malignancy. Thus, the early hope that MRI would permit the differentiation of benign from malignant masses has not been fulfilled.

Intracardiac Thrombi

The accuracy of MRI in the diagnosis of an LV thrombus is comparable with angiography, CT, and echo (145,146,267). Interpretation of S-E MRI is complicated by the presence of intraventricular flow signal, resulting from stagnant blood within areas of LV dysfunction. The demonstration of even-echo rephasing or phase shifts in regions of slowly flowing blood is helpful in excluding the diagnosis of a thrombus (267). Similarly, cine can exploit flow-related enhancement to distinguish slow flow from a thrombus (146) (eFig. 54.3.3).

Nevertheless, the signal intensities of intracardiac thrombi on S-E MRI have been variable and not reliably distinguishable from those of nonthrombotic masses (307,309).

Primary Cardiac Tumors

The exclusion or verification of the presence of an intracardiac mass suggested by a prior echo has been a frequent indication for MRI (267); this complementary role of MRI in the evaluation of intracardiac masses is now well established in clinical practice. Frequently, MRI excludes the presence of an intracardiac mass initially suggested by echo. In some cases, MRI identifies an anatomic variant (e.g., distortion of cardiac anatomy by a pectus deformity) as the source of the false-positive echo result (309).

Video 54.10 Transesophageal view demonstrating the right atrium with the inferior vena cava off to the left of the screens, the superior vena cava to the right, and the left atrium at the top, with the interatrial septum in the middle. This view shows a hemangioma in the interatrial septum found incidentally at the time of preoperative transesophageal echo for mitral valve replacement for severe mitral regurgitation. Intraoperatively, the mass was highly vascular as expected and was resected. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

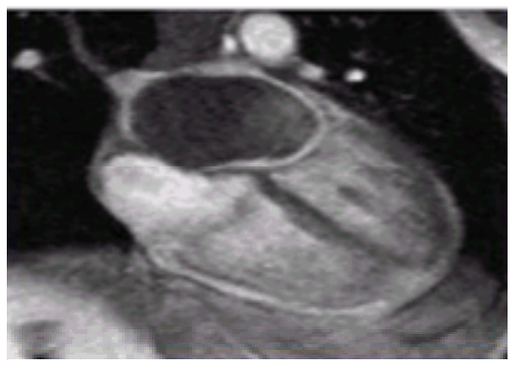
Video 54.11 Four-chamber transesophageal view of a patient with a cystic-appearing mass on the tricuspid valve. *This video must be viewed with QuickTime. If you do*

not have QuickTime you may download it here.

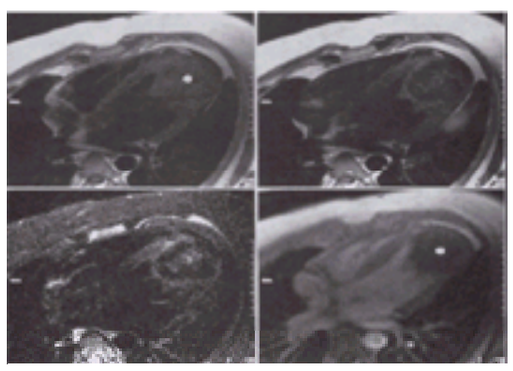
The ability of MRI to identify a variety of benign or malignant tumors primarily involving the cardiac chambers is well known (307,308,312). Studies comparing MRI with echo have indicated that MRI more clearly demonstrates the relationship of masses to normal intracardiac structures and extension into adjacent vasculature or the mediastinum (312,313). When MRI confirms the presence of a mass, definition of anatomy is the most useful parameter for establishing a specific diagnosis (267,307,312). For example, the location of the mass within the left atrium is the main criterion for differentiation between myxoma (i.e., almost always arises from the interatrial septum) and thrombus (i.e., usually occurs near the posterolateral wall or atrial appendage).

MRI tissue characteristics of intracardiac masses add some specificity to their diagnoses (267). Myxomas typically appear brighter than myocardium on T2-weighted S-E MRI because of their increased T2 relaxation times (307) (eFig. 54.27.2). Variability in the appearance of myxomas may reflect their variable composition of water-rich myxomatous tissue (long T2; high signal intensity) versus fibrous tissue and calcification (short T2, low proton density; low intensity). Similarly, fibromas show decreased signal intensity relative to myocardium (eFig. 54.27.3). Lipomatous hypertrophy or lipomas of the interatrial septum have the distinctive short T1 and high signal intensity of adipose tissue (Fig. 54.28). Various other benign intracardiac masses have been described.

Video 54.12 Atrial myxoma (long-axis). A myxoma attached to the interatrial septum is seen. During diastole, the myxoma moves through the mitral orifice into the left ventricle. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



***e*FIGURE 54.27.2** Atrial myxoma (long axis). A myxoma attached to the interatrial septum is seen. During diastole, the myxoma moves through the mitral orifice into the left ventricle.



***e*FIGURE 54.27.3** Myocardial fibroma (T1-, T2-, and T1/T2-weighted spin-echo and ultrafast; horizontal long axis). A large intramyocardial mass of the left ventricle apex (*closed circles*) is characterized by low signal intensity, caused by fibrous tissue, on all four types of images. Lack of evidence of edema or hypervascularity indicates its benign nature.

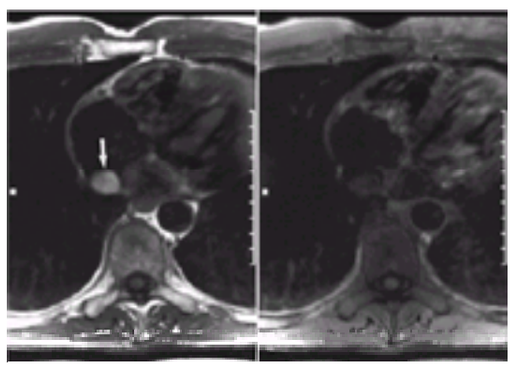


FIGURE 54.28 Atrial lipoma (T2-weighted spin-echo; transaxial). Because of its fatty composition, the signal intensity of the relatively bright, rounded intracardiac lipomatous mass (*arrow*) within the right atrium **(left)** is suppressed with application of fat-saturation techniques **(right)**.

The pattern of invasion by intracardiac malignancies is also well defined using MRI, which permits more accurate diagnosis and description than angiography, CT, or echo (267). MRI findings in cases of intracardiac malignancies have correlated extremely well with findings from surgical exploration or postmortem examination (313).

Various primary intracardiac malignancies have been detected by MRI (267,307). Angiosarcomas are typically found in the region of the right atrioventricular groove and are associated with significant pericardial disease, including complex effusion (Fig. 54.29).

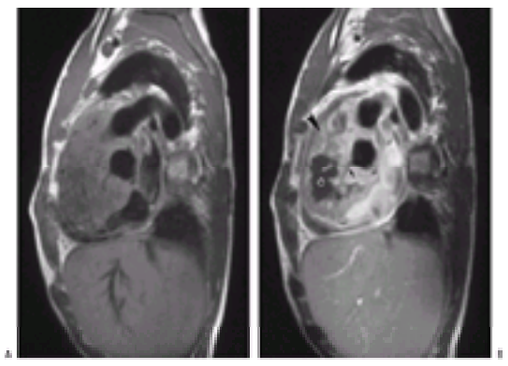

FIGURE 54.29 Angiosarcoma (T1-weighted spin-echo; short axis). Although the mass created by this primary cardiac tumor is easily seen in the right atrioventricular groove before administration of gadolinium chelate **(A)**, the use of contrast enhancement demonstrates peripheral hyperperfusion (*arrowhead*) and its central zone of necrosis (*open circle*) **(B)**; encasement of the right coronary artery (*arrow*) is better seen after injection of the magnetic resonance imaging contrast agent.

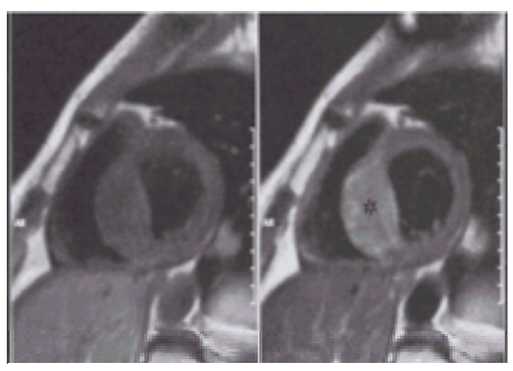
Anatomic relationships between primary paracardial tumors and the heart are well demonstrated on MRI (267). Signal intensity differences between tumor (long T1 and long T2), myocardium (long T1 and short T2), and pericardial and epicardial fat (short T1 and intermediate T2) provide excellent image contrast. Furthermore, MRI is useful in differentiating a variety of benign intrapericardial lesions from extrapericardial masses (314). Paracardiac masses external to the pericardial sac are often benign and their characteristics are easily appreciated on MRI (267).

Secondary Tumors

Secondary intracardiac malignancies may involve the cardiac chambers via intravascular or transmural extension. Few have been described by MRI (267).

Secondary paracardiac malignancies, including tumors directly extending or metastasizing to the pericardium or pericardial space, are well seen on MRI (315). Unfortunately, their MRI tissue characteristics are nonspecific (long T1 and long T2) (eFig. 54.29.1). Masses abutting the pericardium with penetration can be easily differentiated from those in which there is direct extension of the tumor to involve the pericardium or myocardium. Compression of the cardiac chambers, interposition of the masses between the spine and the left atrium, and extension of the invasive tumors through the wall of a cardiac chamber are readily demonstrated by S-E MRI. Cine can aid in assessing the extension of such tumors into the pericardium or cardiac chambers because of the appreciation of the relative motion of these structures. Various secondary paracardiac tumors have been evaluated using MRI (315,316).



***e*FIGURE 54.29.1** Myocardial metastasis (T1- and T2-weighted spin-echo; short axis). Seen as an isointense myocardial mass of the interventricular septum with T1-weighting (**left**), the metastatic lesion from a peripheral muscle sarcoma is represented as an area of increased signal intensity with T2-weighting (*asterisk*, **right**); this appearance is related to edema and hypervascularity from the tumor.

Congenital Heart Disease

Despite the plethora of reports demonstrating MRI to be an accurate modality for diagnosing many forms of CHD (231,317), its role in this area remains largely supportive to echo. In particular, in adults with CHD, the diagnostic information provided by transthoracic echo is often incomplete because of the larger body, associated chest deformities, and paucity of adequate imaging windows (318,319). This provides the incentive for using MRI and transesophageal echo, but MRI has the advantage over transesophageal echo of imaging in any desired plane chosen by the operator to include the structures of interests and related anatomy, thereby becoming useful for clarification of complex structural relations in space.

The unique role of MRI in the assessment of adult CHD is primarily in (a) noninvasive shunt quantitation; (b) pursuit of hard to find lesions; (c) evaluation of complex anomalies; (d) assessment of congenital great vessel disease; and (e) postoperative assessment.

VIDEO

Video 54.13 Coarctation of aorta (oblique). A signal-void jet is visible in the proximal descending aorta due to a short-segment narrowing representing a coarctation. Left ventricular hypertrophy is also present. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Noninvasive Shunt Quantitation

Direct quantitation of the amount of shunting as an indicator of the anatomic size of a defect is a useful parameter for planning corrective surgery. For this purpose, ventricular volumes can be accurately determined directly from a series of cine image loops encompassing the full extent of the RV and LV (69). For an atrial septal defect with left-to-right shunting, shunt quantitation can be accomplished with cine in the absence of associated valvular insufficiency or additional shunts by evaluating the difference between the larger RV and smaller LV stroke volumes. Shunt volume for a ventricular septal defect could theoretically be derived by subtraction of the smaller RV stroke volume from the larger LV stroke volume. However, it has been found that RV stroke volume may also be increased in such left-to-right shunts, depending on the location of the ventricular septal defect (154). Therefore, the ventricular volume method may not be as accurate in the setting of a ventricular septal defect.

Some of the previously mentioned limitations of ventricular volume analysis for shunt quantitation may be overcome using volume-flow analysis of great artery flow with velocity mapping. With this approach, quantitation of shunt size can be accomplished by measurement of net blood flow volumes within the main pulmonary artery and ascending aorta over a cardiac cycle. Shunts produce discrepant pulmonary and systemic arterial flows, with the former exceeding the latter in left-to-right shunts, and the converse in right-to-left shunts (Fig. 54.30) (320). This difference can be expressed either in absolute terms (e.g., shunt volume) or in relative terms (e.g., Qp/Qs). Values for shunting derived by volume-flow analysis have correlated well with the results from cardiac catheterization or nuclear first-pass ventriculography (320).

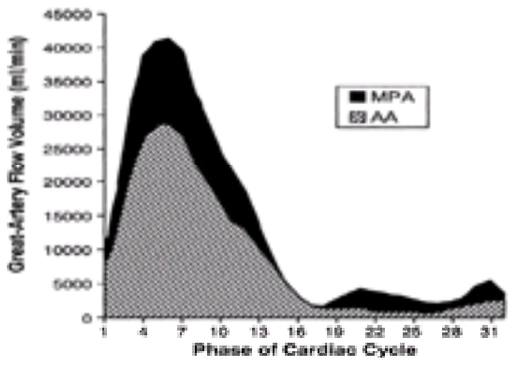


FIGURE 54.30 Flow-volume analysis of atrial septal defect with left-to-right shunting. Volume-flow analysis using velocity mapping permits direct measurement of great artery volume flows over the cardiac cycle after integration of the areas under the curves resulting from plotting of mean instantaneous volume flows passing through a cross section of each artery. The relative difference in volume flow between the main pulmonary artery (MPA), representing systemic stroke volume plus shunt volume, and the ascending aorta (AA), representing only stroke volume, may be used to derive a quantitative measure of left-to-right shunting, such as Qp/Qs. (From White RD. Magnetic resonance imaging of congenital heart disease. In: Pohost GM, ed. *Cardiovascular applications of magnetic resonance*. New York: Futura ublishing, 1993:59, with permission.)

Pursuit of Hard-to-Find Lesions

Echo provides a rapid, repeatable method for assessing the anatomy and functional significance of a simple congenital defect. Therefore, it remains the mainstay of noninvasive assessment of congenital heart disease. Nevertheless, some lesions remain elusive to echo in an adult. Examples of simple lesions often hard to find in the adult on echo, even when a transesophageal approach is used, are sinus venous atrial septal defect and partial anomalous pulmonary venous return (Fig. 54.31) (318,319).

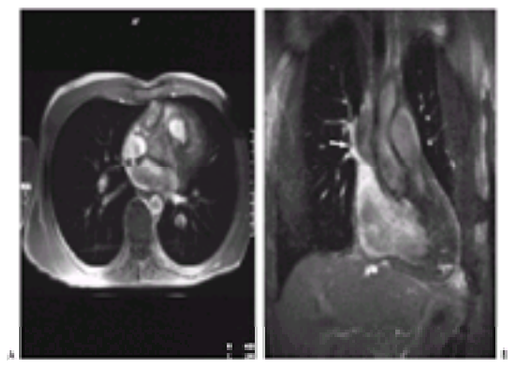

FIGURE 54.31 A hard-to-find sinus venosus atrial septal defect (cine; transaxial and oblique-coronal). High in the sinus venosus portion of the interatrial septum, immediately below the confluence of the superior vena cava with the right atrium, an atrial septal defect (*asterisk*) is noted **(A)**. The frequently associated anomalous return of the right upper pulmonary vein (*arrow*), in this case to the lower superior vena cava, is also demonstrated **(B)**.

Evaluation of Complex Anomalies

To capitalize on the anatomy that MRI demonstrates, application of the segmental approach has proven to be useful to characterize complex CHD in the adult (317,318 and 319,321). Although the morphology of the appendages may be helpful, the received veins generally offer the best clues as to the nature of the atria visualized on MRI; the normal state (atrial situs solitus) is easily distinguishable from the inverted condition (atrial situs inversus), and both conditions can be easily differentiated from classic isomerism (situs ambiguus with either bilateral right-sidedness or left-sidedness). The ventricular positions define the bulboventricular loop; in the dextro (D)-loop, the normal state, the morphologic RV is situated to the right of the morphologic LV, and the reverse occurs with a levo (L)-loop. The morphologic RV, generally the more trabeculated, is characterized by the infundibulum separating the semilunar and atrioventricular valves, whereas the LV, generally the smoother walled, has its atrioventricular valve in fibrous continuity with the associated semilunar valve. Definition of the relationship of the great arteries is also part of the segmental approach, and it is clearly demonstrated with MRI; normally, the ascending aorta is located posteriorly and to the right of the main pulmonary artery, but the relationship is more difficult to define in the setting of atresia of either great artery. This relationship is disrupted with transposition variants, whereby the ascending aorta may become positioned anterior-rightward (D-transposition), anterior-leftward (L-transposition), or alongside the main pulmonary artery. With generally high sensitivity at high specificity levels, MRI may be used to detect abnormalities of visceroatrial situs, venoatrial connection, atrioventricular connection, bulboventricular loop, ventriculoarterial connection, and great artery relationship (Fig. 54.32) (319,321).

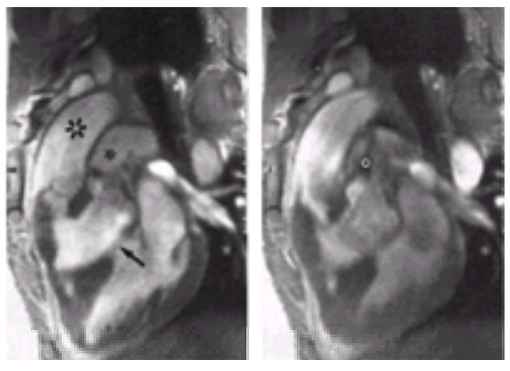

FIGURE 54.32 Complex congenital heart disease with abnormal ventriculoarterial connection and great artery relationship (cine; oblique-sagittal). In communication with an anatomic left ventricle through a muscular ventricular septal defect (*arrow*) is a small hypertrophic anatomic right ventricle, giving rise to both the aorta (*large asterisk*) and the main pulmonary artery (*small asterisk*) in a transposed arrangement. Valvular pulmonic stenosis is manifested by a signal-void jet (*open circle*).

Assessment of Congenital Great Vessel Disease

Imaging of the great arteries and veins by conventional echo can be problematic in adults, because imaging windows are limited by the surrounding lungs (318,319). Because MRI does not require an imaging window, the great vessels and their connections are visualized with the same clarity as cardiac structures.

Congenital Abnormalities of the Aorta

Coarctation

Defining the anatomy of coarctation is important, and for this reason MRI is of particular value (318). With MRI, the whole of the thoracic and abdominal aorta can be visualized with precise anatomic detail. Thus, MRI is a sensitive tool in the investigation of coarctation; the type of coarctation and the severity of stenosis can be seen easily on these images (Fig. 54.33 and *e*Fig. 54.33.1) (317,322). Other details, including the length of the stenotic segment, the presence of arch or isthmic hypoplasia,

the relationship of the coarctation to the aortic arch branches, and the presence of a ductus, are also accurately demonstrated.

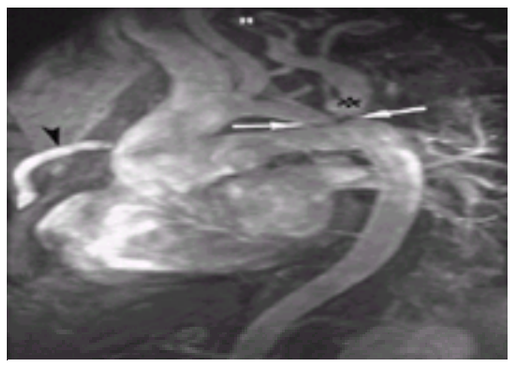

FIGURE 54.33 Complete interruption of the aorta (contrast-enhanced, three-dimensional magnetic resonance angiography; maximal intensity projection). Immediately beyond the stenotic origin of the dilated left subclavian artery (*asterisk*), there is complete interruption of the juxtaductal region of the aortic isthmus (*arrows*). A large internal mammary artery (*arrowhead*) serves as a systemic collateral vessel.

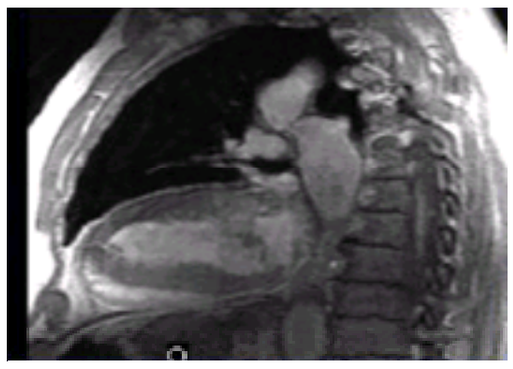


***e*FIGURE 54.33.1** Coarctation of aorta (oblique). A signal-void jet is visible in the proximal descending aorta caused by a short segment narrowing representing a coarctation. Left ventricular hypertrophy is also present.

Although the anatomy and degree of luminal stenosis are clearly visible on S-E images, a pressure gradient cannot be determined. However, the use of cine can both detect basic hemodynamic alterations resulting from stenosis and the resulting pressure gradient and provide further valuable insight into the collateralization from the nature of the turbulent downstream jet (231,318,323). Specifically, a low-signal jet can be visualized passing through and distal to the area of a significant stenosis, although this signal loss must be differentiated from normal signal decrease caused by antegrade flow (323). However, in the setting of complete or high-grade narrowing, flow may be primarily through collaterals and a transcoarctation jet may not be present. Velocity mapping allows quantitative assessment of the coarctation severity based on measurement of transstenosis velocity (99,324). In addition to the site and severity of aortic narrowing, other abnormalities associated with coarctation (e.g., collateral vessels and poststenotic dilatation) may be seen with MRI.

MRI is particularly valuable when applied on a serial basis during regular follow-up of patients who have undergone coarctation repair; it can provide high-resolution images of the repair site and determine the extent of recoarctation (317,318). In patients who have undergone balloon dilatation of either a native coarctation or recoarctation, MRI provides an ideal serial investigation to watch for the development of aneurysm formation at the dilatation site.

Aortic Arch Branching Abnormalities

The value of MRI in the detection of congenital anomalies of the aorta has been well established (322,325). The morphology of the arch, its branching pattern, and its effect on adjacent structures can be recorded with a high degree of detail.

All types of vascular rings and the various anomalous branching patterns of the aortic arch (e.g., double aortic arch) are reliably seen on MRI (324,325). In older patients, or in those who have undergone surgery, MRI shows arch anomalies with greater clarity than transthoracic echo (322). Three-dimensional displays are often valuable for visually relating or connecting in a single image the often tortuous and obliquely oriented arterial components of a vascular ring (326).

Congenital Pulmonary Artery Abnormalities

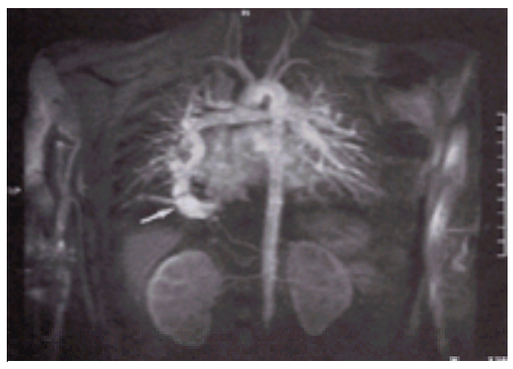
Because MRI is not limited by the acoustic penetration of ultrasound or by the vascular access required for angiography, visualization of central pulmonary vessels (whether a true pulmonary artery or one arising from systemic-to-pulmonary collaterals) can be readily imaged with a high degree of spatial resolution (318,327). The origin, size, and morphology of these vessels can be determined with relative ease using MRI. Stenoses of the main pulmonary artery and central arteries are detected better using cine than S-E imaging; pulmonary artery stenoses result in flow disturbances manifested by jets of signal void on cine (328).

Although MRI accurately delineates the anatomy of the central pulmonary artery system and can identify the aortic origin of major collateral vessels, it often fails to demonstrate the intrapulmonary segments of the arteries and collaterals, thus making the diagnosis of peripheral pulmonic stenoses difficult (319). Although evaluation of the pulmonary artery system within the lungs may be problematic for MRI, evaluation of the main pulmonary artery and central arteries appears to be as accurate as angiography and more accurate than transthoracic echo.

Congenital Abnormalities of the Pulmonary and Systemic Veins

Although the proximal portions of the pulmonary veins near their insertions into the left atrium are usually easily demonstrated with S-E MRI, G-E imaging has the advantage of displaying flow-related signal enhancement within the veins, thereby readily identifying them within the lungs (329). Consequently, cine or MRA is preferable to S-E MRI for the identification of anomalous pulmonary venous drainage, and it may aid in the diagnosis of congenital abnormalities of the systemic veins (330).

MRI has been shown to be effective for demonstration of all types of anomalous pulmonary venous connections, comparable with or more accurate than echo and angiography (321,329,330). In addition to showing anomalous connections (*e*Fig. 54.33.2), venous stenosis or stenosis at an anastomotic site is accurately demonstrated. Reduced sensitivity for detecting the return connections of the pulmonary veins by S-E imaging, compared with G-E MRI or MRA, is probably related to the aforementioned inherent limitations in this technique.



***e*FIGURE 54.33.2** Anomalous pulmonary venous connection (contrast-enhanced, three-dimensional magnetic resonance angiography; maximal intensity projection). The right pulmonary venous system is shown to collect into a common pulmonary vein (*arrow*) draining inferiorly into the junction of the inferior vena cava with the right atrium.

Postoperative Assessment

As more patients with CHD undergo corrective surgery and survive longer, postoperative clinical evaluation becomes increasingly important. MRI is an important adjunct to echo and an alternative to angiography for morphologic examination of CHD after surgery (318,319). The combination of capabilities described earlier for the evaluation of anatomic aspects makes MRI uniquely suited for this pursuit. In contrast to echo, MRI is not severely restricted by postoperative scarring.

The course and patency of extracardiac shunts (e.g., Blalock-Taussig shunt) may be well visualized using S-E or G-E MRI (331), with G-E images more sensitive to identification of blood flow through vascular structures and differentiation between vessels and airway. MRI is somewhat less important for the evaluation of intracardiac postsurgical changes because its morphology is demonstrated as well or better with echo. However, in those instances in which an echo does not provide sufficient intracardiac detail, such as in older patients, MRI remains an important alternative diagnostic modality (330,332).

Important postoperative anatomic features of various surgical procedures for CHD (e.g., Fontan procedure for tricuspid atresia) have been successfully detected and delineated using S-E MRI (331,332). Cine has also been used successfully for postoperative evaluation of CHD patients (330); it has the advantage over S-E MRI of improved differentiation between blood vessels and air-filled structures. Finally, using cine, postoperative complications (e.g., peripatch leak after defect repair) have also been detected based on the presence of signal-void jets. However, the artifacts from metallic surgical materials are more prominent on G-E imaging than on S-E imaging because of greater sensitivity of the former to local magnetic field inhomogeneities, and this may increasingly hinder adequate visualization of structures using cine.

With an increasing number of interventional therapeutic devices, such as umbrellas, coils, and stents, as well as surgical materials being placed for therapy in patients with CHD, there may be increasing limitations of the postoperative diagnostic capabilities of MRI because of increasing problems related to artifacts (319).

FUTURE DIRECTIONS

There is a need for better understanding of the disease processes affecting the heart and vasculature, particularly for (a) their early prevention; (b) improved accuracy for diagnosis and therapeutic planning; and (c) cost-effective, minimal risk, and reproducible monitoring. An improved understanding of three basic and extremely important aspects of CV disease appears to be feasible in the near future because of unique attributes of MRI; these aspects include (a) myocardial characterization; (b) load-independent measures of myocardial function; and (c) noninvasive arterial wall imaging. Anticipated insights from application of MRI to these three aspects should greatly enhance our understanding of the various forms of CV disease, from the standpoint of natural course, manifestations (histologic, anatomic, and physiologic), modes of prevention, and yields from various therapies.

The most common disease process affecting the myocardium is ischemic injury, representing a spectrum with induced reversible ischemia at one end and frank MI at the other. The characterization of intermediate stages of ischemic injury (e.g., “stunning,” resting ischemia, or “hibernation”) has remained a topic of great interest because of the importance in therapeutic planning, and because of the inability of other imaging modalities to completely or reliably meet this challenge. MRI permits direct high-resolution, 3-D visualization of the myocardium and can potentially characterize the myocardium based on assessments of tissue composition, geometry, perfusion, contraction, and relaxation and filling. An important advance in cardiac MRI is the delineation of necrotic myocardium with the delayed-enhancement technique, being the only cardiac imaging modality that is able to directly visualize the amount of necrosis transmurally.

Unfortunately, the commonly used measures of myocardial function are flawed. Consequently, more meaningful measures of myocardial contraction and relaxation and filling, independent of interpatient and intrapatient variability in loading, are needed for a better understanding of the outcome and the effects of different therapies, overall and per patient.

In many patients dying suddenly of CAD, there are no previous signs, such as angina caused by flow-limiting coronary narrowing. Thus, there is a compelling need to appreciate, directly (in the coronary artery itself) or indirectly (in another more easily imaged but representative artery), the presence of unstable nonstenotic atherosclerosis potentially affecting the coronary arteries.

It is reasonable to assume that further development of MRI as a noninvasive diagnostic imaging modality for comprehensive evaluation of CV diseases, especially ischemic heart disease, will be a future pursuit. Packaging of the various capabilities of CV MRI into comprehensive studies establishing unique imaging profiles, such as an atherosclerosis profile, a myocardial ischemia profile, or a post-MI reperfusion profile, seems feasible. For example, a post-MI reperfusion profile might be based on the assessment of myocardial signal indicating postreperfusion edema or hemorrhage; the assessment of myocardial mechanics, with or without low-level pharmacologic stress, to differentiate between residual endocardial and epicardial contraction; or the assessment of flow within an MI-related artery or of distal myocardial perfusion within its distribution to determine adequacy of an acute intervention. Such profiles could appropriately direct patients toward or away from invasive, costly procedures.

CONTROVERSIES AND PERSONAL PERSPECTIVES

In several large institutions, such as ours, MRI has been actively applied to the routine clinical evaluation of a variety of CV diseases over a number of years. In some clinical settings, MRI has gained great acceptance and is now regarded as the diagnostic imaging procedure of choice, whereas in other settings, the yield has been disappointing and MRI is regarded as, at most, an infrequently used adjunct to other modalities, such as echo. Based on our experience, which includes over 1,700 clinical CV MRI examinations per year, a practical weighting of the relative value of MRI, compared with state-of-the-art echo and ECG-referenced multidetector CT, is presented in Table 54.1; in this weighting, relative study cost, portability, and clinical stability of the patient are considered.

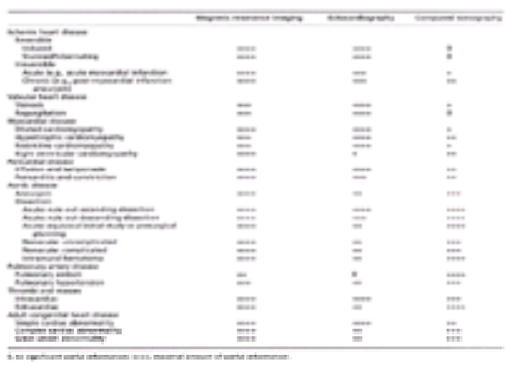


TABLE 54.1 PRACTICAL VALUE OF CARDIOVASCULAR MAGNETIC RESONANCE IMAGING RELATIVE TO OTHER AVAILABLE NONINVASIVE DIAGNOSTIC IMAGING MODALITIES BY DISEASE GROUP

Probably more than any other modality currently available, MRI has the potential to contribute to the improved understanding of CV diseases based on diagnostic imaging; this potential is now rapidly gaining increased attention by the medical community and manufacturers of medical imaging equipment. For this potential to be realized, however, several types of obstacles must be overcome.

Not the least of these obstacles is the current medical environment with its increasing emphasis on cost containment and capitated reimbursement; in this environment, expensive technology, in particular MRI, has already been targeted. Included in this environment are (a) pressures on ordering physicians to avoid use of CV MRI, even when it is thought to be the best first-line diagnostic imaging study and possibly the only one needed, because the charge per examination is relatively greater

(e.g., approximately $200 more than transesophageal echo and $600 more than CT at our institution); (b) increasing demands on physicians involved in CV MRI to pursue clinical productivity in more basic diagnostic imaging areas, where reimbursement may be better established; (c) greater and greater limitations on research time and institutional support for needed clinical investigation in CV MRI; and (d) decreasing availability of MRI equipment for CV imaging because of reduced numbers of scanners or increasing limitations on scheduled scan time for greater patient throughput.

Another obstacle has been largely created by the MRI community itself. It is the problem related to lack of a history of meaningful large clinical studies dealing with outcome and efficacy. Since the advent of clinical MRI, research has rewarded the development of cutting-edge technology in which only alterations in acquisition and postprocessing schemes along with the speculation, but no proof, of improved clinical care have been sufficient to gain recognition in the form of grant funding, support from manufacturers, and relatively unchallenged acceptance of written reports for publication in peer-reviewed journals. In an area with such seemingly endless technologic potential as MRI, this tendency has created a rewarding path of least resistance in clinical investigation with a heavy emphasis on uniqueness and individualism. An unfortunate outcome that now hinders the future of CV MRI has been the passive discouragement of large multicenter patient studies addressing the clinical value of information about CV diseases provided by the more widely available, nonproprietary, and validated MRI techniques; the common argument against past efforts to develop such outcomes and efficacy studies is the anticipation of technologic obsolescence by the time of their completion. Consequently, there is currently little ammunition to fight off cost-containment efforts directed against CV MRI.

Finally, another obstacle that must be overcome is the issue of “ownership,” whether it be that dealing with control of patients or of equipment. MRI is an expensive technology, with scanner costs alone exceeding those of echo and CT by approximately tenfold and twofold, respectively. Siting costs in MRI, which in some circumstances match equipment costs, greatly add to the relatively greater expense of MRI compared with other imaging modalities, especially echo with its negligible siting needs. Although the manufacturers of medical imaging equipment are now demonstrating the ability to reduce the costs of purchasing and installing MRI systems, there appears to be a limit to which the costs can be reduced before the research and development of MRI is no longer regarded as being economically viable. In addition, as long as MRI continues to evolve, the regular allocation of significant funds for hardware and software upgrades, along with the significant routine maintenance costs, will have to be factored annually into institutional budgets. Therefore, a state-of-the-art MRI will probably need to be viewed increasingly, from an economic standpoint, as a technology that is most appropriate for larger medical facilities.

In the case of CV MRI, its potential will be best realized at major CV centers, if it is regarded as an institutional effort, and the leadership responsibility is shared among the following groups: (a) radiology, (b) adult and pediatric cardiology, and (c) cardiothoracic and vascular surgery. To this common effort, radiology departments can contribute expertise in the application of general imaging and MRI principles and in the interpretation and use of the resulting data; experience with quality assurance of an MRI facility; oversight of the performance of routine CV imaging and non-CV issues that arise; and direction in the implementation of new acquisition and postprocessing schemes originating from the general imaging and MRI communities. Adult and pediatric cardiology departments can contribute to the identification of new medical applications of MRI to the evaluation of acquired and congenital CV diseases; leadership in overseeing the monitoring and the manipulations (e.g., stress testing) of patients during physiologic CV MRI examinations; expertise in the interpretation and use of physiologic data from MRI and its correlation with other findings, such as from echo; and experience in conducting meaningful large clinical research studies of CV diseases using MRI. Finally, cardiothoracic and vascular surgery, the clinical groups probably profiting the most to date from CV MRI, can contribute to the identification of new applications of MRI to the presurgical and postsurgical evaluation of CV diseases; expertise in the interpretation and use of morphologic data from MRI; and leadership in exploring the possibility of less invasive surgical therapies, incorporating indirect anatomic visualization by MRI rather than direct surgical visualization. This type of cooperative effort should allow MRI to develop further as a valuable clinical tool for the evaluation of CV diseases.

THE FUTURE

With diseases of the CV system cumulatively representing the number one killer in the United States, there is a need for better understanding of the fundamental histologic, anatomic, and physiologic manifestations of disease processes affecting the heart and vasculature. Technical advances, applicable to the assessment of the CV system, may facilitate MRI’s gaining a more significant role in evaluating these areas. Because MRI permits direct high-resolution, 3-D visualization of the myocardium, it can potentially characterize the myocardium based on assessments of tissue composition, geometry, perfusion, contraction, and relaxation and filling.

It is difficult to determine which, if any, of the expensive technologic advancements currently under investigation in MRI might have a future role in CV imaging. Current research and development with high-field spectroscopic MRI (333), interventional MRI (334), metabolic MRI contrast agents (335), and high-resolution vessel-wall characterization (289) may eventually find clinical applications to future work in CV MRI.

OVERVIEW

Positron emission tomography (PET) represents the most advanced scintigraphic imaging technique developed for *in vivo* quantification of cardiac physiology and biochemistry. The state-of-the-art PET instrumentation allows delineation of regional tracer activity with high spatial (4 to 8 mm) and temporal resolution (few seconds per image). A large number of radiopharmaceuticals have been developed to study myocardial perfusion, energy metabolism, and autonomic innervation of the heart. Initial research applications included assessment of fatty acid and glucose metabolism, followed by the quantification of regional myocardial perfusion in patients with coronary artery disease (CAD). More recently, newer tracers such as radiolabeled beta-receptor antagonists allow the presynaptic and postsynaptic evaluation of sympathetic cardiac innervation. Metabolic imaging with fluorine-18-fluorodeoxyglucose (F-18-FDG) has emerged as an important clinical application for assessment of tissue viability in patients with impaired left ventricular function with well-validated diagnostic and prognostic information. F-18-FDG has also been used in combination with single-photon emission computed tomography (SPECT) imaging to exploit the physiologic information, without the need for expensive imaging technology such as PET. PET, in combination with perfusion tracers, provides accurate diagnosis and localization of CAD. The development of less costly PET imaging devices and new radiopharmaceuticals for specific tissue characterization is needed to ensure that PET remains a competitive research and clinical tool in cardiology.

GLOSSARY

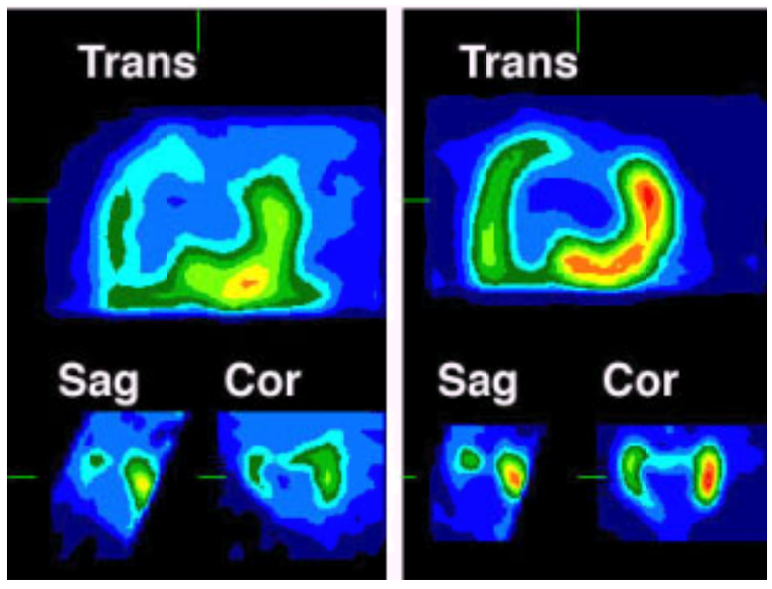
Polar map: Planar representation of tracer accumulation in the left ventricular myocardium, determined by volumetric sampling of the scintigraphic data.

Tracer: Very small amount of substance, labeled with a radioactive isotope, and the decay can be detected externally.

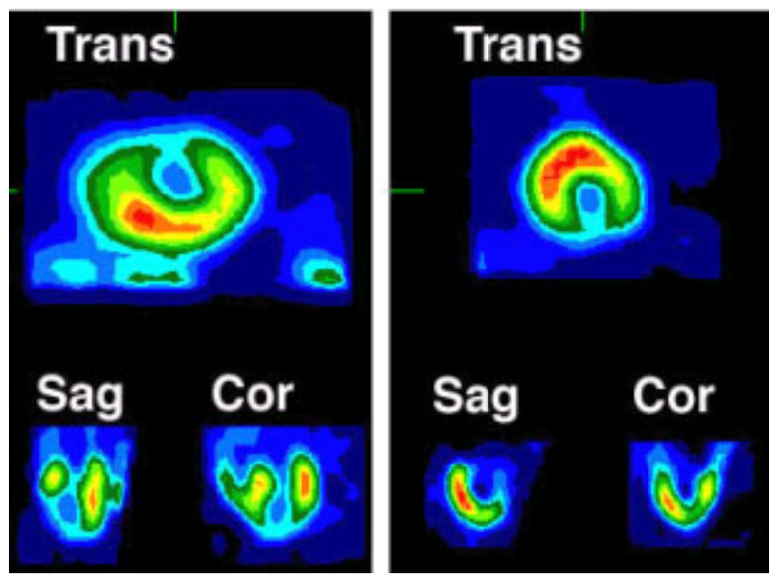
Transmission scan: Measurement of photon attenuation using external sources. Data are used for correction of emission data.

HISTORICAL PERSPECTIVE

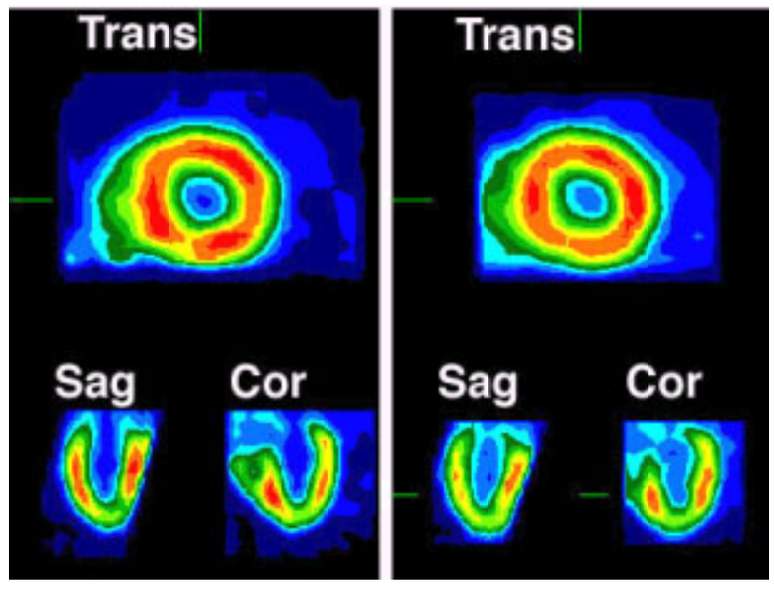
PET was developed as a noninvasive method for quantitative imaging of tissue tracer distribution *in vivo* (autoradiography). Three important technical requirements contribute to this method: the labeling of a biologic substance with short-lived positron emitters, the detection of the annihilation radiation, and the reconstruction of the two-dimensional tracer distribution in transversal slices through the body. Radiopharmacy, instrumentation, and data processing have evolved since the discovery of artificial radioactivity by I. Curie and F. Joliot in 1934. Radioactive isotopes such as carbon-11 (C-11), nitrogen-13 (N-13), or F-18 became available in the late 1930s and early 1940s after the development of the cyclotron by E. O. Lawrence and were used in biologic (1) and the first human studies (2). The advantage of using coincidence measurements for collimation became apparent and was implemented for the first time in a positron probe by Brownell (3) and in a positron scanner for brain studies by Aronow (4). Short-lived radionuclides proved useful for metabolic studies and the first cyclotron that was dedicated to medical application was installed at the Hammersmith Hospital in 1955. With the tomographic imaging of single photon emitters, Kuhl introduced transverse section scanning using a backprojection algorithm (1963) (5). These advances in reconstruction also promoted the development of tomographs for positron imaging in the early 1970s, when the research group of Hoffmann, Phelps, and Ter Pogossian at Washington University built the first positron emission tomograph for brain imaging (6).



Matched resting rubidium (*left*) and radiolabeled fluoro-deoxyglucose (*right*) positron emission tomographic images. Transverse, sagittal, and coronal positron emission tomographic images demonstrating extensive scar in the left anterior descending and right coronary artery territories with evidence of myocardial hibernation in the left circumflex artery territory and right artery territory (including the right ventricle).



Matched resting rubidium (*left set*) and radiolabeled fluoro-deoxyglucose positron emission tomographic (*right set*) images. Transverse, sagittal, and coronal positron emission tomographic images demonstrating myocardial hibernation in the left anterior descending artery territory.



No fixed or transient changes in between stress (*left*) and resting (*right*) rubidium-82 positron emission tomographic images on transverse, sagittal, and coronal slices, demonstrating a dilated left ventricular cavity and a lack of myocardial scar or ischemia in a patient with nonischemic dilated cardiomyopathy.

PET was introduced in the 1970s as a new imaging modality in cardiology by investigators at Washington University in St. Louis (7). Initial studies used metabolic tracers such as F-18-FDG and C-11 palmitate for the noninvasive characterization of myocardial substrate metabolism. These investigations took advantage of the availability of biologically active tracers labeled with short-lived isotopes such as C-11 and F-18 and demonstrated the ability of PET to describe the interaction of various substrates for cardiac energy metabolism. With the introduction of flow markers such as N-13 ammonia and oxygen-15 (O-15) water, the application of PET shifted toward the evaluation of myocardial perfusion primarily in patients with CAD. Since then, the technical advances of PET have allowed sophisticated biochemical and physiologic investigations of the heart, using a large number of radiopharmaceuticals to examine not only flow and metabolism, but also the autonomic innervation of the heart. The method provides quantitative measurements of spatial as well as temporal distribution of radioactivity within the blood and myocardium. Although other imaging modalities provide similar information, PET should be considered the most validated and accurate tool to measure myocardial perfusion and to allow quantitative tissue characterization assessing various aspects of cardiac function.

This chapter reviews the current role of PET in the functional evaluation of CAD and other cardiovascular disorders. Established clinical applications, as well as experimental concepts, are discussed. Finally, the results obtained with PET are compared with those derived from SPECT and other imaging modalities to define the clinical role of PET in cardiology.

IMAGING PRINCIPLES

Imaging of regional tracer concentration is accomplished by the unique properties of positron decay and annihilation. Positron-emitting radionuclides have a nuclear imbalance characterized by an excess of protons. To restore stability to the nuclear structure, a proton is converted to a neutron, and a positron is emitted. This energetic positron traverses a few millimeters through the tissue until it becomes thermalized by electrostatic interaction between the electrons and the atomic nuclei of the media and combines with a free electron to form a two-particle atom-like entity called a *positronium*. The positronium quickly decays by annihilation, which converts the positron and electron mass into energy and generates a pair of gamma rays. Conservation of energy and momentum of the positronium before annihilation require the photons to travel in nearly opposite directions (180 degrees apart) with an energy of 511 keV each (Fig. 55.1). The opposed photons from positron decay can be detected by using pairs of colinearly aligned detectors. Gamma rays interact with these aligned detectors within a predefined time window and are registered as radioactive events (coincidence counting). The detector pairs of a PET system are installed in a ring-like pattern, which allows measurement of radioactivity along lines through the organ of interest at a series of angles and radial distances. This angular information is used to reconstruct tomographic images of regional radioactivity distribution. State-of-the-art PETs consist of multiple, closely packed rings of detectors that enable simultaneous imaging of several image planes.

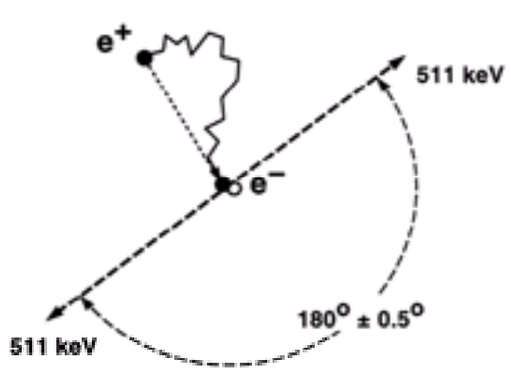


FIGURE 55.1 Positron emission and decay. The energetic positron (e^+) travels several millimeters in the tissue before it combines with an electron (e^-). The positron and electron annihilate, resulting in two opposing gamma rays with 511 keV each. See text for details.

Because the left ventricular wall is approximately 10 mm thick, high spatial resolution is necessary for the quantitative analysis of tissue tracer concentration (Fig. 55.2). The spatial resolution of PET approaches 5 to 7 mm in all axes and is expected to improve to approximately 2 to 3 mm in the future. Myocardial movement and change in wall thickness during the cardiac cycle affect the image resolution. PET data quality can be improved by ECG gated acquisitions (8).

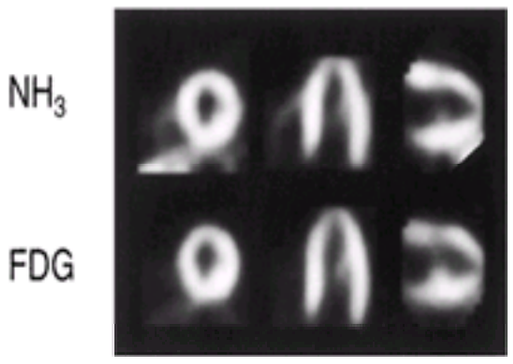

FIGURE 55.2 Positron emission tomographic images of normal volunteer with nitrogen-13 ammonia (NH_3) and fluorine-18-fluorodeoxyglucose (FDG).

Correction of photon attenuation is a prerequisite for tracer distribution measurements in the heart to avoid artifacts caused by tissue surrounding the heart. External sources are used to perform a transmission scan, which allows estimates of regional attenuation factors. Ring or rotating pin sources made of positron emitters are used for this purpose (9,10).

The PET detector system has to perform linearly over a wide range of count rates and allow for short scan time intervals to monitor the rapid uptake and release of tracers. Most of the current commercial tomographs use block detectors made of scintillation crystals (bismuth germanate) and photomultipliers (11). New detector materials such as lutetium oxyorthosilicate and lutetium aluminum perovskite may improve imaging performance at a reasonable cost. Lutetium oxyorthosilicate has a shorter scintillation light-decay time, higher light output, and approximately the same attenuation length compared with bismuth germanate (12).

Collimators have been designed for imaging 511-keV gamma rays from positron emitters with SPECT systems. Although spatial resolution (15 to 20 mm) and detection efficiency (eight times less) are lower in these systems compared with PET, good imaging quality can be achieved for cardiac studies. The concept of dual-head SPECT cameras without collimators in coincidence mode was introduced. By exploiting the electronic collimation inherent in coincidence detection, sensitivity is increased. Using conventional nuclear medicine instrumentation could facilitate the widespread use of imaging positron emitters (13,14).

PRINCIPLES OF RADIONUCLIDE PRODUCTION AND RADIOCHEMISTRY

C-11, N-13, O-15, and F-18 are the most common positron-emitting radionuclides, all of which have a short physical half-life ranging from 122 seconds for O-15 to 110 minutes for F-18 (Table 55.1).

Radionuclide	Physical half-life	Radiopharmaceutical	Application
Rubidium-82	76 sec	Rubidium	Flow
Oxygen-15	120 sec	Water	Flow
Nitrogen-13	10 min	Ammonia	Flow
Carbon-11	20 min	Palmitate	Fatty acid metabolism
		Acetate	Oxygen consumption
		Hydroxyephedrine	Catecholamine uptake
		CGP-12177	Beta-receptor density
Fluorine-18	110 min	Deoxyglucose	Glucose metabolism
		Misonidazole	Hypoxia
		FTHA	Fatty acid metabolism

FTHA, 14(R,S)-[18F]-fluoro-6-thiaheptadecanoic acid.

TABLE 55.1 TRACERS COMMONLY AVAILABLE FOR CARDIAC POSITRON EMISSION TOMOGRAPHIC APPLICATIONS

These radionuclides do not occur naturally; they must be produced using a nuclear reaction. The predominant and most efficient production method is to modify the nuclear structure of specific stable radionuclides by accelerated particle bombardment with either protons or deuterons. A cyclotron is a particle accelerator used most often for radioisotope production in PET imaging (15,16).

Few positron-emitting radionuclides are generator produced. A generator consists of a parent–daughter radionuclide pair in an apparatus that permits a separation and extraction of the daughter compound from the parent. The daughter radionuclide is replenished continuously by decay of the parent. The most common generator system in cardiology is strontium-82/rubidium-82 (17). The preparation of radiopharmaceuticals for PET requires a dedicated radiopharmaceutical facility. Because of the short half-lives of the isotopes, novel adaptations of sometimes complex synthetic procedures are needed to prepare useful amounts of molecules. Because there are positron-emitting radionuclides of oxygen, carbon, and nitrogen, it is theoretically possible to label any organic compound of interest, whether it is a natural substance or a synthetic drug. Fluorine, although not often found in naturally occurring molecules, can be readily substituted for a hydrogen or hydroxyl group and is a favorite of radiochemists designing new pharmaceuticals. With these four radionuclides a large number of positron-emitting tracers can be synthesized and used in clinical studies.

TRACER KINETIC MODELING

Current PET instrumentation allows for the acquisition of scintigraphic data, with high temporal resolution necessary for the description of tracer kinetics in myocardial and vascular structures. In contrast to other organs, the large blood chambers of the right and left ventricle allow simultaneous measurements of radioactivity in blood and tissue. Several studies have validated the accuracy of this approach for the noninvasive determination of the arterial input function without the need for arterial blood sampling (18).

Combining temporal sequencing of activity changes in blood and myocardium, tracer tissue uptake rates as well as clearance of activity from tissue can be quantitated (19). Depending on the radiopharmaceutical used, tracer kinetic models can be used to derive estimates of myocardial blood flow, metabolic rate, and tissue tracer retention. The most commonly used kinetic models are two- or three-compartment models. Although physiologic processes are more complicated than can be described by such simple models, limitations in counting statistics and duration of data acquisition require a simplification of the physiologic process with such models. Please refer to references 19 and 20, both excellent reviews that discuss details of tracer kinetic modeling.

ASSESSMENT OF MYOCARDIAL BLOOD FLOW

Flow Tracer

Blood flow tracers can be classified based on their physiologic behavior. O-15 water, for example, represents a freely diffusable tracer that washes in and out of myocardial tissue as a function of blood flow. The first-pass extraction of O-15 water in the heart is not diffusion limited, nor is O-15 water tissue extraction affected by any metabolic pathways (21,22 and 23) (Fig. 55.3).

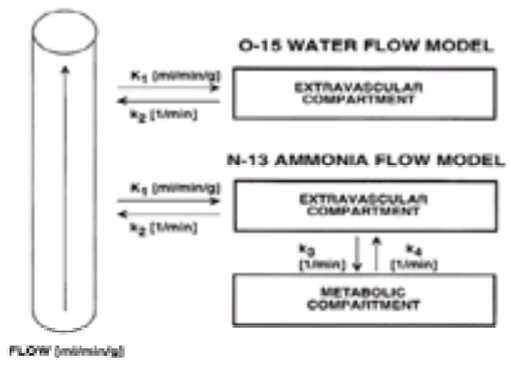

FIGURE 55.3 Schematic diagram illustrating the compartment models for oxygen-15 water (*top*) and nitrogen-13 ammonia (*bottom*).

The second group of flow markers are radiotracers, which are retained in myocardial tissue proportional to myocardial blood flow. For these radiopharmaceuticals, the initial tracer extraction (first-pass extraction) and their tissue retention are important factors defining their suitability as blood flow tracers. N-13 ammonia is highly extracted by myocardial tissue in the form of N-13 ammonia (24,25 and 26). Within the tissue, the tracer can either back diffuse into the vascular space or be trapped in the form of N-13 glutamine.

Ionic tracers such as rubidium-82, rubidium-81, or potassium-38 display similar tracer kinetics to thallium-201 (27). Initial extraction of these compounds ranges between 50% and 70%. For both N-13 ammonia retention and ionic tracer extraction, a nonlinear relationship exists between blood flow and tissue tracer extraction (27,28).

Clinical Application

Qualitative Assessment of Regional Myocardial Blood Flow

Initial applications of PET for the detection of CAD consisted of the visual assessment of regional myocardial tracer distribution under rest and stress conditions (29,30,31,32 and 33). In most studies, pharmacologic stress testing has been used to assess coronary reserve (29). The advantage of this approach is the standardized stress procedure, which can be performed in the PET gantry without moving the patient between rest and stress imaging (34).

The most commonly used tracers are rubidium-82 and N-13 ammonia (24,32). With rubidium-82, the rest/stress protocol can be completed in approximately 1 hour, whereas N-13 ammonia blood flow studies require approximately 2 hours. Extensive clinical data exist with both radiopharmaceuticals to document the high diagnostic accuracy with sensitivity and specificity values ranging from 85% to 95%. Demer et al. demonstrated that there is little difference between the use of either tracer for the detection of CAD (33). Most studies used visual data analysis similar to the methods used routinely for thallium-201 or technetium-99m sestamibi SPECT imaging (25,30,35,36). Automated techniques for semiquantitative data analysis, similar to those used for SPECT imaging, have also been developed for PET flow studies (37,38) (Fig. 55.4).

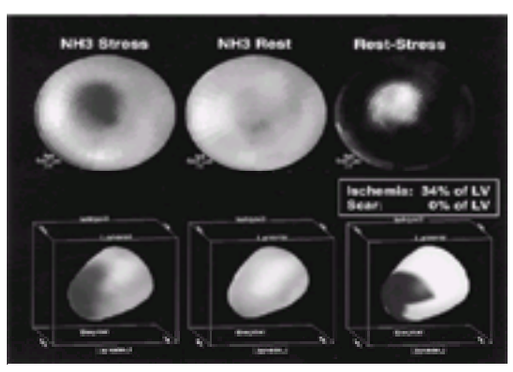

FIGURE 55.4 Polar maps (*top*) and three-dimensional visualization (*bottom*) of nitrogen-13 ammonia (NH_3) uptake in a patient with a stress-induced defect. Results provide semiquantitative assessment of ischemic and scar tissue. LV, left ventricle.

Although PET investigations are more expensive than conventional SPECT imaging or stress echocardiography, data by Patterson et al. (39) indicate that the use of PET in the diagnostic workup of patients with suspected CAD may be cost-effective, especially when patients with low and intermediate pretest likelihood for CAD are evaluated.

Demer et al. demonstrated that the severity of perfusion abnormalities determined by PET imaging correlated with the angiographically predicted coronary reserve measurements for a given vascular territory (33). More recently, Gould et al. reported a significant gradient in regional perfusion from base to apex in patients with mild but diffuse arteriographic disease, suggesting greater downstream flow abnormalities in the absence of regional limiting stenoses (40).

In addition to the diagnosis of CAD, the follow-up of patients with CAD by noninvasive means is of clinical interest (41). Longitudinal studies evaluating the effect of therapeutic or lifestyle interventions provide objective outcome criteria and are especially important in patients considered at high risk for progression of disease severity. Gould et al. have used PET and angiography to follow 20 patients undergoing cholesterol-lowering diets over 5 years. The semiquantitative PET parameters describing severity and extent of stress-induced perfusion abnormalities indicated much more profound changes following therapy as compared with angiographic criteria (Fig. 55.5). The relative magnitude of changes in size and severity of PET perfusion abnormalities was comparable with or greater than the magnitude of changes in percent diameter stenosis, absolute stenosis lumen area, or stenosis flow reserve documented by quantitative coronary arteriography (42).

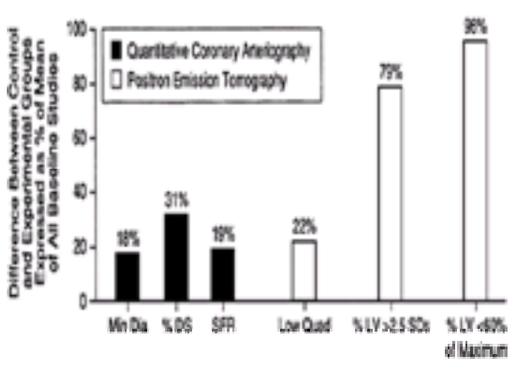

FIGURE 55.5 Comparison of changes by positron emission tomography and quantitative coronary arteriography. The positron emission tomography measures were myocardial quadrant with the lowest average activity (Low Quad), percentage of left ventricle (LV) outside 2.5 standard deviations of normals, and percentage of LV activity less than 60% of maximal activity. Measurements by quantitative coronary arteriography were minimum absolute lumen diameter (Min Dia), percent diameter stenosis (% DS), and stenosis flow reserve (SFR) derived from the integrated effects of absolute lumen diameter, % DS, and cumulative length effects based on fluid dynamic equations. The absolute difference in changes between the control and experimental groups was expressed as a percentage of the mean of each measurement at baseline for all patients. (From Gould KL, Ornish D, Scherwitz L, et al. Changes in myocardial perfusion abnormalities by positron emission tomography after long-term, intense risk factor modification. *JAMA* 1995;274:894–901, with permission.)

Quantitative Assessment of Myocardial Blood Flow

The potential of PET for the quantitative assessment of myocardial blood flow represents a major advantage over SPECT imaging. Such measurements provide flow estimates in milliliters per minute per 100 g of tissue, which can be used to assess myocardial microcirculation under resting and stress conditions as well as before and after pharmacologic interventions. For such flow measurements, dynamic data acquisition is necessary to describe arterial input function as well as tissue response.

Oxygen-15 Water

O-15 water can be administered either as bolus injection or O-15–labeled CO_2 inhalation (22,23,43,44). Radiolabeled CO_2 is rapidly converted to water in lung tissue and transported to the heart as O-15 water. Both approaches use the uptake as well as washout of radioactivity from the myocardium, assuming a constant partition coefficient (0.80 to 0.90) of water between vascular and tissue space (Fig. 55.3). The water method also assumes homogeneous tissue within the region of interest used for quantitation of myocardial blood flow. To delineate myocardial tissue boundaries, the blood pool contribution has to be removed from O-15 water studies. For this purpose, a separate inhalation of O-15–labeled CO is commonly used (23). More recently, spectral analysis of dynamic O-15 water has been shown to allow for delineation of myocardial structures. The tracer kinetic model approach for O-15 water flow measurement includes a term correcting for the geometric distortion caused by limited image resolution provided by PET (partial volume effect, activity cross-contamination) (21,23,45). The use of O-15 water (as a blood flow marker) has been validated in various animal models and has demonstrated close agreement with microsphere flow measurements (45,46 and 47). Correction of flow values with the perfused tissue fraction leads to a determination of an index describing the relative amount of perfused tissue within a myocardial segment (48). In addition, methods have been developed to quantify not only flow, but also oxygen metabolism using O-15 water (49).

Nitrogen-13 Ammonia

Several approaches have been introduced to describe the myocardial kinetics of N-13 ammonia using a compartmental model that relates the N-13 activity in the vascular, free intracellular, and metabolic space (50,51 and 52) (Fig. 55.3). Assuming the first transit extraction (EF) of N-13 ammonia is approximately 100%, the model estimate (K_1) serves as a quantitative index of perfusion (F) ($F = K_1 \times EF$) (24). These methods have been validated in the animal laboratory comparing N-13 ammonia perfusion measurements with microsphere measurements as a gold standard, or with O-15 reference PET measurements (46,52,53).

Other Tracers (Rubidium-82, Copper-62 PTSM, Potassium-38)

Rubidium-82 has been proposed for quantitative flow measurements (54,55). Data in the animal model and preliminary clinical results demonstrate the feasibility of using this radiopharmaceutical for quantitative flow measurements. Copper-62 PTSM [pyruvaldehyde bis(N4-methyl)thiosemicarbazone] has also been used for the assessment of myocardial blood flow (56). Quantitative flow estimates are limited because of the rapid sequestration of activity in red blood cells, which alters the arterial input function and the availability of tracer to tissue.

Clinical Application

The quantitation of regional coronary flow reserve has been advocated by Gould et al. for the functional assessment of the severity of coronary artery stenosis in patients with CAD (57). The parameter flow reserve describes not only the functional significance of a given coronary lesion but also vascular reactivity and collateral blood flow in the poststenotic vascular territories. Such functional measurements complement the anatomic description of CAD and link the morphologic alterations of epicardial arteries with perfusion patterns assessed at the level of microcirculation. Limitations of angiographic characterization of CAD are widely appreciated because of the complex three-dimensional nature of atherosclerotic plaques as well as considerable interobserver variability in angiographic data interpretation (41,57,58 and 59).

PET approaches have been extensively validated in animals and in healthy volunteers. There is good reproducibility of blood flow measurements under resting as well as stress conditions in volunteers and patients with CAD, as shown by the consistent measurements of coronary reserve values (60,61). Coronary flow reserve over 2.5 times resting flow must be considered *normal* based on the standard deviation of measurements in individuals at low likelihood of CAD (62,63).

A relationship between coronary reserve measurements and age in subjects without CAD has been demonstrated (64,65). However, there are other factors, such as left ventricular hypertrophy, hypertension, and syndrome X, which may affect coronary reserve measurements in the absence of vascular abnormalities defined by angiography (66). Animal and clinical data have indicated that arterial hypertension leads to reduced coronary flow reserve. It also has been shown, using PET, that therapy of patients with arterial hypertension may improve regional coronary reserve measurements (67).

Relationship Between Positron Emission Tomography Flow Measurements and Angiographic Assessment of Coronary Artery Disease

In patients with CAD, coronary flow reserve measurements are reduced (62,68,69,70 and 71). A correlation between the severity of coronary artery disease and severity of flow reserve impairment has been documented (62,70,71 and 72) (Fig. 55.6).

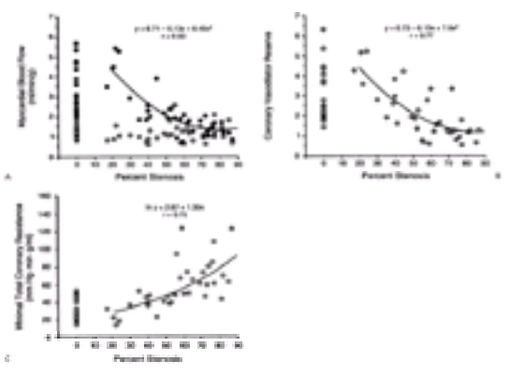

FIGURE 55.6 Myocardial blood flow **(A)**, coronary flow reserve **(B)**, and coronary resistance **(C)** in relation to stenosis expressed as percent of vessel diameter. (From Uren NG, Melin JA, De-Bruyne B, et al. Relation between myocardial blood flow and the severity of coronary-artery stenosis. *N Engl J Med* 1994;330:1782–1788, with permission.)

Detection of Preclinical Coronary Artery Disease by Flow Measurements

Comparing the incidence of abnormal coronary flow reserve with the severity of stenosis, as defined by quantitative angiography, reveals a high sensitivity of coronary flow reserve measurements for the detection of severe coronary artery stenosis (greater than 95%). The high incidence (approximately 30%) of abnormal coronary flow reserve in territories with only mild CAD is surprising as defined by angiography (63). These data have been confirmed by several laboratories, indicating that coronary flow reserve with pharmacologic stress agents may provide more sensitive means to detect early CAD than angiographic criteria alone (62,73). This hypothesis has been addressed by several investigators (74,75,76 and 77), who have demonstrated that coronary flow reserve was abnormal in asymptomatic male patients without clinical evidence of myocardial ischemia, but at high risk for the development of CAD based on risk factor profile. A significant relationship between the impairment of coronary flow reserve and plasma cholesterol, low-density lipoprotein, high-density lipoprotein, and oxidized low-density lipoprotein has been reported. Coronary flow reserve has been shown to be reduced in young men with familial hyperlipidemia, especially with combined abnormalities in cholesterol and triglyceride serum levels (phenotype IIB) (78). Furthermore, reduction of flow reserve has been observed in asymptomatic patients with insulin-dependent and non–insulin-dependent diabetes mellitus (74). The pathophysiologic mechanism of the reduced coronary flow reserve in territories with no or only mild angiographic evidence of stenoses is not yet known but may represent a complex interplay of vascular alterations, as well as endothelial dysfunction (79). The hemodynamic response to dipyridamole or adenosine can be modified by alpha- or beta-receptor blockade enhancing the range of coronary flow measurements (80,81). First results using cold pressor stress testing in combination with PET confirm the results obtained in the catheterization laboratory using intracoronary acetylcholine infusion (82,83). In addition, mental stress has

been used to investigate coronary vascular reactivity in normal and CAD patients, which demonstrated reduced flow response in this patient group (84).

PET measurements have been used to assess the acute and chronic effect of smoking on dipyridamole-induced flow changes. Smoking during the PET study decreased the dipyridamole-induced hyperemia and coronary reserve (77). The effects of smoking on coronary vascular reactivity can be reversed by intravenous L-arginine (82) or administration of the antioxidant vitamin C (77).

Cardiovascular conditioning is thought to favorably alter the natural history of CAD. Czernin et al. (85) investigated patients undergoing a short-term exercise and diet program. The beneficial effect of this program on heart rate, blood pressure, and cholesterol was associated with a significant increase in flow reserve. Pharmacologic therapy with lipid-lowering drugs (simvastatin, fluvastatin) is associated with improvement of coronary flow reserve (86,87 and 88). Guethlin et al. reported a delayed response when flow measurements at 2 months were compared with those obtained at 6 months after initiation of lipid-lowering therapy. These data suggest that other factors than only lipid serum levels may be responsible for the beneficial effects of statins on vascular reactivity.

Quantitative regional flow measurements may be useful in preclinical CAD, identifying abnormal vascular reactivity as an early marker of the atherosclerotic process with diagnostic and prognostic value (76,89). In advanced disease PET provides a means to monitor pharmacologic interventions as well as to assess the effect of regional revascularization by percutaneous coronary intervention and surgery (90,91,92,93,94,95,96,97 and 98).

Other Cardiovascular Diseases

Quantitative flow measurements with PET have been used in patients with cardiac transplantation to study coronary physiology in this patient population. Several studies have indicated that coronary reserve is maintained in the cardiac transplant patient (69,99). Wolpers et al. (100) also demonstrated a relationship between angiographic evidence of vasculopathy and PET flow reserve. In contrast to angiography, flow reserve values were homogeneously reduced, suggesting a diffuse obstruction of the microvascular bed in patients with posttransplant vasculopathy. Quantitative PET flow measurements were also performed in patients with cardiomyopathy (101). Patients with hypertrophic cardiomyopathy display a reduced coronary reserve, which not only affects the hypertrophied interventricular septum but also the free lateral wall (68). These findings indicate that the pathophysiologic process involving the myocardium of patients with hypertrophic cardiomyopathy may not be limited to the hypertrophied interventricular septum (68). In patients with dilated cardiomyopathy, there appears to be a reduction in coronary flow reserve, which may provide prognostic information (102,103). Studies by Merlet et al. (104) indicate that PET blood flow measurements are in close agreement with invasive assessment of flow velocity by Doppler methods in this patient population. Furthermore, data by Parodi et al. (105) show that the flow response to pacing and dipyridamole is altered in patients with dilated cardiomyopathy, suggesting endothelial dysfunction. This hypothesis is supported by data reporting decreased flow response to cold pressor testing in this patient population (106).

ASSESSMENT OF SUBSTRATE METABOLISM

Several PET radiopharmaceuticals have been developed to investigate the myocardial energy metabolism that depends on the oxidation of various substrates (Table 55.1). Under fasting conditions, the majority of cardiac adenosine triphosphate production relies on the oxidation of free fatty acids (107,108). Free fatty acids are avidly extracted by the myocardium where long-chain acyl-coenzyme A (CoA) is rapidly formed. Activated fatty acids are used in the synthesis of triglycerides or phospholipids. The majority of acyl-CoA, however, is transported via the carnitine shuttle into the mitochondria where beta-oxidation takes place (Fig. 55.7). The end product of beta-oxidation is acetyl-CoA, which enters the tricarboxylic acid cycle, the final pathway of oxidative metabolism of all substrates. In the presence of high free fatty acid and low insulin plasma levels, only a small amount of glucose is extracted by the myocardium. However, in the postprandial state, glucose transport into the cell is enhanced and the glycolytic rate is increased. But even after carbohydrate loading, only approximately 30% to 50% of overall cardiac substrate metabolism depends on oxidative metabolism of glucose (109). During physical exercise, plasma lactate levels increase and contribute to myocardial energy metabolism (110).

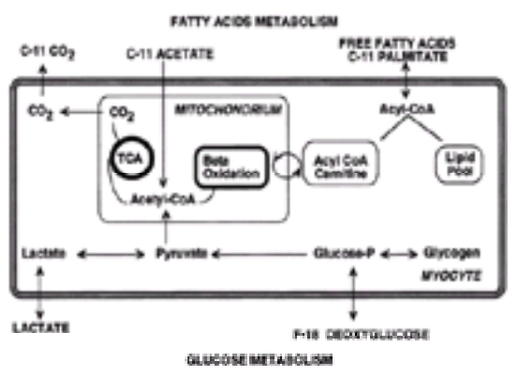

FIGURE 55.7 Conceptual model illustrating metabolic fate of various substrates in the myocardium. Acyl-CoA, acyl-coenzyme A; TCA, tricarboxylic acid cycle.

Aside from the physiologic increase of glycolysis in the postprandial state, glycolysis plays an important role during and after myocardial ischemia. Experimental studies have shown that myocardial glucose transport and metabolism are upregulated during myocardial ischemia with production and release of lactate (111,112). However, after ischemic episodes, glycolysis remains enhanced, with evidence of oxidative and nonoxidative use of exogenous glucose. There is preliminary evidence that enhanced myocardial oxidative glucose metabolism persists after an ischemic episode, most likely because of an upregulation of glucose transport (113,114 and 115). Biopsy studies in patients with severe CAD and chronic dysfunction of left ventricular segments have shown increased glycogen storage, as evidence of chronic alterations of glucose metabolism in hibernating myocardium (116). Such a metabolic pattern may reflect cell dedifferentiation in repetitively ischemic myocardium with predominant glycolytic metabolism (117) as a protective mechanism to avoid cell death in the form of apoptosis or acute necrosis (118).

Fatty Acid Metabolism

The first radiopharmaceutical used in combination with PET for the assessment of regional cardiac metabolism was C-11 palmitate. Experimental studies changing cardiac workload or cardiac substrate availability demonstrated changes in C-11 palmitate kinetics (119). To avoid the complexity of substrate interaction defining the relative contribution of long-chain fatty acids and carbohydrates to overall oxidative metabolism, C-11 acetate has been proposed as an alternative probe to describe oxidative metabolism. C-11 acetate is converted to C-11 acetyl-CoA in the mitochondria and enters the TCA cycle. C-11 activity equilibrates within TCA cycle intermediates and C-11 activity clears from the myocardium in the form of C-11–CO_2 (Fig. 55.7). Several studies have indicated that C-11 acetate kinetics, as assessed by dynamic PET imaging, correlate closely with myocardial oxygen consumption. Kinetics of C-11 acetate are only sparsely affected by substrate interactions and thus allow quantification of myocardial oxygen consumption, yielding parameters of oxidative metabolism as well as blood flow (120,121,122,123 and 124).

Glucose Metabolism

F-18-FDG traces transmembranous transport, as well as phosphorylation of exogenous glucose (125,126). F-18-FDG-6-phosphate does not enter any further metabolic pathways but accumulates in myocardium proportional to glucose transport and phosphorylation (127,128). Experimental studies in isolated rabbit septum as well as canine models demonstrated a close relationship of FDG uptake and exogenous glucose metabolism measured by Fick's principle (128). However, FDG molecules display different affinities for glucose transport and phosphorylation than the glucose molecule. To correct this discrepancy, a correction term is necessary for the quantification of exogenous glucose use of the myocardium by FDG. This correction term (lumped constant) is assumed to be constant under physiologic and most pathophysiologic conditions. More recent data, however, indicate that under rapidly changing conditions the lumped constant may actually change as a function of altered affinities for glucose transport, as well as for the hexokinase reaction (129). Exogenous glucose use can be quantified using a simple fitting procedure of FDG myocardial kinetics and parametric display of regional metabolic data (130). The comparison of C-11 acetate uptake and clearance with regional FDG kinetics in normal volunteers demonstrated an inhomogeneity of regional glucose use in the heart (131). Regional FDG uptake is increased in the lateral wall of the left ventricle and slightly decreased in the area of intraventricular septum (132). FDG measurements have been performed to evaluate cardiac glucose metabolism in patients with insulin-dependent and non–insulin-dependent diabetes mellitus. In patients with insulin-dependent diabetes, there was no significant difference in overall glucose use as compared with a control population, if insulin was substituted by an euglycemic-insulin clamp (133,134 and 135). The quantitative nature of the PET measurements allows for *in vivo* studies under varying conditions to study the relationship of insulin and glucose metabolism in heart and skeletal muscle (136).

Clinical Application of Metabolic Imaging

Ischemic Heart Disease

Specific changes in regional substrate use can occur during acute myocardial ischemia and in patients with chronic ischemic heart disease as demonstrated by PET imaging (137,138,139 and 140). Myocardial ischemia results in impaired oxidative metabolism of fatty acids and increased myocardial glucose use (112). Comparing regional myocardial FDG uptake and myocardial blood flow, as assessed by microspheres during acute myocardial ischemia, showed a dissociation of myocardial blood flow and glucose use (112). In severe ischemia, however, both blood flow and glucose use are reduced, whereas there is evidence for increased FDG uptake during moderate ischemia. Marshall et al. were the first to investigate the relationship of increased FDG uptake in patients with acute myocardial infarction and clinical signs of ongoing ischemia, as well as electrocardiographic changes (141). This study indicated that in a considerable number of patients with acute myocardial infarction, residual metabolic activity could be demonstrated in the infarct territory, which was associated with a higher incidence of postinfarct angina and electrocardiographic signs of recurrent ischemia.

Metabolic Evaluation of Dysfunctioning Myocardium

Animal and clinical studies using FDG as metabolic tracer have shown that reversible left ventricular dysfunction (stunned, hibernating myocardium) is associated with maintained or even increased tissue FDG uptake (137,140,142). Experimental data support the notion that reversible chronic left ventricular dysfunction in patients with advanced CAD does not represent ongoing ischemia but downregulation of function (118,143). There are two experimental conditions that may serve as a model for the clinical presentation of reversible dysfunction in ischemic heart disease. First, transient ischemia with restoration of blood flow leads to slow functional recovery on the basis of *stunning* (144). Second, chronic reduction of blood flow in the animal model is associated with metabolic adaptive changes that minimize the imbalance of oxygen supply and demand, limiting the development of irreversible cell injury (hibernation) (145,146). There is increasing evidence that similar mechanisms are involved in the pathophysiology of reversible chronic dysfunction in patients with advanced CAD (147,148). Rahimtoola (147) first described this condition as *hibernating myocardium*. His definition included chronic reduction of blood flow as a culprit for the observed dysfunction, implying chronic ischemia. However, subsequent studies with PET have shown that blood flow either can be normal or only slightly decreased in dysfunctioning viable myocardium. Vanoverschelde et al. demonstrated near normal perfusion in collateral-dependent viable, but dysfunctioning, myocardium distal to an occluded coronary artery. Sophisticated measurements of blood flow corrected for tissue loss (perfused tissue fraction) also indicate that dysfunctioning myocardium may not be limited by oxygen supply under resting conditions (48,149). Based on these results, there is ongoing discussion as to whether reversible left ventricular dysfunction in severe ischemic heart disease reflects repetitive stunning or hibernation (143). The clinical situation in most patients is characterized by a heterogeneous ischemic injury, consisting of necrosis or scar in the subendocardium surrounded by viable but compromised tissue. The dynamic nature of ischemic heart disease renders these segments ischemic during daily life activities, which may lead to repetitive stunning. On the other hand, severe flow restriction may result in chronic hypoperfusion fulfilling the original criteria of hibernation. One can speculate that both conditions coexist in patients with advanced CAD and impairment of left ventricular function (150). From a clinical point of view, the pathophysiologic discussion is less important because many studies have shown that revascularization results in functional improvement of both stunned and hibernating myocardium (150). Therefore, differentiation between reversible and irreversible dysfunction in patients with severe impairment of left ventricular function has become a major clinical question for the decision-making process concerning revascularization. Qualitative evaluation of PET flow studies demonstrated decreased N-13 ammonia and increased FDG uptake (mismatch) in viable myocardium, which has been considered the scintigraphic hallmark of hibernation (140) (Fig. 55.8). Although such a pattern suggests reduced blood flow, the intensity of tracer uptake depends not only on flow, but also on left ventricular wall thickness (partial volume effect). Therefore, reduction of N-13 ammonia uptake may reflect wall thinning or an admixture of viable and scarred myocardium (151). Flow measurements with O-15 water are less sensitive to partial volume effects, but may overestimate transmural flow (152). In contrast, the FDG signal indicates a relatively higher FDG extraction compared with N-13 ammonia. Using information on both blood flow and glucose metabolism, sensitive specific identification of viable myocardium can be performed. This was first shown by Tillisch et al. (140), who compared relative FDG uptake in patients with advanced CAD and impaired regional and global function before and after revascularization. This study demonstrated that maintained FDG uptake in dysfunctioning segments with reduced flow is associated with functional recovery after revascularization, whereas segments with concordantly decreased flow and metabolism did not recover after restoration of blood flow. Subsequently, a large number of similar studies confirmed the predictive value of FDG imaging. Table 55.2summarizes clinical PET results, which were collected from several laboratories documenting the high predictive value of PET metabolic imaging for tissue recovery after revascularization. In all studies, recovery of regional function after revascularization served as the gold standard for tissue viability. It has been shown that functional recovery of hibernating myocardium may require several months (150,153).

TABLE 55.2 PREDICTIVE VALUE OF VIABILITY ASSESSMENT

Comparison with Other Imaging Modalities

Numerous investigations exist comparing regional FDG uptake with electrocardiographic criteria, standard thallium-201 and Tc-99m flow agents, imaging stress echocardiography, and MRI imaging (154,155). Early observations of discrepant results between FDG distribution and thallium-201 redistribution patterns emphasized the limitations of thallium-201 redistribution imaging for assessment of tissue viability, which are partly overcome by reinjection techniques (156). Tc-99m sestamibi also provides clinically useful information on tissue viability. In combination with nitrate application, the predictive value of Tc-99m sestamibi imaging can be enhanced. Comparing scintigraphic data with those obtained after positive inotropic interventions, it appears that tracer retention provides more sensitive markers of viable myocardium, whereas assessment of contactile reserve is associated with higher specificity for reversible myocardial dysfunction (156,157).

Prognostic Significance of Metabolic Imaging

Aside from the predictive value of FDG for tissue recovery, the prognostic information provided by FDG uptake in segments with reduced perfusion as assessed by N-13 ammonia PET has been emphasized by several groups (Table 55.3). Retrospective data analysis revealed a high incidence of cardiovascular complications in patients with decreased blood flow, but maintained FDG uptake in patients who did not undergo revascularization (158,159 and 160). In contrast, the incidence of cardiovascular complications was similar in groups with scintigraphic evidence of scar or normal myocardium, regardless of whether they were revascularized. These data indicate that the mismatch pattern identifies a subgroup of patients at increased risk for cardiovascular complications. The prognostic information appears independent of the traditional markers such as left ventricular ejection fraction or New York Heart Association classification, which were not different among the

investigated subgroups. Survival was significantly higher in revascularized patients with mismatch, as demonstrated by DiCarli et al. (161,162).

TABLE 55.3 PROGNOSIS OF POSITRON EMISSION TOMOGRAPHY

The degree of functional recovery of patients after revascularization can be predicted based on the scintigraphic pattern, as well as extent of mismatch (151,162). DiCarli et al. reported an 80% likelihood of functional improvement in the presence of mismatch exceeding 18% of the left ventricle. Pagano et al. indicated that the extent of viability correlates not only with functional recovery, but also survival (163). Furthermore, delay of revascularization in these patients is associated with increased mortality, confirming the prognostic significance of the identification of viable, but jeopardized, myocardium (164). Patients with severe left ventricular dysfunction are at higher risk for complications associated with revascularization. Dreyfus et al. (165) reported that assessment of tissue viability in such patients before surgery improves the selection process for revascularization with low perioperative mortality. Haas et al. (166) confirmed this prognostic role of PET by comparing short- and midterm survival after surgical revascularization in two groups of patients with three-vessel disease and impaired left ventricular function. Attempts to exploit the clinical significance of the FDG signal by less costly means included the use of high-energy collimators for SPECT systems and coincidence circuitry in gamma cameras. Initial results indicate the feasibility of such approaches with comparable diagnostic and prognostic performance (157,167).

Carbon-11 Acetate in the Assessment of Tissue Viability

Regional FDG uptake is modulated by plasma substrate levels and hormonal milieu. Many patients with CAD have diabetes mellitus or prediabetic conditions affecting glucose tolerance. Therefore, the image quality following oral glucose loading and intravenous injection of FDG is limited in some patients undergoing tissue viability studies (133). As an alternative, C-11 acetate has been proposed for the assessment of residual oxidative metabolism in patients with severe CAD. Studies by Gropler et al. demonstrated that C-11 acetate may also be useful in the assessment of tissue viability in patients with chronic stable CAD (168,169). More recently, Gerber et al. applied C-11 acetate kinetics to investigate the relationship between flow and oxygen consumption in patients with unstable angina. Reversible dysfunctioning myocardium displayed normal flow and oxygen consumption, suggesting the presence of stunning in these patients (170). C-11 acetate serves as an alternative to FDG imaging. However, the assessment of C-11 acetate kinetics requires dynamic data acquisition and sophisticated image processing, limiting widespread clinical use (168,169).

Metabolic Imaging in Patients with Other Cardiovascular Diseases

Dilated Cardiomyopathy

C-11 palmitate has been used to study fatty acid metabolism in patients with dilated cardiomyopathy. Observations by Geltman revealed a heterogeneous fatty acid metabolism in patients with dilated cardiomyopathy in the presence of relatively homogeneous perfusion, as measured with thallium-201 scintigraphy (171). Kelly et al. (172) addressed the role of C-11 palmitate in probing mitochondrial enzyme defects resulting in an impairment of beta-oxidation. These investigators were able to demonstrate that oxidation of C-11 acetate was dissociated from that of C-11 palmitate in patients affected with this enzyme disorder. As discussed previously, C-11 acetate allows the noninvasive assessment of myocardial oxygen consumption (173). This tracer approach can be used to probe myocardial oxygen consumption in healthy as well as diseased cardiac muscle. In addition, this technique can be used to assess right ventricular oxygen consumption, as demonstrated by Hicks et al., who described a close relationship between right ventricular acetate kinetics in patients and pulmonary artery pressure (174). Wolpers et al. first introduced the concept of noninvasively assessing myocardial efficiency by PET as defined by external work of the left ventricle divided by oxygen consumption (175). Such a parameter allows the assessment of the link between mechanical performance and metabolic demand under various pathophysiologic conditions as well as after therapeutic interventions (122,176).

Beanlands et al. applied this method in patients with cardiomyopathy before and after therapy with dobutamine and nitroprusside (177). Myocardial efficiency increased after both pharmacologic interventions. In both instances, the improvement in cardiac efficiency was most related to changes in left ventricular afterload. More recently, Beanlands et al. demonstrated the beneficial effect of beta-blockade (metoprolol) on metabolic left ventricular performance in heart failure patients using C-11 acetate (122).

ASSESSMENT OF AUTONOMIC INNERVATION

Tracer approaches are uniquely suited to the assessment of specific tissue function. Although tracers have been developed for the parasympathetic nervous system, the sparse cholinergic innervation of the left ventricle limits the presynaptic evaluation of this system *in vivo*. Therefore, most imaging approaches focus on the scintigraphic delineation of the presynaptic and postsynaptic sympathetic nervous systems because the left and right ventricles are densely innervated by sympathetic fibers. Figure 55.9 displays the nerve terminal, which is an important functional unit of the sympathetic nervous system.

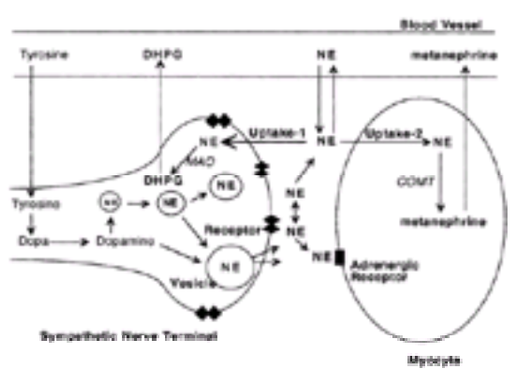

FIGURE 55.9 Conceptual model of sympathetic nerve terminal. COMT, catechol-*O*-methyl transferase; DHPG, 3,4-dihydroxyphenylglycol; MAO, monoamine oxidase; NE, norepinephrine.

Postganglionic sympathetic fibers travel along vascular structures on the surface of the heart. On entering the myocardial wall, the fibers branch into multiple sympathetic varicosities. These nerve terminals include vesicles, which represent the storage pool for neurotransmitters, enzymes, and other proteins (178). Norepinephrine, the predominant cardiac neurotransmitter, is synthesized from the amino acid tyrosine by several enzymatic steps (Fig. 55.9) and is released on nerve stimulation by exocytosis. Several receptor systems have been postulated to exist on the membrane of the presynaptic nerve terminal, modulating norepinephrine release. As much as 80% of the norepinephrine that is released from the nerve terminal is taken up via a mechanism known as *uptake 1*. Reuptake is an important mechanism to regulate the norepinephrine concentration in the extraneuronal space. A fraction of the released norepinephrine diffuses back into the vascular space where it can be measured as norepinephrine spillover in the coronary sinus venous blood (179). Only a small amount of norepinephrine in the synaptic cleft activates receptors on the surface of the myocytes or enters cardiac cells directly (uptake 2 mechanism). Norepinephrine undergoes rapid metabolism in neuronal and extraneuronal tissue. Metabolism of the neurotransmitter in the neuronal tissue is mediated by the enzyme monoamine oxidase, while extraneuronal norepinephrine is

metabolized by the catechol-*O*-methyltransferase enzyme system.

Imaging of Presynaptic Nerve Terminals

The use of radiolabeled norepinephrine or analogs appears to be most promising for the visualization of the sympathetic nerve terminals. C-11 hydroxyephedrine (HED) has been synthesized at the University of Michigan (Fig. 55.10) (180). This norepinephrine analog is taken up by the nerve terminal but is not metabolized by the intraneuronal enzyme systems. The myocardial retention of this tracer reflects the activity of uptake 1 mechanism and, to a lesser degree, the storage of norepinephrine in nerve terminals (181). In contrast, the more recently introduced compound C-11 epinephrine is not only taken up by the nerve terminal, but also stored in the vesicles of nerve terminals (182). A further analog of epinephrine is phenylephrine, which enters the nerve terminal via uptake 1, but is primarily metabolized by the monoamine oxidase enzyme system (183). Phenylephrine, therefore, allows the evaluation of the enzymatic integrity of the nerve terminal. Other radiopharmaceuticals for the characterization of the presynaptic nerve terminal include F-18 dopamine and F-18 norepinephrine, as well as MBBG (metabromobenzylguanidine) (184,185 and 186).

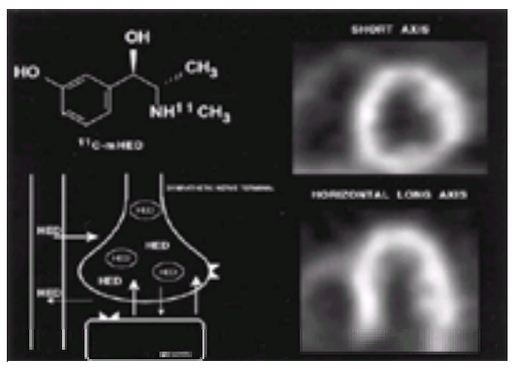

FIGURE 55.10 Illustration of molecular structure of carbon-11 hydroxyephedrine (HED), a model of the uptake mechanism, and positron emission tomographic images of the tracer in a healthy volunteer, showing homogeneous distribution of the tracer.

Clinical Application

Initial clinical applications of C-11 HED show excellent image quality with high contrast between myocardial tracer activity and blood pool, as well as lung tissue surrounding the heart (Fig. 55.10). The specificity of the tracer approach for neuronal tissue has been well documented by studies in cardiac transplant patients, which showed a marked reduction of tracer uptake, suggesting only little nonspecific binding of this tracer (181), which allows for quantitative image analysis (187). Studies in transplant patients at various time points following surgery indicate partial reinnervation of transplanted myocardium by retention of C-11 HED in the anterior septal segments of the left ventricle in transplant recipients several years after operation (188). These data suggested for the first time that regional reinnervation occurs in the human transplant. First results comparing this scintigraphic pattern with heart rate variability suggest that the partial reinnervation of the left ventricle is associated with electrophysiologic evidence of functional reinnervation (189,190 and 191). Allman et al. used C-11 HED in the assessment of patients with acute myocardial infarction undergoing thrombolytic therapy (192). Experimental data indicated that the extent of neuronal damage following transient ischemia is larger than the area of tissue necrosis. Wolpers et al. demonstrated a decreased retention fraction of C-11 HED in reperfused canine myocardium, suggesting a high sensitivity of neurons to ischemic injury. Similar data have been observed in the clinical setting (193). The area of neuronal dysfunction, as evidenced by C-11 HED defects, was significantly larger than the area of perfusion abnormalities in patients with acute myocardial infarction and correlated closely with the area of risk as assessed by Tc-99m sestamibi imaging in the same patients, confirming the experimental data (194). C-11 HED PET studies were also performed in patients with diabetic neuropathy. These studies revealed a correlation between the results of autonomic nervous system testing and the abnormalities of HED distribution. The finding that regional cardiac denervation represents a heterogeneous process in patients with diabetic neuropathy was surprising. C-11 hydroxyephedrine defects were most severe in the apical segments of the left ventricle and least severe in the proximal segments of the left ventricle (195,196 and 197). Comparison of neuronal dysfunction and blood flow measurements by PET revealed impaired vasodilator response in diabetic patients (198).

Preliminary studies suggest the possible role of HED imaging in patients with congestive heart failure. Several investigators demonstrated decreased HED uptake in patients with severely impaired left ventricular function, suggesting neuronal damage in this patient population (199,200). Again this process appears to be heterogeneous with pronounced abnormalities in the apical segments of the left ventricle.

Postsynaptic Receptor Sites

The development of radiotracers and the initial clinical validation of tracer methods for the visualization of the adrenergic receptor system have been initiated by Syrota et al. The specific visualization of cardiac beta-receptors became possible by the successful radiosynthesis of a more hydrophilic beta-receptor antagonist (CGP-12177). This nonselective C-11–labeled beta-receptor antagonist provided excellent image quality of the postsynaptic binding sites in the heart (201). A tracer kinetic model approach has yielded estimates of receptor densities in agreement with *in vitro* beta-receptor density assessments (202). Clinical validation of this approach confirmed the *in vitro* demonstrated reduction of beta-receptor density in patients with congestive heart failure. This approach has also been adapted by Camici et al. and used in patients with hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and syndrome X (203,204,205 and 206). These PET studies demonstrated a reduction in beta-receptor density as well as presynaptic function in patients with hypertrophic cardiomyopathy. The reduced beta-receptor density was not limited to the intraventricular septum, but included the entire left ventricular myocardium, suggesting a global change in beta-receptor density. These initial studies using beta-receptor antagonists for visualization of the adrenergic receptor system indicate the potential of PET imaging in monitoring pathophysiologic alterations in beta-receptor density and in probing the effect of various pharmacologic interventions on the sympathetic neurotransmission (207).

SUMMARY OF CURRENT STATUS

The improved imaging technology of PET, including attenuation correction and high spatial resolution, allows for the highly accurate detection of CAD. Coronary reserve measurements may be useful in the early detection of vascular abnormalities and follow-up of therapeutic interventions designed to halt or reverse CAD. Finally, such measurements can serve as end points in the evaluation of new drugs altering endothelial function.

Assessment of tissue viability has become an important application for PET in cardiology. Metabolic imaging documented the high incidence of reversible dysfunction in patients with severe CAD. These PET findings resulted in increasing diagnostic efforts to identify viable myocardium by various methods. At the current time, PET must be considered the reference method for identification of tissue viability with established diagnostic and prognostic value. In patients with high-risk interventions and in transplant candidates, PET best supports the selection process for revascularization. Finally, new tracer approaches designed to map cardiac innervation may not only prove useful in clinical research assessing neurophysiology of various cardiovascular disorders, but also provide important prognostic information in patients with congestive heart failure.

CONTROVERSIES AND PERSONAL PERSPECTIVES

PET imaging of the heart provides important clinical information and promising new avenues for clinical research. The quantitative nature, as well as the in-depth validation, of this technology, makes it an attractive research tool. For example, PET represents the most validated noninvasive method to quantitate regional myocardial perfusion. Although there are defined clinical indications for the use of regional quantification of myocardial perfusion, there are many scientific questions regarding coronary physiology and cardiac microcirculation, which can be addressed noninvasively by PET. However, this technology is not widely available and requires a well-developed academic infrastructure to exploit its research potential. It is expected that physiologic parameters beyond flow will gain importance in the future. It is, however, difficult to predict whether the resolution of scintigraphic methods will ever permit the study of the vascular wall of the coronary arteries. Specific tracers, which provide high contrast for a given physiologic process (e.g., thrombocytes activation inflammation), may enable imaging of vulnerable coronary plaques. In addition, tracer approaches may be useful in the monitoring of gene expression (208). Emphasis on further development of molecular imaging by PET clearly depends on basic cardiovascular research, providing new insights into the cell signaling and receptor systems. Tracer approaches are uniquely suited to study physiologic and biochemical consequences of altered cell interaction, providing *functional genomics*. This potential to characterize the phenotype may not only apply to human studies but may also be especially attractive for research in transgenic animals.

Metabolic imaging with PET provided the first insights into the adaptive processes in response to repetitive cellular stress (e.g., ischemia). Based on clinical

observations in hibernating myocardium, new experimental models are being developed to study the consequences of ischemia on myocardial substrate metabolism using molecular biology approaches. Similar interaction between imaging of human pathology and experimental work can be envisioned for other systems modifying cardiac performance—for instance, autonomic innervation of the failing heart.

There seems to be a gap between the technical potential of modern imaging modalities and the integration of functional information in the clinical decision-making process. Despite advances in functional imaging, physiologic and biochemical signals are often too complex to be readily accepted and exploited in daily patient care.

THE FUTURE

The future clinical role of PET depends primarily on the development of simplified PET methods, centralized distribution of radiopharmaceuticals, and the clinical acceptance and integration of complex physiologic information. It is expected that PET and SPECT technology will overlap in the future, and the uniqueness and usefulness of clinical information provided by each of these modalities will define their place in clinical cardiology.

ACKNOWLEDGMENTS

The authors appreciate the excellent secretarial help of Gabriele Sonoda and thank Dr. S. Nekolla and Ngoc Nguyen for the careful preparation of illustrations.

OVERVIEW

Cardiac computed tomography (CT), like echocardiography, provides image slices or tomograms of the anatomic features of the heart. These two modes of tomographic imaging complement each other. On the one hand, the natural echocardiographic contrast difference between fluid and solid tissues allows noninvasive visualization of intracavitary and endovascular lumina and even the visualization of detail in valve leaflets and occasionally the lumen of the left coronary artery. This distinction of blood and tissue would require injection of contrast with CT. On the other hand, the higher spatial resolution of CT allows visualization of coronary arteries both with and without contrast enhancement. The accentuated absorption of x-rays by elements of high atomic number such as calcium and iodine allows excellent visualization of small amounts of coronary calcium as well as the contrast-enhanced lumina of medium-sized coronary arteries. Figure 56.1 illustrates the major differences between these two types of imaging.

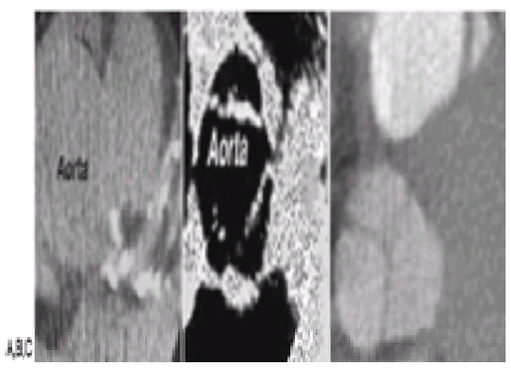

FIGURE 56.1 A: A computed tomographic (CT) scan at the level of the aortic valve. **B:** An echocardiogram at approximately the same anatomic location. **C:** A contrast-enhanced CT image of the aortic valve. The figure illustrates important differences between noncontrast CT, contrast CT, and echocardiography. The presence and severity of coronary calcium are easily seen in the left coronary artery in the computed tomogram on the left, whereas it is invisible in the echocardiogram. The distinction between valve leaflets and aortic wall from aortic blood pool can only be seen on the ultrasound image and the contrast-enhanced CT image. The periarterial fat is shown as a dark area around the left coronary artery on the CT image on the left, whereas this is not seen at all on the echo.

There are significant tradeoffs when comparing CT with ultrasound imaging. CT capable of accurately imaging the heart is relatively unavailable, often more expensive, and involves the use of ionizing radiation and often iodinated contrast injection. Without the latter, CT, like all radiographic imaging, cannot distinguish intracavitary and intraluminal blood from the muscular walls of vessels and cardiac chambers. Echocardiography is capable of this distinction even without injections.

There are large initial expenses involved in the purchase and installation of CT scanners. These costs, particularly regarding electron beam CT scanning, have induced some medical centers to invest in unusual public marketing campaigns of their technologies. Indeed, the frequent marketing of this technology to the American public, since the early 1990s, is a striking example of how the need to balance large initial and ongoing maintenance costs with needed revenues can influence the application of a diagnostic test.

The authors of this chapter are ardent proponents of cardiac CT and coronary calcium scanning. We believe that this exciting technology should and will find a useful place in the diagnostic armamentarium of physicians. We also believe that the development of this application should be evidence based and linked to the guidelines published by the professional societies.

This chapter presents all aspects of rapid CT scanning of the heart but emphasizes its most common use, which is, for better or worse, coronary calcium screening.

GLOSSARY

Calcium score: A mathematical calculation related to the amount of calcium determined by multiplying the area of calcified plaque by a weighting factor based on the CT number or Hounsfield unit of the calcified plaque. Weighted volume of calcium.

Spatial resolution: Quality of image as a function to resolve minute anatomic features.

Temporal resolution: Quality of image as a function of speed of acquisition.

Tomogram: Image slice of the body.

TECHNICAL ASPECTS

Scanning the Heart: A Technical Challenge

CT of the heart presents significant technical obstacles and dilemmas. The heart is far from quiet, and its continuous rhythmic displacement as well as even small degrees of respiratory motion cause great difficulty for imaging with standard CT techniques. Conventional scanners, whose exposure time exceeds one-half of a second, cannot possibly “freeze” this motion. More rapid scanning of the heart has been limited by the speed with which a single tomogram can be acquired. To better understand some of the advances that have allowed crisp images of cardiac anatomy and pathology, we have written this section.

Types of Computed Tomography Systems or Scanners

Two kinds of scanners are used to image the heart. Electron beam scanners use an x-ray source, which consists of a 210-degree arc ring of tungsten, and are activated by bombardment from a magnetically focused beam of electrons fired from an electron gun behind the scanner ring. For most scanning applications, it takes one-tenth of a second to complete a rotation of the electron beam using electron beam computed tomography (EBT) scanners. Subsecond, non–electron beam [multidetector computed tomography (MDCT)] scanners use a rapidly rotating x-ray tube and several rows of detectors, also rotating. The tube and detectors are fitted with slip rings that allow them to continuously move through multiple 360-degree rotations. Present versions complete a 360-degree rotation in approximately one-half of a second. These scanners’ exposure times can be decreased to as little as 0.25 seconds by using only a portion of the 360-degree rotation. Further reduction is also possible but at the expense of increased radiation or less rapid acquisition of progression from one tomographic image to the next. For coronary calcium noncontrast scanning, the EBT scanner can acquire only one tomogram at a time; the MDCT scanner can acquire up to four tomograms at a time. Both the speed and the maximum number of tomograms are likely to increase for both types of scanners.

MDCT is also known as *multislice* and is an evolution from single-slice helical or spiral CT systems. The MDCT systems use a rotating x-ray tube and detectors with variable rotation times of less than 1 second. These scanners operate in two modes, helical and sequential, and it is somewhat misleading to call them *helical scanners*. Helical or spiral CT scanning refers not to a different type of scanner but rather to a different method for acquiring and reconstructing images. When used normally, in sequential scanning mode, modern scanner tables move the patient through the scanner ring by a set increment of length (from 1 to 15 mm). Between table increments, the x-ray exposure occurs, during which the x-ray tube and detector array rotate slightly greater than a full 360 degrees. These exposures usually have a thickness (collimation) equal to the table increment. With a modern generation MDCT system, rather than a single 10-mm row of detectors, there is a detector array. The detector array allows the same 10-mm slice (x-ray beam collimation) to be divided into four channels or slices. So instead of one 10-mm slice, four 2.5-mm slices are obtained. Likewise, an eight-channel MDCT system could produce eight 1.25-mm slices. Thinner slices improve spatial resolution along the z-axis (head to foot).

Helical or spiral mode is possible secondary to the development of the slip-ring interconnect. This allows the x-ray tube and detectors to rotate continuously during image acquisition because no wires directly connect the rotating and stationary components of the system (i.e., no need to unwind the wires). With the gantry continuously rotating, the table moves the patient through the imaging plane at a predetermined speed. The relative speed of the gantry rotation table motion is the scan pitch. Figure 56.2 shows how both kinds of scanning work. The smooth rapid table motion or pitch in helical scanning allows complete coverage of the cardiac anatomy in 15 to 25 seconds. A disadvantage of this method in cardiac scanning, however, is an increase in radiation dose.

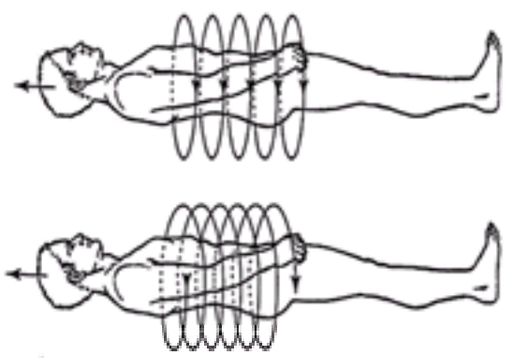

FIGURE 56.2 The top figure shows sequential scanning. The bottom figure shows helical scanning.

How Do Scanners Create Images?

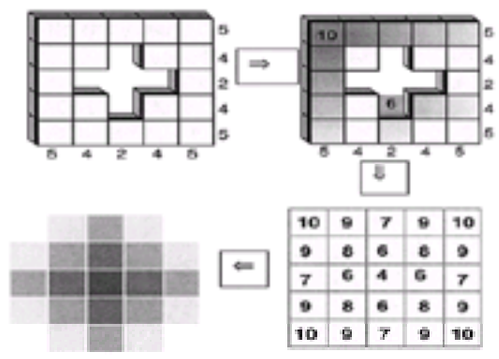
All CT systems create images using the same basic principles. An x-ray source is used to create a filtered and collimated beam of x-ray photons, which irradiate the patient from a known point. On the other side of the patient, a detector array measures the x-ray photons, which exit the patient. The source and possibly the detector array rotate around the patient, providing different views or projections. These views fill a mathematical matrix referred to as *radon space*. This information is then transformed through a filtered backprojection algorithm to create an x-ray attenuation map of the area or slice evaluated, which is generally recognized as the CT image.

Gating and Reconstruction

Gating refers to timing exposures to a point in the cardiac cycle when the heart is most still. EBT scanners have usually used 80% of the electrocardiographic RR interval for scanner triggering, although there are some more recent reports showing that earlier diastolic triggering might provide better images with less motion artifact (1,2 and 3). MDCT scanners usually trigger at 50% of the RR interval (4). *Reconstruction* refers to the computer calculations, which convert the digitally transformed data from the scanner’s x-ray detectors into images of the heart and surrounding structures.

Image reconstruction was the breakthrough that won Dr. Hounsfield the Nobel Prize in 1972 and that makes any kind of CT scanning possible.

Reconstruction can be understood with a simple diagram (*e*Fig. 56.2.1). Assume that the x-ray source has two possible positions, on top of and to the left of the object scanned. Assume that the heart, in this simplified scanner ring, consists of blocks, as shown in the figure. As the x-rays pass through the blocks, they are absorbed and the total absorption is registered on the detectors, as shown on the right and the bottom. We can do our own reconstruction now by adding the numbers at the ends of the rows and columns and putting the results in the blocks where the rows and columns intersect.



***e*FIGURE 56.2.1** Cross (*upper left*) is exposed to two perpendicular sources of x-rays. One source is directed down, the other to the right. The image is created by computation (addition) of x-ray absorptions from both projections (*lower left*).

The array of digital numbers, when translated into tiny blocks of light with brightness proportional to their values, is the reconstructed image. Of course, this is an oversimplification of a more complex process, but we at least can see why the tomograms are called *computed*. Each individual tomogram can be thought of as a virtual slice of tissue consisting of blocks (voxels) containing numbers, each of which is proportional to the absorption of x-rays at that point and with a thickness and width determined by the reconstruction. Figure 56.3 shows a diagram of a tomogram.

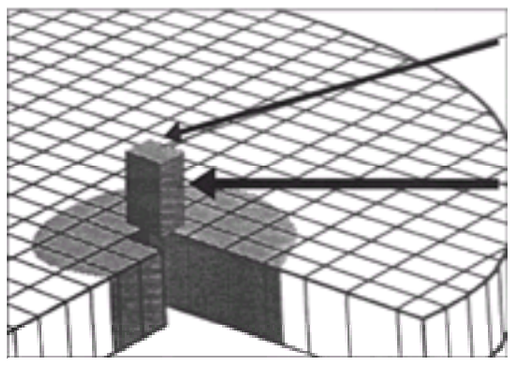


FIGURE 56.3 Each tomogram consists of voxels of given thickness (*thick arrow*) and width (*thin arrow*). One number between –1,000 and 2,000 represents each voxel.

Specific Problems with Specific Scanners

If time per scan were everything, the EBT scanners would be ahead of the pack. For at least a few years, the MDCT scanners will not be able to drive exposure times down to one-tenth of a second or better without sacrificing other important advantages they enjoy. Furthermore, it is unlikely that Imatron, the only company in the EBT business, will remain inactive. They are likely to further decrease their exposure times and otherwise improve the quality of their images.

There are few carefully executed, head-to-head comparisons between the two scanner types. EBT scanners are still better for most cardiac applications. However, present EBT scanners have some distinct disadvantages, including excessive image noise, especially in obese patients. The limitation to only one or two detector rows is another concern. This limits the speed with which the entire heart can be imaged. Increased expense and difficult maintenance as well as relatively poor image quality for scanning other parts of the body are significant problems.

Motion Artifact versus Misregistration

Despite their high speed, modern CT scanners still suffer from motion blurring due to the rapid motion of the base of the heart in diastole. Motion artifact, when it is in the plane of an image slice (*x*,*y*-plane), causes degradation of images and measurements made from them. When motion is in the long axis of the body (*z*-axis), it causes misregistration of image data between image levels. This problem is especially acute when imaging small structures, such as coronary arteries, particularly the right coronary artery.

Perhaps more problematic is the inevitable misregistration of the tomograms caused by even small degrees of chest motion or errors in electrocardiographic gating. This misregistration causes gaps or overlaps between image levels. This effect results in large rescan variability for many measurements (5,6 and 7). Current generation scanners, by virtue of their slower temporal resolution of 250 to 500 ms, are prone to greater motion artifact. This motion artifact results in blurring, which leads to quantitative errors in analyzing images.

Noisy Images

When an x-ray beam encounters thick layers of tissue, absorption and scattering of x-ray photons within the tissue increase and thus fewer direct photons reach the detectors to record the image. Scattered x-ray photons result in noise. The signal-to-noise ratio is used as a measure of image quality. If the CT detector arrays record a high number of direct x-ray photons relative to scattered photons and other sources of noise within the CT system, then a clear and high-resolution image of acceptable signal-to-noise ratio will be obtained.

Current generation EBT scanners are unable to increase the number of x-ray photons without increasing image time. Thus, high levels of noise in the resulting images are observed, particularly for obese individuals. For this reason, EBT scanners cannot be used for subjects who weigh more than 300 lb. MDCT scanners usually have an upper limit of weight of at least 400 lb and have the added advantage of a variable tube current for obese subjects. The ability to increase tube current with patient size allows for image noise to be independent of patient size.

CLINICAL APPLICATIONS

Coronary Calcium: Pathophysiology

Atherosclerotic calcification is an organized process similar to bone formation in cartilage plates (8). It occurs when the other aspects of atherosclerosis are present. Gla-containing proteins that are involved in the transport of calcium out of vessel walls are also involved in atherosclerotic calcification. Calcified plaque also contains mRNA for bone morphogenetic protein, a potent factor for osteoblastic differentiation as well as cells that are capable of osteoblastic transformation (9). These cells may be the precursors of vascular calcifying cells. Calcification is thus an active process and not simply passive calcium phosphate precipitation. Although calcification is found more frequently in advanced lesions, it may also occur in the lesions that are seen as early as the second decade of life. The relation of arterial calcification to the probability of plaque rupture is unknown. Though the extent of calcification is directly related to the volume of plaque, this relationship is far from perfect, and it is not known if the amount of calcium tracks the amount of plaque over time. Teleological speculations and some empirical evidence (10) lead us to believe that calcification may represent an attempt to protect threatened myocardium by strengthening weakened atherosclerotic plaque that is prone to rupture.

Coronary Calcium: Historical Perspective

Other Modalities: Chest Radiography and Fluoroscopy

Units for acquiring plain chest radiographs are universally available. Lenck (11) reported a chest radiograph showing left coronary calcification in 1927. In 1950,

Hobbe and Wright (12) reported a chest radiographic prevalence of 3% among hospitalized patients. In 1978, Souza and Bream proposed the examination of the *CAC triangle* (coronary artery calcification triangle) in every adult chest radiograph (13). In 1983, Kelley and Newell (14) reported that by using a higher energy, the sensitivity of the chest radiograph could be greatly increased for detecting coronary calcium.

Individual physician-scientists who were searching for more accurate diagnoses drove research in this field. Despite encouraging initial results, we know of no further research or clinical interest in using the plain chest radiograph for detecting coronary calcium, although there remains continued interest in evaluating arterial calcification of the aorta and other vascular beds with conventional radiography as indicated by studies evaluating aortic calcium and arterial calcium with mammography.

The fluoroscopic image intensifier has been standard equipment in hospitals for decades. With the advent of cardiac catheterization laboratories, image intensifier sales blossomed. These units were somewhat expensive, but the demand for better diagnosis spurred increased use for angiographic studies in patients with chest pain.

The first reports on the use of noninvasive fluoroscopy for detecting coronary calcium appeared in the 1960s (15,16). There was a surge of interest, which culminated in the late 1980s with a metaanalysis (17) and the development of two modifications, which increased sensitivity and accuracy (18,19). The metaanalysis concluded that although the sensitivity of fluoroscopy appeared to be low, its specificity was high and its accuracy compared well with most forms of stress testing. The most striking and encouraging finding was that of Margolis et al. (20), who followed a group of symptomatic adults who had undergone cardiac fluoroscopy and angiography and found that fluoroscopic calcium predicted a fourfold increase in future mortality and that calcium was an independent predictor of mortality even after controlling for extent of angiographic disease. Due to a dearth of economic pressure, and despite promising research results, neither medical centers nor professional societies gave serious consideration to the clinical application of cardiac fluoroscopy in the diagnosis of coronary heart disease.

Computed Tomography

CT scanners have been used since the 1970s. Scanners, like image intensifiers, are expensive. They serve for imaging multiple organs, both with and without contrast injections. Reinmuller and Lipton (21) in 1987 reported CT for coronary calcium to be more sensitive but less specific than fluoroscopy for predicting angiographic stenoses. Masuda et al. (22) and Timmins and Pinsk (23) also found CT to have increased sensitivity for stenoses, and Moore et al. (24) found that coronary calcium identified on CT scans predicted a worse outcome in symptomatic patients. The increased contrast resolution of CT is the reason for its expected increase in sensitivity. Localization of calcifications is also more accurate and easier with tomography than with projection imaging such as fluoroscopy.

Electron Beam Computed Tomography

Figure 56.4 shows an EBT scan, positive for coronary calcium. EBT scanners were introduced into the American market in the 1980s and represented a remarkable breakthrough in CT technology. The ability of EBT scanners to obtain rapid scan acquisition, as fast as 50 ms, makes them well suited for imaging the heart. To date, design tradeoffs to acquire these extremely high temporal resolution images have resulted in EBT not being widely accepted by the medical community for general CT imaging of the brain, liver, and other body parts.

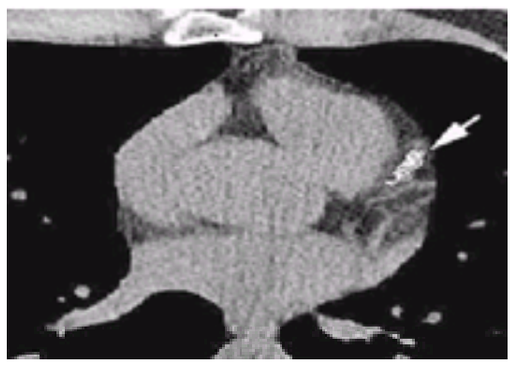

FIGURE 56.4 Tomogram from a study showing calcification in the left coronary artery (*arrow*).

Reports on their potential for imaging coronary calcifications began early with the papers of Tannenbaum and Kondos (25) and Agatston et al. (26). Tannenbaum and Kondos (25) were the first investigators to report the association of EBT coronary calcium with angiographic stenoses. Several other investigators (27,28 and 29) reported accuracies for predicting angiographic stenoses that are comparable with those of exercise testing. We know of one metaanalysis that shows encouraging results in this regard (30). Despite the fact that proponents of EBT frequently claim that it is far more accurate and useful for calcium assessment than either conventional CT or fluoroscopy, there have been few head-on comparisons. We believe that the accuracy of EBT exceeds that of other imaging modalities, but, in the case of multirow subsecond scanning, this difference in accuracy is modest or nonexistent (31,32).

After considering three possible clinical indications for calcium assessment using EBT, the American Heart Association concluded that there was a clear indication only in symptomatic adults with atypical chest pain (33). This was similar to the conclusions of the metaanalysis, published almost a decade earlier regarding cardiac fluoroscopy (17).

Some investigators have also done studies to determine the value of coronary calcium detected with this technique for predicting future coronary events in asymptomatic adults (34,35). These studies in asymptomatic subjects have received enormous attention and have produced widely divergent results and conclusions.

Measures of Coronary Calcium

All measures of coronary calcium depend on an inherent definition of a calcified lesion. Such definitions depend on two factors: a minimum brightness value (Hounsfield number) assigned to a pixel in the anatomic distribution of the coronary tree and a minimum number of adjacent or contiguous pixels that have that brightness value. The National Institutes of Health standard set by the Multi-ethnic Study of Atherosclerosis (MESA)/Coronary Artery Risk Development in Young Adults (CARDIA) CT committee is a brightness value of at least 130 Hounsfield units and four contiguous pixels using a 35-cm field of view.

The most popular measure of coronary calcium is the calcium score (26). This is a radiographic density-weighted volume of plaques whose pixel numbers exceed 130. A simpler and perhaps more reproducible measure is the calcium area or volume (26,36). The calcium volume is the total volume of all voxels with a Hounsfield number of at least 130. Callister et al. have developed an interpolated volume scoring method, which smooths adjacent voxel numbers between image slices (36). They have found their method to be more reproducible, although this remains to be confirmed. Few reports have conclusively shown that any of the other measures are superior in accuracy and reproducibility when compared with the calcium score.

Prevalence

The prevalence of coronary calcium in asymptomatic as well as symptomatic persons is well known. Table 56.1 (26,37,38 and 39) shows the prevalence in young asymptomatic men and women of various ages. The prevalence in women lags behind that of men until well into the postmenopause period. The table shows the prevalence of coronary calcium in persons generally symptomatic and undergoing coronary angiography. These data thus indicate that the prevalence in symptomatic persons is generally higher than that in asymptomatic persons, and prevalence is age dependent. The prevalence in men is evidently higher than the prevalence in women. The lower prevalence of coronary calcium in those with myocardial infarction and negative coronary angiogram results is not shown in the table.

	Symptomatic (%)	Asymptomatic (%)	
Decade (yr)	Men and women	Men	Women
30–40	26	21	11
40–50	43	44	28
50–60	81	70	50
60–70	83	84	73
70–80	—	94	89
>80	—	100	100

TABLE 56.1 PREVALENCE OF CORONARY CALCIUM IN SYMPTOMATIC AND ASYMPTOMATIC ADULTS

Reproducibility and Progression

Serial coronary calcium studies have been proposed to follow the progression of atherosclerosis. Such studies would be useful if the following conditions were met: (a) The progression of coronary calcium tracked the progression of unstable coronary plaque; as noted previously, the extent to which this is true is still a matter of debate; and (b) the measurement error, defined as the rescan percent variability, was much lower than the percent physiologic change over time.

Although coronary calcium is known to progress (40,41), the extent to which this progression tracks the progression of atherosclerotic plaque is unknown. Unfortunately, many who investigate temporal changes in calcium score over time have not considered that our understanding of the significance of atherosclerotic calcification is poor. A well-publicized retrospective nonrandomized review of subjects undergoing multiple scans showed decreased progression of calcification in a subgroup on effective lipid-lowering therapy (41).

Furthermore, the ability to track progression of calcium depends on the rescan variability compared with the expected rate of progression. If the former is much smaller than the latter, then progression within a year or two will be easy to detect in a single individual. If this is not true, it may take several years to be sure that progression is real and not due to measurement error.

The results of studies on reproducibility are listed in Table 56.2. Variability is seen to be at least 30% in most studies. Percent variability decreases rapidly for higher amounts of calcium. The reason for this is obvious because small calcium amounts can increase by 100% for spurious reasons.

Author	Year	No.	Variability (difference/mean; %)
Kajinami et al. (5)	1993	25	34
Bielak et al. (7)	1994	177	51
Shields et al. (42)	1995	50	38

Wang et al. (3 mm slice) (6)	1996	72	29
Wang et al. (6 mm slice) (6)	1996	77	14

TABLE 56.2 RESCAN VARIABILITY IN FIVE STUDIES

Examination of age-dependent scores in cross-sectional data can most easily assess expected changes or progression over time. The approximate yearly increase in calcium score in such studies is between 20% and 35%. There are a few prospective studies showing similarly rapid progression of coronary calcium over time (40,41,44,45). Statistical arguments suggest that even with this rapid rate of progression, at least 4 years would have to pass before perceived changes in calcification could be judged to be significant in a single individual. This limitation on the clinical use of CT calcium assessments is similar to that seen for other types of vascular imaging such as coronary angiography (46). This drawback has far less effect on the utility of coronary calcium assessments for research studies when used in samples of at least 100 persons (47).

Coronary Calcium and Coronary Angiography

Available evidence suggests that a negative CT scan result for calcium does not completely exclude the presence of atherosclerotic plaque, but does imply a low likelihood of significant luminal obstruction. Most patients with angiographically normal coronary vessels have negative scan results and a low risk of coronary heart disease within 4 years after their scans. A positive scan result does indicate the presence of atherosclerotic plaque. Table 56.3 and references 7, 28, 29, and 47,48,49,50 and 51 give the sensitivities and specificities of CT coronary calcium for predicting angiographic stenoses. Shemesh et al. (48) have found that infarct-related arteries are less likely to be heavily calcified than those not related to myocardial infarctions. These results remain to be confirmed.

Author	No. of patients	Mean age (yr)	Sensitivity	Specificity
Breen et al. (28)	100	47	100	47
Fallavolita et al. (29)	106	44	85	45
Bielak et al. (7)	256	45	90	62
Devries et al. (49)	140	58	97	41
Rumberger et al. (50)	139	52	99	62
Budoff et al. (51)	710	58	95	44

TABLE 56.3 RELATIONSHIP WITH CORONARY ANGIOGRAPHY

All of these studies show that although sensitivity of coronary calcium for predicting coronary stenoses is high, specificity is low. This gives coronary calcium a high predictive value for ruling out but a low predictive value for identifying stenoses. It is on this basis that the American Heart Association writing group approved the use of coronary calcium for assessing patients with atypical chest pain (33). More recently, however, the combined American College of Cardiology/American Heart Association consensus panel took a more conservative stance on the same issue (52).

Screening and Predicting Events

This is an area that has generated much controversy and debate. The monograph by Morrison (53) contains an excellent definition of the purpose of screening for chronic diseases. “Screening for disease control can be defined as the examination of asymptomatic people in order to classify them as likely or not likely to have the disease that is the object of screening. . . . The goal of screening is to reduce morbidity and mortality from disease among the people screened by early treatment of

the cases discovered."

There are two aspects of this definition that are unfortunately ignored during much of the debate regarding calcium screening. The first is that experiments to evaluate clinical screening should use asymptomatic research subjects. The second is implied in the phrase "reduce morbidity and mortality." If this goal cannot be achieved, then screening will not achieve its purpose and cannot be deemed effective. For example, cholesterol screening is effective only because lipoproteins are clinically effective targets for preventive therapy; mammographic screening for breast cancer and occult blood screening for colon cancer have been proven to be effective in certain groups, not solely because they predict clinical disease and mortality, but also because screening leads to a course of action proven to save lives.

Before we can endorse massive coronary calcium screening of the entire population, or even a subpopulation, of adults, we need to have a screening test that leads to effective preventive therapy when applied to asymptomatic persons. Thus, the test must predict clinical disease in asymptomatic persons in a way that allows therapeutically effective decisions to be made based on the results.

It is sometimes argued that coronary calcium measurements can be helpful in certain subsets of persons, based on risk factor status and specifically on lipoprotein levels. For example, some would aggressively treat a 45-year-old man with reductase inhibitors, angiotensin-converting enzyme inhibitors, and aspirin if his low-density lipoproteins were in the range between 100 and 160 and he had a coronary calcium score of 400 (well above the ninetieth percentile for age and gender). They would argue: "I know he has coronary disease. Therefore, he should be in a secondary prevention category, and I should treat him as if he had suffered a myocardial infarction." Logical though it seems, this argument has an important flaw. The flaw lies in the expanded definition of coronary heart disease from *clinical* to *preclinical* disease. A calcium score of 400 is simply not the same as a prior myocardial infarction. Those with prior infarctions have been proven to benefit from aggressive low-density lipoprotein lowering. Those with calcium scores of 400 may also receive such benefit, as the recent Air Force Coronary Artery Prevention Study (AFCAPS) has shown (54). However, even if a score of 400 in this person predicted a grave prognosis, we could not be sure that any benefit would be garnered from intervention.

One might argue, of course, that treatment could be justified based on high risk alone. If those with scores over 200 are more than ten times more likely to develop clinical disease, then one probably should not wait for a clinical trial of calcium screening to make a decision to treat. We would agree that if, indeed, there were conclusive proof of a large increased probability (at least eight times) of a morbid coronary event based on a coronary calcium score, treatment would be justified even in the absence of a corroborative clinical trial.

How well does coronary calcium predict coronary events? O'Malley et al. (55) have reviewed most of the literature on using CT calcium to predict future events in asymptomatic adults. Their results are summarized in Table 56.4. We see from the table that the relative risk of calcification varies from 1 to 22 with a weighted mean of 4. There seems to be general agreement that calcium predicts events. There is little agreement as to how well it can do this. Thus, the predictive value of coronary calcium for new cardiac events still remains to be determined. The National Heart, Lung and Blood Institute has sponsored a study called MESA that will examine this issue as one of its major hypotheses. MESA will use a cohort of 6,500 American adults who will undergo CT scanning and will be followed for coronary events for 7 years.

TABLE 56.4 RELATIVE RISKS OF CORONARY CALCIUM ACCORDING TO PUBLISHED PROGNOSTIC STUDIES

Position of the Professional Societies

In 1996, the American Heart Association, at the persistent suggestion of the proponents of scanning, assembled a writing group on the application of EBT coronary calcium scanning. This group concluded that EBT had not yet been proven to be useful for screening asymptomatic subjects and that more research was needed (33).

Interestingly, this enormously expensive technology is the only one that has found a limited degree of acceptance and popularity in the medical community. Of the more than 40 EBT scanners in the United States, most are used almost exclusively for coronary artery calcium screening. This technology—not fluoroscopy, not conventional CT—has been the subject of not one, but three reviews by national consensus panels (33,52,59,60 and 61).

The application of calcium assessments has been confined largely to screening asymptomatic populations for whom there are only scanty supportive data. This use began long before the publication of any prognostic data and before most of the cross-sectional studies were reported. An estimated 60,000 Americans have been so screened.

Fortunately, the American Heart Association and the American College of Cardiology have taken responsible positions on this issue. In Table 56.5 we suggest the potential indications for which coronary calcium scanning should and should not be considered as indicated, based on the consensus documents published by the professional societies.

	Screening asymptomatic adults	Selected patients with intermediate risk (e.g., low-density lipoprotein [100–160], etc.)	Diagnosis in those with chest pain	Prognostication in those with known coronary disease
Definitely indicated	-	-	-	-
Probably indicated	-	+	-	-
Possibly indicated	-	-	Atypical chest pain only	-

+, indicated; -, not indicated.

TABLE 56.5 INDICATIONS FOR CORONARY CALCIUM SCANNING

In this paradigm, a clinical examination including history, blood pressure measurement, and lipoproteins should always be used to determine the indication for a coronary calcium examination. General screening of asymptomatic adults should be discouraged, and coronary calcium studies should be restricted to those at intermediate risk who might benefit from aggressive risk factor modification and possibly to those with atypical chest pain.

Computed Tomographic Coronary Angiography

Medical and surgical management of coronary heart disease is in large part predicated on alterations in the lumen of the coronary arteries as demonstrated at coronary angiography. Although it is becoming clear that stenosis is only one domain of a complex process, as detailed in other chapters, the presence and distribution of arterial diameter reduction remain important determinants of patient management.

Cardiac CT, like cardiac magnetic resonance imaging (MRI), can produce a four-dimensional image of the beating heart. Although cardiac MRI provides superior tissue contrast, velocity mapping, myocardial tagging, and kidney-friendly intravascular contrast agents, cardiac CT has several characteristics that, with continued technological advances, may make it a major and perhaps front-line technique for cardiac and coronary imaging. Several advancements in CT technology are driving the renewed interest in contrast-enhanced cardiac CT. These include continued evolution of EBT techniques using equipment with improved gating, detector arrays, and table motion. For helical CT systems, the development of 0.5-second gantry rotation time, the addition of cardiac gating, the development of four- and eight-slice detector arrays with sub–1-mm slice thickness and sophisticated multiphasic volumetric reconstruction algorithms are driving a renewed interest in contrast-enhanced cardiac CT. This section reviews current and developing techniques and application of contrast-enhanced CT in the heart.

VIDEO

Video 56.1 Contrast-enhanced computed tomographic (CT) angiography with angioscopy. This video demonstrates a volume rendering of the heart and coronary arteries in the left frame, axial images in the upper right hand frame, and the lumen-view, or angioscopy, in the lower right frame. As the movie plays, the indicator on the volume images cross references the location of the lumen view within the left anterior descending coronary artery as it approaches and then passes through the stent located in the left anterior descending coronary artery. Techniques like this are under development. Efforts to reduce the amount of human and computer postprocessing required and increasing the spectrum of patients that can be imaged reliably and with high quality are under way. Further validation of these techniques is needed before introduction into clinical practice, but there is significant promise for these methods. Contrast-enhanced CT coronary angiography study performed on a Siemens Volume Zoom four-slice multidetector CT system operating in helical mode with cardiac gating. (Images courtesy of Christoph R. Becker, University of Munich—Klinikum Grosshadern.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Without the addition of an intravascular contrast agent, differentiation of the vessel wall from the vessel lumen is not possible in most instances with CT. This is due to the similar x-ray attenuation of blood and soft tissue. Cardiac CT is a four-dimensional multiplanar imaging technique. This multiplanar capability can provide quantitative information on vessel lumen, relatively irrespective of stenosis orientation, with a single acquisition (Fig. 56.5). In the next section we consider current technical aspects of contrast-enhanced CT imaging of the heart, review the published scientific literature, and conclude with areas of active research.

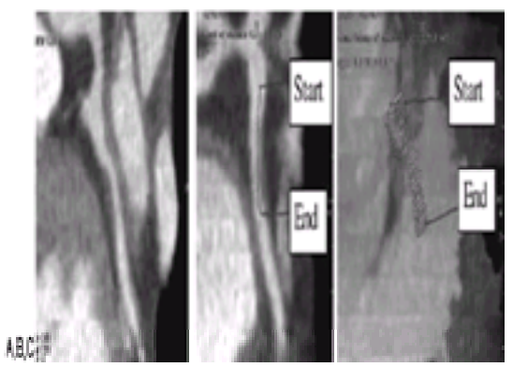

FIGURE 56.5 A–C: Contrast-enhanced computed tomographic coronary angiography. Left circumflex: curved reformatted image through the center of the lumen of the proximal left circumflex (segment 11) from a contrast-enhanced multidetector computed tomography study, helical acquisition with retrospective cardiac gating (General Electric Medical Systems LightSpeed Plus). Three-dimensional computer processing of the computed tomographic image data allows identification of the start and end points of various coronary segments with a potential stenosis **(B)** and determination of the central path of the vessel contrast column. From the central path, the orthogonal vessel cross-sectional area can automatically be determined and quantitative indices of stenosis measured from a wireframe representation **(C)**. Although there remain numerous challenges to validating techniques such as this for clinical application, they have the potential to provide quantitative information concerning coronary artery luminal dimensions noninvasively.

Technique

The goal of CT angiography is to image the coronary arteries during arterial enhancement after the intravenous injection of contrast material. In most instances, the test can be performed on an outpatient basis in 45 minutes of patient time. Procedure-related complications are rare and are related to the power injection of contrast media (venous extravasation), anaphylactoid reactions to contrast, and nephrotoxicity.

The generic examination consists of one or more planar scout images, unenhanced cardiac-gated CT, a timing scan, and a contrast-enhanced CT angiogram.

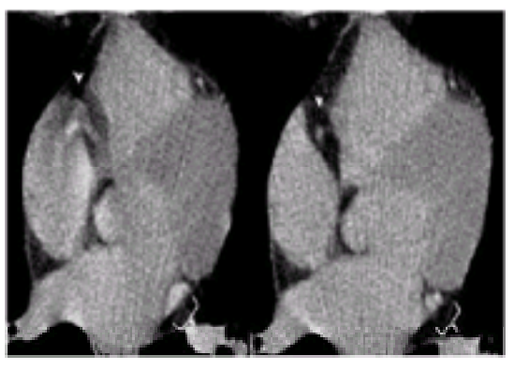
Scout images are planar tomograms, “landmarked” to the patient by a laser alignment system. The CT operator uses the scout images to prescribe subsequent scan volumes.

The unenhanced cardiac-gated CT is used to identify the location of coronary calcium, stents, catheters, foreign bodies, or other findings that partially obscure the contrast agent.

The timing scan is used to determine the transit time of contrast from the injection site to the ascending aorta. This sequence typically consists of a single slice repeated at some time interval (every 2 to 10 seconds) using a low-dose technique in the ascending aorta to determine the transit time of contrast. The transit time is then used as the delay time from the start of the contrast injection to imaging start for the CT coronary angiogram. The patient-specific delay time ensures that images are obtained in conjunction with the arrival of the intravenous contrast at the coronary circulation.

Contrast-enhanced EBT of the coronary arteries typically uses a sequential scan mode with prospective ECG triggering. Overlapping 3-mm slices are obtained by incrementing the table only 2 mm for each table position. Debate remains as to the optimal trigger point within the RR interval.

As discussed previously, MDCT systems can operate in either the sequential or helical mode. In the sequential mode, a four-or eight-slice scanner can acquire four or eight simultaneous data channels of image information. Thus, an eight-channel system can acquire, within the same cardiac cycle, 10 mm or 20 mm in coverage per heartbeat. In the helical or spiral mode of operation, a four or eight MDCT system can acquire four or eight simultaneous data channels while there is continuous motion of the CT table. The relative motion of the rotating x-ray tube to the table speed is called the *scan pitch* and is particularly important for cardiac gating in the helical mode. By combining information from each of the detector rows, the effective temporal resolution of the images can currently be set at between 100 and 200 ms, and the various cardiac phases can be reconstructed (*e*Fig. 56.5.1). An advantage of the helical acquisition mode is that there is a continuous model of the heart from base to apex, as opposed to the sequential cine mode in which there are discrete slabs of four or eight slices that have been obtained in a “step and shoot” fashion.



***e*FIGURE 56.5.1** The figure to the left demonstrates a standard half-scan reconstruction with a temporal resolution of 400 ms, with image data acquired on a four-channel multidetector computed tomography system, 1.25-mm slice collimation, 0.6 gantry speed, and a heart rate of 77 beats/min (General Electric LightSpeed Plus). The image to the right demonstrates the same helical scan data but processed with a two-sector reconstruction algorithm, resulting in an effective temporal resolution of 180 ms. Note how the proximal right coronary artery (*arrowhead*) and the left circumflex and great coronary vein (*bracket*) are resolved and motion-free on the multisector reconstructed image.

Computed Tomographic Angiography: Clinical Studies

Dr. Stephan Achenbach and colleagues have performed pioneering research in CT angiography with both EBT and MDCT. They have reviewed the ability of contrast-enhanced EBT to evaluate coronary artery bypass grafts (62), detect high-grade restenosis after percutaneous transluminal angioplasty (63), and determine patency of an infarct-related coronary vessel (64). They have also compared EBT coronary angiography with catheter-based coronary angiography in a study of 125 patients (65,66). The study was a direct comparison of the proximal and middle segments of the major coronary arteries, using the American Heart Association reporting system with both EBT and conventional coronary angiography. In this study, 25% of coronary vessels could not be evaluated (124 of 500 vessels), mostly because of respiratory artifacts and coronary calcifications. The number of patients with none of the four major coronary arteries of sufficient quality to evaluate was 15%. After excluding the 124 vessels, which could not be evaluated, EBT angiography correctly categorized 69 of 75 (92%) coronary vessels as having high-grade stenoses or occlusions, and 282 of 301 (94%) vessels were normal or had stenoses of less than 75% reduction in vessel diameter as compared with the standard of conventional catheter-based angiography (Fig. 56.6).

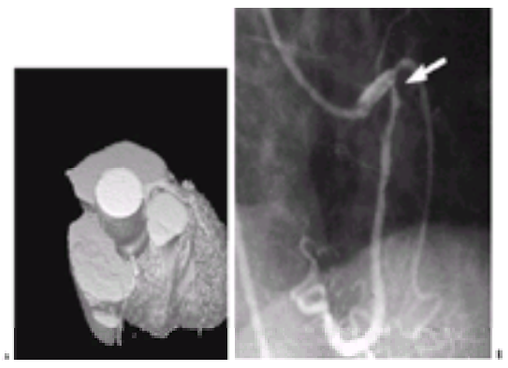


FIGURE 56.6 High-grade stenosis of proximal right coronary artery. Shaded surface display of a high-grade stenosis of the right coronary artery is demonstrated with contrast-enhanced cardiac computed tomography **(A)** (Imatron C150) and compared with stenosis (*arrow*) in the conventional coronary angiogram **(B)**. [Courtesy of S. Achenbach, Department of Internal Medicine II (Cardiology), University of Erlangen-Nuremberg.]

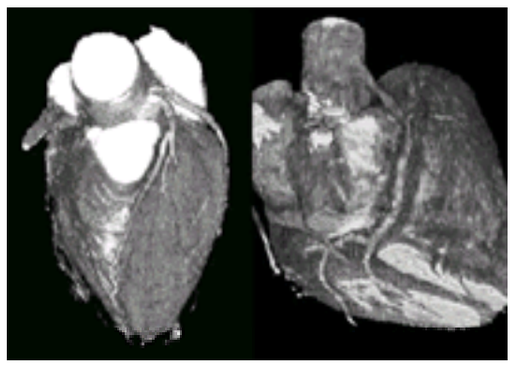
The authors noted that the majority of missed stenoses (false-negative results) were located in the right and left circumflex coronary arteries, in the segments coursing perpendicular to the transverse imaging plane where the 3-mm slice thickness and volume averaging may be important factors. They concluded that when image quality is sufficient, EBT contrast-enhanced coronary angiography “may be useful to detect or rule out high-grade coronary-artery stenoses and occlusions.”

Budoff and colleagues performed an additional study comparing EBT to conventional coronary angiography in 52 patients (67). They had similar high agreement between the two techniques for identifying coronary stenosis and reported good agreement between observers with the technique (kappa, 0.86). They also noted technical difficulties in the right and left circumflex coronary arteries related to “cardiac and respiratory motion and poor electrocardiographic gating.”

More recently, Achenbach and colleagues have evaluated MDCT in a study of 25 patients who at coronary angiography were excluded from having a hemodynamically significant stenosis (*e*Fig. 56.6.1) (65). They found no significant difference in measured coronary artery diameters at 100 points and a high correlation between MDCT-measured diameters and those at quantitative coronary angiography (R = 0.86). This initial study of contrast-enhanced cardiac-gated MDCT is encouraging in several respects. Greater lengths of the major coronary arteries were demonstrated with the four-channel MDCT than with previous validation studies using EBT and MRI, and there was a high correlation with quantitative coronary angiography. However, there remain unresolved problems of right coronary artery motion artifacts, limitations in image quality secondary to changes in heart rate during the scan acquisition, and radiation dose concerns.



***e*FIGURE 56.6.1** Normal computed tomographic coronary angiography (Siemens Volume Zoom). **Left:** The left anterior descending coronary artery from origin to cardiac apex is demonstrated. The proximal extent of the left circumflex coronary, which originates directly from the ascending aorta, is also seen. **Right:** The same three-dimensional data are viewed such that the origin and course of the right coronary artery is demonstrated in the atrioventricular groove. [Images were displayed using a volume rendering technique and are courtesy of S. Achenbach, Department of Internal Medicine II (Cardiology), University of Erlangen-Nuremberg.]

The continued rapid technological advancement of MDCT and EBT suggests that there will be further improvements in CT coronary angiography. Early efforts have demonstrated the feasibility of CT coronary angioscopy. In the near term, the development and introduction of MDCT systems with more than eight channels is likely. A 16-channel MDCT system could use the additional detector rows to improve temporal resolution, reduce breath-hold time, and reduce contrast dose. We will observe continued rapid advancement in CT for coronary angiography and a series of comparative studies evaluating these new CT techniques with existing measures of coronary heart disease.

Computed Tomographic Evaluation of Coronary Revascularization

Aortocoronary bypass grafts can be well demonstrated by modern CT techniques (Fig. 56.7). Through appropriate positioning of the imaging volume over the graft origin in the ascending aorta, the entire length of the graft can be imaged. When technically adequate studies are obtained, extremely high sensitivity and specificity for graft occlusions and hemodynamically significant stenosis can be achieved (Fig. 56.8) (62). Problems remain regarding poor breath holding and improper positioning of the imaging volume, which results in the proximal aspect of the aortocoronary graft not being imaged. Visualization of internal mammary grafts is often problematic. For all grafts, the presence of metallic surgical clips results in streak artifacts. These metallic artifacts typically prevent evaluation for stenosis at their location.

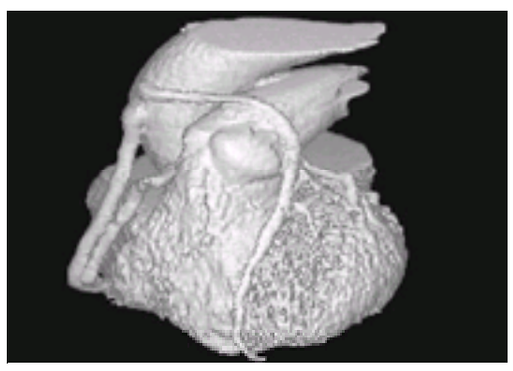


FIGURE 56.7 Patent aortocoronary vein grafts, patent (EBT Imatron C150). Two patent grafts are demonstrated in this three-dimensional shaded surface display. The more superior venous graft from the ventral aspect of the ascending aorta crosses the main pulmonary artery before anastomosis with the left anterior descending artery. The second vein graft courses alongside of the proximal right coronary before the anastomosis. [Courtesy of S. Achenbach, Department of Internal Medicine II (Cardiology), University of Erlangen-Nuremberg.]

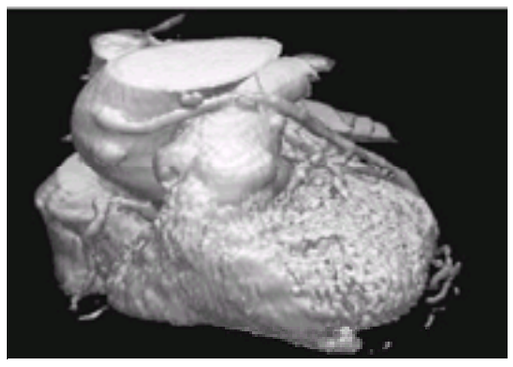

FIGURE 56.8 Aortocoronary vein graft occlusion (EBT Imatron C150). A patent aortocoronary graft to the left circumflex coronary is demonstrated. Note the proximal occlusion of the vein graft to the right coronary, which is identified as only a slight outpouching at the graft origin from the ascending aorta. [Courtesy of S. Achenbach, Department of Internal Medicine II (Cardiology), University of Erlangen-Nuremberg.]

Coronary stents have become one of the mainstays of interventional cardiology. Cardiac-gated CT can accurately describe stent location. Flow through stents can be evaluated and occlusion assessed. However, the metal intrinsic to current generation stents prevents CT from imaging the stent interior (Fig. 56.9).

FIGURE 56.9 Coronary stent (General Electric LightSpeed). A metallic coronary stent is demonstrated in the left anterior descending coronary artery. Although contrast enhancement can be seen proximal and distal to the stent, the higher attenuation of the metallic stent prevents direct visualization of the stent interior in most cases with existing computed tomographic reconstruction techniques. (Courtesy of Drs. Geoffrey Rubin and Curtis Coulam, Stanford University.)

Cardiac Valves and Chambers

Transthoracic echocardiography remains the major modality for imaging cardiac valves. However, in cases in which emphysema, obesity, or body habitus make transthoracic echo difficult, either transesophageal echo, MRI, or rapid CT can be used. Valve and mitral chordal thickening and valve stenosis can be identified using rapid CT. Vegetations and ring abscesses can also be detected. EBT has been used to image paravalvular pathology (68).

Rapid CT in patients with valvular abnormalities can reliably detect left atrial thrombus. Tomada et al. (69) studied 23 patients with valvular heart disease by conventional CT and found that it accurately detected left atrial thrombus. All patients with thrombus detected by CT had thrombus at surgery and 13 patients with no thrombus by CT were found to have no thrombus at surgery. Helgason et al. (70) compared EBT with transthoracic echocardiography in 40 patients presenting with stroke. EBT detected evidence of left atrial or left ventricular thrombus in 12 patients, whereas echo detected thrombus in only two patients.

Assessing Ventricular Function and Cardiomyopathies

Here too, however, rapid CT plays a supportive role to echocardiography. Employing the cine mode protocol provided on rapid CT scanners, the entire left and right ventricles can be imaged throughout the cardiac cycle. Sufficient contrast enhancement is usually achieved with 30 to 40 mL of contrast medium injected in a peripheral arm vein. These images accurately define the endocardial boundaries and allow precise measurements of ventricular volumes, ejection fraction, and left ventricular mass (71,72). In single-valve regurgitation, rapid CT can measure regurgitant fraction. The ability of contrast-enhanced rapid CT to quantify regional ventricular wall motion is important in the assessment of coronary artery disease. Ventricular function can also be evaluated during dobutamine infusion in a manner similar to that in echocardiography (73).

One interesting application of rapid CT is in the evaluation of patients with known cardiomyopathy, in whom the knowledge as to etiology might assist in management. Both EBT and MDCT have shown capability of distinguishing ischemic from nonischemic cardiomyopathy by the detection of coronary calcium (74,75).

Pericardial Disease

The fat found on the surface of the heart and the surrounding air-filled lung provides natural contrast that permits easy identification of a normal pericardium. Thickening of the pericardium can easily be identified, and this technology surpasses any other in identifying chronic pericarditis, particularly when it is calcific (Fig. 56.10). CT is therefore ideal for differentiating constrictive pericarditis from restrictive cardiomyopathy. The presence of normal pericardial thickness (i.e., 2 to 3 mm) excludes the diagnosis of constriction (76).

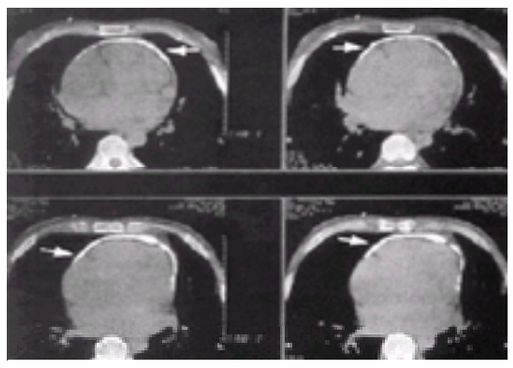

FIGURE 56.10 Thick, calcified pericardium is clearly demonstrated (*arrows*).

The tomographic format of CT makes it an excellent method to define primary and metastatic tumors of the pericardium. Extension into nearby mediastinal structures and to the lung can also be identified (77).

Congenital Heart Disease

Management of patients with congenital heart disease requires accurate information regarding structure and function of the cardiac chambers and great vessels. The traditional way of obtaining this has been with cardiac catheterization, and this remains the standard against which other imaging modalities are used in some institutions. Echocardiography is particularly useful and has replaced angiography to a great extent. There have been many reports of the use of CT as a modality to define abnormalities in structure and function of the heart. However, the role of CT in this application remains largely supportive to angiography and perhaps even more so to echocardiography.

In some adults with congenital heart disease, the diagnostic information provided by transthoracic echocardiography is limited because of chest deformities and difficulties finding adequate imaging windows. In these cases, ancillary methods such as transesophageal echocardiography, MRI, and CT can be of great help. The choice of these modalities depends largely on local experience and availability.

When imaging the hearts of infants and small children, it is essential to use a slice thickness that is small enough not to miss small structures such as the ductus arteriosus or anomalous coronary arteries. Most rapid scanners have the option of a 1.5-mm slice thickness or less. Another consideration in imaging tiny hearts is temporal resolution. There is little experience using MDCT scanners for imaging the hearts of infants. The experience with EBT scanners would suggest that the best temporal resolution achievable would be needed.

The most prominent role of CT in the assessment of congenital heart lesions involves structures that are relatively inaccessible to the ultrasonic probe, such as the pulmonary artery, the aorta's ascending and descending branch and arch, and the right ventricle.

These studies nearly always involve injection of contrast agent and, therefore, standard precautions should be taken. Scanning should begin within 10 to 20 seconds after injection of contrast. Usually a dose of 1 to 2 mL per kg is sufficient per injection. MDCT and EBT scanners should not require more than one injection to obtain high-quality images of cardiac chambers and vessels. Most scanners operate in a mode that allows visualization of the washin and washout of contrast from the cardiac chambers. When using EBT scanners, this is called the *flow mode*. Blood flow and shunt calculations can be done in a manner similar to that using indicator dilution methods in the cardiac catheterization laboratory. However, this is fraught with some difficulty due to beam hardening and other physical errors.

Specific problems for which rapid CT is indicated include determining the origin of the coronary arteries (78), visualization of the pulmonary arteries in cyanotic congenital heart disease (79), precise definition of aortic geometry in Marfan's disease (80), and partial or total anomalous pulmonary venous drainage (81). CT can also be used for visualization and assessment of patent ductus arteriosus (79,82) and aortic coarctation (83,84 and 85).

Aortic Disease

The thoracic aorta is an integral component of the cardiac CT examination and thoracic imaging in general. CT is the primary means of imaging the lung, thoracic trauma (blunt and penetrating), aneurysms, and aortic dissections (86). In the situation of an acute life-threatening event, CT can provide extensive information concerning the heart, aorta, and great vessels. In addition, during the same examination, the brain and spinal canal can be evaluated. The entire global CT examination (head, cervical spine, chest, abdomen, and pelvis) can be completed on modern MDCT systems in less than 15 minutes. These capabilities have made modern CT an indispensable tool in emergency departments and medical centers worldwide, and the development of the four-channel MDCT systems have further expanded these capabilities (87).

In the setting of blunt and penetrating trauma, CT of the chest can be extremely useful in diagnosis and as an aid to surgical management (86,88,89). Contrast CT can rapidly identify aortic tears, intramural hematoma, and dissection. In addition, the presence of mediastinal hematoma and other associated injuries can be assessed. These examinations are performed in critically ill patients who may require mechanical ventilation, invasive monitoring, intravenous infusion pumps, and cardiac pacing. The well-designed CT imaging suite is hospitable to life-support equipment, which can remain in the room and operational throughout the imaging procedure.

CT is playing an increasingly important role in the diagnosis and management of thoracic aortic pathology (90,91 and 92). Although MRI and transesophageal echocardiography can provide exquisite and unique information, the robust nature of CT often makes it the imaging modality of choice.

Contrast-enhanced CT can identify and classify aortic dissections and aortic aneurysms (Fig. 56.11 and Fig. 56.12) (93).

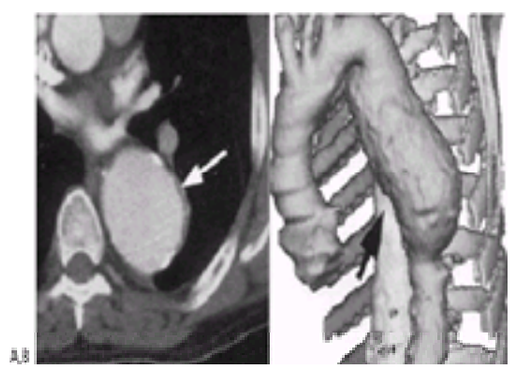

FIGURE 56.11 Descending thoracic aortic aneurysm. **A:** Image slice of atherosclerotic aneurysm (*arrow*). **B:** Three-dimensional reconstruction of thoracic aneurysm (Imatron C-150). Arrow points to large, cyndrical aortic aneurysm.

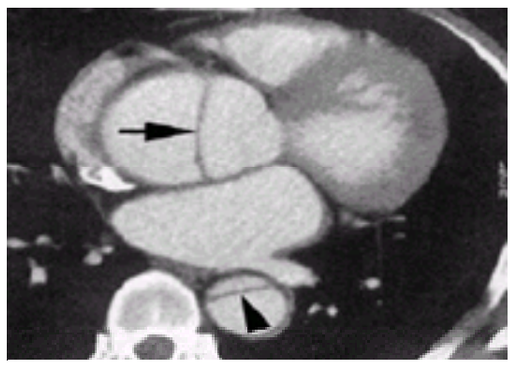

FIGURE 56.12 DeBakey type I or Stanford type A aortic dissection. Intimal flap is seen in both ascending and descending aorta (*arrows*) (Imatron C-150).

Advantages are the ability to image the entire aorta and beyond, demonstration of surrounding structures and organs, quantitative measures of aneurysm size and location, and a rapid examination time. Limitations are the negative effects of iodinated contrast on renal function, the rare adverse reactions to iodinated contrast, and the inability to directly measure blood flow. A current MDCT protocol for CT angiography provides high-resolution arterial phase images from the thoracic inlet to the femoral arteries. This coverage incorporates the entire aorta, as well as the organs of the chest, abdomen, and pelvis. Beyond classifying dissections as involving the ascending (Stanford type A) or descending (Stanford type B), CT can demonstrate associated findings critical to patient care such as mediastinal hematoma, pericardial effusions, pseudoaneurysm formation, and active extravasation of contrast from the aorta. Quantitative measurement of aneurysm size, location, and relation to branch vessels can be used for planning operative or intravascular repair and for monitoring postprocedure anatomy. The necessity for precise and quantitative measurements with CT has become more critical with the continued advancements in endovascular repair with stent grafts (94).

CONTROVERSIES AND PERSONAL PERSPECTIVES

To ensure efficacy and safety, national governments, including our own, have instituted regulatory agencies such as the Food and Drug Administration to ensure that research results and conclusions are accurate and appropriate. These measures are costly and something of a nuisance, but they protect the populace and the medical community from unscrupulous and evangelical crusades such as those of the laetrile enthusiasts of the 1960s. Much diagnostic testing has escaped from legal regulation (94). Doctors order and patients refer themselves for tests in order to discover hidden pathology and arrive at effective treatment. Much of this testing has questionable scientific validity.

During the 1990s, headlines appeared in the popular press regarding a new procedure for detecting heart disease and predicting heart attacks. At that time, there was no supportive scientific literature regarding the value of the new test, EBT, and for its stated purpose, to say nothing about its usefulness in improving outcomes.

Due to the initial popularity of the test, venture capital firms, small marketing operations, and university medical centers strapped for sources of income initiated and supported more coronary calcium screening projects. These grew into a kind of industry, organized by its strong bond to the, until relatively recently, unique manufacturer of CT equipment capable of performing this test. This industry promises to continue to mutate into other varieties of unproven radiographic self-diagnosis. Some coronary calcium screening centers already offer lung cancer screening and a few have expanded to “full body examinations,” which proclaim themselves capable of finding multiple pathologies.

Participants in this new calcium screening industry compiled calcium score databases and followed participants for coronary events. These research subjects rarely knew they were a part of a study and were usually not asked to sign consent forms verifying that they had agreed to participate in the evaluation of an investigational test. In 1999, the calcium screeners founded a new society, The Society of Atherosclerosis Imagers. They state that this new organization is dedicated to unbiased research regarding all aspects of arterial imaging. However, in its initial years, the major focus of the society has been to attempt to validate the conclusions that its members have already accepted, i.e., that EBCT and only EBCT can be used to guide therapy for coronary atherosclerosis.

Greed is not the major factor motivating the new society or the spread of coronary calcium screening adventures. The primary leadership of the calcium screening industry are well meaning enthusiasts who believe that they are executing rigorous scientific research. Indeed, the coronary calcium screeners have made important contributions toward the understanding of subclinical atherosclerosis. However, they often design their research not around hypotheses that require proof, but instead around preconceived conclusions that are then engineered backward into manipulated analyses of specially selected data.

It is hoped that this chapter can provide some balance to the almost exclusive opinion that has been heard, not only in the professional journals but on radio advertisements and commercial Web sites. In our opinion, CT of the heart will have an important role in medicine. In order to realize that role, researchers and clinicians must base medical decisions on evidence rather than on marketing.

SUMMARY

Rapid cardiac CT has remained outside of the realm of commonly used imaging technologies for the past two decades. This is partly due to justified reluctance of the medical community to accept new concepts and to limitations in available technology. It is probably largely due to the relative unavailability of scanners with the rapid exposure times required to image the beating heart.

Only now is rapid CT finding its place in the armamentarium of imaging technologies. Its application to screening for subclinical heart disease has received a limited endorsement from the American College of Cardiology and American Heart Association. The newer technology of MDCT is less expensive, more available, and probably equally accurate for cardiac imaging. We estimate that there are approximately 300 MDCT scanners made by four manufacturers and located in the United States that are capable of imaging the heart if fitted with the proper software and operated by knowledgeable personnel.

This has stimulated greater interest in CT imaging of the heart among cardiologists and radiologists. The failure of MRI coronary angiography to produce adequate endoluminal images and the promise of this achievement from rapid CT has sparked a flurry of trials of CT angiography of the coronary arteries.

Accepted applications of this technology at this time include evaluating for the presence of subclinical atherosclerosis in those at intermediate risk, evaluation of certain congenital heart lesions when other methods are not available or fail to produce adequate images, evaluation of aortic dissection or other aortic pathology when other methods are not available or fail to produce adequate images, and evaluation of the patency of aortocoronary bypass grafts and stents. The *a priori* use of CT coronary angiography, although promising, still awaits an accepted niche in cardiac diagnosis.

We hope that some of the readers of this chapter will take sufficient interest in this exciting field to pioneer further research and development of this evolving technology.

THE FUTURE

The recent history of CT coronary imaging has been unique in two ways.

First, until relatively recently, only one company produced equipment (EBCT) capable of obtaining accurate images of coronary calcium and of contrast-filled coronary lumina. Fortunately, several large medical imaging firms are now producing comparable equipment, which produces the same results at a reduced technical cost. This healthy industrial competition will lead not only to better images but also to more credible research.

Second, radiologists have largely rejected the accuracy of the older EBCT technology for scanning other organs or body parts due to high noise levels and other artifacts. Thus, once purchased, EBCT instruments must be used almost exclusively and extensively for coronary artery screening and CT angiography, or those responsible for the purchase must admit large fiscal mistakes. The advent of the newer MDCT scanning technology has obviated this problem in that these scanners can be shared between departments and have multiple approved uses.

These two features have stimulated the extreme positions taken by many in the coronary calcium screening industry that advocates therapeutic decisions based only on arbitrary thresholds of calcium score. This screening vogue is another American aberration soon to be cured by that even more American phenomenon, the free market.

MESA (47) will shed considerable light on the validity of coronary calcium screening. The results of MESA will determine whether a clinical trial similar to those that have proven the benefits of mammography is needed. If MESA shows powerful predictive values (relative risks greater than 8) for coronary events, then such a trial may not be necessary. However, if, on the other hand, the results of MESA are more modest, a decision as to whether or not such a trial is needed will have to be made.

ACKNOWLEDGMENT

The editorial assistance of Zephyr Detrano is deeply appreciated.

OVERVIEW

Intraoperative echocardiography (IOE), mostly using transesophageal methods, provides an important means of assessing cardiac structure and function during cardiac and noncardiac operations (1,2,2a). IOE helps refine surgical plans immediately before cardiac surgery by defining the surgical mission and determining the severity and mechanism of the cardiac dysfunction. This provides the surgeon with an up-to-the-minute definition of the patient's anatomy and physiology, to help define or refine the objectives for surgery and to optimally plan repair of the dysfunctional valves, congenital abnormalities, coronary problems, and other disease. After surgery, the postpump IOE provides a safety net for immediately checking the success of the procedure at a time when further surgery can be performed (a second pump run) during the same thoracotomy. The frequency of changes in operative management varies directly with the difficulty of the procedure involved and is substantial for valve repair of various types, especially high for aortic valve repair, aortic homograft implantation, and myectomy for hypertrophic cardiomyopathy. This chapter describes the history, purposes, methodology, and effectiveness of IOE, as well as its impact on numerous types of surgeries. It is likely that IOE will contribute to the future development of innovative and emerging surgical procedures.

GLOSSARY

Contrast echocardiography: Imaging during injections to increase visualization of selected structures.

Epicardial echocardiography: Performed with the transducer placed directly on the surface of the heart during surgery.

Loading conditions: Factors related to intravascular volume and the pressures on the input and output sides of the heart.

Postpump: Refers to the IOE done after discontinuation of cardiopulmonary bypass.

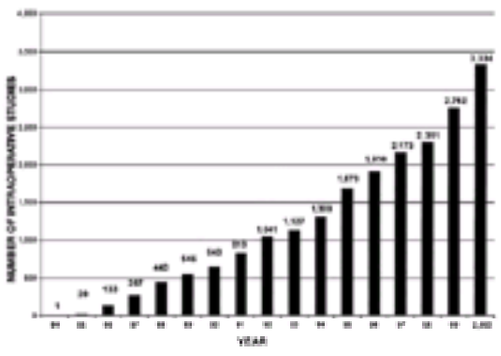
Prepump: Refers to the IOE done before institution of cardiopulmonary bypass.

Second pump run: A second run of cardiopulmonary bypass for additional surgery done to correct residual problems after the initial surgery was thought to be sufficient.

Valve repair: Surgery to correct valve dysfunction using the native valve tissue, without removing or replacing the valve.

HISTORICAL PERSPECTIVE

IOE has grown substantially over the last decade (*e*Fig. 57.0.1). Its first use was in 1972 by Johnson et al. (3) with the premise, now substantiated, that immediate evaluation of valve function would aid in mitral valve operations. In 1975, M-mode transesophageal echocardiography (TEE) was reported by Frazin et al. (4); from 1977 to 1981, two-dimensional TEE for black and white imaging was reported (5,6). However, imaging of the quality available then, without flow information, provided little practical benefit to the surgical process. The first modern use of intraoperative TEE was reported by Kremer et al. from San Francisco in 1982 (7,7a) during general surgery. Topol et al. (8) in 1984, using TEE with imaging alone without Doppler, looked at recovery of dysfunctional segments immediately after coronary bypass surgery. In the same year, Goldman et al. (9) showed the first practical use of IOE in valve surgery, with epicardial contrast echocardiography using transthoracic transducers. Soon thereafter, color flow mapping was applied to the evaluation of valve repair using epicardial techniques (10,11,12 and 13). TEE with color Doppler became available in 1987 (14,15) and has become the dominant mode used in the practice of IOE over the past 14 years (16). The advent of biplane (1989) (17) and multiplane (1992) (18) TEE probe technology further added to the clinical capabilities of IOE. Newer technologies including parallel processing, harmonic imaging, Doppler tissue imaging, three-dimensional imaging, and digital storage place intraoperative TEE in the forefront of the development of modern cardiac surgery.



***e*FIGURE 57.0.1** The Cleveland Clinic experience with 20,509 intraoperative echocardiography studies, performed from 1984 to 2000, showing the number of intraoperative studies done per year.

PREPUMP INTRAOPERATIVE ECHOCARDIOGRAPHY: GENERAL CONSIDERATIONS

Purposes

IOE before cardiopulmonary bypass (prepump) is useful in certain groups of patients undergoing cardiac surgery, for several important reasons. It provides an accurate way to determine the mechanism and severity of the problem requiring surgery (19). The prepump study is also helpful to obtain baseline information about an anesthetized patient that may be of better quality or reflect interval changes compared with preoperative studies.

Performed appropriately, echocardiography has the attribute of completeness, with its ability to diagnose the structure and function of all cardiac valves (19a) and chambers, even those that are not the primary problem mandating surgery. Dysfunction of other valves that is not treated effectively can lead to serious and potentially life-threatening complications and be mistaken for failure of the primary operation. This results from mistakes in the preoperative definition of the patient's problem or from changes that occur in the interval between workup and surgery. The prepump TEE often finds problems that were not detected on the preoperative evaluation, most commonly, a clot in the left atrial appendage or a patent foramen ovale.

A final purpose of the prepump IOE is to define methods of cannulation. This is particularly important when there is severe aortic atheroma, with its potential to embolize if disrupted by the operative process. It is also important in placement of intracardiac devices such as those used for port access surgery (19b). The prepump study has also been used to define optimal methods of cardioplegia administration (19c). For example, aortic regurgitation (AR) of even moderate severity may limit the effectiveness of antegrade cardioplegia administration via the aortic root (20). Placement of a coronary sinus catheter for retrograde cardioplegia can also be confirmed by TEE (21,22).

Methods

Two methods of intraoperative imaging have been employed, TEE and epicardial echocardiography. TEE has substantial advantages in most situations, including the ability to monitor cardiac function without an echocardiographic transducer entering the sterile field or interrupting the surgical process. Posterior structures such as the atria and pulmonary veins are seen better with transesophageal echocardiography.

However, there is a small risk of serious trauma with the TEE probe (23), including a slight increase in swallowing problems (23a). After use of intraoperative TEE, a 12% incidence of transient postoperative hoarseness has been reported (24), although this may result also in part from the endotracheal tube. One study of 7,200 intraoperative TEEs found severe odynophagia in 0.1%, dental injury in 0.03%, endotracheal tube malpositioning in 0.03%, upper gastrointestinal hemorrhage in 0.03%, and esophageal perforation in 0.01% (24a).

The TEE transducer is introduced after the patient is anesthetized, the trachea intubated, an orogastric tube inserted temporarily to remove stomach contents, and the hypopharynx filled with liberal amounts of water-soluble lubricant. If “blind” passage of the TEE scope with gentle anterior traction on the jaw is unsuccessful in passing the scope beyond the hypopharynx (20-cm depth), then a laryngoscope is employed to guide insertion of the transducer. Further details on TEE probe insertion in awake patients are provided in Chapter 52.

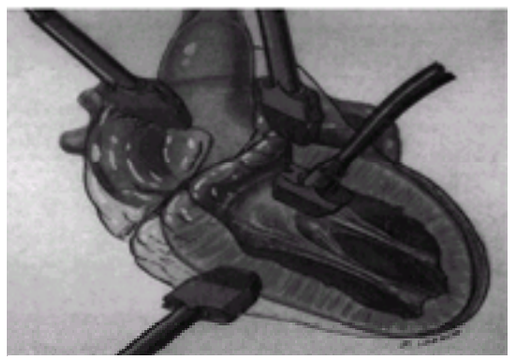
For epicardial echocardiography of the heart itself, a standard transthoracic phased array transducer (3.5 to 5.0 MHz) is used. Epicardial echocardiography has the advantage that certain anterior structures, including the left and right ventricular outflow tracts and ascending aorta, are in the near field (25,26). For epivascular imaging, a standard pediatric transthoracic phased array transducer (5 to 8 MHz) or a linear array transducer (6 to 10 MHz) is used. The probe is inserted inside two sterile sleeves with sterile lubricant between them and on the surface of the probe to eliminate air (13). The transducer is placed on the surface of the beating heart or the aorta (27,28).

During epicardial echocardiography, the surface of the heart should be moistened with saline, but the pericardium does not need to be filled with fluid. Although it is not needed for most purposes, a standoff device, such as a glove filled with saline, is a valuable way to see the near field within the first few millimeters of the face of the transducer. The echocardiographer, who is scrubbed for surgery, must verbally direct another individual who is in the nonsterile portion of the operating room to adjust the instrument controls on the echocardiographic machine in concert with the designs of the study.

Epicardial and epivascular echocardiography is now used mainly for epiaortic scanning for atheroma. It is also used for selected other cases when the available TEE capability falls short of the clinical needs, for example, for recording the left ventricular (LV) outflow tract gradients in hypertrophic cardiomyopathy (26), recording the right ventricular outflow tract gradients in congenital pulmonic stenosis, or other cases in which TEE data appear to be suboptimal or unobtainable.

Imaging Planes

The tomographic planes available for diagnosis using multiplane TEE have been described in multiple publications (29,30,30a,30b) and elsewhere in this book. We have described four epicardial transducer positions and imaging planes (*e*Fig. 57.0.2) making up a complete evaluation of cardiac anatomy and physiology (13,31,32). The parasternal and subcostal equivalent views are similar to the transthoracic windows of the same name. The aorta–pulmonary artery sulcus view is obtained by placing the transducer against the left side of the aorta, in the sulcus between it and the pulmonary artery, using the aorta as a standoff device so that the primary areas of the left heart are in the focal zone of a standard transducer. A fourth view, the aorta–superior vena cava view, is obtained by placing the transducer against the right side of the ascending aorta, pointing inferior toward the LV outflow tract and aortic valve. The latter is extremely useful for measuring LV outflow tract velocities using continuous wave Doppler-echocardiography.



***e*FIGURE 57.0.2** The four standard positions for epicardial transducer placement: the parasternal equivalent view, the aorta–pulmonary sulcus view, the subcostal equivalent view, and the aorta–superior vena cava view. (From Cosgrove DM, Stewart WJ. Mitral valvuloplasty. *Curr Probl Cardiol* 1989;14:359–415, with permission.)

Goal-Oriented Study

IOE is usually time-limited by the pressing needs to reduce anesthetic and personnel time. The design of the IOE study should provide an efficient balance between the objectives of focusing on the primary surgical mission versus obtaining a complete imaging and Doppler examination of the entire heart and great vessels. The first thing to examine should be the structures related to the objectives that mandated the IOE study (e.g., the anatomy and physiology of the valve on which surgery is planned) (32a). Doing this in the first few minutes may become particularly important if the patient thereafter becomes hemodynamically unstable, the electrocautery must begin, or the surgical team must prematurely initiate cardiopulmonary bypass. In most cases, there is sufficient time after the most important questions are answered to record a complete study, involving a long-axis and short-axis view of all four chambers, the great veins and arteries, and all four valves, using various imaging and Doppler modalities.

Idealizing Room and Loading Conditions

For diagnostic intraoperative studies, the imaging conditions, instrument controls, and transducer contact should be optimized, including dimming the operating room lights, avoiding electrocautery during key periods, and periodically relubricating the imaging portion of the esophagus with water-soluble lubricant.

Usually the amount of valvular dysfunction on the TEE matches that of the preoperative assessments (33). However, the loading conditions in the operating room can sometimes be quite aberrant. Often there is relatively less sympathetic tone and less intravascular volume during anesthesia, compared with ambulatory conditions. Therefore, the ejection fraction, amount of valvular regurgitation, or stenotic gradient found by IOE is often slightly different from what it was in the echocardiography laboratory or the catheterization laboratory (31,34), which is probably more reflective of the patient’s real life. Manipulation of loading conditions may change the amount of regurgitation (35). To optimize diagnostic information in some cases, it is useful to give hemodynamic challenges, such as increasing intravascular volume or transiently raising afterload with multiple 100-µg boluses of intravenous phenylephrine.

Record Keeping and Image Archival

A written record of the diagnoses made by TEE is an important part of the job of IOE. In addition, archiving images either by videotape or digital methods (35a) is important for comparison with previous and subsequent studies. Both of these issues are important when medical-legal issues regarding the operation are raised.

Indications for Intraoperative Echocardiography

The types of patients for whom intraoperative TEE is useful are detailed by the groups of disease states listed in this chapter. Thys et al. have published guidelines for perioperative echocardiography, delineating three categories: category I for those supported by strong evidence of clinical value for improving outcome; category II for

applications supported by weaker evidence; and category III for applications that are uncertain to have clinical benefit (35b). This chapter discusses most of these indications in detail.

Outcome Studies for Prepump Intraoperative Echocardiography

One study by Chaliki et al. compared the prebypass TEE findings with surgical observations in a large group of 918 cases; TEE information was found to be quite reliable, showing discrepancies with operative findings in only 2.5% of cases (35c).

Several studies have determined the frequency with which the prepump IOE contributes to a change in surgical management. In several studies of mixed multiple groups of valvular lesions, prebypass imaging diagnosed unsuspected findings that changed the planned operation in 10.8% to 19.0% of patients (36,36a). In another study of 246 patients with ischemic mitral regurgitation (MR), prepump TEE resulted in a change in the operative plan with respect to the mitral valve in 27 patients (11%), involving less MR than expected in 22 patients and more MR in five patients (34). In patients who come to the operating room in an emergent situation with unstable hemodynamics, the emergency intraoperative TEE has an even larger impact on clinical outcome, with new findings discovered in 80% of patients and an alteration of the planned surgical procedure in 23% (36b).

Ungerleider et al. (37) studied 328 patients before surgery for congenital heart disease and found that IOE played a role in surgical planning in 44% and discovered previously unappreciated details of anatomy in 18% of patients. Another author found a major problem on the prebypass echocardiogram that led to a change in plans in 6.7% (37a). In an early study of a mixed group of 426 consecutive patients with a mixture of valvular problems, our group found that 40 patients (9%) had a change in the operative mission based on the prepump IOE (unpublished data). In another study from our institution, Secknus et al. (38) evaluated 121 patients in whom prepump intraoperative TEE studies were performed to assess MR and the need for mitral repair; changes in operative plan occurred in 6.1%, mostly in cases in which less mitral disease was found than was expected on the basis of the preoperative workup.

Some findings, such as a thrombus in the left atrial appendage, should prompt operative removal. When this is found in a patient without mitral valve disease, removal may require bicaval rather than single-stage cannulation for the venous return to the heart-lung machine. However, it is not certain whether closure of the appendage should be recommended, as it remains at least partly open even after attempted closure in 36% of such cases (37b).

Click et al. from the Mayo Clinic reported a large series of 3,245 patients undergoing IOE, in whom new information was found before bypass in 15% of patients. This directly affected surgery in 14% of the patients. The most common new prepump finding was a patent foramen ovale, which was closed in the majority of patients (38a). The series by Click et al. is probably the most intensively reported large group of patients undergoing IOE. The important changes in plans included a decision to do something that had not been planned in 9.6% of the total, including a new decision to close a patent foramen ovale in 2.7%, to perform valvular surgery in 2.7%, and to remove a previously undiagnosed thrombus in 1.1% of the total. There were also decisions based on the prepump echocardiogram *not* to do something that had been planned in 3.9% of the total, which were mostly decisions not to do surgery on a valve for which the preoperative workup had indicated a need for surgery (3.6% of the total of 3,245 patients) (38a).

Another more recent study by Couture et al. found that prepump IOE led to a modification of planned surgical intervention in 30% of cases, with a frequency of 39% in complex surgical procedures, 19% in valvular surgery, and 10% in coronary artery bypass surgery (38b). Still another study of 5,016 cases by Mishra et al. found that prebypass imaging yielded unsuspected findings that either helped or modified the surgical plan in 12% of valve procedures and in 27% of coronary procedures (38c).

Of note, the decision not to do surgery that had been planned by the physicians who referred the patient for surgery is a change in plans that should not be taken lightly. Doing the right surgery is as important as doing it well. All patients who have cardiac surgery should have complete preoperative evaluation to decide on the surgical mission. As in all clinical medicine, decisions must be based on an integrated picture of the patient's age, overall health, ventricular function, and myriad other valvular and nonvalvular determinations. The prepump study should not be a substitute for a thorough workup before the patient enters the operating room. Because the physician performing the IOE often has not had extensive contact with the patient before surgery, integrating the IOE examination with the preoperative and general health considerations of the patient must often be done through the chart. When new considerations arise with the IOE, a telephone call to the primary clinician who referred the patient for surgery may help to integrate the intraoperative decisions. Only in dire circumstances should one rely solely on the prepump IOE to define the objectives of the operation.

POSTPUMP INTRAOPERATIVE ECHOCARDIOGRAPHY: GENERAL CONSIDERATIONS

Purposes

The primary purpose of echocardiography done after cardiopulmonary bypass (postpump) is to determine the success of the primary surgical mission. Like the prepump study, the postpump study should be goal oriented, examining the most important issues first (32a), with one modification. The postpump IOE should first evaluate the most vulnerable aspect of the surgery for immediate failure, which may be different from the primary indication for surgery. For example, in a patient with mitral stenosis with severe mitral calcification and functional tricuspid regurgitation (TR), the mitral replacement may be more important in the clinical improvement than tricuspid repair, but the most important problem to examine first on the postpump TEE study is the tricuspid repair, because the mitral prosthesis is less likely to have initial failure.

The postpump TEE is much more relevant if performed after establishing hemodynamic stability under conditions that match the ambulatory state, whereas misinformation can result from studies done during aberrant transient conditions early after coming off bypass. Imaging should be done before administration of protamine and removal of the arterial and venous cannulae, so that cardiopulmonary bypass can be reinstituted if problems are found. The exception to this is the patient with mild periprosthetic regurgitant jets found on postpump TEE, which have a tendency to improve after protamine is given (38e).

In some cases, the primary problem mandating surgery persists (e.g., residual valvular regurgitation after attempted repair of that valve). In occasional cases, new problems occur, such as new regurgitation of an additional valve not previously abnormal, or another complication. In general, we consider *no* valvular regurgitation to be the ideal result of surgery and mild (1+) regurgitation to be an acceptable outcome. Moderately severe or severe (3+ or 4+) are problematic and warrant a "second pump run" for further surgery during the same thoracotomy to correct the problem. In most cases of moderate (2+) regurgitation, further surgery is usually indicated, but the situation must be individualized, depending on the patient's age and overall condition. In such cases, we recommend careful, complete echocardiographic evaluation for a period of 5 to 10 minutes, without giving protamine or decannulating, during which time the hemodynamic conditions should be idealized and even provoked. Sometimes the regurgitation decreases in severity with recovery of ventricular function. In other cases, the regurgitation is obviously bad enough for further surgery. In many cases with moderate residual regurgitation, we find it useful to increase mean arterial pressure, observing the amount of regurgitation with this "afterload stress" echocardiogram. If the amount of MR or AR persists at a moderate (2+) level, or increases, the patient should probably undergo further surgery with a second pump run.

Numerous types of intraoperative provocation can be used to bring out postpump valvular dysfunction in cases in which the amount of residual problems is borderline or when loading conditions might otherwise lead to false reassurance. The most commonly used is the phenylephrine challenge, which is useful for borderline amounts of aortic and MR (39). Boluses of 100 µg of phenylephrine are given every 30 to 120 seconds to bring mean arterial pressure up to approximately 110 transiently. If moderate or more regurgitation results, consideration should be given to further surgery on that valve. Other types of provocation used in the operating room include isoproterenol for hypertrophic cardiomyopathy, intravascular volume challenge for any lesion, and partial pulmonary artery occlusion for TR. It is far better to know of a latent problem immediately in the operating room than to learn about it a day or a week after surgery.

Another purpose of postpump intraoperative imaging is to diagnose complications of surgery. These include iatrogenic problems generic to cardiac surgery, including outflow and inflow obstruction, aortic dissection at the site of aortic cannulation (38d), atrial septal defect, periprosthetic regurgitation, and intraoperative myocardial infarction. Definition of these cases by IOE allows a rational basis for pharmacologic management or for performing further surgery during the same thoracotomy.

The frequency of second pump runs overall is 5.4% of IOE studies in our series (19a), and it varies depending on the type of surgery performed and its complexity (Table 57.1). The procedures at highest risk of initial failure are myectomy for hypertrophic cardiomyopathy and aortic valve repair. Which surgery is most vulnerable to initial failure should be a factor in deciding which patients to invest resources for IOE and which problem to address first with the postpump study (16). Surprisingly, over the past 15 years, the frequency of second pump runs at our institution has essentially stayed the same, both overall and within each of the categories followed.

	Cases (no.)	Second pump runs (no.)	Second pump runs (%)
Total	9,826	531	5.4
Mitral repair	3,032	199	6.6
Aortic repair	516	74	14.1
Tricuspid repair	518	28	5.3
Congenital	681	39	5.7
Hypertrophic cardiomyopathy	232	42	17.9
Thoracic aneurysm	560	21	3.8

TABLE 57.1 FREQUENCY OF SURGERIES STUDIED WITH INTRAOPERATIVE ECHOCARDIOGRAPHY AND SECOND PUMP RUNS PERFORMED (1984 TO 1996)

In the large study from the Mayo Clinic by Click et al., new information was found by IOE after bypass in 6% of the patients, resulting in a change in surgery or hemodynamic management in 4% of the total; it was highest in a selected group of patients with coronary artery bypass graft surgery (CABG), aortic surgery, and hypertrophic cardiomyopathy (38a). Michel-Cherqui et al. reported a frequency of 2.5% of 203 cases in which immediate surgical intervention was required on account of the postpump TEE findings (36a).

The converse of these data is that the postpump study finds a satisfactory result with resolution of the initial problem in the majority (94% to 97%) of patients; this also provides a substantial benefit to the patient. When abnormal hemodynamic changes occur outside the operating room in the early postoperative period, the management team can be confident that the changes are not due to failure of the primary surgical mission if the postpump study has shown that it was accomplished.

Another purpose of the postpump study is to reassess ventricular function. It is important to document changes resulting from elimination of the primary surgical problem and to determine a new baseline for later comparison. However, early after cessation of cardiopulmonary bypass, LV function may be transiently depressed by residual effects of hyperkalemic cardioplegia or air embolization to the coronary bed. Finally, IOE can define the location and severity of intracardiac air to assist in its removal.

Outcome Studies

In the case of residual lesions on the postpump study, there is the opportunity to correct the problem while the chest is still open during the same thoracotomy. Although one study showed a good correlation between residual regurgitation found by the postpump IOE and postoperative angiography results (40), the amount of regurgitation found with both studies is subject to variations in loading conditions (40a). Selective performance of second pump runs for further surgery may improve patient outcome. However, no controlled trials exist to determine the eventual outcome if persistent valvular dysfunction or other problems are not immediately addressed. Furthermore, determination of the exact threshold for second pump runs is difficult, also because of the lack of adequate case-control studies.

In our experience with patients having second pump runs for mitral repair, there was no excess in-hospital mortality or complication rates compared with matched controls who had no problems evident on postpump imaging (41). However, Duran et al. did find a higher mortality (16.6%) in those whose initial repair failed, requiring a second pump run, compared with the mortality in patients who had initially successful repair (1.4%) or mitral replacement (4.0%) on the initial pump run (42). This obviously depends on the threshold of going back on pump and whether there were predisposing factors about those patients that were associated with higher risk to begin with.

The policy of performing further surgery after procedures that are less than completely successful was reinforced by an early study by Sheikh et al. (36), in a group of 154 consecutive patients having valvular surgery. Because of the newness of IOE and uncertainty about its validity, the surgery was not revised, despite moderate to severe postpump valvular dysfunction. The patients with residual valve dysfunction on the postpump study had a greater risk of early postoperative complications (86% vs. 15%) and mortality (43% vs. 5%).

In one study of wall motion after coronary bypass, postpump ischemia diagnosed by TEE was a significant predictor of outcome. One-third of patients with postbypass ischemia by TEE had adverse outcomes versus none of those without TEE ischemia (43).

In several groups of patients, a borderline amount of valvular dysfunction after surgery was present on the postpump study that was at or below the threshold for second pump runs, usually mild or moderate (1+ or 2+) regurgitation. This group was compared with patients with an “echo perfect” result who had no residual valvular dysfunction by postpump TEE. In the case of mitral valve repair (44), homograft aortic valve replacement (45), and aortic valve repair (45d), there is greater risk of reoperation in early follow-up that is predicted by mild to moderate postpump valvular dysfunction by IOE. In one follow-up study of mitral repair, the group of patients who had intraoperative echocardiographic studies performed were less likely to require reoperation within 10 years of follow-up than patients who did not have IOE (45a).

MITRAL VALVE REPAIR

In mitral valve dysfunction, IOE is particularly useful for determination of the mechanism of the problem, prediction of the methods that will be required for surgical repair, diagnosis of complications of repair, and assessment of the postrepair results of the surgery.

The prepump IOE has been found to change the operative plans in 6% to 17% of cases (36a,38). With both imaging and color Doppler, the mitral valve is investigated systematically by TEE using a short-axis view from the transverse transgastric window, and multiple midesophageal long-axis views (2,45b,45c). Most of the long-axis views help define *which leaflet* is involved. For examining which *portion* of the leaflet is most involved (Fig. 57.1), the best views are the short-axis transgastric view and the midesophageal intercommissural long-axis view. The latter is obtained from the midesophageal window with the multiplane angle at approximately 60 degrees, with the plane parallel to the line between the mitral commissures.

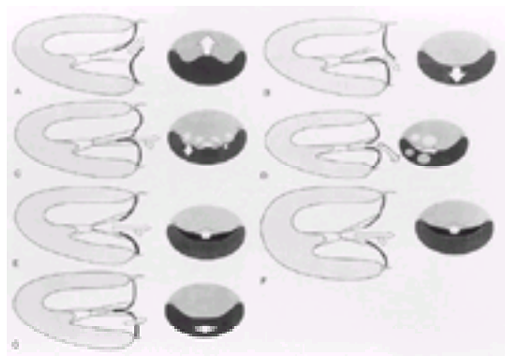

FIGURE 57.1 Mechanisms of mitral regurgitation, determined by echocardiographic assessment of leaflet motion and Doppler assessment of jet direction. Diagrams show long-axis views (left side of each pair) and short-axis views (right side of each pair). **A:** Posterior leaflet flail or prolapse with an anterior jet direction. **B:** Anterior leaflet flail or prolapse with a posterior jet direction. **C:** Bileaflet chordal elongation, flail, or prolapse with a central or posterior jet direction. **D:** Posteromedial papillary muscle infarction causing elongation or disruption of support to both leaflets at the commissure with a jet emanating from the medial commissure, directed posterolaterally. **E:** Leaflet restriction with a central or posterior jet direction. **F:** Ventricular-annular dilation displacing the papillary muscles outward with a central or posterior jet direction. **G:** Leaflet perforation with an eccentric location of the jet origin, originating from the leaflet body, away from the coaptation line. (From Stewart WJ, Currie PJ, Salcedo EE, et al. Evaluation of mitral leaflet motion by echocardiography and jet direction by Doppler color flow mapping to determine the mechanisms of mitral regurgitation. *J Am Coll Cardiol* 1992;20:1353–1361, with permission.)

Quantitating the severity of MR (a topic covered in Chapter 51) is accomplished using a weighted average of information from left atrial spatial mapping (31,46,47), proximal jet width (48), pulmonary vein pulsed Doppler (49), and proximal flow convergence information (50). It appears that TEE and epicardial echocardiography give relatively equivalent assessments in quantifying MR (51). Both are more sensitive than transthoracic echocardiography. As mentioned previously, hemodynamics in the operating room often include less intravascular volume and less afterload than the ambulatory state, which often decreases the amount of MR (51a).

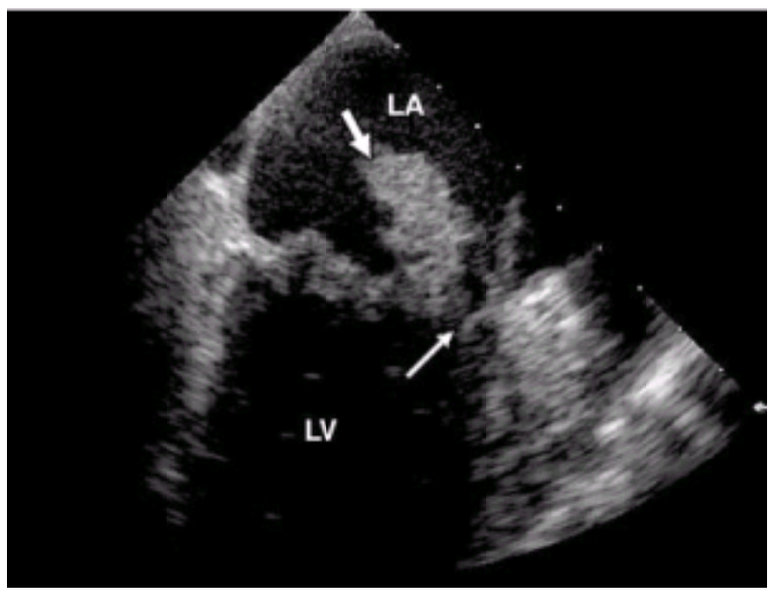
Determining the Mechanism of Mitral Regurgitation from Leaflet Motion and Jet Direction

For determination of the mechanism of MR, IOE uses two-dimensional evaluation of leaflet motion and color flow Doppler evaluation of jet direction (19). Leaflet motion is separated into MR associated with excessive, normal, and restricted leaflet motion, a system derived from the surgical system used by Carpentier et al. (52). These leaflet motion groups, associated with jet direction characteristics, characterize the various mechanisms of MR (Table 57.2).

Leaflet motion	Problem	Jet direction	Leaflet surgery	Annulus
Excessive				
	PL MVP	Anterior	Quad resection	Annuloplasty
	AL MVP	Posterior	Chordal transfer (chordal shortening, artificial chordae)	Annuloplasty
	Bileaflet MVP	Central*	Quad resection	Annuloplasty
	Papillary muscle rupture	Commissural	Papillary muscle reimplantation	Annuloplasty
	Commissural chordal rupture	Commissural	Suture commissure, chordal transfer	Annuloplasty
Normal				
	LVE, apical tethering	Central/posterior	None	Annuloplasty
	Perforation	Eccentric origin	Suture, patch	Annuloplasty
Restricted				
	Restricted leaflets	Central/posterior	CMC, debridement, division of fusion	Annuloplasty

AL, anterior leaflet; LVE, left ventricular enlargement; MVP, mitral valve prolapse; CMC, open mitral commissurotomy; PL, posterior leaflet.
*In bileaflet prolapse, jet direction reflects the most dominant problem; may be anteriorly directed with posterior greater than anterior prolapse, or posteriorly directed with anterior greater than posterior prolapse.

TABLE 57.2 INFLUENCE OF JET MECHANISM AND CHARACTERISTICS ON SURGICAL PLANNING



Intraoperative transesophageal echo of a myxomatous mitral valve with large vegetation (*thick arrow*) and a large perforation (*thin arrow*) at the base of the anterior mitral leaflet from endocarditis. One can easily see this hole on two-dimensional imaging, and the color flow can be seen on image.

Each mechanism demands specific surgical techniques for optimal correction, and the feasibility of repair varies by the mechanism of regurgitation as defined by the preoperative echocardiogram (Table 57.3) (53) and by the etiology (54). In valves that are extensively calcified, fibrotic, or destroyed by endocarditis, repair is impossible. No matter what the mechanism of MR, almost all patients undergo annuloplasty as a component of the repair, in addition to the other surgical maneuvers, detailed in the following sections.

	No.	Feasibility of repair (%)	Initial failure of repair (second pump runs)
Excessive	222	82.9	4.4
Posterior	109	89.0	1.8
Anterior	49	61.2	8.2
Posterior and anterior	64	82.8	0
Restricted	140	35.7	10.0
Normal	65	84.6	0
Total	427	67.7	4.5

From Sun JP, Yang XS, Wayer DL, et al. Mitral valvular leaflet excursion by echo is a marker for the feasibility of repair and risk of failed repair. Circulation 1999;[illegible]

TABLE 57.3 PREDICTION OF THE FEASIBILITY OF REPAIR BASED ON THE PREOPERATIVE ECHOCARDIOGRAM

For *excessive* leaflet motion, the jet is deflected *away* from the most abnormal leaflet. The easiest type to repair is a flail or prolapsing posterior leaflet (Fig. 57.2), which most commonly involves the middle scallop and can be repaired in 89% of cases (55). The excessive leaflet motion is readily detected by two-dimensional echocardiography and the jet is deflected anteriorly, as assessed by color Doppler in the operating room before cardiopulmonary bypass. This problem is corrected by quadrilateral resection of the unsupported leaflet followed by suture closure of the gap (54).

AO, aorta; LA, left atrium; LV, left ventricle; RA, right atrium.

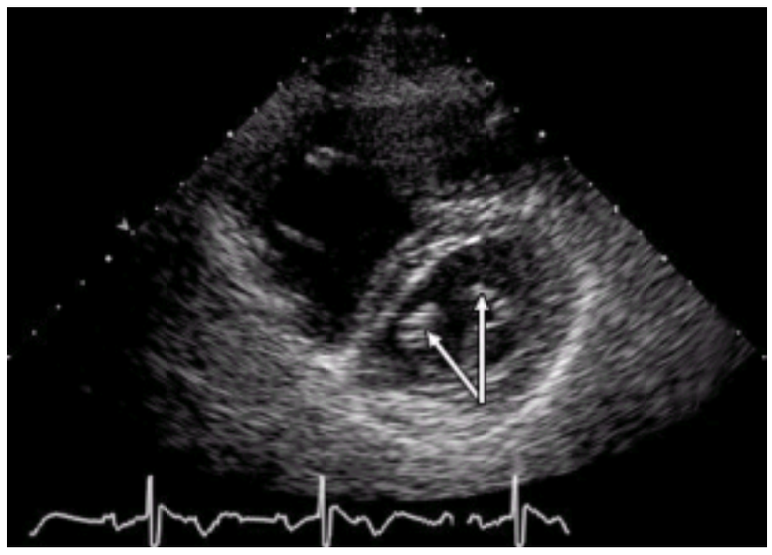
By comparison, other types of MR are more difficult to repair. For example, it is feasible in 61% of cases to repair MR due to prolapse or flail of the anterior leaflet (Table 57.3). This is diagnosed by its characteristic posterior jet direction (19). Repair requires a surgical maneuver to provide chordae to the unsupported anterior leaflet, which can be done with chordal transfer, or less commonly with chordal shortening (54) or replacement with artificial chordae (56). Repair of MR due to prolapse of both leaflets can usually be corrected by surgery only on the posterior leaflet, involving a quadrilateral resection, without anterior leaflet maneuvers (56a). However, when there is extensive destruction and flail of both leaflets, repair is feasible in only 41% of cases (55).

For MR due to *restricted* leaflet motion, the jet is directed *toward* the most abnormal leaflet. Most commonly the jet direction is posterior, with a fixed posterior leaflet, or central, from balanced bileaflet restriction. This occurs mostly from rheumatic mitral valve disease, and only 36% of cases can be repaired. In these patients, repair is more likely when there is a lower echocardiogram score, or “splitability index,” an echocardiographic measure defined by four assessments, each on a scale of 1 to 4, of leaflet mobility, leaflet thickness, calcification, and subvalvular involvement, for a total score of up to 16 (57,58). Repair is more feasible in younger patients, but carries a greater risk of progressive disease and reoperation (59,60), likely due to more active fibrosis or recurrent valvulitis.

Patients with significant mitral stenosis with a low splitability index (not associated with calcification or extensive fibrosis) are usually candidates for percutaneous balloon valvotomy. In more recent years, the ones who come to surgery are those who are not suitable for balloon valvotomy, because they have a splitability index that is high (greater than 9) or concomitant MR. Therefore, most of the surgical repairs currently involve more extensive débridement, decalcification, and commissurotomy, as well as annuloplasty (60). When the echocardiography score (splitability index) is high, however, there is less likelihood of successful repair and more likely early failure of the repair (60a).

Patients with *normal* leaflets have a *central* (or sometimes posterior) jet direction. This type of MR is usually due to LV enlargement and dysfunction, which cause “relative restriction of normal leaflets” due to outward displacement of the papillary muscles, and therefore apical displacement of the coaptation line (61). This “apical tethering” results most commonly from ischemic MR (62). It is a misunderstood entity and really does not result from annular dilation, but rather from change in the shape of the LV (sphericalization), which makes the leaflet-chordal-papillary muscle length relatively short compared with the increased distance outward to the LV walls. The mitral annulus in these patients also appears to have reduced cyclic variation in annular shape and area (62a). Paradoxically, repair is currently accomplished with an annuloplasty alone. This is feasible in 85% of patients (Table 57.3) but is associated with a significant rate of return of MR over months to years, mainly due to progression of LV dysfunction, often due to repeat infarction or volume overload.

Occasionally, patients with MR due to normal leaflets have a leaflet perforation or congenital cleft (62b). This can generally be sewn primarily or patched with a piece of pericardium, as long as there are no additional problems, such as disrupted leaflets or chordae from endocarditis. Of note, in patients with congenital cleft mitral valves, it is difficult to obtain a long-lasting repair, particularly in patients with Rastelli’s type A or a divided inferior mitral leaflet.



Parasternal short-axis view (transesophageal echo) of a cleft mitral valve. Notice the cleft in the center of the anterior mitral leaflet with its characteristic opening. (This patient also had a primum atrial septal defect, a commonly associated lesion). The double arrow demonstrates the two halves of the split anterior mitral leaflet.

Postpump Imaging and Second Pump Runs

After valve repair for MR, the vast majority of patients have a successful result, as defined previously and evidenced by the postpump IOE (Fig. 57.3). In the series from our institution, 6.6% of patients had problems discovered on the postpump TEE that warranted further surgery during the same thoracotomy (19a).

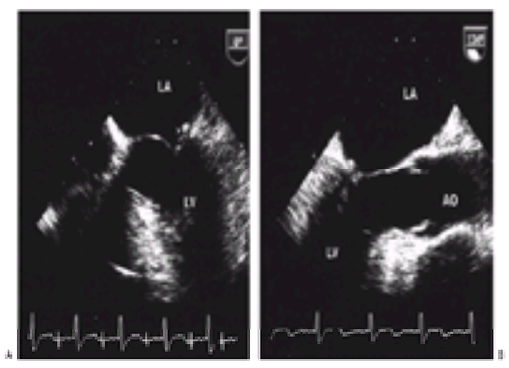

FIGURE 57.3 Postpump images after successful repair of mitral regurgitation from the same patient shown in Figure 57.2. **A:** Transverse (0 degrees) midesophageal four-chamber view showing no prolapse or flail. The annuloplasty is shown (*arrowhead*). **B:** Long-axis midesophageal view (134 degrees) showing no residual prolapse or flail. AO, aorta; LA, left atrium; LV, left ventricle.

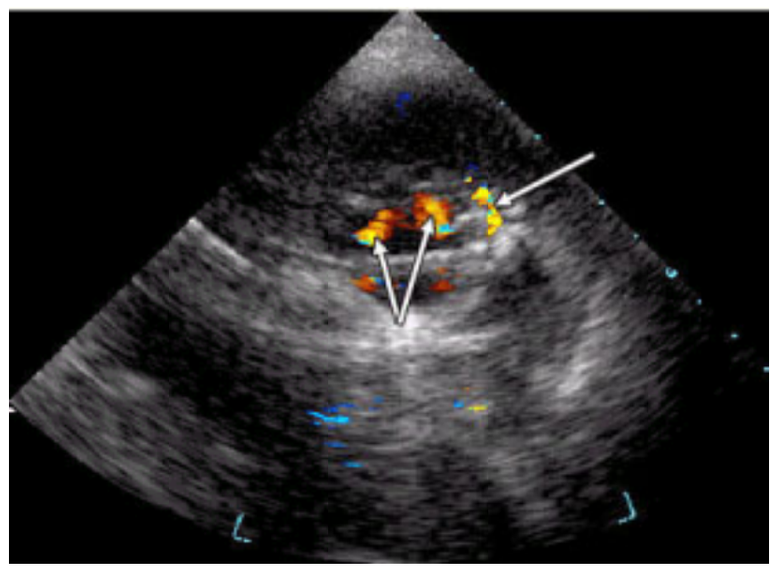


Transgastric short-axis view during intraoperative transesophageal echo of a paravalvular leak of a CarboMedics mitral valve replacement. Note the two normal physiologic prosthetic jets of mitral regurgitation (within the sewing ring) as designated by the double arrow and the one abnormal, laterally originating jet outside the sewing ring (to the right of the screen) designated by the single arrow. There was significant mitral annular calcification (MAC), making it difficult to achieve close contact between the annulus and the sewing ring.

Video 57.4 Postpump echo (with color Doppler) after repair of the flail posterior mitral leaflet. There is a Cosgrove-Edwards annuloplasty ring in place. There is no residual mitral regurgitation and there is no systolic anterior motion of the mitral leaflets, which can sometimes complicate mitral valve repair. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 57.5 Two-dimensional intraoperative 120-degree view imaging of a mitral valve after repair. Notice the annuloplasty ring in place without any residual prolapse or flail and no systolic anterior motion of the mitral leaflet (a complication that can be seen after surgical repair). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Others have reported frequencies ranging from 2% to 8% (34,63,64,64a,65). Primarily, the second pump run has been done for persistent MR. After repair for MR, the incidence of mitral stenosis as the problem found by postpump imaging mandating a second pump run is small, 0.7% in one series (64a), occurring mostly in rheumatic MR patients and those repaired using commissural plication or other suture plication such as the edge-to-edge technique. In the majority of patients, the surgery done in the second pump run is repair, particularly if the TEE after the initial attempt is able to find a fixable mechanism that explains the residual dysfunction. In these cases, there is significant pressure on the echocardiographer to define precisely what is wrong to facilitate further repair. Use of the same leaflet motion and jet direction techniques described previously is again helpful. The most common etiologies of persistent regurgitation are residual prolapse, residual flail, or a perforation at the site of leaflet resection or sliding plasty.

In patients who undergo nonprosthetic surgery for pure mitral stenosis (i.e., open mitral commissurotomy), the frequency of immediate problems leading to further surgery during the same thoracotomy is approximately 9%, mostly entailing replacement in patients with more extensive valvular scarring and calcification (60a).

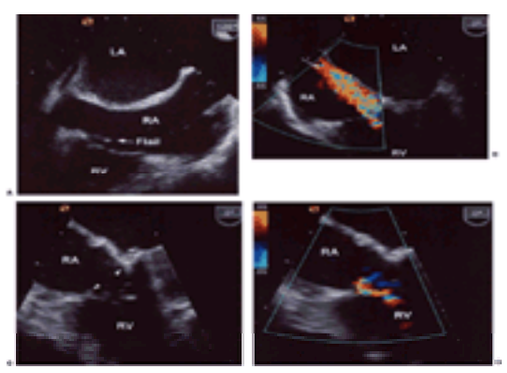
In 1% to 2% of cases after mitral valve repair, dynamic outflow tract obstruction occurs, with systolic anterior motion (SAM) of the mitral valve (31,64). SAM occurs most commonly in patients with redundant myxomatous mitral valves and LVs that are normal or small in size and normal or hyperdynamic in function. It is more common when the annuloplasty is performed with a stiff ring (66). Outflow tract obstruction is associated with anterior displacement of the mitral coaptation line, which results mainly from a large, redundant posterior leaflet (67). In many circumstances, SAM resolves in response to increasing intravascular volume and stopping catecholamine medications (68,69). If it persists, SAM can often be corrected using the sliding posterior leaflet advancement technique (70,71). This can be done as a preventive measure during the initial repair or during a second pump run in response to finding SAM on the postpump TEE. Rarely, mitral valve replacement or septal myectomy is required (31,72).

The mechanism of MR also affects the durability after repair for valvular regurgitation caused by degenerative disease. Durability is greatest after quadrangular resection and annuloplasty for posterior leaflet prolapse (45a).

TRICUSPID VALVE REPAIR

IOE is also useful in performing tricuspid valve repair. TR causing the need for tricuspid surgery arises most commonly due to left-sided congestive heart failure of any cause. Both intravascular volume overload and pulmonary hypertension can cause enlargement of the right ventricle, causing TR. In chronic conditions, the tricuspid annulus also dilates. Of patients having surgery for mitral or aortic valvular heart disease, tricuspid surgery is needed in approximately 25% (73). Over 93% of tricuspid surgery entails repair (74), in contrast to much lower percentages in other valves.

The tricuspid valve is assessed by TEE using a midesophageal four-chamber view at a 0-degree multiplane angle, a midesophageal 45-degree view at the level of the short axis of the aortic valve, a midesophageal 135-degree view at the level of the right atrium and tricuspid valve (eFig. 57.3.1), and a transgastric view at 90 degrees showing the long axis of the right ventricle and right atrium. Additional value is obtained from deep transgastric views of the hepatic vein and inferior vena cava to detect systolic flow reversal using pulsed Doppler as an indicator of severe TR.



***e*FIGURE 57.3.1** Transesophageal echocardiogram images before and after tricuspid repair for flail leaflet. **A:** Midesophageal two-dimensional image at 126 degrees showing a long-axis view of the right atrium (RA), including the flail tricuspid leaflet (*arrow*). **B:** Midesophageal transverse color flow image at 0 degrees showing moderately severe 3+ tricuspid regurgitation (*arrow*) in the RA before repair. **C:** Postrepair two-dimensional image at 0 degrees showing the tricuspid annuloplasty band (*arrowheads*) and no tricuspid prolapse or flail. **D:** Midesophageal transverse color flow image at 0 degrees showing mild 1+ tricuspid regurgitation (*arrow*) after repair. LA, left atrium; RV, right ventricle.

In doing the prepump IOE for tricuspid valve surgery, semiquantitative assessment of the amount of TR correlates with preoperative assessments (75,76). However, compared with other valves, the severity of TR is even more volatile and extremely dependent on loading conditions. Evaluating leaflet morphology such as prolapse or rheumatic leaflet restriction is important as the former may enhance and the latter may reduce the likelihood of successful repair. In addition, measurement of the maximum tricuspid annulus diameter may identify patients who need repair because the TR is less likely to resolve merely by fixing the left-sided valvular abnormalities (76).

VIDEO

Video 57.6 Postoperative four-chamber transesophageal echo after tricuspid valve repair with placement of an annuloplasty ring. Note that although there is still prolapse of tricuspid valve tissue, there is only minimal residual tricuspid regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Postpump Assessment after Tricuspid Repair

TEE of TR after repair (77,78 and 79) uses similar techniques as the prepump study. In some cases, TR is found to be new or increased compared with that on prepump studies; this requires a second pump run for repair (80). At our institution, second pump runs were required in 5.3% of tricuspid repairs, based on the results of the postpump IOE (19a).

Again, the patient should be stabilized off cardiopulmonary bypass and ambulatory conditions established before assessments. In borderline cases of moderate or more regurgitation, tricuspid competency should be retested during provocation, using additional intravascular volume and increased right ventricular afterload by transient partial occlusion of the pulmonary artery.

In a study of 401 patients undergoing tricuspid valve surgery, mostly with other concomitant cardiac surgery, the surgical plan was altered at the time of surgery to ensure a successful outcome in 32 (10%) of 335 patients based on IOE findings (80a). Despite a successful result of tricuspid repair on the postpump study, some patients still develop TR in follow-up (79). This may reflect new myocardial dysfunction or the severity of the underlying cardiac pathology causing right ventricular volume overload, rather than the effectiveness of the tricuspid repair (81).

Several groups reported performing DeVega annuloplasty with the ends of the sutures brought out to the external surface of the heart. If the TEE showed persistent TR after the patient came off cardiopulmonary bypass, these sutures were tightened by the surgeon to eliminate the TR (82,83). Externally adjustable rings have also been used for mitral and tricuspid valve annuloplasty, allowing adjustment of tension after the initial postpump TEE (84).

AORTIC VALVE REPAIR

Compared with the past, when only bioprosthetic and mechanical prosthetic valve replacement was available, surgery for aortic valve disease has newly expanded options including aortic valve repair, homograft implantation, stentless bioprostheses, and Ross procedure. There are advantages and disadvantages of each option, but none of these is an ideal substitute for a normal native valve. Which surgery is best to use in each individual patient depends on the nature, etiology, and severity of the aortic valve dysfunction, and the clinical characteristics, age, and personal preferences of the patient. The prepump IOE has been found to change the operative plans in 15% of cases undergoing aortic valve surgery (38).

Aortic valve repair is applicable only to a small, highly selected subset of patients undergoing aortic valve surgery (85,86 and 87), particularly those with pure AR who are free of appreciable fibrosis or valvular thickening. Like mitral repair, this surgery demands the most from the echocardiographer and the surgeon, because of the necessity to understand the mechanism of the dysfunction. The prepump IOE is extremely useful in this group (88,89) to determine the mechanism and severity of regurgitation and the size of the aortic annulus and ascending aorta.

Determination of the Severity and Mechanism of Aortic Regurgitation

The severity of AR is judged intraoperatively from a weighted average of information from LV outflow tract spatial mapping (90), the flow convergence on the superior side of the regurgitant orifice, and the downstream events of descending aortic diastolic flow reversal (91) (see also Chapter 22). The proximal jet width in long-axis views and the jet area in short-axis views provide important and reliable criteria for severity (91a). Similar to MR, it is useful to separate the leaflet motion in AR into groups with normal, excessive, and restricted leaflet motion. Most patients with aortic valve disease have restricted leaflet motion resulting from degenerative and rheumatic etiologies. However, the vast majority of patients with AR has restricted leaflet motion, because of the predominance of degenerative, rheumatic, and fibrocalcific etiologies of aortic valve disease. These processes cause retraction of the leaflet size, leaving a central leak; 70% of patients have a central jet origin and direction (94). This type of aortic valve disease is not generally amenable to durable repair.

VIDEO

Video 57.7 Intraoperative transesophageal echo (120-degree view) with color Doppler demonstrating aortic insufficiency due to aortic dilatation (sinuses measure 5.0 cm) causing failure of leaflet coaptation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The primary group of patients in whom repair is feasible have noncalcified, nonstenotic valves with pure regurgitation resulting from aortic valve prolapse. Prolapse occurs most commonly in the settings of a congenital bicuspid aortic valve (Fig. 57.4) or a trileaflet valve with prolapse of one coronary cusp, usually the right. Prolapse of a trileaflet valve may result from leaflet fenestration or a congenital membranous ventricular septal defect (VSD) (92,93). In any of these categories, the regurgitation results from excessive length of the edge of the prolapsing leaflet, causing it to have a lower diastolic position. In 70% of patients with excessive leaflet motion, the jet is deflected to the opposite side of the LV outflow tract by the prolapsing leaflet (94). AR resulting from prolapse is surgically corrected using triangular resection of a small portion of the prolapsing leaflet, to adjust the length of the leaflet edge, causing its diastolic position to be at the same level as the opposing ones, thus promoting coaptation. In addition, pledgeted sutures at the commissures, a “commissuroplasty,” bring the points of suspension of leaflets inward to improve coaptation (85,95).

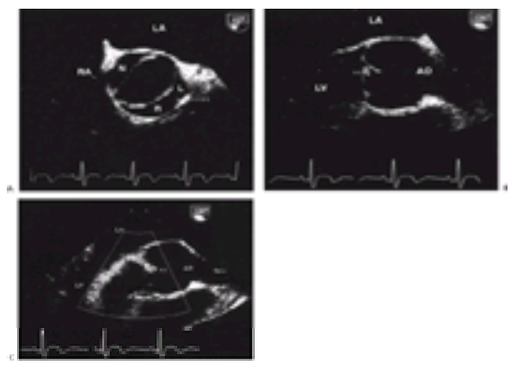


FIGURE 57.4 Aortic regurgitation amenable to valve repair. **A:** A short-axis, 62-degree, midesophageal view of the same patient, showing fusion of what would be the right (R) and left (L) cusps into a larger anterior cusp, compared with the posterior cusp, which would otherwise be the noncoronary (N) cusp. Arrowheads show the anterior raphe. **B:** Long-axis, 136-degree, midesophageal view of the aortic valve showing the aortic valve prolapse (*arrowheads*). **C:** Black and white copy of a color image in a long-axis view of the outflow tract, showing the posteriorly directed jet of aortic regurgitation emanating from the coaptation line (*arrowheads*) at the site of prolapse (*arrows*). AO, aorta; AR, aortic regurgitation; LA, left atrium; LV, left ventricle; RA, right atrium.

Repair can also be successful in certain patients with regurgitation from normal aortic leaflets. This type of AR has a central jet direction emanating from central failure of coaptation of a trileaflet valve. The regurgitation usually results from ascending aortic dilatation, because of outward displacement of the sinotubular ridge, causing “relative restriction of normal leaflets” similar to MR from LV dilatation, as detailed earlier in this chapter. AR from aortic dilatation is also repaired with a commissuroplasty. In certain cases, a structurally normal native aortic valve can be resuspended during surgery for conduit placement in patients with ascending aortic dilatation or aneurysm (96 and 97a).

In patients with restricted leaflets, for whom other options are available, repair is not the first choice of operation. When the clinical situation favors repair, such as in underdeveloped countries (98) for whom the cost of a prosthesis is unacceptable or anticoagulation is impossible, repair of this type of AR can be accomplished (99,100). Although the initial results are adequate, regurgitation redevelops quickly (101).

Another role for the prepump IOE in aortic valve disease is to look at the anatomy of the ascending aorta, especially the relative diameters in the long-axis view of the aortic annulus (at the hinge points of the aortic valve), and the sinotubular junction. Normally, these two measurements are approximately equal and roughly 19 to 23 mm. In bicuspid valves and other congenital aortic valve disease, the annular diameter is usually enlarged (approximately 26 to 32 mm). In patients who have central regurgitation with normal aortic leaflets, the diameter of the sinotubular junction is often larger than the annular diameter.

Postpump Intraoperative Echocardiography in Aortic Valve Repair

After aortic repair, the amount of regurgitation, the valve anatomy, and the mechanism of residual dysfunction are again checked (86,88,102). Because aortic valve repair is more difficult to accomplish than mitral repair, the frequency of initial failure of repair is higher, occurring in 14.4% of aortic valve repairs (19a).

In successful repair, the aortic valve is still morphologically abnormal. Valvular densities from the sutures at the triangular resection site and at the commissures are often visible in the short-axis view. After successful repair of a prolapsing valve, the amount of valvular prolapse is less, and the two leaflets coapt at the same level with a diastolic shape that reflects good apposition. Systolic doming in long axis also persists in patients with bicuspid valves, which still have two leaflets in short axis, because the conjoined leaflet is not split by the repair.

As in other cases mentioned previously, an acceptable result after repair is to have no regurgitation or mild regurgitation. Note that the incidence of persistent AR, making up the initial failure of repair, is higher than that after mitral repair, also reflecting the increased difficulty of aortic repair. When there is significant regurgitation, it is quite important to determine the mechanism of persistent leak, to facilitate repair on the second pump run. Because of the difficulty of aortic repair, the majority of second pump runs involves valve replacement (88,89).

In follow-up studies of 150 patients after aortic valve repair at our institution, the subgroup of 19 patients with a less than “echo perfect” result (more than 1+ regurgitation) on the postpump study, compared with those with no postpump AR, carried a greater risk of recurrent AR (61% vs. 17%, p <.05) in follow-up over 27 ± 16 months (103). Among another group of patients having repair for regurgitation of a bicuspid valve, 89.5% were free from reoperation at 24 months (95).

AORTIC HOMOGRAFTS, STENTLESS BIOPROSTHETIC VALVES, AND ROSS PROCEDURE

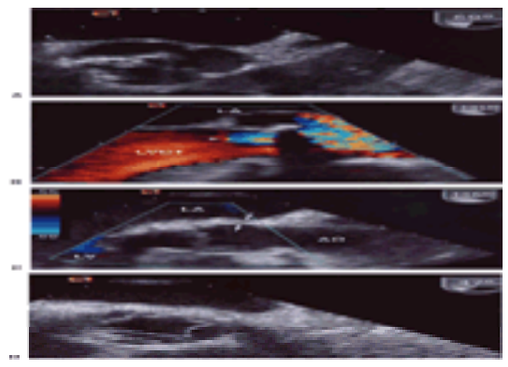
A case can be made for routine TEE (104) in the course of a standard aortic or mitral valve replacement, as it is unquestionably more sensitive for detection of prosthetic dysfunction than transthoracic echocardiography (105,106). However, because of limited resources and the low incidence of changes in operative management based on echocardiography, IOE is not performed routinely when a standard prosthesis is planned. IOE is useful in aortic valve replacements with a homograft (human valve) or pulmonary autograft (the patient’s own pulmonic valve) (107).

The homograft and autograft are particularly useful for younger patients and those with active endocarditis (108). The cryopreserved homograft is an excellent form of aortic valve replacement, which has a low transvalvular gradient and a remarkably good durability, with 10-year freedom from reoperation for graft-related causes of 92% (108a). Ross procedure entails replacing the aortic valve with a pulmonary autograft, and replacing the pulmonic valve with a pulmonary homograft (81). The autograft may have advantages in the young due to the ability of the living tissue to grow with the patient. It has been used successfully in patients with aortic valve endocarditis (108b). Both procedures are more technically difficult, because they entail working with malleable biologic tissue. There is no stiff sewing ring or Dacron annulus as there is in a conventional heterograft or mechanical prosthesis. Because the coronary arteries must be reimplanted, there is also some additional potential for ischemic difficulties.

With implantation of the new nonstented heterografts (108c,109), intraoperative echocardiography appears to be quite useful. It reveals contraindications to implantation of the nonstented valve and allows measurement of the aortic annulus and sinotubular junction diameters for correct prediction of prosthesis size (109a). Some small periprosthetic jets seen by postpump IOE appear to improve or resolve spontaneously and may not require intervention with a second pump run (109b).

Prepump Intraoperative Echocardiography in Homograft and Ross Procedures

In addition to determining the severity of valvular dysfunction, ventricular function, and the status of other valves, the prepump study is useful for determination of the diameters of the aortic and pulmonic valve annulae and the sinotubular junction. The supply of aortic homografts is limited, and most range from 19 to 22 mm in size. The measurement that corresponds to homograft size is the maximum obtainable aortic annulus diameter, measured at the level of the hinge points of the aortic valve, in a true long-axis view, usually the mid-esophageal view at approximately 130-degrees (*e*Fig. 57.4.1). Making this measurement with echocardiography before cardiopulmonary bypass can save approximately 20 minutes of ischemic time that is otherwise wasted if the homograft is not thawed until the valve is measured by the surgeon after the aortotomy (110,110a). In 51 patients undergoing prepump IOE studies before homograft implantation, the aortic annular size, obtained in a true long-axis view, differed from the annular size measured by the surgeon by an average of 0.6 mm, being less than 2 mm in all and less than 1 mm in 94% of patients (112). The diameter of the sinotubular junction is also measured by the prepump IOE, because normal valve relationships depend on normal proportions between valve size and the supravalvular ridge (111).



***e*FIGURE 57.4.1** Transesophageal echocardiogram of a patient with aortic stenosis undergoing aortic homograft valve replacement. **A:** Prepump midesophageal short-axis view of the aortic valve at 68 degrees showing the calcified aortic valve with thickened edges of all three leaflets. **B:** Magnified midesophageal long-axis view at 131 degrees of the aortic valve in systole showing the flow convergence (*arrowhead*) on the left ventricular outflow tract (LVOT) side and the turbulent flow pattern on the aortic side due to aortic stenosis. **C:** Midesophageal long-axis view at 146 degrees of the newly implanted homograft aortic valve. Note the thickness (*arrows*) of the sinuses of Valsalva, which includes both donor and recipient aortic tissue. **D:** After aortic valve replacement midesophageal short-axis view at 47 degrees showing normal opening of the newly implanted homograft. AO, aorta; LA, left atrium; LV, left ventricle.

Another consideration for the prepump study is to discern the likely etiology of valve dysfunction from the valve morphology. When the aortic valve dysfunction results from rheumatic heart disease, progressive valvulitis may develop in the autograft or homograft, causing early postoperative aortic valve dysfunction (113).

When Ross procedure is planned, the integrity of the pulmonic valve is checked on the prepump echocardiogram. Significant pulmonic valve dysfunction or distortion of morphology (e.g., a bicuspid valve) on the prepump study, a rare occurrence, should cancel plans for Ross procedure.

It is also important to compare the annular diameter of the pulmonic and aortic valves. In a series of 58 patients undergoing Ross procedure, the echocardiographic measurements of annular size had an impact on outcome, with less postpump and early postoperative regurgitation of the autograft when the difference between the aortic and the pulmonic annular diameters measured on the prepump imaging was less than 3 mm (45).

Postpump Echocardiography after Homograft Valve Replacement or Ross Procedure

IOE is also useful for checking the result after these two procedures (114). Because the level of surgical difficulty is higher than, for example, mitral valve repairs, the frequency of initial failure of surgery is also higher. Second pump runs were required in 10 (11.6%) of 86 homograft patients in our experience (112), although it was only 3% of patients in another report (115). Similarly, second pump runs have been needed after 7 (12.1%) of 58 Ross procedures.

VIDEO

Video 57.8 A 120-degree postpump intraoperative transesophageal echo after placement of an aortic valve replacement conduit. The St. Jude aortic valve replacement is toward the left of the screen, and the aortic graft can be seen in the center of the screen. *This video must be viewed with QuickTime. VIDEO

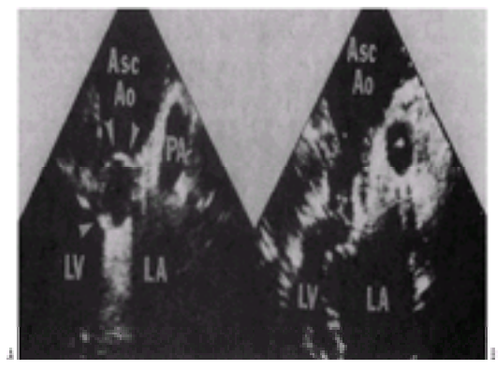
Video 57.9 Postpump intraoperative echo after placement of an aortic valve homograft. Notice that the leaflets look like a native valve. The only clue that it is a homograft is the thickening at the annulus and the proximal ascending aorta due to the double thickness of the graft cuff with the native aorta. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The primary problems found on the postpump TEE are persistence of regurgitation of the new aortic valve, myocardial ischemia from the reimplanted coronaries, or (rarely) regurgitation of the pulmonic homograft (45). In one study, there was a 10% incidence of ischemia found by the postpump TEE after Ross procedure; this ischemia was more frequent in patients with bicuspid aortic valve and coronary anomalies and resolved completely in most patients with revision of the coronary implantation (115a).

Attention to the mechanism of persistent leak on the postpump study can facilitate its correction. Most homografts are now done as a miniroot procedure, which is easier and more reliable than a freehand subcoronary implantation. Even so, postpump TEE has found in some patients that the valve was not suspended appropriately. If the image shows that the valve prolapses and one side of the wall of the sinuses of Valsalva is more lax, this indicates the need to suspend the commissure higher on that side by removing tissue from the aortic wall above the sinotubular junction on that side.

Where the valve is implanted as an inclusion cylinder, bleeding and hematoma can develop in the potential space between the donor and recipient walls of the sinuses of Valsalva, causing distortion of the root or even outflow obstruction (*e*Fig. 57.4.2). In patients with a dilated ascending aorta having an inclusion cylinder implanted, it is normal to see some echo-free space that is not completely eliminated despite optimal surgery; this resolves in weeks to months. However, after implantation, there should be no high-velocity flow within the space as assessed by color flow mapping. Localizing the high-velocity flow by color flow mapping marks the point of dehiscence of the upper or lower suture line, which can be repaired with a second pump run.



***e*FIGURE 57.4.2** Epicardial images after implantation of an aortic homograft. **A:** A hematoma (*arrowheads*) between the inclusion cylinder and the native ascending aorta (Asc Ao) caused a 47 mm Hg gradient. **B:** After evacuation of the hematoma, the images show resolution of the obstruction. LA, left atrium; LV, left ventricle; PA, pulmonary artery. (From Currie PJ, Stewart WJ. Intraoperative echocardiography for surgical repair of the aortic valve and left ventricular outflow tract. *Echocardiography* 1990;7:273–288, with permission.)

Follow-up studies on patients undergoing Ross procedure showed a greater incidence of significant recurrent AR, in five (50%) of ten patients whose postpump IOE

showed 1+ or more AR, compared with 1 (2%) of 43 patients whose postpump IOE showed an “echo perfect” surgical result (45). Although stenosis of the pulmonary homograft does not occur at the time of the immediate postpump image, it has developed in some patients at the time of midterm follow-up, with progressive right ventricular dysfunction. In homograft and Ross procedure patients, long-term studies will be required to compare the outcome with that of standard aortic valve replacement using mechanical and bioprosthetic valves.

AORTIC ANEURYSM SURGERY

With its rapidity and portability, TEE is extremely useful in the preoperative management of patients with aortic aneurysms and aortic dissection (116). By the time the patient comes to the operating room, in some cases a significant time interval has elapsed since the preoperative studies. Because the potential exists for interval progression or development of more complications, repeat evaluation in the operating room before surgery is often useful. TEE is also useful in transluminal endovascular stenting to repair thoracic aortic aneurysms, for navigating the graft placement and tailoring without intimal damage, and especially to assess perigraft leakage (116a) and graft kinking immediately after deployment (116b).

Prepump Intraoperative Echocardiography in Aortic Aneurysms

In patients with thoracic aorta aneurysms, IOE is helpful in defining the pathology to assist with operative planning. Prepump IOE results change the operative mission in 18% to 33% of cases (36a,117). The preoperative and prepump objectives for TEE diagnosis in this disease (118) include (a) diagnosing the presence and location of the aneurysm (the DeBakey or Stanford type), (b) identifying the presence and location of the dissection, (c) determining the morphology and functional status of the aortic valve, (d) identifying pericardial fluid or hemopericardium, (e) assessing ventricular function and myocardial infarction, (f) identifying entry and exit sites of the dissection through the intimal flap (119), and (g) detecting involvement of branch vessels in the dissection, particularly coronary arteries and great vessels. Of these, TEE is accurate for all but the last. After femoral cannulation and institution of cardiopulmonary bypass, TEE can verify retrograde flow in the true lumen (120).

VIDEO

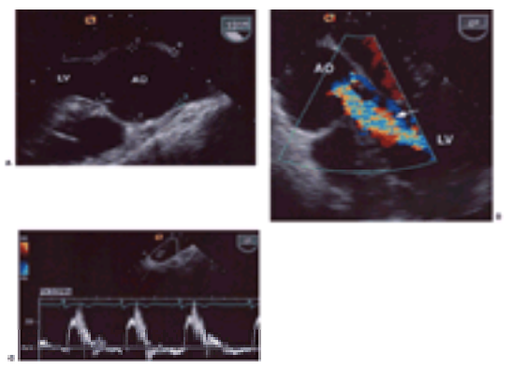
Video 57.13 Intraoperative 120-degree transesophageal echo of an ascending aortic dissection. Note the large, complex flap in the ascending aorta seen originating near the origin of the right coronary artery. There is a small amount of aortic insufficiency. Flow is seen in the true lumen (*left*) whereas no flow is seen in the false lumen (*right*). *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

In certain patients, the aortic valve can be preserved during ascending aortic conduit placement, using either a supracoronary graft or the David procedure with resuspension of the native aortic valve within the ascending aortic conduit (96,97) (eFig. 57.4.3). Knowing the aortic valve anatomy and physiology can help plan for the optimal surgical options. For example, the amount of dissection of the valve annulus correlates with the amount of leaflet prolapse (97a). AR in ascending aneurysms can occur due to upward leaflet tethering by the dilated aortic root, leaflet prolapse due to disrupted leaflet attachments, or prolapse of the dissection flap through the valve orifice (120a).

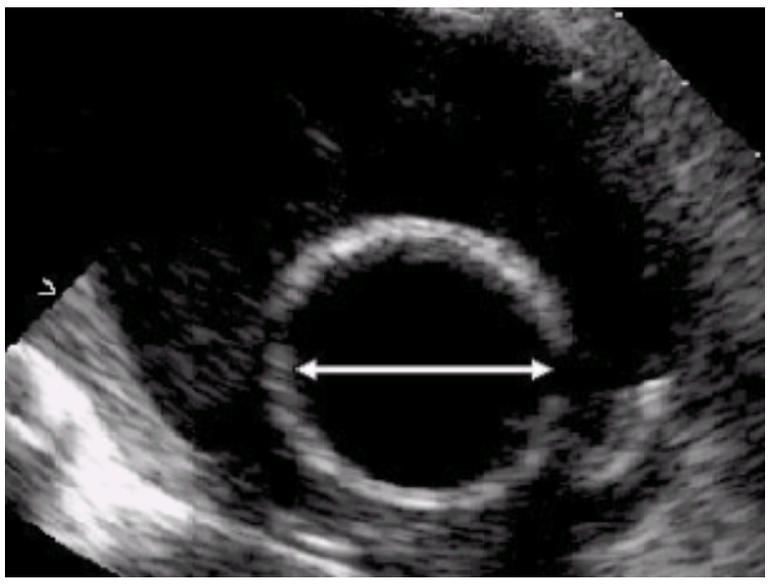


***e*FIGURE 57.4.3** Prepump transesophageal echocardiographic images showing functional aortic regurgitation of normal leaflets due to ascending aortic dilation, amenable to aortic valve resuspension. **A:** Midesophageal long-axis view of the aortic valve showing the methods of measuring the diameters of the (1) aortic annulus at 2.2 cm, (2) sinuses of Valsalva at 4.1 cm, and (3) sinotubular junction at 2.8 cm. **B:** Midesophageal transverse view showing severe aortic regurgitation (*arrow*) with a central jet. **C:** Pulsed Doppler recording of the proximal aortic arch, showing (*top*) the position of the sample volume, and (*bottom*) antegrade flow in systole (above the horizontal line) and retrograde flow (below the horizontal line) in diastole from the severe aortic regurgitation. AO, aorta; LV, left ventricle.

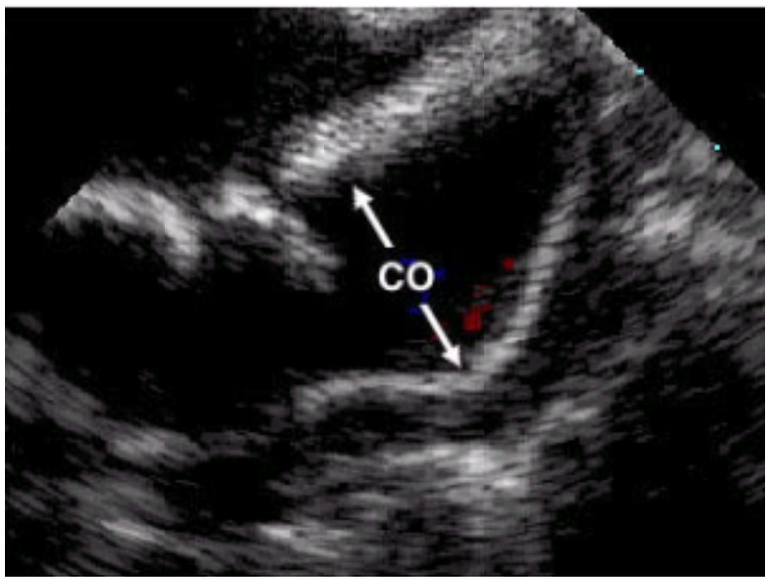
In addition, aortic aneurysms can be complicated, with involvement of branch vessels such as the coronaries, the great vessels, the spinal arteries, and the abdominal organs. When extensive resection is planned, such as for a thoracoabdominal aneurysm, TEE is particularly helpful. In some cases, the surgery is staged in two portions, doing the ascending aorta and arch first, and leaving the free end of the conduit hanging in the descending aorta like an “elephant trunk.” At a later date, a lateral thoracotomy is done to implant a descending aortic conduit that is hooked up to the previously implanted conduit (121,122).

Postpump Intraoperative Echocardiography

After aneurysm surgery, IOE is used to evaluate the anastomoses of the conduit, aortic valve, LV (for ischemia or infarction), and major aortic branches (to confirm that sufficient flow is present, particularly if they are fed by the false lumen) (10). When the aortic valve has been resuspended in the setting of aortic aneurysm surgery, the likelihood of persistent regurgitation increases, which may require a second pump run for valve replacement. Another important new finding is a new segmental wall motion abnormality, which might imply difficulty with coronary reimplantation. The frequency of second pump runs is 3.8% after aortic aneurysm surgery (19a).



This short-axis view of the descending aorta is seen by intraoperative transesophageal echo showing the distal end of the aortic graft following the first stage of an elephant trunk procedure. Note the circular appearance of the graft within the aneurysmal descending aorta. The arrow demonstrates the diameter of the descending aortic graft.



Intraoperative echo demonstrating the distal end of the aortic graft after the first stage of an elephant trunk procedure seen in long axis. Note the tubular free end of the graft within the aneurysmal descending aorta. CO designates the diameter of the conduit.

Video 57.14 Long-axis view of the descending aorta from an intraoperative transesophageal echo after an elephant trunk procedure. Note the cylindrical structure within the dilated descending aorta; this represents the free end (distal) of the vascular graft with color flow within it. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

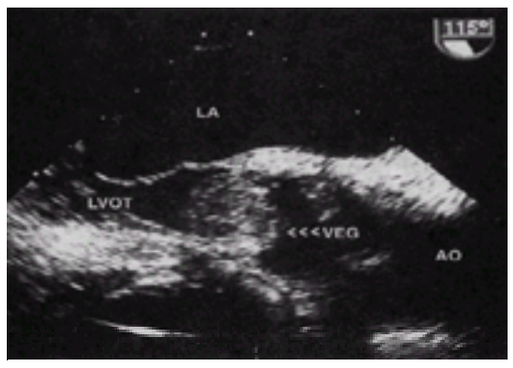
Video 57.15 Short-axis view of the descending aorta from an intraoperative transesophageal echo after an elephant trunk procedure. Note the circular structure with in the larger, more dilated aorta. This represents the distal end of the vascular graft in short axis hanging free within the descending aortic aneurysm. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The descending aorta and arch should be examined after surgery for flow in the false lumen and true lumen, as well as intramural hematomas. It appears that the presence of flow in the false lumen and the absence of thrombus are variables that carry an adverse prognosis, greater risk of extension of the dissection to additional parts of the aorta, and a reason for closer follow-up (116).

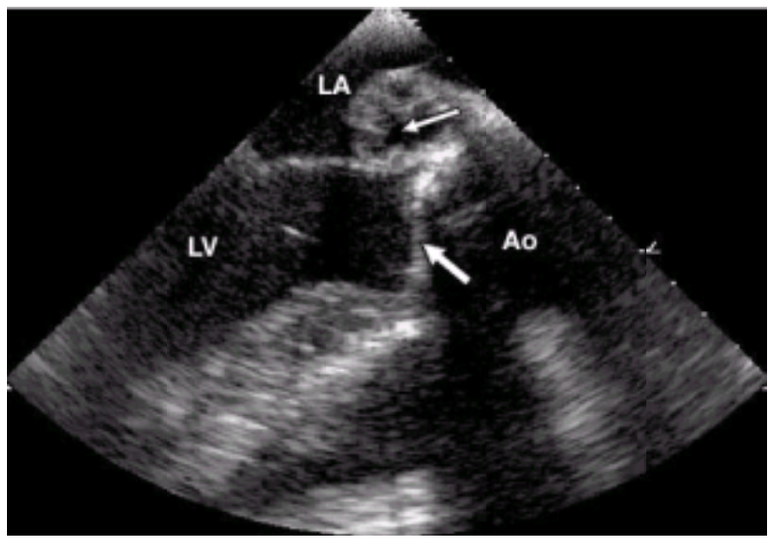
ABSCESSES OR FISTULAS OF THE HEART

IOE is extremely useful in patients who have endocarditis, both for preoperative definition of the surgical mission and for postoperative verification of successful results. The prepump TEE is particularly valuable to characterize the vegetations (*e*Fig. 57.4.4) and to look for additional sites of infection in patients in whom there has been an interval of time between the preoperative workup and surgery. The TEE plays an essential role in surgery for abscesses and fistulas of the heart (123), a dreaded

complication of endocarditis.



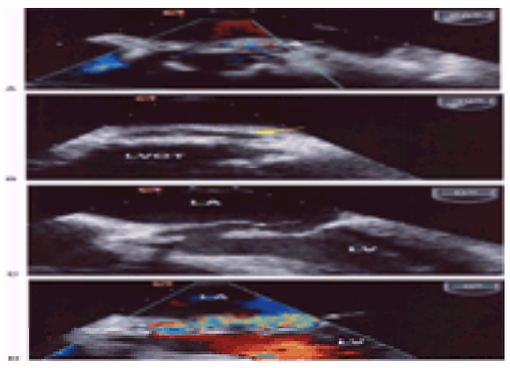
***e*FIGURE 57.4.4** Long-axis (115 degrees) midesophageal view of the left ventricular outflow tract (LVOT) in a patient with endocarditis showing a large vegetation (VEG) attached to the aortic valve. The intraoperative echocardiography was important to exclude interval spread of infection, especially additional sites of infection and involvement of the perivalvular tissue, because the preoperative echocardiographic workup had preceded surgery by 4 days. AO, aorta; LA, left atrium.



A 120-degree transesophageal echo of an aortic valve abscess seen in the inner annular fibrosa. The thin arrow designates the abscess cavity, while the thicker arrow demonstrates the aortic valve.

In endocarditis, infection may also spread from one valve to another valve, due to endocardial abrasion from a regurgitant jet hitting another area of the heart, causing the endocardial surface to be abraded and allowing tissue invasion. This occurs most commonly in patients with AR in which the jet hits the anterior mitral leaflet and causes an abscess, perforation, or a fistula into the left atrium (124).

Deep tissue and multivalvular infections occur predominantly in patients with prosthetic valves in place because of the foreign body phenomenon predisposing to infections. As the tissue becomes weakened, a fistula may develop where the high-pressure LV vents into another space. Around an aortic prosthesis, the shunt may go from the periaortic portion of the LV outflow tract to the right ventricle (VSD), to the right atrium (like a Gerbode VSD), to the left atrium (perforated anterior mitral leaflet), to the adjacent intervascular space (pseudoaneurysm), or to the aorta (periprosthetic leak) (eFig. 57.4.5). In fistulae around a mitral prosthesis, the shunt may go from the perimitral portion of the LV to the left atrium (periprosthetic leak), to the coronary sinus (left-to-right shunt), or to the pericardial space (pseudoaneurysm).



***e*FIGURE 57.4.5** Prepump transesophageal echocardiographic image in a patient with a periprosthetic abscess and mitral leaflet perforation. **A:** Midesophageal short-axis view of the aortic prosthesis showing high-velocity flow shown in color (*arrow*) within a pocket seen within the posterior aortic annulus. **B:** Magnified midesophageal view at the level of the short axis of the left ventricular outflow tract (LVOT) showing the echo-free space (*arrow*) in the posterior aortic annulus. **C:** Perforation of the base of the mitral leaflet (*arrow*) shown in a midesophageal transverse view of the left atrium (LA) and left ventricle (LV). **D:** Magnified midesophageal transverse view showing mitral regurgitation through the mitral anterior leaflet perforation (*arrow*).

IOE is important in the management of these patients to determine the location and extent of infection to completely extirpate the infection. Sometimes, this entails débriding significant infected tissue and even excising important structures of the heart such as the intervalvular fibrosa. In such cases, TEE is useful after reconstruction of those structures.

The surgeon can sometimes use pericardium to reconstruct the defect. In addition, it is an advantage to avoid implantation of prosthetic material; therefore, valve repair (125) or homograft valves (126,127) are good options, although technically demanding. All of these surgeries are complex and unique, and TEE is useful before and after to guide the planning and check the results.

MASSES AND TUMORS OF THE HEART

The removal of a mass in the heart is also assisted substantially by the prepump and postpump use of TEE. Unexpected masses found during prepump IOE in a patient coming for surgery for something else are not uncommon. The most common is a thrombus in the left atrial appendage in a patient with atrial fibrillation or mitral valve disease. In suspected pulmonary emboli, epicardial echocardiography can be used to visualize the proximal right and left pulmonary arteries and pick out the exact location of thrombi (126a).

Some of the masses are tumors, of which most are benign and noncancerous. The most common tumor coming to surgery is a myxoma, which most frequently is attached to the interatrial septum; however, they can be seen in the right atrium, in both atria, or in the ventricles. The presence of a mobile mass on a valve in a patient who is not infected is commonly a fibroelastoma, most commonly seen on the aortic side of the aortic valve. However, many fibroelastomas occur on valves that are thickened by other degenerative or fibrotic processes and are seen by TEE but not identified as being a tumor until the histology of the resected valve tissue is done (127a).

For any patient coming to surgery with a mass of unknown histology type, a complete preoperative evaluation with TEE in the echocardiography laboratory and magnetic resonance imaging is mandatory. The malignancies are particularly challenging and unpredictable. Malignancies are most commonly seen in the right heart, pericardium, and infiltrating into the left atrium from the pulmonary veins. The prepump echocardiogram is useful for defining the location and extent of the tumor invasion and planning the extent of resection. The postpump echocardiogram is helpful in redefining the integrity of cardiac chambers and valvular function. In perivalvular masses, it is often possible to resect a tumor and reconstruct the valve, given the safety net of having valvular function checked reliably with TEE. In the series of 75 patients from the Mayo Clinic coming to surgery for mass removal, intraoperative TEE affected intraoperative management in 12 (16%), including return to bypass for valve repair in three patients (127b).

Tumor within the heart by extension from a venous structure is another important indication for IOE. The most common scenario is a renal cell carcinoma that has extended up the inferior vena cava, sometimes into the right atrium. In some patients, radical nephrectomy should be performed with the patient on cardiopulmonary bypass, to assist with safe removal of the mass in the right side of the heart. Tumor migration and air embolus can be detected by TEE and corrected immediately (127c,127d).

MYECTOMY FOR HYPERTROPHIC CARDIOMYOPATHY

For patients with surgical indications for myectomy, there is a particular need for IOE. This results from the variability of the location and extent of hypertrophy in patients with hypertrophic cardiomyopathy and the dynamic nature of the outflow tract obstruction. Echocardiography is an indispensable tool in planning and instituting effective surgical relief of the obstruction (128,129).

Prepump Echocardiography in Myectomy

Both transesophageal and epicardial echocardiography are useful in patients undergoing myectomy (Fig. 57.5). Either can define the location of hypertrophy and the location of the SAM. The location of the systolic contact of the mitral valve with the intraventricular septum and its distance from the aortic annular line in a long-axis view of the outflow tract are determined. This zone of SAM-septal contact is used as a guide to the best location for the myectomy. The surgeon must know the septal thickness in this region, to plan the extent of myectomy with the goal to resect all but approximately 1 cm of septal thickness at that location. It is also important to extend the myectomy beyond the zone of SAM-septal contact, especially in an apical direction. Measurement of the LV outflow tract velocity by continuous wave Doppler is also important during the prepump study, as a baseline for improvements that result from myectomy.

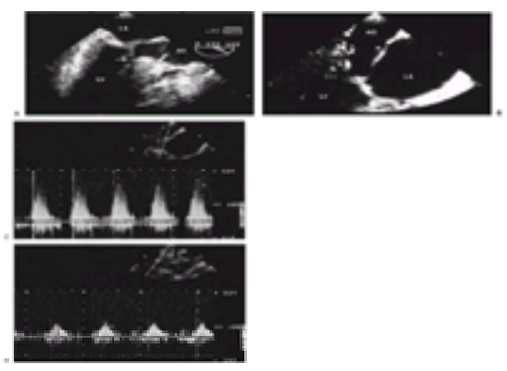

FIGURE 57.5 A patient with hypertrophic obstructive cardiomyopathy undergoing myectomy. **A:** A midesophageal image at a multiplane angle of 139 degrees showing the thick upper septum and the systolic anterior motion of the mitral valve touching the septum (*arrow*) causing dynamic outflow tract obstruction. **B:** An epicardial image taken from the aorta–superior vena cava transducer position, from which clean Doppler measurements of the outflow tract velocities can reliably be recorded. Arrowheads show the systolic anterior motion touching the septum. **C:** Prepump continuous wave Doppler recorded from an epicardial transducer, showing a 4.7 m per second maximum velocity (at the *X*, marked *A*), indicating a gradient of 88 mm Hg. **D:** Postpump continuous wave Doppler, showing a 1.7 per second maximum velocity (at the *X*, marked *A*), indicating an insignificant gradient of 12 mm Hg after myectomy. AO, aorta; LA, left atrium; LV, left ventricle.

With a TEE probe, the deep transgastric view can be used for measurement of the outflow tract velocity in some patients, but the transgastric measurements are not adequate in all patients. Occasionally, the midesophageal view can be used for this, but the continuous wave Doppler-echocardiographic signal of MR is often mixed with the LV outflow tract signal from this vantage point. To be certain that the correct jet is recorded, the TEE-derived continuous wave Doppler recordings should show a clean velocity envelope with a clear-cut, sigmoid-shaped, early systolic rising shape (26). Epicardial continuous wave Doppler-echocardiography is more reliable in obtaining the highest velocity to estimate the maximum instantaneous gradient (26). From the aorta–superior vena cava transducer position on the right side of the ascending aorta (Fig. 57.5B), outflow tract velocities can be reliably recorded. When resting gradients are normal, the degree of inducible obstruction is assessed using continuous wave recordings during infusions of isoproterenol, usually at around 10 µg per minute or when the contractility of the heart is visibly increased. Pacing does not suffice as a substitute inducement for latent obstruction.

MR resulting solely from dynamic outflow tract obstruction may occur later than the timing of mitral closure, due to the “eject-obstruct-leak” sequence (130). It is also important to assess the morphology of the mitral valve on the prepump study because of the frequent concomitant presence of myxomatous mitral valve disease (131). In patients without independent mitral valve disease, LV outflow tract gradients average 23, 44, 70, and 104 mm Hg, for trivial, mild, moderate, and severe MR, respectively (131a).

Postpump Intraoperative Echocardiography

After myectomy, patients are studied both at rest and during isoproterenol infusion at approximately 10 µg per minute to bring out latent obstruction. A successful result is present if the patient does not, either at rest or during provocation, have significant SAM that touches the intraventricular septum, significant MR, or an outflow tract gradient of more than 50 mm Hg. If these thresholds are exceeded after myectomy, the echocardiographic imaging is used to determine the location of residual SAM-septal contact, which is where further myectomy should be performed during a second pump run to relieve the obstruction (129). If moderate or more MR is found on the postpump TEE, a more aggressive search for a significant LV outflow tract gradient or intrinsic mitral valve disease should be considered and investigated.

The frequency of second pump runs in myectomy is 17.9%, the highest frequency of any type of cardiac surgery that our group has studied, which underscores the difficulty in the surgical approach to this lesion. The percentage of second pump runs in hypertrophic obstructive cardiomyopathy is high in part because of the policy of giving isoproterenol to all patients insisting on elimination of even latent outflow tract obstruction or significant MR (19a).

CONGENITAL HEART DISEASE

IOE is extremely useful in many types of congenital heart surgeries. Epicardial echocardiography has been traditionally used in a higher frequency of pediatric patients than adults, particularly in children smaller than appropriate for the available transesophageal probes (132,133). However, since the availability of the smaller pediatric TEE probes (133a,134), epicardial echocardiography has become much less common.

Ventilatory compromise is infrequent in small infants undergoing TEE examination and can be avoided by careful ventilatory monitoring (134a). TEE is useful in this population to guide accurate placement of central venous catheters in congenital heart surgery patients (134b). However, esophagoscopy after intraoperative TEE shows minor traumatic abnormalities, particularly in patients weighing less than 9 kg, although no long-term feeding or swallowing difficulties were noted (134c).

Epicardial echocardiography may also be required in defining certain problems not easily visualized with TEE, such as abnormalities of the LV outflow tract (25) and right ventricular outflow tract (135), which are in the far field of TEE. Doubly committed subarterial VSD is particularly difficult to diagnose by TEE (136). For either epicardial echocardiography or TEE, a segmental approach to cardiac anatomy should be used, analyzing cardiac situs, atrioventricular connections, ventricular arterial connections, and expected anatomic variants. Using both color flow imaging and contrast imaging is more sensitive to detect shunts than is either one alone (137).

Prepump Imaging in Congenital Heart Disease

Because of the difficulties in doing outpatient TEE in young people, the operating room is the most common place where children with congenital heart disease are first examined with TEE. The additional window to the anatomy often provides improved image quality and imaging planes different from those of transthoracic imaging.

Most simple abnormalities, like atrial and VSDs, are well diagnosed by transthoracic echocardiography. In some cases, however, the prepump study finds additional information not discovered preoperatively, despite apparently good clinical and echocardiographic workup (eFig. 57.5.1). This is particularly true when there are multiple congenital abnormalities. For example, it is not uncommon for TEE to find an endocardial cushion or muscular VSD where only a membranous defect was expected.

In a study by O'Leary et al. (138), the prepump imaging findings had "significant impact" on intraoperative management in 16.3% of congenital heart surgeries and led to alteration of the planned procedure in 10.6%. Gussenhoven et al. (139) similarly found that IOE contributed to an alteration of the surgical approach in 13% of cases. In a study by Stumper et al. (140), prepump IOE found important new information in 25% of patients. IOE is better than preoperative transthoracic echocardiography in identifying VSDs (92). More recently, Durongpisitkul et al. found a significant impact of postpump IOE in 14% of congenital cases, of which approximately one-half were found primarily by the echocardiogram (37a). However, one author found no difference on TEE compared with preoperative studies (140a).

IOE has also been useful as a hemodynamic monitor during certain surgical procedures done for congenital heart disease, for example, to monitor right ventricular function and outflow tract gradients during pulmonary artery banding. During ligation of congenital arteriovenous fistulas, TEE can monitor the locations of venous drainage and look for myocardial ischemia (141). Balloon atrial septostomy can be performed using TEE guidance, providing better control and management of therapy (142).

Postpump Imaging in Congenital Heart Disease

After congenital heart surgery, the postpump IOE provides an important safety net on the results of surgery. The most common problems found after congenital surgery are new or persistent valvular regurgitation or new or persistent obstruction of the right ventricular or LV outflow tract. The frequency of second pump runs at our institution is 5.7% (19a). In the largest series of 1,000 patients undergoing a wide spectrum of congenital heart surgery, Ungerleider et al. (143) reported that 44 patients (4.4%) underwent intraoperative revision of their repair during a second pump run based on echocardiographic findings, of which 39 had successful elimination of the problem.

In a study by Gussenhoven et al. (139), the postpump imaging information led to immediate further surgery during the same thoracotomy in 3% and to inotropic drug therapy in 2% of patients. In a cohort at the Mayo Clinic, postbypass biplane TEE led to immediate revision of the initial repair in 8.7% of cases (138). Sheil and Baines found moderate or severe residual defects in 11.0% of cases, with 5.3% of the total group returning to bypass for further surgery, with which most, 4.0% of the total group, achieved complete or adequate amelioration (140a).

In surgery for tetralogy of Fallot, residual gradients across the right ventricular outflow tract are found in some patients, requiring a second pump run in up to 12% of patients (143a). Kaushal et al. considered significant gradients to be those with a gradient above 40 mm Hg, a right ventricular to LV pressure ratio above 0.85, or a fixed appearance by imaging, with no change in right ventricular outflow tract dimensions during the cardiac cycle. By comparison, dynamic obstruction in which dimensions increased appreciably in diastole appear to improve significantly without revision, irrespective of their severity (143a). However, the postpump TEE can miss residual pulmonary branch stenosis in patients with tetralogy (143b).

Patients who undergo modified Fontan's operations or subaortic resections had the greatest frequency of second pump runs, 40% and 33%, respectively, in one study (138). Stumper et al. (140) found an 18% incidence in patients with Fontan's procedures. Using IOE in Fontan's procedures, Fyfe et al. (144) found that TEE can nicely visualize atriopulmonary and cavopulmonary anastomoses and lead to second pump runs in 42% of cases.

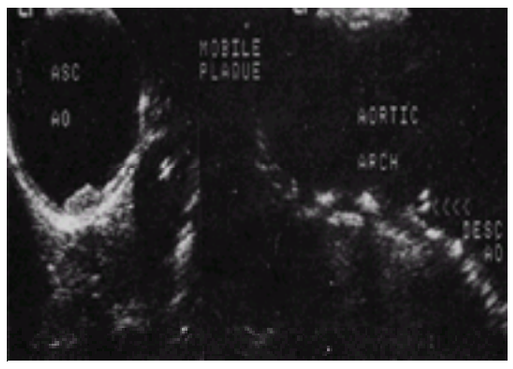
After closure of VSDs, IOE often finds residual shunts, particularly at the edges of the VSD patch, some of which do not require repair. Hsu et al. (146) found residual defects in 11 of 25 patients after VSD repair; one required a second pump run, and eight defects resolved spontaneously. Similarly Yang et al. found a residual VSD in one-third of 294 patients after VSD repair, of which two-thirds closed spontaneously by TEE before hospital discharge; nine patients (3% of the group) returned to bypass for further surgery, all with residual VSD color jet diameters greater than 3 mm (146a). However, Gussenhoven et al. (147) found postpump residual shunts in 10% of VSD repairs, 60% of which were reoperated on during the same thoracotomy, with the common findings of partial patch dehiscence. Two studies have suggested using intraoperative oximetry to determine pulmonary to systemic flow ratio, using a threshold of a pulmonary-to-systemic flow ratio of greater than 1.50 as a criterion for intervening with a second pump run (145,146a).

DEFINING THE LOCATION AND SEVERITY OF AORTIC ATHEROMA

Of the complications that can occur after cardiac surgery, one of the most devastating is the phenomenon of atheroemboli. This can cause extensive microcapillary occlusion, with end-organ damage in the brain, liver, kidneys, spleen, and skin and is a common cause of perioperative death (148). Diffuse atheroemboli produce the phenomenon of the "blue toe" syndrome (149). Despite that atherosclerotic lesions in the aorta are common in patients undergoing surgery for coronary or aortic atherosclerosis, observable events are surprisingly infrequent. Risk factors for clinical embolization include age, smoking, peripheral vascular disease, previous stroke, diabetes, and aortic knob calcification on chest radiographic films (151). Events are more common in patients who have larger atheromas of the thoracic aorta as defined by echocardiography (150)—as high as 15% in one series (151a).

Methods of Definition of Atheroma from Echocardiography

Echocardiography is one of the best ways of defining the location and presence of atheroma. The farther the atheroma protrudes into the lumen and the more mobile it is (*e*Fig. 57.5.2), the more likely that showers of atheroemboli will occur spontaneously (152) with a high risk of death (153).



***e*FIGURE 57.5.2** Epicardial intraoperative echocardiography of a patient with significant atheroma of the ascending aorta (AO) (*arrowheads*), viewed in the short (*left*)

and the long axis (*right*). This put the patient at higher risk of perioperative stroke. (From Stewart WJ. Intraoperative echocardiography. In: Skorton D, ed. *Cardiac imaging—principles and practice*. Philadelphia: WB Saunders, 1996:566–581, with permission.)

In one IOE study, patients with mobile atheroma had a 25% incidence of stroke versus 2% in those without a mobile atheroma (154). Emboli of atheromatous material also occur in response to surgical manipulation, such as aortic cross-clamping, aortotomy for valve surgery, aortic venting, placement of catheters for cardioplegia, and proximal vein graft anastomoses. In addition, flow from the arterial cannula for cardiopulmonary bypass may causes a “sand blasting” effect on the inside of the aorta, with the likelihood of dislodging atheroma and causing stroke (155).

IOE is used to learn the location and severity of aortic plaques to help to avoid such complications. By epiaortic echocardiography, the finding of nonisoechoic walls correlates with the risk of deformities at the cross-clamping site and the presence of atheroma as assessed by the histology of tissue punched from the ascending aortic wall at the location of proximal vein graft anastomosis (155a).

It is clear that intraoperative aortic palpation is not sensitive to atheroma at risk for embolization (156). In fact, both manual palpation and TEE are inaccurate methods for detection of atheroma in the ascending aorta (156a). TEE is insensitive in the ascending aorta, probably because of far-field attenuation and because of the 2- to 4-cm blind spot anterior to the trachea (157). The ascending aorta is imaged best by epivascular echocardiography, using a high-frequency sector transducer or a linear array transducer (158,159).

The routine for evaluating the ascending atheroma with epivascular echocardiography entails four parts. First, the sleeved high-frequency transducer is placed directly on the ascending aorta and moved up and down to obtain a set of short-axis and a set of long-axis views of the posterior wall of the ascending aorta. Then the short- and long-axis views are repeated using a standoff device to systematically view all portions of the anterior wall of the ascending aorta. Without using a standoff device, such as a glove partially filled with warm saline solution, the anterior wall is hidden in the near-field “bang” artifact.

Changes in Surgery Based on Echocardiographic Findings

Based on the echocardiographic information, several aspects of the process of cardiac surgery can be changed if it is expected that this will reduce the likelihood of dislodgment of atheroma. The arterial cannula can be placed in a different location in the ascending aorta to avoid areas of atheromatous plaque, particularly the soft friable ones. The arterial cannula can be placed elsewhere, such as the brachiocephalic, axillary, or femoral artery (160). The location or mode of giving cardioplegia or attachment of proximal portions of vein grafts can also be changed. Cardioplegia can be administered solely in a retrograde fashion through the coronary sinus, rather than making another wound in the ascending aorta. Another potential change is placing the aortic cross-clamp where it will do the least damage, particularly avoiding the dense calcified plaques. In cases in which the ascending aorta is severely diseased, internal balloon occlusion of the ascending aorta can permit exclusion of the systemic arterial flow from the operative field (161). In addition, cold ischemic circulatory arrest can be used during coronary grafting instead of cardiopulmonary bypass (156,162). The best option may be off-pump coronary bypass, using internal mammary arteries, doing coronary grafting on the beating heart without touching the aorta, which usually avoids atheroemboli (162a). Finally, in selected patients with severe atheroma at high risk for embolization if standard surgical techniques are used, replacement of the most diseased section of the aorta with a synthetic conduit is an option (163). One option that is not beneficial is endarterectomy, which was associated with a threefold increase in perioperative stroke (151a).

Wareing et al. (164) published an extensive series of patients who underwent cardiac operations with the guidance of epivascular echocardiography. This population had extensive aortic atherosclerosis at 10% or more risk of neurologic complications, according to historical controls. They obtained low complication rates using an echocardiography-guided approach. Despite the high risk of embolization and an extensive list of special modifications of surgical technique, no patient had a permanent neurologic deficit, compared with a 1% incidence in the patients at lower risk who did not have IOE.

MINIMALLY INVASIVE CARDIAC SURGERY

Surgical techniques have been developed in which certain cardiac surgical procedures can be performed through smaller incisions, avoiding a full midsternal thoracotomy (165,166) and avoiding some of the trauma of the traditional methods of cardiac surgery. These minimally invasive procedures have also been called less invasive operations, or sometimes “keyhole surgery.” In some circumstances, there appear to be advantages, including fewer complications, less pain, less bleeding, less recovery time, and less in-hospital expense. However, numerous disadvantages occur, including the inability to directly visualize the anterior epicardial surface of the heart and the inability to lift the cardiac apex for needle evacuation of air. Another disadvantage is the additional cost of special equipment that enables the surgery or cardiopulmonary bypass to be accomplished with special methods.

Several varieties of minimally invasive procedures have been developed, including hemisternotomy, port access operations, videoscopic surgery, and off-pump coronary bypass. In our experience with approximately 1,700 hemisternotomy cases, most of which were single mitral or aortic valve procedures, less than 1% of surgeries begun using minimally invasive procedures have developed problems requiring conversion to a midsternal thoracotomy, using a larger incision. The bleeding rates, morbidity, length of stay, and hospital costs have all been lower than with use of a standard midsternal incision, and the reoperation rates are unchanged.

Purposes of Intraoperative Echocardiography in Minimally Invasive Surgery

In minimally invasive procedures, IOE is useful for determining ventricular filling, ventricular function, and the presence of intracardiac air. In addition, IOE is useful in delineating the exact cardiac pathology that requires surgery and excluding additional problems that the surgeon is otherwise unable to determine due to lack of exposure (167).

Intraoperative echocardiography can detect new wall motion abnormalities to define intraoperative myocardial ischemia, which is associated with reduced postoperative prognosis (167a). TEE has also been used in hemisternotomy cases to determine the precise location for “T’ing” off the sternotomy, rather than approximating the sternotomy site by physical examination and chest radiography (167b).

In port access procedures, TEE is useful for correct positioning of various devices, including the endopulmonary vent catheter, the coronary sinus retrograde cardioplegia catheter, the venous cannula, and the aortic balloon catheter (endoclamp) used for internal occlusion of the aorta. The latter is used to exclude the systemic circulation receiving pressurized cardiopulmonary flow without the trauma of external aortic cross-clamping, but the balloon must be monitored by TEE constantly during the procedure, as it can migrate up or down, affecting the endoaortic occlusion or even damaging the aortic valve (166a,167c). TEE is also used to visualize the coronary sinus for placement of the retrograde cardioplegia catheter, obviating the need for fluoroscopy (166b).

Coronary bypass surgery can be done off pump, which has been called *minimally invasive direct coronary bypass* or MIDCAB, which appears to be useful in some situations (167a). The distal coronary graft anastomosis is done using heart-stabilizing instruments. Proximal anastomoses are avoided if possible by the preferential use of *in situ* mammary arteries, sometimes with side branches or an additional venous jump graft off the mammary. However, to perform the distal anastomosis requires temporary occlusion of the coronary artery, which causes focal wall motion abnormalities as defined by TEE in two-thirds, most of which are transient. However, in approximately 10% of patients, the wall motion abnormality persists to the time of chest closure, in which case they are likely to be permanent, with higher levels of cardiac enzyme release, more ST-T changes on the electrocardiogram, and more clinical problems than patients in whom the wall motion abnormality resolves before chest closure (167f). Intraoperative contrast echocardiography has been used in off-pump CABG to assess flow and verify the patency of the coronary artery (167g), similar to the Allen’s test. This can help to determine which graft to place first to cause the least ischemia.

Because they are done without aortic cross-clamping, both minimally invasive direct coronary bypass and port access techniques are excellent for management of patients with severe aortic atheroma, to avoid trauma to the ascending aorta and systemic embolization of debris. In a series of port access operations, the patient survival rate was 99%, the incidence of perioperative stroke was 1%, and the incidence of aortic dissection was 1% (19b), which are better statistics than historical controls in this population.

After the minimally invasive surgery is finished, IOE is useful to define the adequacy of volume filling and inotropic drug therapy and to assess the success of the primary surgical mission. Because the surgeon cannot see the LV, IOE is important for determining optimal fluid replacement.

TEE is also useful for defining the presence of intracardiac air, most commonly seen in the anteroapical LV and the anterior portions of the left atrium. Additional surgical measures or more time on cardiopulmonary bypass may be necessary for removal of the air. In our experience, new LV dysfunction on the immediate postpump TEE was noted in 20% of 112 patients having minimally invasive valvular surgery, being more common (30%) in patients with extensive air by IOE compared

with those without extensive air (10%) (168a). These LV wall motion abnormalities usually resolve.

From the literature about standard midsternal thoracotomy surgery, numerous factors are known about intracardiac air. First, it is seen more commonly after valvular than coronary surgery and generally needs no specific treatment if it is not excessive (168). Particularly after procedures in which the heart is actually opened, larger amounts of air pool in anterior structures (169), including the right upper pulmonary vein, LV apex, left atrium, right coronary sinus of Valsalva, left atrial appendage, left upper pulmonary vein, and pulmonary artery (170). When excessive amounts of intracardiac air are present in the ascending aorta, coronary embolization occurs readily (171). The right coronary ostium is anterior in the ascending aorta and therefore the more likely site for air, causing inferior infarctions, usually small in magnitude, in up to 5% of patients undergoing mitral repair using a standard midsternal incision in one report (172).

TREATMENT OF SEVERE LEFT VENTRICULAR DYSFUNCTION

Several devices are useful for treatment of patients who are critically ill or in cardiogenic shock, including the ventricular assist device, the extracorporeal membrane oxygenator, and the intraaortic balloon pump. For patients who require these devices, echocardiography has a role in implantation, positioning, safety, and determination of the hemodynamic effects on the patient.

In patients with hypotension, mechanical causes including pericardial tamponade (176), occult valvular disease (177), and hypovolemia can be diagnosed by echocardiography. In patients with heart failure, echocardiography can also be influential in diagnosing the etiology. In cardiogenic shock patients, TEE can guide therapy and help adjust pharmacologic treatment.

For patients who require an intraaortic balloon pump, TEE is useful for its insertion, to define the location of the distal tip in the upper descending aorta (173,174), and to determine its effects on LV function, aortic atheroma, and myocardial ischemia. During placement of the intraaortic balloon pump, the guidewire can easily be detected by TEE as it appears in the descending aorta. As the catheter itself is introduced, its prominent echocardiographic reflections can be tracked up the descending aorta. The tip of the catheter should be in the upper descending aorta below the distal aortic arch. If the catheter is placed too far superiorly, its tip may raise a flap of intima, which TEE can detect as a linear projection into the lumen (175).

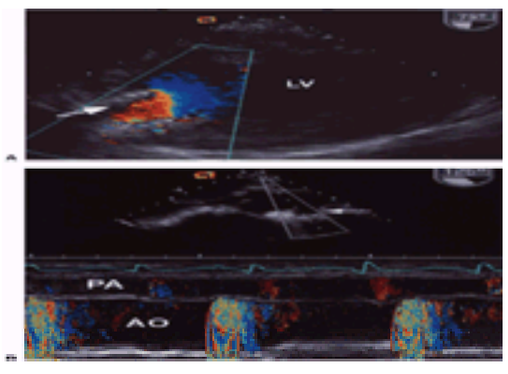
IOE has also been used in heart transplantation, particularly in patients with suspected atrial thrombi or TR (178). When the postimplantation TEE notes clinically significant right ventricular volume overload, it is important to assess the integrity of interatrial anastomosis for atrial shunting (179) and the valves for regurgitation, especially the tricuspid valve. In lung transplantation, TEE can monitor improvement in right ventricular function as the severe pulmonary hypertension resolves (180) and assess patients for subpulmonic obstruction secondary to long-standing right ventricular hypertrophy.

Extracorporeal membrane oxygenation is a temporary support system for patients who have cardiogenic shock with severe hypoxia. Blood is taken out of a large artery or vein using a large cannula, bubbled through a membrane to absorb oxygen and release carbon dioxide, and pumped back into a systemic vein. At the point of weaning the patient off of extracorporeal membrane oxygenation in the intensive care unit, TEE is used to monitor cardiac function while the output of the pump is reduced. If the patient's blood pressure falls, the echocardiographic images are used to determine how and why cardiac function is inadequate.

The temporary assist device is an external pump used in patients with severe left-sided heart failure to take over the mechanical function of the left side (LVAD) or the right side (right ventricular assist device) of the heart. A large cannula is placed into the left atrium to remove blood, oxygenate it, and pump it at systemic arterial pressure into an artery such as the ascending aorta or femoral artery (181). TEE can detect malfunction of the device (182,182a). It also may define resolution of transient cardiac abnormalities that may allow discontinuation of support (183), as well as complications such as intracardiac thrombi that can develop (184).

Echocardiography in the Implantable Left Ventricular Assist Device

In contrast to the temporary type, ventricular assist devices that are implantable have been increasingly used to provide a bridge to transplantation. In these, the entire pump and the conduits are inside the body, with the body of the pump usually placed in the anterior abdominal wall inferior to the ribs. Instead of the left atrium, the LV apex is the site where the outflow cannula is inserted (*e*Fig. 57.5.3). Use of the implantable LVAD has substantially improved the physical condition of many patients at the time they undergo heart transplantation (185).



***e*FIGURE 57.5.3** Postpump transesophageal echocardiographic color images after insertion of an implantable left ventricular assist device. **A:** Transgastric long-axis view of the left ventricle (LV) at 79 degrees showing flow out of the LV into the inflow cannula (*arrow*) of the left ventricular assist device. **B:** Midesophageal long-axis image of the ascending aorta (*top*) showing the position of the cursor through the outflow cannula and (*bottom*) the color M-mode illustrating the timing of flow from the pump into the ascending aorta (AO), which occurs less frequently than flow in the pulmonary artery (PA), which occurs lined up with systole on the electrocardiographic tracing above it.

IOE is a useful adjunct before insertion of an implantable LVAD. Importantly, several specific cardiac abnormalities should be ruled out, including right ventricular dysfunction, patent foramen ovale, LV apical thrombus, AR, and ascending aortic atheroma (182a,186,187). When discovered, a patent foramen ovale should be corrected in the process of LVAD implantation. If correction is not accomplished, a right-to-left shunt may result when left atrial pressure is reduced by the LVAD. The same applies to significant AR found by TEE. When AR is present, the LVAD creates a continuous loop of ineffective flow, so aortic valve surgery may be indicated during LVAD implantation.

After implantation, examination of the functional integrity of the LVAD is useful. Under normal conditions of LVAD demand function, the aortic valve often does not open because it is bypassed in the circuit. An item of interest is that during demand function, the flow into the LV apical cannula occurs in a dyssynchronous fashion with respect to ventricular contraction. However, the LV apical outflow cannula can become angulated, causing partial obstruction, which tends to increase the velocity of flow above 2 m per second. In addition, the bioprosthetic valves at the inlet and outlet of the cannula can malfunction by degenerative changes or infection. A sudden increase in the output of the pump weeks to months after implantation should signal a need to look for LVAD valve regurgitation.

CORONARY ARTERY BYPASS SURGERY

Purposes and Indications for Intraoperative Echocardiography

The purposes of the prepump study in patients undergoing CABG are to define global ventricular function, assess segmental LV function in each coronary artery territory, define the need for intravascular volume replacement, determine indications for inotropic drug therapy, plan arterial cannulation, and identify the presence and severity of valvular dysfunction. We do not use TEE during every coronary bypass operation, although some centers do (188). IOE is particularly useful in CABG patients who are at high risk of complications, particularly those with significant LV dysfunction, older age, concomitant vascular atherosclerosis, or unstable hemodynamics. Michel-Cherqui et al. reported that the prepump IOE changed the operative plans in 4.6% of coronary bypass cases (36a). In addition, patients with complications of myocardial infarction (189) such as ischemic VSD (190,191) or MR (192) benefit substantially from intraoperative TEE.

Savage et al. (200) studied a consecutive series of 83 high-risk patients undergoing coronary bypass who did not have other indications for IOE on the basis of valvular disease or other factors. This group represented a population with a high incidence of vascular disease, myocardial dysfunction, and unstable hemodynamics. In 33% of patients, the IOE altered the surgical decision process. This included changes in the arterial cannulation site or methods, decisions to do coronary bypass without

cardiopulmonary bypass or on circulatory arrest, unplanned valve procedures, unplanned additional coronary grafts, decisions to rush the patients onto bypass, and institution of an LVAD. The postpump study found problems that necessitated a return to bypass in 3% of the group studied. In this group of high-risk coronary bypass patients, IOE initiated major anesthetic or hemodynamic changes in 51% (200).

Transesophageal Echocardiographic Anatomy Corresponding to Coronary Artery Distributions

It is important to understand the regional anatomy of each coronary artery bed with respect to the tomographic imaging planes available with TEE. Figure 57.6 shows a diagram of three midesophageal long-axis views and one transgastric short-axis view of the LV, coded for the distribution of each coronary artery. These four views allow analysis of all 16 segments of the LV surface, composing the segmental model used by the American Society of Echocardiography. Obviously, the dominance of the right versus circumflex coronary artery supply determines which artery supplies the posterior segments of the heart. Other individual anatomic variations also affect, for example, whether the basilar posterior wall is perfused by the right or the circumflex coronary artery, whether the midseptum is perfused by the right or the left anterior descending artery, and whether the midlateral wall is perfused by the circumflex or the left anterior descending artery.

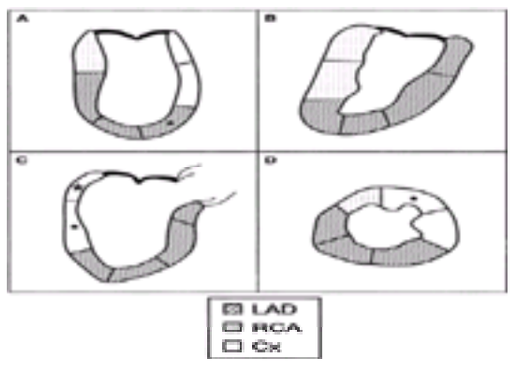


FIGURE 57.6 The four standard transesophageal echocardiographic monitoring views showing the distributions of the left anterior descending (*hatched*), right (*stippled*), and circumflex (*white*) artery territories. **A:** Basilar transverse (0 degrees) plane showing the septal (*left*) and lateral (*right*) walls from apex to base. **B:** Basilar 60-degree view showing the inferior (*left*) and anterior (*right*) walls. **C:** Basilar 120-degree plane showing the posterior (*left*) and anteroseptal (*right*) walls. **D:** Lower right transgastric short-axis view showing the midventricular segments of all six walls. The star and asterisks indicate segments that vary in their coronary artery supply depending on the dominance of the circulation.

Methodology of Analysis of Left Ventricular Segmental Function

Similar to stress echocardiography, side-by-side simultaneous moving images in a gated loop format are best for qualitative assessment of subtle differences in segmental wall motion. It is useful to store standard cine loops in a digital format from each of the four basic planes at baseline for later comparison. The methods of evaluating LV size, segmental function, and ischemia (see the section Decisions in Noncardiac Surgery Based on Intraoperative Echocardiography) for noncardiac surgery are equally applicable in coronary bypass patients.

IOE can also be useful in following improvement in LV systolic wall thickening after CABG. Wall thickening improves most in those segments with the abnormal preoperative function that had chronic ischemia or hibernation preoperatively (8,197). More immediate improvement is seen in severely abnormal, chronically underperfused segments than in mildly hypokinetic segments, presumably because of reversal of hibernation (198).

Before CABG, some have advocated evaluating segmental wall motion during an infusion in the operating room of 5 to 10 µg per kg per minute of dobutamine, to determine which walls would benefit the most from revascularization (193). Augmentation in response to low-dose dobutamine of a segment that has abnormal function at rest was predictive, in one published series, of sustained improvement of the segment after CABG (194).

Diagnosis of Ischemia after Coronary Bypass

TEE can be used to evaluate myocardial ischemia after bypass surgery on the basis of new wall motion abnormalities; however, the frequency of this occurrence is quite variable depending on the population and the methods. At one extreme, Leung et al. (195) diagnosed myocardial ischemia using the postpump TEE in 30% of patients undergoing coronary bypass. At the other, Deutsch et al. (104) found immediate vein graft occlusion that was not otherwise suspected in only 2 (4%) of 50 patients undergoing TEE after coronary bypass.

One study found that perioperative ischemic episodes were infrequently triggered by changes in hemodynamics. These episodes of wall motion abnormalities found by TEE could not be predicted by pulmonary artery or arterial pressure monitoring. The authors suggested that a primary decrease in myocardial oxygen supply may be an important mechanism for most perioperative ischemia as manifested by a regional abnormality on echocardiography (196). Whether this represents spasm, activity within unstable atherosclerotic plaques, or another mechanism is not clear. Another surprising result is that there is more deterioration of wall motion early after surgery in segments subtended by new internal mammary artery grafts than by new vein grafts (199).

Contrast Echocardiography in Coronary Bypass Surgery

Contrast echocardiography has been used for endocardial border opacification, Doppler signal enhancement, and myocardial perfusion evaluation. The first two are not usually necessary in surgery because access to the heart is usually so good. Perfusion imaging is still in its infancy, and most of the details of how to perform it and how to analyze the imaging data are still debated and not ready for clinical use. Contrast echocardiography prolongs the operation by 10 to 15 minutes and does not cause perioperative complications (201).

Contrast echocardiography has been proposed before coronary bypass surgery as a means to determine collaterals and assess the exact perfusion beds of each coronary artery. Contrast agents can be injected into the aortic root in an effort to define hypoperfused areas of the myocardium. Echocardiographic images of the LV in multiple planes are evaluated for contrast enhancement with time-intensity curve analysis (202,203 and 204). This can provide information about the magnitude and topographic distribution of runoff of coronary artery bypass grafts and enable identification of poorly perfused myocardial regions (205). Pulsing the ultrasound to destroy the bubbles, then evaluating the rate of replenishment, can objectively quantitate flow (206).

Identification of perfusion beds of diseased vessels that receive collateral perfusion flow has been studied using contrast IOE (207). Contrast echocardiography can help to determine the optimal sequence of coronary grafting. By grafting the most ischemic vessel first, perioperative ischemic damage might be lessened. Contrast agents can also be injected into the free proximal end of a venous graft after coronary anastomosis, while the heart is arrested. Intraoperative contrast opacification has been used to determine adequacy of myocardial perfusion and can predict regional myocardial function 1 week after surgery (207a). In theory, finding regions of poor flow could guide the need for additional grafts.

Contrast echocardiography can be used for evaluation of the intensity and distribution of cardioplegia delivery, which may relate to intraoperative myocardial protection and eventual ventricular function (208). This might be important in avoiding perioperative ischemia of the territories of the most severely diseased vessels. In some cases in which antegrade cardioplegia does not reach specific coronary beds, retrograde cardioplegia may provide effective local myocardial protection (209).

After bypass, contrast can identify improvements in myocardial flow and failure to reperfuse, which correlates with preoperative coronary stenoses (204). Contrast echocardiography has also been used experimentally to identify the patterns indicative of successful versus inadequate coronary perfusion from an internal mammary graft to the left anterior descending artery (210) and to determine the effects of transmyocardial laser revascularization of the ischemic myocardium.

DECISIONS IN NONCARDIAC SURGERY BASED ON INTRAOPERATIVE ECHOCARDIOGRAPHY

IOE is quite useful in patients undergoing noncardiac surgery. The purposes are to monitor development of myocardial ischemia, assess ventricular volume for fluid replacement, and define other cardiovascular abnormalities that affect hemodynamics and perioperative management. IOE is useful in a selected minority of

noncardiac operations, particularly when the risk of problems is higher because of the type of surgery planned or the patient's underlying cardiac condition (211).

IOE is particularly useful in vascular surgery involving cross-clamping of the upper abdominal aorta (212) in which a sudden increase in afterload occurs, causing an increase in myocardial oxygen demand (213). During insertion of a cemented femoral hip prosthesis, there is a substantial incidence of new segmental wall motion abnormalities (214). TEE has also been used to determine the intraoperative occurrence of intrapulmonary shunting, presumably due to fat embolization, to help develop new cementing techniques during hip replacement (214b). Similarly, IOE benefits cases such as liver transplantation, in which a sudden or severe shift in intravascular volume status occurs. In operations done in the sitting position, intraoperative TEE can help detect venous air embolism (214a).

Detection of Myocardial Ischemia

Intraoperative TEE helps to determine the presence and severity of myocardial ischemia to facilitate pharmacologic treatment (215). In many circumstances, detection of segmental abnormalities due to ischemia is enabled by judicious use of simultaneous, side-by-side, gated cine loop displays, showing matched imaging planes before or after the onset or cessation of an abnormality. As a baseline at the beginning of each case, it is useful to store the standard LV views in a quad-screen format, including the transgastric short-axis view and midesophageal long-axis views at multiplane angles of 0, 60, and 120 degrees (Fig. 57.6). These are recalled for direct comparisons with later images at a time when ischemia or hypovolemia is clinically suspected or must be ruled out.

TEE detection of intraoperative myocardial ischemia has good concordance with, but is more sensitive than, electrocardiographic monitoring (215,216). Side-by-side cine loop comparisons are much more definitive than serial observation for qualitative diagnosis of new wall motion abnormalities and mild changes in blood volume (217). These may be quite subtle and difficult to see if viewed sequentially from tape playback. The detection of wall motion abnormalities has an intraobserver variation in only 5% of segments, whereas the interobserver variation is only 9% of segments (218).

However, one should be aware of the impact of plane orientation on apparent wall motion. Off-axis cuts can produce patterns that look similar to segmental wall motion abnormalities. In addition, false-negative assessments for ischemia are obtained if an inadequate number of imaging planes are assessed or side-by-side comparisons are not made with great care (219). One biplane TEE study found that 20% of segmental wall motion abnormalities were found by the transverse plane alone, 35% by the longitudinal plane alone, and 45% were detected in both planes (220).

In one study of patients at high risk of ischemia undergoing vascular surgery, alterations in ventricular wall motion were noted in almost 50% of patients, in whom 71% of the alterations were completely reversed by immediate and specific fluid and pharmacologic interventions without any evidence of permanent myocardial infarction (221). When acute segmental wall motion abnormalities persist to the conclusion of surgery, myocardial infarction is likely to have occurred (216) and postoperative intensive monitoring is mandatory.

Determination of the Adequacy of Intravascular Volume

Intraoperative TEE provides a useful direct means of visualizing the adequacy of LV volume. At the extremes, this can rapidly be determined subjectively by the presence of a contracted or expanded LV (222,223). However, subtle shifts in ventricular volume are best assessed qualitatively by serial imaging from the same imaging plane (224).

In many respects, TEE images of LV volume provide more direct, better quality data about LV filling than does the capillary wedge pressure from the pulmonary artery catheter, which is relatively inaccurate for determining adequacy of preload (225). It is also important to remember that LV cavity size is also affected by afterload, increasing with phenylephrine even in the absence of a change in intravascular volume (226), so blood pressure must be monitored, along with either TEE or a pulmonary artery catheter.

Although it takes more effort to obtain quantitative assessment of forward flow, TEE can also determine cardiac output accurately, using combined diameter and spectral Doppler velocity measurements, with accuracy that is comparable with thermodilution measurements (227,228 and 229). Similarly, quantitation of ventricular systolic and diastolic volumes can be accurately done with a modicum of effort. Although care must be taken to avoid foreshortening the long-axis diameter, quantitation can be done from TEE images using hand tracing (230) or automatic boundary detection (231). The latter is an automated technique that requires experience in its operation, with the potential for inaccurate estimates, especially if the echocardiographer is not diligent to ensure that the primary images remain on axis and optimally recorded (232). With qualitative or quantitative techniques, careful attention to the quality of the primary ultrasound images is essential.

Echocardiography of Diastolic Function and Ventricular Filling

Numerous pulsed Doppler velocity patterns assessed by TEE can be useful adjuncts to direct visualization of the ventricles in determining the adequacy of ventricular filling during noncardiac surgery (233,234).

For example, elevated LV filling pressures are evidenced on the LV inflow recordings by a short mitral valve deceleration time, an elevated E-wave velocity, and an elevated E/A ratio (235). High filling pressures also cause systolic blunting of the pulmonary vein systolic velocity or a long duration or high velocity of the atrial reversal (236). These patterns are typical of the restrictive filling patterns and elevated preload (237). On the converse are the delayed relaxation patterns, which often indicate relatively low LV filling pressures. These are characterized by a low E-wave velocity, reduced E/A ratio, and long deceleration time on pulsed Doppler of the LV inflow (237), while the pulmonary vein flow velocity profile shows a normal or high systolic-to-diastolic ratio and a short, low-velocity atrial reversal wave (236). The entire constellation of intracardiac velocity patterns, integrated with images of right ventricular and LV size, are better than taking one measurement out of context (235).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Anesthesiology versus Cardiology Qualifications: Who Should Do What in the Operating Room?

Various considerations are relevant to the question of who should perform IOE. Experience and training are more important than the specialty of the person doing the echocardiogram (237a).

Because the anesthesiologist is present during the entire case, he or she may naturally be the best person to do IOE for cardiac surgery, provided the individual has training and expertise in echocardiography. Because of their management role in surgery, the anesthesia team is also more likely than a cardiologist to use the TEE information to optimally manage the patient in surgery, especially when monitoring is the primary function. However, the anesthesiologist who is responsible for hemodynamic management is often busy doing just that, so it is best to have a second person do the echocardiography. The most crucial times to image the heart are also the times of most clinical instability, when the anesthesiologist needs to concentrate on patient management. Whether the second person who is doing TEE is from one specialty or the other, it is useful to have another experienced echocardiographer for backup when the TEE is primarily managed by the person who is also giving anesthesia.

In other respects, the cardiologist is the best person to do IOE, provided the geographic considerations make him or her available at the appropriate times. The people who are most current and skilled at performing diagnostic TEE studies, often the cardiologist who does them in the echocardiography laboratory, are likely to also provide the most reliable determinations for valvular problems, complex congenital heart disease, and other diagnostic determinations that are needed in surgery (238). However, most cardiologists are not consistently available for IOE, nor are they comfortable with the process or politics of the operating room. Many of the hemodynamic perturbations regarding cardiopulmonary bypass and anesthesia are unfamiliar to the cardiologist unless he or she has developed substantial experience in surgery.

In some cases, it works well for the surgeon to take the trouble to learn echocardiography and perform the IOE studies. The easiest method for many surgeons is to use epicardial echocardiography (28,239). This usually requires the presence of a separate person outside the sterile field, sometimes a sonographer, who operates the machine controls. One disadvantage of this is that the surgeon is therefore also the diagnostician and may be biased against finding fault with the procedure(s) he or she has just performed, in contrast to a separate person who can usually be more objective.

No matter what the specialty is from which a physician launches into IOE, the process requires education and experience in echocardiographic diagnosis and knowledge of ultrasound technology, image acquisition, interpretation, and clinical applications in the operating room environment (241,242). There is clearly a long learning curve (242a) to become an expert in echocardiography (243). Each of the potential contributors to the IOE team has a challenging learning curve, and who the best person to do IOE is depends on the situation in each individual hospital.

Training and Credentialing for Intraoperative Echocardiography

Training for performance and interpretation of IOE has been the subject of some investigations and policy statements. The decisions required from intraoperative echocardiography make accuracy and reliability of diagnosis with this technique quite important. The educational goals for individuals desiring to develop competence in TEE in the operating room include a substantial amount of tutored learning and precepted performance of echocardiographic studies (241,241a). Participation in IOE without appropriate training appears to adversely affect the prevalence and detection of significant residual problems and the outcome of patients undergoing complex operations (243a). The Society of Cardiovascular Anesthesia and the American Society of Echocardiography have recognized the need for a policy that will likely lead to new recommendations for fellowship training programs in cardiovascular anesthesia. In addition, the accreditation of echocardiography laboratories and the availability of board certification in echocardiography may affect the requirements for performance of TEE and other advanced echocardiographic practice.

A major disparity between idealism and reality was pointed out in an interesting study of intraoperative TEE credentialing and performance (240). Based on a 1995 survey of practice patterns at 108 anesthesiology residency programs, of which 91% use intraoperative TEE, interpretations were rendered by anesthesiologists in 54% and by cardiologists in 46%. However, only 35% of anesthesiologists had formal echocardiography training in residency or fellowship, only 42% leave a formal interpretation on the chart, and only 43% bill specifically for performing TEE. Only 32% of programs reported that their institutions actually mandated formal credentials for performance of intraoperative TEE (240).

A decade ago, we instituted a training program in which a series of anesthesiology staff have each undertaken a 6-month fellowship for training in echocardiography, including a substantial time in the echocardiographic laboratory (242). Although this is not possible for most anesthesiologists who need to do IOE, an equivalent learning experience obtained on the job with available resources, such as a consulting cardiologist-echocardiographer, is necessary to achieve competence in this field (244).

It is important to maintain good records of IOE studies, including difficulties encountered with probe insertion (for medical-legal reasons) and a written chart report for *every* patient studied. An ongoing continuous quality improvement program should evaluate record keeping, accuracy, and quality of imaging, as judged by independent reviewers who should generate objective evidence of reviews performed (245,246).

Cost versus Efficacy

IOE involves finding the unexpected, monitoring for unanticipated problems, and imaging repeatedly to diagnose the change or lack of change expected from surgery. Despite the known frequencies of second pump runs in each type of surgery, it is not possible for the surgeon to predict the need for a revision based on his or her confidence in the repair. All of the patients who have had a second pump run were thought by the surgeon to have a good enough result to come off pump, but IOE revealed the need for operative revision.

When patients do return to the operating room later in their hospitalization for revision of a repair not fixed initially, the additional hospital costs are estimated to be much greater than for those whose repairs are revised during the initial thoracotomy ($94,000 vs. $21,000) (143). More important, many hidden costs arise in the patient whose initial surgery is unsuccessful, including additional hospitalizations for treatment of complications or reoperation.

Benson and Cahalan (247) performed a detailed cost-benefit analysis of IOE, being careful to keep estimates of direct and indirect costs liberal (high) and estimates of benefits conservative (low). They concluded that IOE results in a minimum savings of $600 per case for congenital heart surgery, $450 per case for valve repair surgery, and $150 per case for coronary bypass. Siwik et al. also looked at the cost-effectiveness of IOE in a series in which surgical therapy was altered by TEE findings in 3%, finding that the superior information reduced the need for additional postoperative studies in the intensive care setting (247a).

THE FUTURE

New technological and clinical developments are likely to be quickly applied to intraoperative diagnosis and treatment. Nowhere is successful clinical application of new techniques as likely to reap benefits in terms of quality, safety, and cost-effectiveness than in cardiac surgery. Innovations in cardiac surgery will undoubtedly continue to require the “safety net” of IOE. There is always a learning curve to a new practice and the potential for mistakes to occur. Therefore, IOE will probably be an important partner in future developments of new diagnostic and therapeutic techniques.

Three-Dimensional Echocardiography in the Operating Room

A technological innovation in cardiac ultrasound technology that is likely to achieve major steps in the near future is three-dimensional echocardiography (see Chapter 46). Three-dimensional echocardiography has already been studied preliminarily for its contribution to planning the surgical approach. With the capability to move the vantage point of viewing a three-dimensional data set to any angle or perspective, three-dimensional echocardiography has the potential to simulate surgical visualization of intracardiac anatomy and to dynamically represent intracardiac structure (248). This might be useful for planning surgery and evaluation of its probable results ahead of time by manipulating images to simulate various surgical options (e.g., determining the size and fit of implantable devices, valves, or other material). In addition to cardiac structure, the three-dimensional morphology of abnormal flow in the heart has also been studied (248c,248d).

Three-dimensional echocardiography may be particularly useful in certain types of surgeries. For valve surgery, it can provide new additional information not provided by two-dimensional echocardiography (248a). It is able to depict the shape, motion, and contour of the mitral annulus (62a,253). The size of prolapsing portions of the mitral valve correlate well between three-dimensional echocardiographic measurements and surgical findings (248b). For some types of congenital surgeries, it appears to add spatial comprehension (249,250). In congenital heart disease, three-dimensional echocardiography is particularly helpful in patients with VSDs (250a), especially doubly committed subarterial and restrictive VSDs and those associated with double inlet LV, as well as subaortic stenosis and supravalvar mitral membrane (251).

Three-dimensional echocardiography is also valuable in patients with cardiac tumors (252). It provides a better appreciation of the complex anatomy and aids in planning resection and deciding if curative surgery is feasible. The representations of cardiac anatomy are in some ways superior to standard intraoperative visualization in that they demonstrate the heart as a dynamic moving structure, as opposed to the empty, nonbeating heart the surgeon observes while the patient is on cardiopulmonary bypass (254).

Application to New Surgical Procedures

With the pace of developments in the field, it is likely that new cardiac surgery techniques will be developed. New practices have an inherent learning curve with the potential for mistakes to occur. Therefore, it is likely that IOE will be an important partner in future developments of new surgical techniques. For example, it is likely that IOE will contribute to the future development of procedures such as mitral homografts (255a), partial left ventriculectomy (255b), transmyocardial laser revascularization, complete correction of congenital heart disease, robotic and video-assisted thoracoscopic surgery (166a,167d), and autologous tissue valves (256), as well as numerous other emerging surgical innovations.

Intraoperative TEE is essential in video-assisted thoracoscopic surgery, which has already been successfully applied to surgical interruption of patent ductus arteriosus (167d) and mitral valve repair. In the latter, a computer-enhanced surgical telemanipulation system is used to robotically perform the surgery remotely from a surgical console; TEE found an inadequate repair in only one of ten patients, allowing further repair through an enlarged left thoracotomy (167e).

OVERVIEW

Progress in our understanding of the mechanisms of cardiac arrhythmias has been dictated by the development of tools to resolve the electrical activity of the heart at several levels. Current approaches extend from electrogram recordings in the *in situ* heart to the recording of electrical activity of single cardiac ion channels in isolated membrane patches.

Available data indicate that the majority of cardiac arrhythmias results from the function of the channels that are responsible for the normal action potential. However, disease states may change the level of expression of the normal channel and alter the ionic gradients that control ion movement through membrane channels. Changes in the intracellular and extracellular milieu may also alter channel gating. In a small, but important, group of patients—those with the long QT and Brugada syndromes—defects have been identified in the genes that code for specific ion channels or their regulatory subunits. Alteration of cardiac structure at a microscopic and macroscopic level that result from myocardial infarction, hypertrophy, or the aging process may also be crucial in the development of arrhythmias.

Reentry is the likely mechanism of most recurrent arrhythmias in chronic heart disease. Its treatment requires drugs that act on ion channels with minimal or no functional disturbance. Specificity and therapeutic index are low. Strategies to limit myocardial scarring following injury may prevent arrhythmias. Abnormal impulse formation, as evidenced by early and delayed after-depolarizations, are the second major cause of clinical arrhythmias. The clinical setting—family history, drug use, or electrolyte imbalance—and electrocardiographic (ECG) findings may suggest these mechanisms. It is important that arrhythmias resulting from abnormal impulse formation be identified so that treatment of greater specificity can be offered. Disturbances in the normal mechanisms of impulse generation in the sinus node are a rare cause of clinical arrhythmias.

HISTORICAL PERSPECTIVE

This chapter reviews normal impulse generation and propagation in the heart and the ways that disturbances of either mechanism result in cardiac arrhythmias. Emphasis is placed on observations made at the cellular and subcellular levels. Analysis of the mechanisms of arrhythmias at the higher levels of tissues and in the *in situ* heart are the focus of Chapter 60 and Chapter 62.

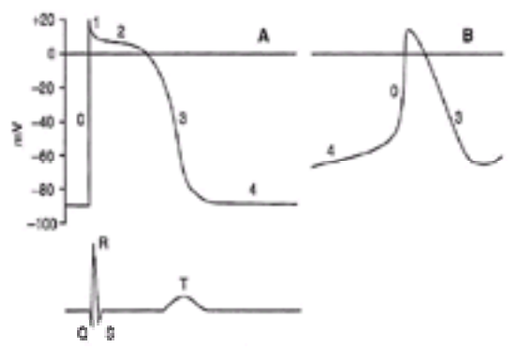
Progress in understanding the mechanisms of cardiac arrhythmias has been dictated by the new tools developed to study cardiac excitability and structure. The recording of unipolar and bipolar electrograms using sensitive string galvanometers replaced measurement of contractility as a means of following the regional spread of electrical activity. Lewis and colleagues used the accurate extracellular recordings to relate propagation velocity to underlying structure (1). Miniaturization of electrode spacing to a few millimeters has given way to the use of voltage-sensitive dyes that permit the tracking of the spread of excitation at the resolution of microns. These approaches provided clear descriptions of the spread of excitation in the basal state and during arrhythmias. The basis for normal and abnormal excitation had to await techniques that permitted *transmembrane* potential recordings. Ling-Genard capillary microelectrodes permitted transmembrane action potential recordings from groups of cells with little apparent damage to the cells. Those studies documented the relationship between the initial QRS complex and the T wave on the ECG to periods of rapid depolarization (phase 0) and repolarization (phase 3) of the action potential. Analysis of the ionic basis of the action potential proved more formidable. Membrane potential was varying with time (dV/dT greater than 0) as excitation propagated over the surface of the heart (dV/dX greater than 0). Marmont and Cole recognized that the analysis of excitation required that one of the independent variables (time *t*, or distance *x*) had to be controlled (zero) as the experimenter varied V (2,3). They developed the voltage clamp technique, which permitted measurement of the underlying current as a function of time as membrane voltage V was varied. This required that V should not vary with distance (i.e., dV/dX = 0, space clamping). The complexity of naturally occurring cardiac preparation severely limited space clamping. However, the preparation of single calcium-tolerant cardiac myocytes by Powel and Twist enabled a quantitative voltage clamp of several of the major currents that contribute to the action potential (4).

Neher and Sakmann introduced the patch clamp technique that permitted quantitative voltage clamp of even the smallest cardiac cells such as those of the sinoatrial (SA) and atrioventricular (AV) nodes (summarized in reference 5). The technique also permitted the resolution of current through single ion channels. All the major ion channels that contribute to the generation of the action potential have now been cloned and functionally expressed. Subgroups of arrhythmias occurring in the structurally normal heart have been shown to be monogenetic, arising from mutations of ion channel genes (6,7). The more common arrhythmias, such as ischemic-induced ventricular tachycardia and atrial fibrillation, are of multifactorial origin, with susceptibility genes playing an important role. Analysis of these and other arrhythmias starts with the premise that aberration of the normal mechanisms of impulse initiation and propagation are central to the genesis of arrhythmias. Therefore, normal impulse initiation and propagation are the starting point for the analysis of arrhythmia mechanisms.

Atrial fibrillation. Narrow complex QRS with irregular RR intervals. Ventricular rate is controlled.

BASIC ELECTROPHYSIOLOGY OF THE ACTION POTENTIAL

The form of the action potential recorded from a ventricular cell is illustrated in *e*Figure 58.0.1. Five phases—0, 1, 2, 3, and 4—are described. Phase 4 describes the membrane potential during diastole. Working myocardial cells maintain a steady diastolic level of approximately –85 mV. Conduction system myocytes in the SA and AV nodes, excitable cells of the mitral and tricuspid value, and the coronary sinus exhibit slow diastolic depolarization during phase 4. Excitation of resting cells results in a rapid transition from phase 4 to phase 0. This phase represents a period of rapid depolarization resulting in reversal of the transmembrane potential, and lasts less than 1 ms. Phase 1 is a period of rapid repolarization that returns the membrane to the level of the plateau. This phase shows the greatest variability between various regions of the heart and between various species. It is prominent in both Purkinje's and epicardial cells and is diminutive or absent in endocardial cells. Phase 2 is the plateau phase of the action potential and lasts up to several hundred milliseconds. It is the phase that most clearly distinguishes the cardiac action potential from the brief action potential of skeletal muscle and nerve. Phase 3 marks the period of terminal repolarization when the membrane potential is restored to its resting level.



***e*FIGURE 58.0.1** Idealized action potentials of nonpacemaker and pacemaker cells. **A:** The action potential of a nonpacemaker cell is shown. Five phases of the action potential, 0, 1, 2, 3, and even 4 can be identified. The membrane potential during phase 4 is stable at approximately –90 mV. The electrocardiogram in the lower section of **A** shows the relationship to the various phases of the action potential: The QRS complex corresponds to phase 0 and the T wave to phase 3. The QT interval approximates the action potential duration. **B:** The action potential from a pacemaker cell is shown. The membrane potential gradually declines during phase 4.

An uneven (nonequilibrium) distribution of ions across the cell membrane is an essential basis for the action potential and is summarized in *e*Table 58.0.1. Under physiologic conditions, the Na^+/K^+ pump moves three Na^+ ions out of the cell in exchange for two extracellular K^+ ions; one molecule of adenosine triphosphate (ATP) is consumed in the process. Because the stoichiometry of ion movement is not 1:1, the Na^+/K^+ pump generates outward current. The overdrive suppression of pacemaker activity following rapid stimulation results from the hyperpolarizing effect of the Na^+/K^+ pump current. Arrhythmias resulting from digitalis intoxication are secondary consequences of pump inhibition. The sodium/calcium (Na^+/Ca^{2+}) exchanger uses the Na^+ gradient established by the Na^+/K^+ pump to transport Ca^+ across the cell membrane. The Na^+/Ca^{2+} exchanger transports Ca^{2+} into the cell at plateau levels of membrane potential and Ca^{2+} out of the cell during diastole. Since the stoichiometry of the exchanger is approximately 3:1, it is also electrogenic. The Na^+/H^+ and HCO_3^-/Cl^- exchangers also contribute to the uneven distribution of ions across the cell membrane.

***e*TABLE 58.0.1** INTRACELLULAR AND EXTRACELLULAR ION CONCENTRATIONS IN CARDIAC MUSCLE

Ion	Extracellular concentration (mmol)	Intracellular concentration (mmol)	E_x (mV)
Na^+	145	20	+52
K^+	4	135	–92
Ca^{2+}	2	10^{-4}	+129
Cl^-	120	10	–64

Ca^{2+}, calcium ion; Cl^-, chloride ion; K^+, potassium ion; Na^+, sodium ion.

During the action potential, selectively permeable ion channels open or close, and the direction of ion movement (and the resulting current) is determined by the ratio of the intracellular and extracellular concentration of each ion and the membrane potential. Ion movement is passive. We now review the ion channels that are crucial to each phase of the action potential in more detail.

Phase 4 of the Action Potential

Nonpacemaker Cells

For cells with a stable resting (phase 4) membrane potential, the inward rectifier K^+ channel I_K has the highest conductance. The membrane potential E_m is only a few millivolts positive to the equilibrium potential for potassium, E_K. The small deviation between E_m and E_K reflects the limited permeability of the I_K channel to Na^+ and the finite conductance of other ion channels at the level of the resting potential. Elevation of the extracellular potassium reduces the membrane potential according to Nernst's relationship:

$$E_m = RT/F \ln[K_o]/[K]_I$$

where R is the universal gas constant, T the absolute temperature, F the Faradays constant, and $[K_o^+]$ and $[K_1^+]$ the extracellular and intracellular K^+ concentrations, respectively. The conductance of most ion channels is independent of the electrochemical driving force, $(E_m–E_x)$, acting on the permeant ion x. In the case of the inward rectifier, channel conductance is increased by elevations in extracellular K^+ concentration. Marked elevation in $[K_o^+]$ around cells is an early event during myocardial ischemia and may play a critical role in arrhythmias associated with acute myocardial ischemia.

Pacemaker Cells

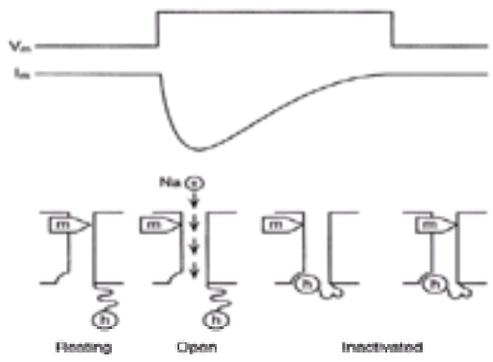
Cells in the SA and AV nodes and the His-Purkinje system undergo slow diastolic depolarization during phase 4. Three ionic currents contribute to this depolarization: (a) a background inward current carried by Na^+ ions; (b) the delayed rectifier current activated during the preceding depolarization; and (c) a hyperpolarization-activated current, I_f, carried by Na^+ and K^+ ions. Pacemaker activity in the SA and AV nodes is primarily dependent on a and b, whereas c plays a more important role in Purkinje's cells (8,9). The relative conductance of other ion channels compared with that of the inward rectifier K^+ channel is substantial in pacemaker cells. These cells are much less sensitive to elevation of $[K_o^+]$, and this may explain the persistence of SA and AV node function in states of marked hyperkalemia.

The rate of discharge of pacemaker cells may be slowed by increasing the maximum diastolic potential, decreasing the slope of phase 4, or decreasing the threshold potential; the opposite changes accelerate discharge rate. Sympathetic and parasympathetic stimulation changes pacemaker rates by two mechanisms: (a) They shift the primary site of the pacemaker within the SA node, and (b) they modify the kinetics of the currents that control pacemaker activity. Vagal stimulation produces a caudal shift in the site of the primary pacemaker; sympathetic stimulation produces a cephalad shift. Acetylcholine increases the maximum diastolic potential by activating the inward K^+ current I_{KACh}. Acetylcholine also shifts the voltage dependence of I_f activation to more negative potentials. As a result, a smaller component of I_f is activated during the pacemaker potential. Beta-adrenergic stimulation has the opposite effect on the activation of I_f.

Phase 0 of the Action Potential

Nonpacemaker Cells

In nonpacemaker cells, an inward voltage-dependent Na current is responsible for phase 0 of the action potential. It is the prototype of voltage-dependent ion channels. The properties of the Na^+ channel are described in detail to illustrate some of the general properties of voltage-dependent ion channels. Two distinct properties, gating and ion permeation, define the behavior of ion channels. *Gating* describes the opening and closing of the ion channel. Voltage-gated channels such as the Na^+ channel have an intrinsic charge and respond to membrane potential with a change in conformational state. During phase 4, Na^+ channels are closed. They open transiently (less than 1 ms) in response to membrane depolarization. The generally accepted gating model is based on the seminal work of Hodgkin and Huxley (10) in the 1950s and illustrated in eFigure 58.0.2. Ion movement through the Na^+ channel is under the control of two gates: the activation, or m, gates and the inactivation, or h, gate. At normal resting potentials, the activation gates are closed and the inactivation gate is open. The activation gates open during depolarization and Na^+ ions move into the cell down their electrochemical gradient. Closure of the inactivation gate follows with a brief delay, and ion permeation is terminated. Repolarization to high levels of membrane potential is required for recovery from inactivation.



***e*FIGURE 58.0.2** The Hodgkin-Huxley model of Na^+ channel gating. The upper trace (V_m) shows a voltage step, and the middle trace (I_m) shows the resulting membrane current. A physical model to account for the transient current is shown in the lower trace. The Na^+ channel is represented as a pore spanning the membrane. In the resting state, the activation (m) gate is in the closed position, and the inactivation (h) gate is in the open position. Following depolarization, the m gate assumes the open position. With both gates open, Na^+ ions move into the cell. The h gate then moves into the closed position, blocking ion movement. When the membrane is returned to the resting level, the m gate moves into the closed position, a process termed *deactivation*. After a variable interval, the h gate moves into the open position, a process termed *recovery from inactivation* (not shown). Na^+ indicates sodium ion.

Membrane depolarization decreases the fraction of Na^+ channel available for opening; at a membrane potential of approximately –75 mV, only 50% of Na^+ channels are available for opening. This voltage-dependent inactivation is important in the genesis of arrhythmias and in antiarrhythmic drug action. Most membrane depressants, such as hyperkalemia and acidosis associated with ischemia and myocardial stretch, cause membrane depolarization and Na channel inactivation. Class I antiarrhythmic drugs decrease the availability of Na^+ channels at all membrane potentials. Some drugs such as lidocaine also bind preferentially to inactivated Na^+ channels and are therefore more effective in blocking conduction in partially depolarized ischemic tissue.

Ion permeation is the second important property of ion channels. The selective permeability to specific ions forms the most common basis for the classification of ion channels. The Na^+ channel has a selectivity ratio for Na^+:K^+ of 12:1. The simplest ion channel would permit inward and outward ion movement with equal facility. This is not the case with many ion channels. A channel is said to rectify in the inward direction if a voltage displacement produces a larger current when ions are moving in the inward direction compared with the outward current produced by a voltage displacement of the same amplitude but opposite direction. Inward rectification is a common property of K^+ channels. Depolarization to positive potentials should markedly increase outward K^+ current as the membrane potential moves positive to the K^+ equilibrium potential. However, K^+ current decreases at depolarized potentials because of inward rectification. Inward rectification of some K^+ channels results from blockade by intracellular polyamines and magnesium (Mg^{2+}) (11).

Pacemaker Cells

At the depolarized level of the maximum diastolic potential of pacemaker cells (approximately –60 mV), the Na^+ channels are inactivated. Inward Ca^{2+} current is responsible for phase 0 of the action potential. Of the two types of Ca^{2+} channels in cardiac muscle, L and T, it is the former that makes the major contribution to phase 0. Like Na^+ channels, Ca^{2+} channels exist in resting, open, and inactivated states. However, the magnitude, kinetics, and ion permeation characteristics differ from the Na^+ channel: (a) Peak amplitude is less than 10% that of the Na^+ current; (b) activation and inactivation occur at more depolarized potentials and are somewhat slower; and (c) Ca^{2+} is the only physiologic charge carrier.

Phase 1 of the Action Potential

A transient, outward K^+ current is responsible for phase 1 of the action potential. Calcium-dependent and calcium-independent K^+ channels are responsible for this current component. The distribution of these channels is consistent with the magnitude of phase 1 of the action potential: The channel density is high in the epicardium and is low in the endocardium. A reduction in the magnitude of the transient outward current is consistently observed in left ventricular hypertrophy and congestive heart failure (12). The resulting prolongation of the action potential duration (APD) may account for the increased susceptibility to arrhythmias in these states.

Phases 2 and 3 of the Action Potential

Phase 2 of the action potential may last tens (atrium) to hundreds of milliseconds (His-Purkinje system and ventricle). A delicate balance of inward and outward currents results in little change in membrane potential. The principal inward currents are the L-type Ca^{2+} current and a small residual component of inward Na^+ current. The significance of the latter has been highlighted by studies of the molecular basis of the long QT syndrome. Several kindreds have been identified in whom the genetic defect has been pinpointed to the locus on chromosome 3 that encodes the cardiac Na^+ channel (13). Genetic defects that have been identified include single amino acid substitutions and a three–amino acid deletion (13,14). The consequence of the defect is a failure of or reversibility of inactivation resulting in an increase in the magnitude of the residual slow component of Na^+ current during phase 2. The increased inward current prolongs the duration of action potential and the QT interval on the surface ECG.

A delayed rectifier current, consisting of rapid and slow components I_{Kr} and I_{Ks}, is activated at depolarized potentials. I_{Kr} is activated rapidly, shows inward rectification, and is unchanged by beta-adrenergic stimulation. I_{Ks} is approximately ten times larger than I_{Kr}, does not rectify, and is increased by beta-adrenergic stimulation. Mutations in the genes encoding I_{Kr} and I_{Ks} or their regulatory subunits may result in a reduction of outward K current, APD and QT interval prolongation, and torsades de pointes. The Na^+/Ca^{2+} exchanger and the Na^+/K^+ pump provide minor current components during phase 2. The activation of I_{Kr} and I_{Ks} initiates phase 3 repolarization. As the resting potential is approached, I_{K1} makes an increasingly important contribution to the net membrane current and hence to terminal repolarization.

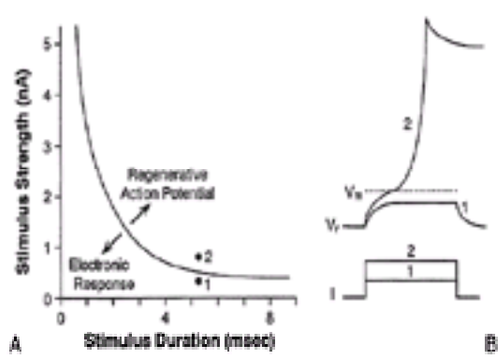
A 51-year-old female patient with torsades de pointes.

Other Ion Channels Contributing to Multiple Phases of the Action Potential

Certain ion channels make a contribution to the action potential only under special circumstances. K_{ATP} channels are present in high density in cardiac cells. Opening of the K_{ATP} channels depends on the adenosine diphosphate (ADP):ATP ratio. Micromolar concentrations of ATP close the channels. Reduction in the ATP concentration during ischemia causes a small fraction of these channels to open. Because of their density, substantial outward current is produced, markedly reducing the APD. As K^+ ions scape into a restricted extracellular space, $[K^+]_o$ rises substantially. Sulfonylureas open these channels and shorten the APD. Chloride-selective channels are present in cardiac cells. Under normal circumstances, they do not account for significant membrane current. However, the chloride current is markedly activated by sympathetic stimulation and may play a role in repolarization under these circumstances.

EXCITABILITY

Excitability is the ability of a cell or group of cells to respond to a stimulus with a regenerative action potential. The membrane potential must be displaced from its resting level, V_r, to a threshold potential, V_{TH}, at which the inward current (Na^+ or Ca^{2+}) becomes regenerative. Excitability depends on the passive and active properties of the cell membrane. The passive properties include the membrane resistance and capacitance and the intercellular resistance. A certain minimum charge has to be applied to the cell membrane to elicit a regenerative response. Excitability is inversely related to the charge required for excitation. The relationship between stimulus amplitude and duration is summarized in the familiar strength-duration curve shown in eFigure 58.0.3. As stimulus duration is increased, the threshold stimulus declines and approaches an asymptotic value at long times. The voltage-dependent properties of the inward current determine the threshold potential.



***e*FIGURE 58.0.3** Stimulus strength-duration relationship of a ventricular cell. **A:** The strength-duration curve represents the minimum stimulus strength (ordinate) required to elicit a regenerative action potential as a function of stimulus duration (abscissa). **B:** Effect that a subthreshold stimulus (point 1) and suprathreshold stimulus elicits (point 2) on the membrane potential. The subthreshold stimulus elicits a nonregenerative (electronic) membrane depolarization. The suprathreshold stimulus elicits a regenerative action potential.

Extracellular electrolytes such as K^+ and antiarrhythmic drugs have a complex effect on excitability. Domiguez and Fozzard (15) showed that small elevations of $[K^+]_o$ increase excitability by reducing the difference between the resting and threshold potentials ($V_r - V_{TH}$); large elevations of $[K^+]_o$ reduce excitability by inducing Na channel inactivation. Antiarrhythmic drugs influence excitability by changing both the passive membrane properties and the inward Na^+ current. Na channel blockers reduce excitability, shifting the curve upward and to the right. K channel blockers shift the curve in the opposite direction and increase excitability. These changes in excitability are reflected in the energy requirements for internal and external defibrillation.

Excitability is particularly important in the analysis of the ability of cardiac cells to undergo reexcitation during phase 3 of the action potential. In addition to the factors discussed previously, the time-dependent changes in current are also crucial.

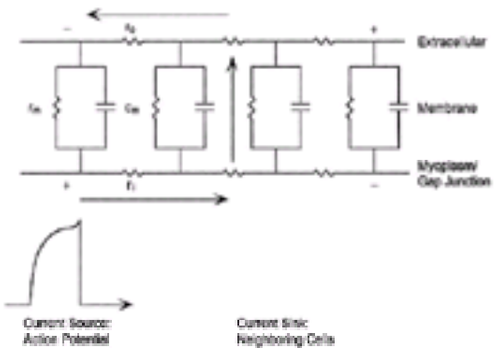
REFRACTORINESS

Refractoriness describes the ability of a cell to respond to repetitive stimulation. This property is important for the normal function of the heart and is a determinant of susceptibility to arrhythmias. Stimulation during phase 2 results in no response, and the cell is said to be absolutely refractory. Stimulation during the middle and late parts of phase 3 may result in a response. However, during most of phase 3, the stimulus intensity has to be increased. There is a brief period in phase 3, the supernormal period, when the required stimulus is actually less than that during phase 4. For reexcitation, repolarization has to occur to a sufficiently negative potential that Na^+ current required to support a response can be activated. As the recovery of the Na^+ channel from inactivation is not instantaneous, the available Na^+ current at each potential during phase 3 is less than that predicted by the steady-state inactivation curve. The time interval between phase 0 of the action potential and the time that a second propagated response can be initiated is the effective refractory period of the cell. The effective refractory period of the cell is one of the determinants of the minimum path length for reentry.

The recovery of normal excitability closely parallels the duration of the action potential. The refractory period may be prolonged by increasing the duration of the action potential or by slowing the rate of recovery of the Na^+ channel from inactivation. Class I antiarrhythmic drugs dissociate from the Na^+ channel slowly and as a result, they decrease the fraction of available Na^+ channels during phases 3 and 4. They also prolong refractoriness on the basis of the change in Na^+ channel kinetics.

CONDUCTION

For effective contraction, atria and ventricles have to be activated synchronously. The successful propagation of the cardiac impulse depends on the coupling of current sources and sinks. An action potential at a given site acts as a current source to excite neighboring cells (the current sinks). Large inward currents during phase 0 favor rapid propagation. Reduction of the magnitude of the inward current (e.g., by membrane depolarization and Na^+ channel blocking drugs) slows conduction. Propagation from a current source occurs by the spread of local circuit currents between neighboring cells. The pathway for current spread is illustrated in *e*Figure 58.0.4 and includes the coupling impedance between cells and the impedance of the sarcolemma, and the extracellular fluid local circuit current discharges the capacity of the membrane of neighboring cells, bringing their potential to threshold. Low intercellular impedance favors rapid conduction. Specialized intercellular connections termed *nexuses* or *gap junctions* are the preferential sites for intercellular current. The gap junctions are formed by a family of proteins, the connexins. They aggregate at the sites of intercellular contacts such as the intercalated disks. Units from each of two neighboring cells associate to form fluid-filled channels. These channels have a gating mechanism that is controlled by intracellular pH and $[Ca^{2+}]_i$. Connexin expression is low in the SA and AV nodes and may be reduced during myocardial ischemia.



***e*FIGURE 58.0.4** Equivalent circuit model of a cardiac fiber. The components of cardiac cells are modeled as equivalent electrical circuit elements. The unit membrane resistance is r_m. The intracellular resistance (r_i) consists of the series resistance of the myoplasm and gap junctions. The resistance of the extracellular space is r_o. c_m is the unit membrane capacitance. The action potential on the far left is the source of current for excitation of this patch of membrane. The current pathway is through r_i, r_m, c_m, and r_o, completing the circuit back to the source.

Until relatively recently, propagation in cardiac muscle was analyzed using a theory developed for current spread in homogeneous medium. Spach et al. (16,17) have emphasized that at both the microscopic and macroscopic levels, cardiac muscle is not a homogeneous excitable medium. The low-resistance gap junctions are not uniformly distributed over the cell surface membrane. Gap junction density is greatest in the direction of fiber orientation. Hence, intercellular impedance is less in the longitudinal than in the transverse direction. With increasing age, connective tissue septae are laid down between fiber bundles and further distort the cardiac architecture. These structural changes may play a crucial role in the genesis of arrhythmias and are discussed in more detail in the section Reentry, later in this chapter.

Changes in Ionic Currents during Pathologic States

Certain clinical states such as myocardial ischemia or reperfusion cardiac failure and myocardial hypertrophy are associated with an increased incidence of cardiac arrhythmias. As the currents that generate normal action potential play a central role in most arrhythmias, these clinical states must exert some effect on the membrane currents. There are relatively few ways that membrane ion currents can be modified. Pathologic states may modify channel function by changing the transmembrane gradients for the permeant ions; alter channel gating by changing intracellular Ca^{2+}, intracellular and extracellular pH, intracellular [ATP], and autonomic tone; and alter the level of expression of ion channels.

Myocardial ischemia is associated with an early rise in $[K^+]_o$, a fall in intracellular and extracellular pH and [ATP], and an increase in $[Ca^{2+}]_i$ and $[Na^+]_i$. Lysophospholipids also accumulate in the ischemic tissues. Elevation of $[K^+]_o$ has two major effects: membrane depolarization and an increase in the inward rectifier K^+ current. The fall in intracellular [ATP] and the associated rise in ADP activates the ATP-sensitive K^+ channel. In general, most ionic currents are reduced by a fall in intracellular and extracellular pH. The threshold for this effect is variable between ion channels. The lysophospholipids, such as lysophosphatidylcholine, block ion channels. They may also change channel gating (e.g., inactivation of the Na^+ current is slowed) (18). In experimental models of acute ischemia, reperfusion is associated with a high incidence of ventricular tachycardia and ventricular fibrillation. Indeed, the prevalence of arrhythmias during reperfusion may exceed that during the proceeding ischemic period. In the clinical setting, vasospastic angina and percutaneous transluminal coronary angioplasty are associated with reperfusion after a variable period of ischemia. Accelerated idioventricular rhythm is the most common arrhythmia in clinical reperfusion; ventricular fibrillation has a much lower prevalence than in the experimental setting. Reperfusion is associated with a restoration of $[K^+]_o$, pH toward normal, and generation of oxygen-derived free radicals. $[Ca^{2+}]_i$ may rise further and reduce the conductance of junctional channels.

An 81-year-old male patient with ventricular tachycardia.

Idioventricular rhythm. Note wide complex QRS with absence of P waves and slow ventricular rate.

Cardiac hypertrophy and failure are associated with a prolongation of the action potential. The most consistent finding is a reduction of the transient outward current. Available data suggest that the decrease in I_{to} is the result of decreased expression of the channel. The mediators of this suppression are not known. Cytokines may play a role.

ELECTROPHYSIOLOGIC MECHANISMS OF CARDIAC ARRHYTHMIAS

Cardiac arrhythmias may result in abnormalities of impulse initiation or conduction. Normal and abnormal automaticity and triggered activity are potential bases for abnormal impulse initiation. Arrhythmias that result from abnormal conduction are based on reentrant excitation. Abnormalities of impulse initiation and conduction may act in concert to induce arrhythmias. A spontaneous beat, by its timing in the cardiac cycle, may result in a functional disturbance in conduction and reentry. In the past, it was proposed that arrhythmias arising from abnormalities of impulse initiation and conduction could be distinguished on the basis of their response to premature stimulation; reentrant arrhythmias could be initiated and abruptly terminated by premature stimulation. It is now apparent that arrhythmias that result from triggered activity share some of these properties.

Abnormalities of Impulse Initiation

Enhanced Normal Automaticity

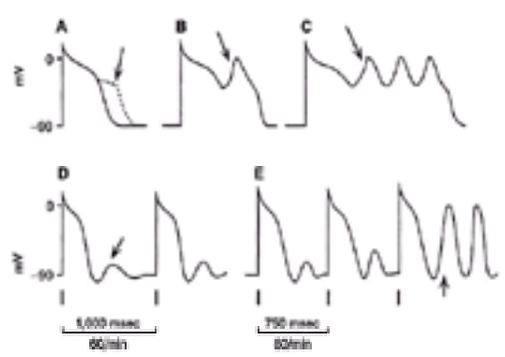
Enhancement of normal phase 4 depolarization in SA and AV node cells and Purkinje's cells is a relatively uncommon mechanism of cardiac arrhythmias. The conclusion that this mechanism is a basis for specific clinical arrhythmias is largely inferential. Inappropriate sinus tachycardia is thought to arise by this mechanism. Patients with this arrhythmia have inappropriately high resting heart rates, and a disproportionate increase in the heart rate in response to exercise and beta-adrenergic stimulation (19). Accelerated idioventricular rhythm also may result from enhanced normal automaticity in Purkinje's cells.

Abnormal Automaticity

Membrane depolarization may result in repetitive activity in most cardiac cell types. A current of injury between depolarized ischemic and relatively normal cells may lead to repetitive activity in the normal cells. The injury current provides the "background current" the decline of the delayed rectifier K^+ current activated during the preceding action potential provides the time-dependent change in current. At high resting membrane potentials (negative to –60 mV), Na^+ current would account for phase 0. The ease of arrhythmia induction is enhanced by adrenergic stimulation. This mechanism of arrhythmia can be readily demonstrated *in vitro*. The accelerated idioventricular rhythm and ventricular tachycardia that occur 24 to 72 hours following myocardial infarction may arise by this mechanism, but confirmation in an experimental model or in humans is lacking.

Triggered Activity

Triggered activity is a form of impulse initiation that arises from after-depolarizations of a preceding or triggering action potential. After-depolarizations are oscillations in membrane potential that may occur during phases 2 and 3 of the action potential (early after-depolarizations) or following complete repolarization (delayed after-depolarizations). These types of after-depolarizations are caused by distinct mechanisms and are illustrated in *e*Figure 58.0.5. *e*Table 58.0.2 contrasts the properties of these two types of after-depolarizations.



***e*FIGURE 58.0.5** Early and delayed after-depolarizations (*arrows*). After-depolarizations are oscillations in membrane potential that may occur during phases 2 and 3 of the action potential (early after-depolarizations B,C) or following complete repolarization (delayed after-depolarizations D,E). (From Wit AL, Rosen MR. Cellular electrophysiology of cardiac arrhythmias. Part 1. Arrhythmias caused by abnormal impulse generation. *Mod Concepts Cardiovasc Dis* 1981;50:1–6, with permission.)

Early After-Depolarizations

Early after-depolarizations occur in the setting of action potential prolongation. An inward shift in net membrane current by an increase in Ca^{2+} current or the late Na^+ current produce the oscillations of early after-depolarization. Alternatively, blockade of the outward current may produce the net inward current shift. Early after-depolarizations are enhanced by slowing the heart rate and suppressed by increasing the heart rate. Both clinical and experimental data suggest that early after-depolarizations are the cellular basis of torsades de pointes observed in congenital and acquired forms of QT prolongation (20).

Genetic, molecular biologic, and biophysical techniques have been combined to determine the basis of congenital QT prolongation associated with normal hearing (Ramano-Ward syndrome). This effort has been led by Keating and colleagues (21,22). The four variants of the syndrome and the underlying defects are summarized in eTable 58.0.3. Three of the defects have been tentatively associated with mutations of K^+ channels. The molecular defect may be the result of a single amino acid mutation or premature chain termination of one of the monomers that form the tetrameric K^+ channel. The result is a dominant negative defect: a reduction of repolarization K^+ current. These mutants presumably result in reduced outward (repolarizing) current. Bennett et al. (23) have described the phenotype of the Na^+ channel mutant in detail. Reversibility of the inactivation process is markedly increased. As a result, a significant component of inward current persists at the plateau levels of membrane potential. The late component of Na^+ current is blocked by mexiletine and lidocaine (24,25). The definition of the molecular basis of this often fatal arrhythmia opens the possibility for more specific treatment.

***e*TABLE 58.0.3** LONG QT (LQT) SYNDROME: MOLECULAR GENETICS, PHYSIOLOGY, AND TREATMENT

Pattern	**Locus**	**Chromosome**	**Gene**	**Protein**	**Mechanism**	**Specific therapy**
Inherited autosomal dominant	LQT1	11	?	?	?	?

Delayed After-Depolarizations

Delayed after-depolarizations arise from the repolarized membrane during phase 4. If their amplitude is sufficiently large, the threshold potential is attained and one or more triggered beats result. The reduction of the membrane potential during delayed after-depolarizations may also result in Na^+ channel inactivation and a slowing of conduction. Their amplitude is enhanced by rapid stimulation. This may be a basis for the observation that arrhythmias dependent on delayed after-depolarizations show overdrive acceleration. Delayed after-depolarizations occur in states of Ca^{2+} overload. Increases in internal [Na^+] (e.g., by Na^+/K^+ inhibition) can decrease Ca^{2+} extrusion by the Na^+/Ca^{2+} exchanger and produce Ca^{2+} overload. Delayed after-depolarizations may also occur in normal fibers (i.e., those of the mitral valve leaflet and the coronary sinus) during heightened sympathetic stimulation.

Two ionic mechanisms of delayed after-depolarizations have been proposed. In states of Ca^{2+} overload, the release of Ca^{2+} from the sarcoplasmic reticulum becomes oscillatory. The increase in cytoplasmic [Ca^{2+}] activates a nonspecific inward current carried by cations. The second potential mechanism of delayed after-depolarization is an inward current generated by the Na^+/Ca^{2+} exchanger. Both mechanisms may be operative *in vivo*. Digitalis toxic arrhythmias of certain catecholamine-sensitive and ischemia reperfusion arrhythmias are widely believed to be dependent on delayed after-depolarizations. The response of some of these arrhythmias to rapid stimulation and Na^+ and Ca^{2+} channel blocking drugs supports this proposed mechanism.

REENTRY

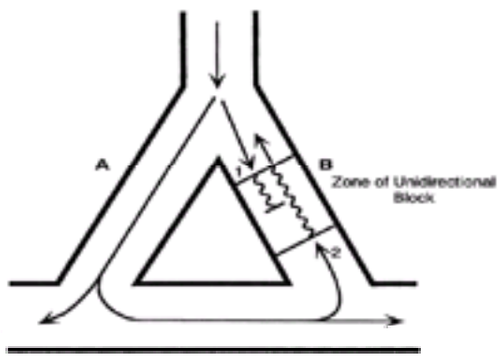
Definition

Following initiation of the cardiac impulse in the sinus node, the wave of depolarization activates the atria, AV node, bundle of His, bundle branches, and ventricles in a sequential manner before being extinguished through encountering recently excited refractory tissue or the anatomic and electrically inexcitable boundaries of the fibrous mitral and tricuspid valve annuli. Since the refractory periods of atrial and ventricular muscle are long (180 to 300 ms) and conduction velocity is rapid, reactivation of recently excited tissue during a single cardiac impulse is normally prevented. Sufficient time must elapse (electrical diastole) to allow recovery of tissue from refractoriness before the sinus node activation can reexcite the heart. However, if a group of muscle fibers fails to be initially activated during a wave of depolarization, they may recover from refractoriness sufficiently early to allow the same wave of depolarization to excite them in a retrograde direction. This phenomenon is known as *reentry*.

Mines (26) proposed three criteria for implicating reentry as the basis for an arrhythmia: (a) demonstration that a region of unidirectional block is necessary for tachycardia initiation; (b) observation that the wave of excitation travels in one direction around the pathway, returns to its site of initiation, and then continues to propagate around the same pathway; and (c) termination of tachycardia by cutting the circuit at a single point.

Requirements for Reentrant Excitation

A basic property of all forms of reentry is that the cardiac impulse is prevented from traveling along its normal course by encountering a region of transient or permanent unidirectional conduction block. The impulse must therefore deviate along an alternative pathway. If conduction time down the alternate pathway is sufficiently slow, an opportunity may arise for the impulse to reenter and excite the previously refractory tissue proximal to the region of unidirectional block, after it has recovered excitability. This schema is illustrated in the simplified circuit of classical reentry depicted in eFigure 58.0.6. The requirements for initiation and maintenance of reentrant excitation are well established and include (a) a region of transient or permanent unidirectional conduction block, (b) a pathway (substrate) over which the impulse may propagate, (c) sufficiently slow conduction within the reentrant circuit to allow recovery of excitability and reexcitation of tissue proximal to the site of unidirectional block, and (d) triggering factor(s) that invoke the necessary electrophysiologic milieu for initiation of reentry.



***e*FIGURE 58.0.6** Classical anatomic reentrant circuit illustrating the requirements for unidirectional block and slow conduction. A premature impulse encounters an area of depolarized myocardium in pathway B, where it blocks (1). The impulse then proceeds in the anterograde direction down pathway A before returning to conduct slowly through the previously depolarized region retrogradely (2). If retrograde conduction through this zone of unidirectional block is slow enough to permit recovery of excitability in proximal tissues, sustained reentry may occur. (From Hoffman BF, Rosen MR. Cellular mechanisms for cardiac arrhythmias. *Circ Res* 1981;49:1–15, with permission.)

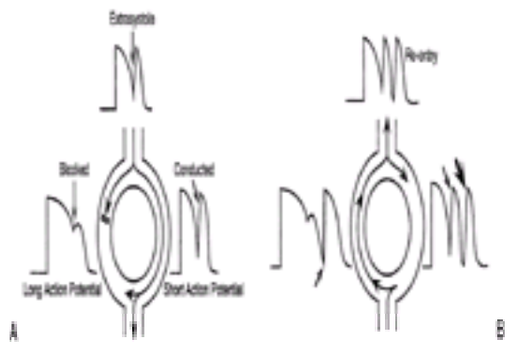
Unidirectional Block

Transient or permanent unidirectional block may arise from functional changes in the active membrane properties that determine excitability and refractoriness of cardiac tissue, nonuniformities of tissue architecture both physiologic and pathologic that influence cardiac conduction, or an interaction between both elements.

Functional Determinants of Unidirectional Block

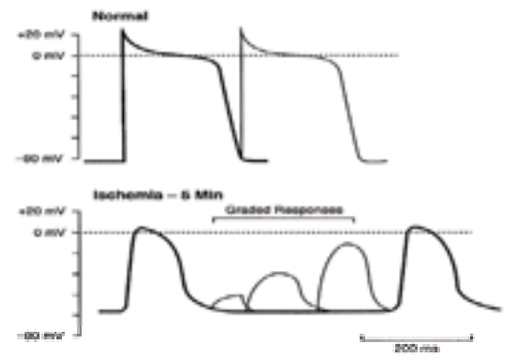
Heterogeneous Recovery of Excitability. The refractoriness of atrial, ventricular, and His-Purkinje cells is determined by the prevailing availability of Na^+ channels for excitation and the ability of the cell membrane to depolarize to threshold voltage required for Na^+ channel activation. Normally, the time course of recovery of excitability closely parallels that of action potential repolarization such that the cell is fully excitable as membrane potential returns to its resting level of approximately –80 mV. However, there is a degree of physiologic heterogeneity or dispersion of APD and hence refractoriness. This dispersion of refractoriness, defined as the difference between the longest and shortest refractory periods, is in the order of 30 to 40 ms in both atrial and ventricular tissue (27,28). Under normal circumstances, this degree of inhomogeneity is insufficient to result in unidirectional conduction block. If, however, a critically timed premature depolarization occurs, Allessie et al. have shown that unidirectional block and sustained reentry can be initiated in atrial muscle at sites on the border between regions with only small differences in refractory periods (less than 20 ms) (28). The mechanism by which a critically timed premature depolarization may produce unidirectional block and initiate reentry is illustrated in eFigure 58.0.7. Premature stimuli are frequently responsible for the initiation of clinical reentrant tachycardias such as supraventricular tachycardia and

monomorphic ventricular tachycardia complicating myocardial infarction and are used to induce these arrhythmias during diagnostic electrophysiologic studies.



***e*FIGURE 58.0.7** Initiation and maintenance of reentry in a ring model based on dispersion of action potential duration and refractoriness. Action potentials from different sites within the circuit are depicted. **A:** An extrasystole blocks after encountering tissue with long action potential durations and hence refractoriness. It is able to conduct through the alternate pathway where action potential duration and refractory periods are shorter. **B:** The impulse conducts retrogradely through the previously blocked pathway, which has now repolarized and recovered excitability. It is then able to reexcite tissue in the site of origin of the original extrasystole and potentially recirculate around the same pathway to cause reentry. (From Wit AL, Hanse MJ. *The ventricular arrhythmias of ischemia and infarction: the electrophysiological mechanisms*. Mount Kisco, NY: Futura, 1992, with permission.)

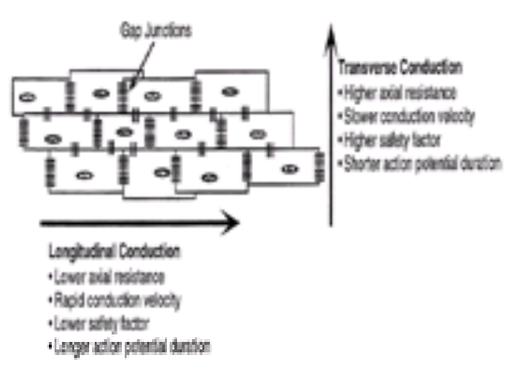
Regional inhomogeneity in refractoriness, and hence the propensity for unidirectional block, may be increased by pathologic processes including myocardial ischemia, reperfusion, and infarction. Another feature of the electrophysiology of ischemic tissue that may increase the likelihood of unidirectional block is prolongation of refractoriness well beyond the time of full repolarization, a phenomenon termed *postrepolarization refractoriness*. Impulses that encounter ischemic tissue within this period of prolonged repolarization only generate action potentials with low amplitude and slow upstroke velocities (graded responses) that conduct slowly or fail to propagate, thus creating localized regions of functional conduction block that may predispose to reentry (eFig. 58.0.8).



***e*FIGURE 58.0.8** Slow conduction of “graded responses” during ischemia due to postrepolarization refractoriness. Schematic representations of the ventricular action potential under normal conditions (*upper panel*) and after 5 minutes of ischemia (*lower panel*). In the normal cell, recovery of excitability coincides with complete repolarization. During ischemia, recovery of excitability is delayed until well after full repolarization (postrepolarization refractoriness). Impulses falling within this prolonged refractory period elicit time-dependent graded responses with decreased maximum upstroke velocity and conduction velocity. (From Whalley DW, Wendt DJ, Grant AO. Effects of acute ischemia and reperfusion and their role in the genesis of cardiac arrhythmias. In: Podrid PJ, Kowey PR, eds. *Cardiac arrhythmia: mechanisms, diagnosis and management*. Baltimore: Williams & Wilkins, 1995:109–130, with permission.)

Structural Determinants of Unidirectional Block: Myocardial Architecture

Although, at a macroscopic level, rapid conduction of an impulse through the cardiac syncytium appears to be a continuous process, at a microscopic level, conduction is inherently discontinuous due to nonuniformity in the distribution of gap junctions, and hence axial resistance (17). In ventricular and His-Purkinje cells, gap junctions are distributed in greatest density at the ends of cells to facilitate preferential conduction in the longitudinal direction, whereas gap junctional density and hence conduction velocity are typically three to five times slower when an impulse excites fibers in the transverse direction (17,29). In addition, the direction of activation also influences APD and refractoriness, with APD being longer during longitudinal propagation compared with transverse propagation (30). This dependence of conduction velocity and refractoriness on fiber orientation is termed *anisotropy*, and under certain circumstances the anisotropic properties of the myocardium can produce the necessary unidirectional block and slow conduction required for reentry (31). In a systematic study of anisotropic reentry in canine atrial muscle, Spach et al. (17) found that unidirectional block was more likely to occur in the longitudinal direction of fiber orientation, possibly due to the larger requirements for excitatory current (lower safety factor) resulting from a lower axial resistance and a greater membrane capacitance compared with the higher resistance and safety factor encountered with transverse propagation. A critically timed impulse may fail to conduct in the longitudinal direction but propagate slowly in the transverse direction, thereby allowing time for recovery from block and reentrant excitation. The electrophysiologic characteristics of anisotropic conduction are illustrated schematically in eFigure 58.0.9. A variety of disease processes, including chronic ischemia and hypertension, as well as the normal aging process, may increase the density of collagen in the extracellular matrix resulting in loss of side-to-side gap junctional coupling between myocytes (32,33). This process, termed *microfibrosis*, changes the electrical properties of involved myocardium from those of uniform to nonuniform anisotropy and is thought to result in a greater propensity to reentrant arrhythmias such as atrial fibrillation (32) and ventricular tachycardia following myocardial infarction (33,34).



***e*FIGURE 58.0.9** Characteristics of anisotropic conduction in the normal working myocardium. Uniform anisotropy: Myocytes are densely packed and electrically coupled via gap junction channels located within intercalated disks. The density of gap junctions is greater at end-to-end intercellular connections than at regions of side-to-side cell apposition. This results in lower axial resistance and more rapid conduction in the longitudinal direction than in the transverse orientation.

Slow Conduction

Unidirectional block is usually insufficient to initiate reentry without the coexistence of conduction slowing. Under physiologic conditions the prime determinant of the magnitude of I_{Na} is the availability of Na^+ channels. Any factor that decreases their availability potentially produces conduction slowing. Such factors include depolarization of the resting membrane potential, which occurs during acute ischemia and during hyperkalemia, a shift in the voltage dependence of Na^+ channel

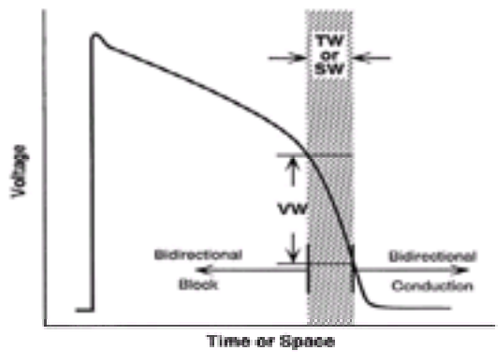
inactivation to more hyperpolarized potentials, and premature stimulation of tissue before full repolarization.

The zone of slow conduction within a reentrant circuit may also arise from tissues that normally display slow upstroke and Ca^{2+} channel–dependent action potentials such as the AV node and sinus node. An example is the role of slow conduction with the AV node in initiating and sustaining orthodromic reentrant tachycardia in patients with accessory AV bypass tracts.

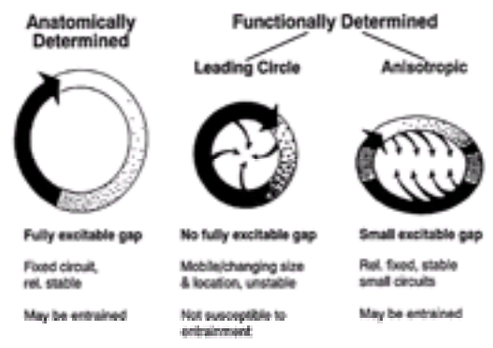
Conduction velocity is also influenced by passive membrane properties, the resistive elements that determine the ease and rate of axial propagation of local circuit current along the cell membrane and between electrically coupled cells. As described previously, the anisotropic properties of cardiac muscle arising from nonuniform spatial distribution and density of gap junctions may result in a significant increase in intercellular resistance and conduction slowing as impulses move transversely across muscle fiber bundles. This slow conduction occurs without any decrease in the maximum upstroke velocity of the propagating action potential. In addition to these microarchitectural determinants of conduction velocity, intercellular coupling resistance is regulated by dynamic changes in the conductance of the gap junctional channels. Elevation of intracellular Ca^{2+} and intracellular acidosis, for example, during acute ischemia, decreases gap junctional conductance and slows conduction velocity (35,36). If ischemia continues for a sufficient time, cell-to-cell uncoupling may occur, an event that has been demonstrated to temporally correlate with the onset of ventricular arrhythmias in the ischemic porcine heart model (37).

Characteristics of the Initiation, Maintenance, and Termination of Reentry

Experimental mapping studies (38,39) and theoretical computer modeling (40,41,42 and 43) have provided important insights into the factors that initiate, perpetuate, and terminate reentry. The ease by which reentry can be initiated may be described by the concept of the *vulnerable window*, defined as the time, voltage window, or both during the refractory period of the propagating action potential (repolarization) in which unidirectional block and reentry may be induced (43). The concept is illustrated in *e*Figure 58.0.10. Premature impulses applied earlier in the refractory period than the vulnerable window undergo complete bidirectional block, whereas those occurring after the vulnerable window propagate without block. The vulnerable window can be widened, and reentry facilitated by factors that (a) increase the spatial inhomogeneity of refractoriness, and (b) decrease cellular coupling via gap junctions. Maintenance of reentrant excitation depends on the critical relationship between the conduction velocity (CV) of the leading edge or “head” of the circulating wavefront, and the refractory period (RP) of tissue in the “tail” of the circuit (eFig. 58.0.11). This relationship is expressed as the wavelength of the propagating impulse, *l*, which is the product of the conduction velocity and refractory period: $l = CV \times RP$ (39). Reentry can only occur if the head of the circuit continuously encounters tissue that has recovered, at least partially, from its refractory period. If it collides with fully refractory tissue in the tail, the circuit would be extinguished. The wavelength of reentry must therefore be shorter than or equal to the path length of the circuit for sustained reentry to occur (i.e., l less than or equal to path length). Using this concept, stability of a reentrant circuit is promoted by any factor that (a) decreases l, such as shortening of refractoriness or decreasing conduction velocity; or (b) increases the length of the circuit. Conversely, the probability of termination of reentry is increased by factors that enhance conduction velocity, prolong refractoriness within the circuit, or both. The *excitable gap* is defined as the portion of a reentrant circuit that has recovered excitability and that can potentially be penetrated by an appropriately timed premature stimulus to modify or terminate reentry (44). The gap may be fully excitable if tissue has recovered fully from refractoriness, or partially excitable if tissue remains relatively refractory due to incomplete recovery of Na^{+} channels from time and voltage-dependent inactivation. The presence and size of the excitable gap reflect the margin of safety for propagation within the circuit and are important distinguishing features between the various types of reentry mechanisms to be discussed subsequently. Beat-to-beat oscillations in the cycle length of a reentrant arrhythmia are frequently seen in experimental models and clinically and may herald the termination of reentry (43,44 and 45). Theoretical modeling has concluded that these oscillations represent a dynamic interaction between the excitatory head of the wavefront and the refractory tail and that they facilitate termination by premature extrastimuli (43).



***e*FIGURE 58.0.10** The vulnerable window (VW) for unidirectional block and reentry: schematic representation of the VW within the refractory period of a propagating action potential. The VW may be considered as a voltage window, time window (TW), or spatial window (SW) during which unidirectional block may arise. Impulses arriving earlier or later in repolarization than the VW will either block or conduct bidirectionally, thereby precluding reentrant excitation. (From Rudy Y. Reentry: insights from theoretical simulations in a fixed pathway. *J Cardiovasc Electrophysiol* 1995;6:294–312, with permission.)



***e*FIGURE 58.0.11** Characteristics of the major types of reentrant excitation.

Types of Reentrant Excitations

Anatomic Reentry

The earliest experimental model of reentry described a simple ring of circus movement in which the wavefront propagated around an anatomically defined circuit with a central anatomic obstacle providing a zone of conduction block. In this classical form of reentry, the length and location of the pathway of reentry are relatively fixed. Anatomic reentry is characterized by the presence of an excitable gap that enables penetration of the circuit by premature stimuli occurring spontaneously or by programmed electrical stimulation and overdrive pacing. Introduction of single premature stimuli or pacing maneuvers during anatomic reentry may terminate, reset, or produce entrainment of the tachycardia, whereby with rapid overdrive pacing the circuit is penetrated and the tachycardia rate is accelerated to the pacing rate without termination (46). If the wavelength of reentry is significantly shorter than the path length of the circuit, there will be a significant fully excitable gap. If, however, the wavelength is only slightly shorter than path length, the excitatory head will encounter tissue in its relative refractory period, conduction velocity will be slowed, and there will only be a small gap of partially excitable tissue. Class III antiarrhythmic drugs, by prolonging APD, may terminate reentrant tachycardia by extinguishing the excitable gap, particularly in arrhythmias in which this gap is small (47). Features of anatomic reentry are illustrated in *e*Figure 58.0.11.

Clinical examples of arrhythmias believed to be based on anatomic reentry include orthodromic AV reentrant tachycardia (ORT) using an accessory pathway, AV junctional reentrant tachycardia, human type 1 atrial flutter, and some forms of ventricular tachycardia (48).

Functional Reentry

In functional reentry, the circuit is not constrained or determined by anatomic obstacles, but is defined by dynamic heterogeneities of electrophysiologic properties in

the involved tissue. There are two well-described forms of functional reentry, leading circle and anisotropic reentry (eFig. 58.0.11).

Leading Circle Reentry. Using isolated rabbit atrial myocardium, without any central anatomic obstacle, Allessie et al. (39) initiated sustained circus movement reentry with premature stimuli. In this leading circle model, the circulating impulse rotates around a central core of functionally refractory tissue. The tissue within this core is maintained in a state of refractoriness by constant centripetal bombardment from the circulating wavefront. The leading circle is the smallest possible pathway in which the propagating wavefront has enough excitatory efficacy to depolarize tissue ahead of it in its relative refractory period (39). The length of the reentry circuit equals the wavelength of the impulse ($CV \times RP$), and as a result, there is generally no fully excitable gap. Since the head of the advancing wavefront is constantly encountering its tail in a state of relative refractoriness, conduction velocity is slowed. Path length is therefore not anatomically determined but is governed by the electrophysiologic properties of the involved tissues. The circuit length is prolonged and tachycardia is slowed by an increase in refractoriness or a decrease in stimulating efficacy of the advancing wavefront. In contrast to anatomic reentry, circuits based on leading circle reentry are often unstable, and their size and location are continuously changing. The lack of a fully excitable gap renders this form of reentry less susceptible to reset, entrainment, and termination by premature stimuli and pacing maneuvers. The characteristics of leading circle reentry are summarized schematically in eFigure 58.0.11.

Based on high-density mapping studies in animal models and human myocardium, leading circle–type functional reentry is thought to be an underlying mechanism for atrial and ventricular fibrillation and at least some of the ventricular arrhythmias associated with acute ischemia (36,49).

Anisotropic Reentry. The functional characteristics underlying anisotropic reentry are directional differences in axial resistance arising from variation in the degree of cell-to-cell electrical coupling via gap junctions, rather than depression of action potential upstroke or resting membrane potential. Anisotropic reentry is typically initiated by a premature stimulus that blocks in the direction of propagation parallel to the long axis of the cells, then propagates slowly in the transverse direction of fiber orientation due to high axial resistance. There is a central line of functional block parallel to the long axis of fibers, and circuits are typically ellipsoid reflecting the directional differences in conduction velocity (eFig. 58.0.11). They are usually relatively stable circuits in size, shape, and location and have an excitable gap allowing entrainment and termination by overdrive pacing.

Studies based on the canine model have demonstrated that anisotropic reentry may be responsible for sustained ventricular tachycardia arising from the epicardial border zone region of healed myocardial infarcts (34,50). Although indirect evidence suggests nonuniform anisotropy as a mechanism of sustained monomorphic ventricular tachycardia in chronic human myocardial infarction, this has yet to be firmly established (34).

Spiral Wave Reentry. The classical schematic representations of functional reentry illustrated in eFigure 58.0.11 depict circular or ellipsoid circuits in two dimensions. Computer simulations and high-resolution optical mapping experiments using canine ventricular and atrial muscle have shown that functional reentrant circuits may actually propagate intramurally as drifting or migrating spiral waves (rotors) (42,51,52 and 53). This theory proposes that at points of critical curvature in the reentrant wavefront, an increased current load imposed by transverse conduction results in failure of propagation. The fundamental difference between this form of reentry and the leading circle mechanism is that the core of spiral waves is potentially excitable by virtue of having well-polarized maximum diastolic potentials, but is not excited, whereas the core of leading circle reentry is inexcitable. Indeed, these studies, together with reassessment of the earlier experiments of Allessie et al. (39), have cast doubts on the leading circle hypothesis of functional reentry and led some investigators to postulate that spiral waves are the primary mechanism of functional reentry (54).

Interaction of Enhanced Automaticity and Reentrant Mechanisms in Arrhythmogenesis: The Evolving Paradigm of Atrial Fibrillation

Although we have discussed abnormal automaticity and reentry as separate mechanisms of arrhythmogenesis, it is clear that both may interact to contribute to initiation and maintenance of a tachyarrhythmia. This is perhaps most clearly illustrated by the syndrome of focal atrial fibrillation in which rapidly discharging foci generally arising from the pulmonary veins (abnormal automaticity) trigger sustained multiple wavelet atrial fibrillation (functional reentry) (55). Furthermore, frequent or sustained episodes of tachyarrhythmia may modify the electrophysiologic properties of cardiac myocytes so as to facilitate the likelihood of further initiation of the tachyarrhythmia: the phenomenon of electrical remodeling (56). In both animal models of atrial fibrillation and studies in humans, atrial fibrillation is associated with shortening of atrial refractoriness, diminished rate adaptation of APD and refractoriness, increased dispersion of atrial refractoriness, and a decrease in conduction velocity within the atria (57), changes that are known to be profibrillatory by reducing the wavelength for reentry. The ionic basis for electrical remodeling and the intracellular signaling pathway(s) involved are under intense investigation and appear to involve downregulation of I_{CaL}, I_{to}, and I_{na} (56,58).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Over the past decade, the major thrust in cardiac electrophysiology research has been in the area of membrane biophysics. This has permitted the quantitative analysis of all the membrane currents that contribute to the action potential. Several molecular defects of membrane ion channels have been identified in patients with the congenital long QT syndrome, Brugada syndrome, and heart block. Identifying the polygenetic basis of common arrhythmias will pose a greater challenge. A small but significant amount of work has been done in the systematic reconstruction of the action potential, normal and abnormal impulse generation, and conduction. A major drawback in systematically reconstructing action potential is that model parameters for the membrane currents have been obtained from different preparations under varying experimental conditions. This compromises a thorough integration of the data available. Nevertheless, there is sufficient information to reconstruct the propagating action potential at the microscopic level. Greater effort should be applied to analyze and reconstruct arrhythmias at the macroscopic level. This is particularly true in the case of arrhythmias that occur in the healed myocardial infarct and in the fibrotic aging atrium. In the former, the normal electrophysiologic properties of the cells surviving in the scarred areas are a clear indication of the importance of abnormal structure. Here, the ion channels do not appear to be the problem. It is unlikely that ion channel-blocking drugs will favorably influence normal cells surviving in the scar and yet have little effect on normal cells in the remainder of the heart. There is a clear need to focus research on the prevention of scarring and fibrosis following insults such as myocardial ischemia and abnormal hypertrophy.

Atrial fibrillation is the most common sustained arrhythmia observed clinically. In the past, it had not enjoyed its rightful place as an important and fruitful area for basic and clinical investigation. More recent studies have demonstrated remodeling of the electrophysiologic properties of the atrium after brief periods of atrial fibrillation. The refractory period of the atrium is shortened by atrial fibrillation. This “electrical remodeling” favors perpetuation of atrial fibrillation. Therefore, more urgent efforts should be made to restore normal sinus rhythm. This has to be balanced against the likelihood that sinus rhythm will be maintained in the face of persistent factors that originally precipitated the arrhythmia.

The study of cardiac arrhythmias from the level of single ion channels to the integrated heart under autonomic control remains a fruitful and exciting area of research, with many implications to patient care. As newer techniques are applied to the study of the problem, significant advances can be anticipated over the next decade.

THE FUTURE

Major research efforts in cardiac arrhythmia mechanisms over the past decade have focused on the molecular basis of arrhythmias. The uncommon inherited arrhythmias that result from single gene defects have been analyzed. Significant advances should be made in determining the polygenetic mechanisms of common arrhythmias such as atrial fibrillation. The combination of molecular biology and membrane biophysics will permit a realistic reconstruction of the critical components of ion channels that control gating and ion permeation. This will permit the development of more selective and effective drugs. Drug therapy will also remain an important complement to physical methods of arrhythmia prevention and treatment such as ablation and implantable devices.

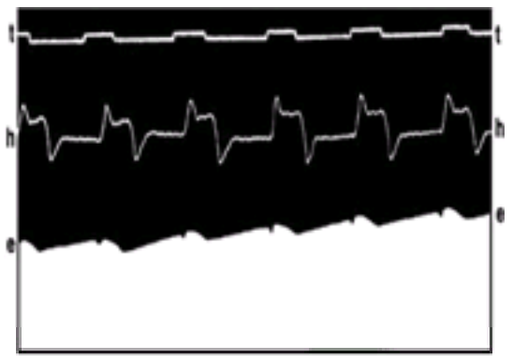
HISTORICAL PERSPECTIVE

The first demonstration of human cardiac activity was made during a congress of physiologists in London by Augustus Waller, who in May 1887 published the first single-lead electrocardiogram (ECG) (1). Waller recorded the electrical activity of the heart from a chest lead with a capillary electrometer (a glass tube filled with mercury) (2). When the electrometer was placed on the body's surface, the current was transmitted from the chest to the mercury column, which expanded or contracted. This movement could be observed only through a microscope and had to be projected onto photographic paper (eFig. 59.0.1).



***e*FIGURE 59.0.1** Reproduction of the first recording of an electrocardiogram by Waller. The electrical activity of the heart is recorded by movement on the surface of a mercury column (*e*). Chest wall movement is recorded by a mechanical lever (*h*). Time is indicated by *t*. [From Waller AD. A demonstration in man of electromotive changes accompanying the heart's beat. *J Physiol (Lond)* 1887;8:229–234, with permission.]

The pioneer of clinical electrocardiography, however, was Willem Einthoven. Einthoven had a background in physics and mathematics and had been present during Waller's demonstration (3). To refine Waller's concept, Einthoven worked in his laboratory in the Netherlands for several years, first with the electrometer and later with the string galvanometer (2). The galvanometer was an instrument developed in 1897 by Clément Ader for telegraphic transmissions. It reduced the distortion of the electrometer because it consisted of a thin wire extended between the poles of a magnet, but it still required the use of both a microscope and photographic paper. Einthoven presented his idea of applying the galvanometer to the recording of the cardiac electrical activity in 1903 (2). He also coined the term *elektrokardiogramm* in German (the dominant language at the time for scientific publications) and labeled the recorded waveforms P, Q, R, S, T, and U to differentiate them from the original—but incomplete—A, B, C, and D described by Waller. The selection of letters from the last part of the alphabet may have been related to a geometricians' convention at the time (which dictated that designations for curved lines should begin at the letter *P*) (2). Einthoven also described numerous abnormal findings and created the bipolar limb lead system known as *Einthoven's triangle* (2).

This progress was observed skeptically by Waller, who in 1911 expressed doubts on the clinical value of electrocardiography (4). The early electrocardiograph was extremely unwieldy and difficult to operate. It required a continuous-flow water jacket for cooling the electromagnet. The camera and the optical system were an integral part of the apparatus, and an arc lamp projected the shadow of the string onto photographic paper. The electrodes were large bowls of saline solution in which the subject immersed his or her hands or feet. The machine occupied two rooms, and five people were required to operate it (5).

Only after many years of these initial efforts did the ECG come to be regarded as a potentially useful tool in clinical practice (6). Several companies in Europe and in the United States initiated the commercial manufacture of electrocardiographs. The first table-model electrocardiograph assembled in London was leased to Sir Thomas Lewis in 1911. Lewis worked intensively in recording both normal and abnormal cardiac activity, and provided a strong impulse to clinical electrocardiography. His work was pivotal in shifting the available knowledge from the laboratory to the clinical field. Keith and Flack had reported on the existence of the sinus node in 1907, and Lewis ascribed the origin of the cardiac impulse to it. He also proved the origin of ectopic tachycardias, studied atrial fibrillation, and introduced the concept of aberrant conduction. Lewis published several books, including the first textbook of electrocardiography (3).

During World War I, Lewis had a prominent disciple named Franklin Wilson, the youngest of a group of American cardiologists selected to work in England with him. At the end of the war Wilson returned to the University of Michigan at Ann Arbor and obtained a string galvanometer. He worked with the galvanometer under the hospital stairwells, the only space appropriate for the large apparatus, which was smaller than the original model but still needed a wheeled trolley for transportation. Wilson's investigations with these limited resources resulted in the theory of the ventricular gradient and in detailed descriptions of the bundle branch blocks (7). Perhaps Wilson's best known contribution is his creation of a unipolar chest lead system connected to a central electrode (8).

By 1920, myocardial infarction had been recognized as an entity because of the cases reported by Herrick (9) and Pardee (10). Although Einthoven was awarded the Nobel Prize in 1924 for his contribution, the relevance of electrocardiographic information to clinical cardiology was not yet fully appreciated. Wilson himself published a paper on disorders of the heartbeat in 1936 with no mention of electrocardiography (11).

Subsequent improvements to the original galvanometer led to further reduction in its size and to the current electronic technology. The first portable model was introduced in 1926, and with it Lewis' vision of electrocardiography as a standard diagnostic tool became a reality (5).

At that time, two distinguished electrocardiographers and investigators, Langendorf and Pick, were attending medical school in Prague. Both physicians made their main scientific contributions later in the United States by perfecting the methodology of deductive reasoning for complex cardiac arrhythmias (12). In 1948—long before the introduction of clinical electrophysiologic studies—Langendorf brilliantly deciphered a pivotal mechanism of arrhythmias and coined the term *concealed conduction* to describe it. As Fisch has pointed out, an understanding of this concept is key to the analysis of most cardiac disturbances (12).

The "post-Wilson era" that began in the mid-1950s has witnessed less radical, but still important, developments in electrocardiography. By means of ingenious clinical-pathologic-electrocardiographic correlations, investigators from different parts of the world elucidated the ECG manifestations of the many cardiac conditions. Outstanding contributors include Lepeschkin, Surawicz, and Castellanos in the United States; Sodi-Pallares and Cabrera in Mexico City; Rosenbaum in Buenos Aires; Schamroth in Cape Town; and Durrer and Wellens in the Netherlands. The introduction of invasive clinical electrophysiologic studies only confirmed in most cases the deductions of these pioneers (13).

In more recent years, emphasis in electrocardiographic research has shifted to the study of dynamic patterns inherent in certain parameters (especially ventricular repolarization) with the aid of the ambulatory recording devices first introduced by Holter in 1961 and then by newer, potent digital storage and analysis techniques. The advent of effective myocardial reperfusion therapies has renewed interest in the electrocardiographic manifestations of the acute ischemic syndromes. Finally, attempts to improve the resolution of standard electrocardiography have relied on increasing the number of recording electrodes (body surface mapping) and on improving the signal-to-noise ratio of the higher frequency signals by averaging and filtering (signal-averaged electrocardiography). Initial results with these techniques are promising, but their roles in clinical practice are still unclear.

Despite the development of more sophisticated and expensive cardiac diagnostic tests, the standard 12-lead ECG remains an integral part of the clinical evaluation of all cardiac patients, particularly those with ischemic heart disease or rhythm disturbances.

ANATOMIC REFERENCES

The position of the heart within the body determines the "view" of the cardiac electrical activity recorded from any ECG electrode on the body surface. When the patient is in the supine position, the heart is a conical structure that lies relatively horizontally with the atria at its base and the ventricles at its apex (14). Because the heart is rotated over its long axis, the right atrium and ventricle are more anterior than the left chambers, and the right and left sides of the heart are not aligned with the homonymous sides of the body (15,16). Thus, the interventricular septum is almost parallel with the frontal—not the sagittal—plane, and the left ventricular free wall (usually considered a lateral structure) includes nearly 300 degrees of the left ventricular circumference and faces superiorly, posteriorly, and inferiorly (14).

ELECTROCARDIOGRAPHIC RECORDING

The 12 Electrocardiographic Leads

Cardiac electrical activity is recorded through 12 surface leads designated I, II, III, aVR, aVL, aVF, V_1, V_2, V_3, V_4, V_5, and V_6. The electrodes that record the first six points are located on the limbs, whereas leads V_1 to V_6 are recorded from the chest (Fig. 59.1).

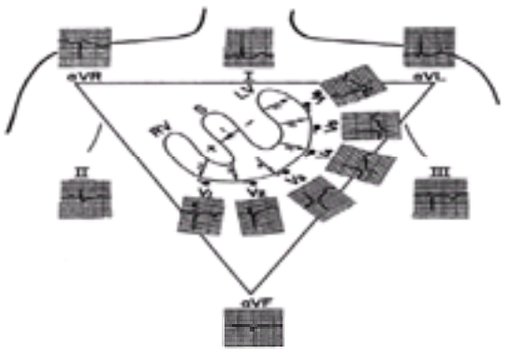


FIGURE 59.1 The standard 12 leads are shown with their recording sites. Both the frontal and the horizontal planes are depicted. Vectors 1 to 7 show the normal sequence of activation of the septum (S) and ventricles from the horizontal plane. LV, left ventricle; RV, right ventricle. (From Gazes PC, ed. *Clinical cardiology: a bedside approach.* Chicago: Year Book, 1983:39, with permission.)

Leads I, II, and III were first used when Einthoven placed recording electrodes on both arms and the left leg to form an equilateral triangle. An additional electrode on the right leg was used for grounding. Leads I to III are bipolar because they record potential differences between two electrodes. For lead I, the left arm electrode is the positive pole and the right arm electrode is the negative pole. Lead II, with its positive pole on the left leg and its negative pole on the right arm, provides a view of the electrical activity along the long axis of the heart. Lead III has its positive pole on the left leg and its negative pole on the left arm. Between leads I, II, and III are 60-degree angles. These wide viewing gaps are filled with the augmented unipolar (aV) leads aVR, aVL, and aVF, which record the electrical activity between the exploring limb electrode and a reference created by connecting the other two limb electrodes together through a 5,000-ohm resistor (Wilson's central terminal) (17). Lead aVF, for example, measures the potential difference between the left leg and the average of the potentials at the right and left arms. The addition of these three aV leads to the triaxial reference system in the frontal plane produces a hexaxial system, with the six leads separated by angles of only 30 degrees. The gap between leads I and II is filled by lead aVR, that between leads II and III by lead aVF, and that between leads III and I, by lead aVL. This provides a perspective of the frontal plane as illustrated in Figure 59.1. The limb leads are presented in the order I, II, III, aVR, aVL, and aVF, which spatially correspond to 0, 60, 120, –150, –30, and 90 degrees, respectively.

The last set of leads introduced into clinical practice were the six unipolar precordial leads (V_1 to V_6) (8). Augmentation is not necessary because the recording electrodes are close to the heart. Wilson's central terminal provides their negative poles, whereas the sites of the exploring electrodes are determined by bony landmarks on the anterior and left lateral aspects of the precordium (*e*Table 59.0.1, Fig. 59.2). The angles between the six transverse plane leads are slightly smaller than those between the six frontal plane leads. Lead V_1 is located where the extension of the heart short axis (i.e., a perpendicular to the interatrial and interventricular septa) intersects with the precordial body surface. Because V_1 provides a right anterior to left posterior view, it distinguishes better between left and right cardiac electrical activity than does a lead providing a right lateral to left lateral view (such as lead I).

***e*TABLE 59.0.1** PLACEMENT OF PRECORDIAL LEAD ELECTRODES

V_1	Fourth intercostal space, right sternal border
V_2	Fourth intercostal space, left sternal border
V_3	Equidistant between V_2 and V_4
V_4	Fifth intercostal space, at the midclavicular line
V_5	Anterior axillary line, at the level of lead V_4
V_6	Midaxillary line, at the level of lead V_4
V_7	Posterior axillary line in the fifth intercostal space
V_8	Midscapular line
V_9	Left paraspinal border
V_3R	Equidistant between V_1 and V_4R
V_4R	Right midclavicular line, fifth intercostal space
V_5R	Right anterior axillary line in the same horizontal plane as V_4R
V_6R	Right midaxillary line in the same horizontal plane as V_4R

Note: Lead V_2R is the same as V_1.

FIGURE 59.2 Location of the precordial lead electrodes. (From The electrocardiogram: fundamentals. In: Goldschlager N, Goldman MJ, eds. *Principles of clinical electrocardiography.* Stamford, CT: Appleton & Lange, 1989:1–10, with permission.)

Limitations of the Current 12-Lead System

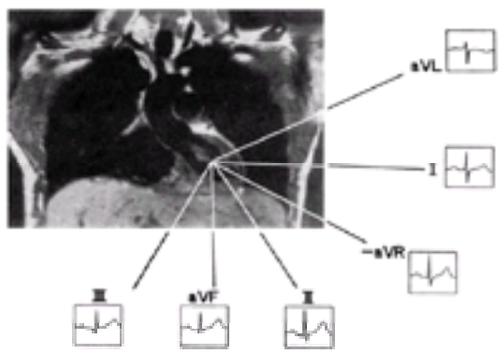
Poor Orthogonality and Redundancy

A set of three ECG leads is considered orthogonal if their lead vectors are at 90-degree angles with each other, which permits the accurate detection of the onset and offset of ECG waveforms in all spatial directions. Orthogonality is meager in the current 12-lead system because the limb leads record poorly the sagittal and anteroposterior components of cardiac activity, whereas precordial leads miss the vertical components (18).

The current 12-lead system provides for superfluous recording points. Estimates are that only eight components of the standard ECG capture independent information on cardiac electrical activity (19).

Inappropriate Lead Sequencing and Gap in the Frontal Plane

The display of the precordial leads represents an orderly progression in the horizontal plane. Leads V_1 to V_6 faithfully show the spatial sequence of electrical activation (from the basal right ventricle to the midposterior left ventricular wall). The limb leads, instead, depict a disordered spatial sequence. Leads I, II, III, aVR, aVL, and aVF correspond spatially to 0, 60, 120, –150, –30, and 90 degrees, respectively. Such an array has been consecrated by usage but is counterintuitive. If an analogous distribution were selected for the horizontal plane, the precordial leads would be reordered as V_2, V_4, V_6, $–V_3$, V_1, and V_5 (20). This would considerably compromise the ability of the interpreter to rapidly understand the electrical phenomena taking place in that plane. A more logical sequencing for the limb leads would be aVL, I, –aVR, II, aVF, and III (or –30, 0, 30, 60, 90, and 120 degrees); the inclusion of a negative aVR would allow recording or ECG phenomena at –30 (eFig. 59.2.1).



***e*FIGURE 59.2.1** The panoramic display of the 12-lead electrocardiogram in an ideal sequential spatial order. (From Anderson ST, Pahlm O, Selvester RH, et al. Panoramic display of the orderly sequenced 12-lead ECG. *J Electrocardiol* 1994;27:347–352, with permission.)

Special Leads

Some leads are not considered part of the standard ECG but are useful in specific circumstances. Posterior leads (V_7, V_8, and V_9) (eTable 59.0.1) increase the ECG sensitivity for injury in the posterior wall (21). Right precordial leads (V_3R, V_4R) (eTable 59.0.1) are particularly useful for the diagnosis of right ventricular infarcts and some congenital abnormalities (22). A routine use of the negative aVR (at 30 degrees) would add useful information to the standard ECG, and it would be less likely to be overlooked during routine ECG interpretation (23,24).

The P wave is not always seen distinctly in the 12-lead ECG, but it may be easily identified with the use of special leads. Distinct P waveforms can be seen by placing the right and left arm leads in various chest positions (if possible, parallel to the vector of atrial depolarization) while recording lead I (Lewis lead). Atrial activity can also be recorded semiinvasively from leads placed in the esophagus because the anterior wall of the esophagus lies against the left atrium. In patients with dual-chamber pacemakers, atrial electrograms can be recorded by telemetry from the pacing electrodes. In patients recovering from cardiac surgery, the placement of temporary epicardial pacing electrodes allows the direct recording of atrial activity.

Electrocardiograph Equipment

Electrocardiographs are calibrated to give a deflection of 10 mm per millivolt (this calibration is usually seen at the beginning or end of the ECG); thus, 1 mm equals 0.1 V. Electrocardiographic paper is graph paper divided in little squares of 1 mm each and larger squares of 5 mm each. The speed of the paper is standardized to 25 mm per second.

Commercial systems provide ECG programs with stereotyped methodologies of measurement. The only ECG limb leads that digital electrocardiographs record are leads I and II; the remaining limb leads are calculated in real time based on the Einthoven law (I + III = II) and using relationships derived from lead vectors for the aV leads. For the calculation of the electrical QRS axis, the entire QRS complex area is used. This is an advantage over the manual QRS-axis estimation, which is based mainly on R-wave measurements.

Modern electrocardiographs use digital technology. Analog data are converted into digital signals that are later processed (25). The use of compression techniques allows storage and subsequent retrieval of serial ECG recordings, as well as remote transmission of electrocardiographic data (e.g., to hand-held computers for “real time” interpretation by a cardiologist) (26). Output data after digital transmission or after retrieval of serial measurements can be compared with input data.

Minute measurement methods (e.g., those for individual waveforms) differ to some extent from one another across ECG programs. This occurs partly because at the time many automated ECG systems were adopted for clinical use, the technical features that are pivotal to produce and process the ECG signal had not been standardized. Some of these features include data compression, storage, and retrieval; filters; sampling rate; and requirements for signal fidelity (25). The existence of such limitations should be considered when ECG automated reports are evaluated and compared.

BASIC PRINCIPLES

Membrane Properties, Action Potential, and Cardiac Activation

Myocytes maintain a potential difference between the interior and the exterior of the cell of approximately –90 mV. This electrical transmembrane gradient depends on the chemical transmembrane gradient, which exists because the concentration of negative ions is higher inside the cell than outside. Such uneven distribution of ions is sustained by a sodium pump housed in the cell membrane (27). Electrical stimuli change the resting potential inside the cell from –90 mV to approximately +30 mV (*depolarization*), and the electrical activity recorded during this process is the *action potential*. Depolarization initiates the propagation of the impulse along both the interior and the exterior of the “polarized” membrane. Thus, the electrical front—which can be represented as a vector—flows from the positively charged (depolarized) to the negatively charged (resting) cells. The earliest ventricular activation occurs in the left side of the septum. The depolarization front then proceeds to the right side of the septum and to the anterior wall, following an inside-out course. Isolated myocytes from endocardium and epicardium have markedly different action potential shapes and durations. This is secondary to differences in the distribution of currents (and channel proteins) among different cardiac layers (28).

Electrical systole continues until the positively charged ions exit the cell, which causes *repolarization* (i.e., restitution of membrane polarity) (27). Atrial repolarization proceeds in the same direction as atrial depolarization, and thus the polarity of the repolarization waveform is opposite to that of depolarization. Ventricular repolarization, however, follows an inverted pattern. The process begins in the epicardium and ends in the endocardium, and therefore the polarity of the repolarization waveform is the same as that of depolarization.

This behavior is the basis for the concept of *ventricular gradient*. The ventricular gradient measures the magnitude of the integral between the QRS complex and the T wave (i.e., between depolarization and repolarization). If all ventricular action potentials had the same magnitude and duration, the ventricular gradient would be zero (29). In the mammalian heart, however, the duration of the repolarization forces is greater in some areas of the ventricles than in others. The resultant mean QRS vector and mean T vector form a narrow angle (27). Repolarization has not yet been mapped simultaneously in all layers of the human heart, but evidence suggests that the areas that depolarize last are the first in completing repolarization (30). The basis for this particular behavior is not known; theories regarding temperature or other gradients have been refuted.

Cardiac Impulse Formation and Conduction

The heart can be considered as a dipole with a positive and a negative charge. At any given time, cardiac cells are in various stages of activation (i.e., depolarization and repolarization). The formation (i.e., pacemaking) and timely conduction of an electrical impulse depends on strategically placed cardiac cells. These cells are arranged in nodes, bundles, and branching networks of fascicles (Purkinje cells). They lack contractile capability but are able to achieve spontaneous electrical impulse formation (act as pacemakers) and to alter the speed of electrical conduction. The intrinsic pacemaking rate is most rapid in the specialized cells in the sinus node

(located in the right atrium) and slowest in the specialized cells in the ventricles. After leaving the sinus node, the wavefront travels through the right and left atria in a centrifugal manner. On arrival at the atrioventricular (AV) node, the impulse is delayed, which allows for a sequential, rather than simultaneous, contraction of the ventricles after the atria. The intraventricular conduction network includes the common bundle of His and its right and left bundle branches, proceeding along the septal surfaces to their respective ventricles. The left bundle branch is a diffuse structure that fans broadly over the ventricular septum toward the two papillary muscles of the mitral valve (31). Two divisions of the left bundle branch can usually be distinguished; they are called anterior and posterior but are indeed superior and inferior, respectively. Because the right bundle branch remains compact until it reaches the distal interventricular septal surface (where it branches into the septum and toward the lateral right ventricular wall), many authors consider that the intraventricular conduction system is trifascicular (32,33 and 34). These intraventricular conduction pathways are composed of Purkinje cells with specialized capabilities for both pacemaking and rapid conduction of electrical impulses. Purkinje fibers in turn branch into networks that extend just beneath the surface of the ventricular endocardium. Because the Purkinje system provides a specialized path for rapid activation, the entire ventricular mass can be depolarized in a short time—similar to the depolarization time in the atria, structures of much smaller mass. The impulses then proceed slowly from endocardium to epicardium throughout the right and left ventricles (35). The normal activation sequence begins at the midseptum, continues at the epicardial right ventricular wall near the apex, then at the lateral and basal left ventricle, and ends at the basal septum (Fig. 59.3).

Electrical Bases for Electrocardiography and Vectorcardiography

Differences in cardiac potentials of a single cardiac cell or a small group of cells do not produce enough current to be detected on the body surface. Electrical representation on the ECG depends on the activation of most of the atrial and ventricular masses. The depolarization process produces a relatively high-frequency ECG waveform, which varies according to the action potential properties, the spread of excitation, and the heart geometry. The earliest QRS complex is recorded in right precordial leads. Although depolarization persists, the ECG recording returns to baseline. Myocardial repolarization is then represented by a waveform of lower frequency, the T wave (36). Once the cells are in their resting state, the ECG records a flat baseline.

Only 10% to 15% of the ventricular activation process can be seen on the 12-lead ECG; the remaining activation forces cancel each other. The normal right ventricle, for example, has no representation on the ECG because its forces are obscured by the dipoles generated in the massive left ventricle. The summation of all cardiac electrical forces can be represented with a single vector that originates at the center of the Einthoven triangle and whose arrowhead points to the positive pole. If all instantaneous single vectors were plotted consecutively, a vector loop would be formed in each of the three spatial planes (frontal, sagittal, and horizontal). Such recording constitutes a vectorcardiogram (Fig. 59.3). The vectorcardiogram integrates two surface leads out of three (named X, Y, and Z) in an orthogonal system and depicts a separate loop for each of the ECG components (P wave, QRS complex, T wave, and U wave). The advantage of the vectorcardiogram over the 12-lead ECG is that it provides information not only on magnitude and direction (i.e., positive or negative) of the signals but also on spatial orientation.

Specific situations in which the vectorcardiogram is superior to the ECG (which is a scalar representation of forces) include the diagnosis of left atrial enlargement and right ventricular hypertrophy, and myocardial infarction with left bundle branch block (LBBB) or left fascicular block (37). Since the vectorcardiogram gives no information on heart rhythm and is expensive to produce, its clinical use has gradually been abandoned. Because it positions the electrocardiographic waveforms in a three-dimensional framework, however, it is still useful as both a teaching and a research tool.

THE NORMAL ELECTROCARDIOGRAM

Overview of the Electrocardiographic Waveforms

Figure 59.4 depicts the waveforms of the normal ECG.

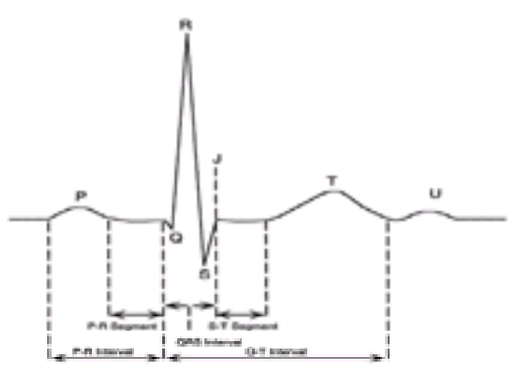

FIGURE 59.4 Waveforms and intervals of the electrocardiogram. (From Wagner GS, ed. *Marriott's practical electrocardiography,* 9th ed. Baltimore: Williams & Wilkins, 1994:13, with permission.)

The origin of the cardiac impulse in the sinus node is electrocardiographically mute; the initial electrical wave of each cardiac cycle is the P wave, which represents the spread of the activation through the atria. The QRS complex is the recording of the ventricular activation and it may appear as one (monophasic), two (diphasic), or three (triphasic) individual waveforms. Low-amplitude or narrow waves are denoted with lowercase letters (e.g., 'q' wave) and taller, wider waves with capital letters (e.g., Q wave).

The T wave represents ventricular recovery and is sometimes followed by a small upright deflection called the U wave. The ST segment is the interval between the end of ventricular activation and the beginning of ventricular recovery. The QT interval measures the time from the onset of ventricular activation to the end of ventricular recovery. This term is used whether the QRS complex begins with a Q or an R wave.

At low heart rates, the PR, ST, and TP segments are at the same horizontal level and form the isoelectric line. This line is considered as the baseline for measuring the amplitudes of the various waveforms. The TP segment disappears at higher heart rates when the T wave merges with the following P wave (38).

P Wave

The first part of the P wave represents the activation in the right atrium, and the middle and final sections of the P wave are recorded during left atrial activation. The normal P wave is rounded and upright in leads I and II and from V_2 to V_6. Its maximum amplitude is 0.25 mV in lead II (or 25% of the R wave) and its duration is 0.08 second. The P-wave axis is approximately 60 degrees. Because of the position of the right and left atria in the thorax, the activation front is directed first anteriorly and then posteriorly. Lead V_1 faces the right atrium; thus, the initial part of the P wave appears positive, whereas its terminal part appears negative.

Ta Segment

The Ta segment (or Ta wave) represents atrial repolarization. It may be seen in normal individuals but is more often obscured by the QRS complex and the early part of the ST segment. The orientation of the Ta wave is opposite that of the P wave. A normal but prominent Ta wave may mimic a pathologic Q wave by producing PR-segment depression.

PR Interval

The time from the onset of the P wave to the onset of the QRS complex constitutes the PR interval, whether the first wave in this complex is a Q or an R wave. The normal PR interval measures 0.12 to 0.22 second and it encompasses the time between the onset of atrial depolarization in the myocardium adjacent to the sinus node and the onset of ventricular depolarization in the myocardium adjacent to the fibers of the Purkinje network.

A major portion of it is inscribed during the slow conduction through the AV node, which is under the influence of the autonomic nervous system. Normally, the PR interval increases with age and shortens with increasing heart rates during exercise or stress. This effect depends on higher sympathetic and lower vagal tones. Incremental atrial pacing at rest, however, *prolongs* the PR interval. The time from the end of the P wave to the onset of the QRS complex is called the PR *segment.*

QRS Complex

The QRS complex represents ventricular activation. The contour of the QRS complex is peaked rather than rounded because it is composed of higher frequency signals than the P and T waves (Fig. 59.4). The normal ventricular activation can be summarized in four vectors (Fig. 59.3): (a) initial septal activation from left to right and anteriorly (inferiorly or superiorly), producing a positive deflection (R wave) at right recording sites; (b) an overlapping wave of excitation involving both ventricles, with the vector directed inferiorly and slightly to the left, which inscribes the midportion of the QRS complex; (c) unopposed activation of the apical and central portions of the left ventricle and of the right ventricle with a resultant vector oriented posteriorly, inferiorly, and to the left. Because the posteriorly positioned left ventricle is much thicker, its activation predominates over that of the anteriorly placed right ventricle, which results in a negative deflection (i.e., S wave) in aVR and in right precordial leads, and in an R wave in leads I, II, III, aVL, and left precordial leads. And (d) activation of the posterior basal portion of the left ventricle and septum with a vector directed superiorly and posteriorly, which completes the S wave in V_5 and V_6.

The QRS complex is measured from the beginning of the first-appearing Q or R wave to the end of the last-appearing R, S, or R' wave, and it tends to be slightly longer in men than in women. Computerized QRS measurements are usually reliable because they integrate information from the 12 ECG leads. The onset of the QRS complex is not recorded simultaneously in all ECG leads; this has implications for measurements of QRS duration. The earliest QRS onset is recorded in right precordial leads in both normal subjects and patients with heart disease (39).

The normal duration of the QRS complex is 0.07 to 0.10 second, and it increases with the subject's height (probably because it correlates with cardiac size) (40).

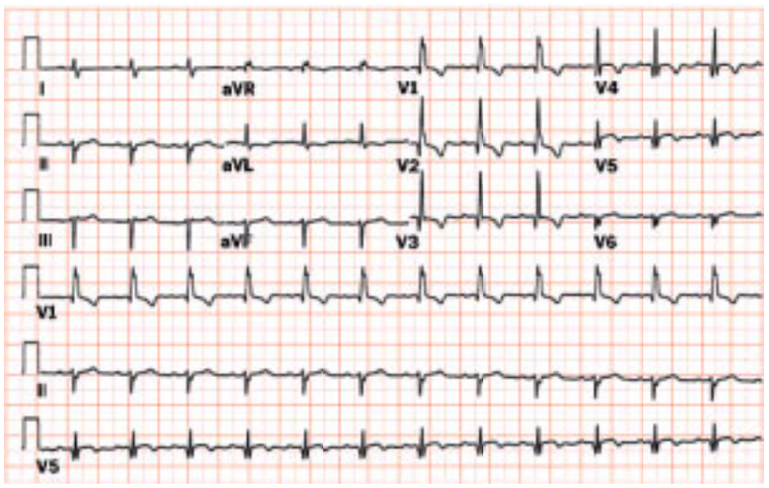
Q Wave

A Q wave is a negative deflection at the onset of the QRS complex. It indicates that the net direction of early ventricular depolarization forces is oriented away from the positive axis of the lead in question, at least by 90 degrees. Normal septal activation results in a rapid 'q' wave in leads I, II, III, aVL, V_5, and V_6 (*e*Table 59.0.2). The presence of Q waves in leads V_1, V_2, and V_3 or the absence of small 'q' waves in leads V_5 and V_6 should be considered abnormal (41).

***e*TABLE 59.0.2** NORMAL VALUES OF THE Q WAVE

Limb leads		**Precordial leads**	
Lead	**Upper limit (sec)**	**Lead**	**Upper limit (sec)**
I	<0.03	V_1	0
II	<0.03	V_2	0
III	—	V_3	0
aVR	—	V_4	<0.02
aVL	<0.03	V_5	<0.03
aVF	<0.03	V_6	<0.03

Modified from Wagner GS, Freye CJ, Palmen ST, et al. Evaluation of a QRS scoring system for estimating myocardial infarct size. I: Specificity and observer agreement. *Circulation* 1982;65:345.



Anterior myocardial infarction. Note anterior Q waves in setting of underlying right bundle branch and left anterior fascicular block.

Positional factors may also result in the inscription of prominent but narrow Q waves. If the septal vector is horizontal, Q waves may appear in lead aVF; if the electrical axis is vertical, Q waves may be present in aVL. Precordial lead electrodes misplaced in a high position may determine a pseudoinfarction pattern from the inscription of Q waves.

In right precordial leads, QR and QS complexes may be normal; they were found in 25% of subjects in V_6R, in 9.7% in V_5R, and in 2.4% in V_4R (42,43).

R Wave

The first positive wave of the QRS complex is the R wave, regardless of whether or not it is preceded by a Q wave. The second vector results in an R wave in leads II and III, and the third vector produces an R wave in leads I, II, III, aVL, aVF, V_5, and V_6. The precordial leads provide a panoramic view of cardiac electrical activity progressing from the right ventricle to the thicker left ventricle, and consequently the R wave increases its amplitude and duration from V_1 to V_4 or V_5. Normal subjects present an rS pattern in leads V_3R and V_4R (42). Larger R waves in V_5 and V_6 may indicate left ventricular enlargement.

The amplitude of the R wave in leads V_5 and V_6 varies directly with left ventricular dimension during exercise and also with variations in the distance of the left ventricle

to the chest wall during positional changes (44). Reversal of the normal sequence with larger R waves in V_1 and V_2 can be produced by right ventricular enlargement.

When a second positive deflection occurs in any lead, it is called R'.

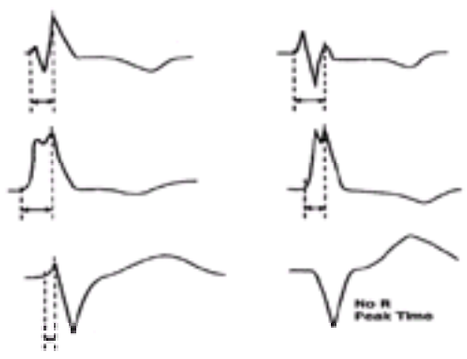
A 42-year-old female patient with right ventricular hypertrophy.

S Wave

A negative deflection after an R wave is an S wave. The third vector produces an S wave in leads aVr, V_1, V_2, V_3, and occasionally V_4. The S wave in the precordial leads is large in V_1, larger in V_2, and then progressively smaller from V_3 through V_6. As with the R wave, ventricular enlargement could alter this sequence. The last vector, directed superiorly and posteriorly, may result in a terminal S wave in leads I, V_5, and V_6. Leads V_4R and V_3R show an rS morphology in 80% of normal subjects (43).

Intrinsicoid Deflection

The time from the beginning of ventricular activation (onset of the QRS complex) to the point at which the impulse arrives under a particular electrode is called the *ventricular activation time*. The downward deflection that follows is the *intrinsicoid deflection.* By definition, the intrinsicoid deflection can only be measured in precordial leads, but some authors have applied this name to the turning point of the cardiac vector along the lead axis for the limb leads as well. For practical purposes, the "R peak time" is preferred as an estimate of the intrinsicoid deflection. It is measured from the onset of the QRS to the peak of the R wave or R' wave (eFig. 59.4.1). The R peak time is 0.04 second or less in V_1 and V_2, and 0.05 second or less in V_5 and V_6 (45).



***e*FIGURE 59.4.1** Measurement of the R peak time. (From Willems JL, Robles De Medina EO, Bernard R, et al. Criteria for intraventricular conduction disturbances and pre-excitation. *J Am Coll Cardiol* 1985;5:1261–1275, with permission.)

QRS Axis

The QRS axis can be manually determined in the frontal plane in three steps: (a) the lead with the equiphasic deflection (defined as positive and negative components of the QRS complex of similar amplitudes) is identified; (b) the lead that is perpendicular to the initial lead is identified; (c) if the predominant direction of the QRS complex in the lead identified in step (b) is positive, the axis is equal to the positive pole of that lead; if the direction is negative, the axis is equal to the negative pole of that lead. The normal electrical axis measures between –30 and +90 degrees (Fig. 59.5). QRS axes between 0 and –30 degrees are considered "left-axis deviation."

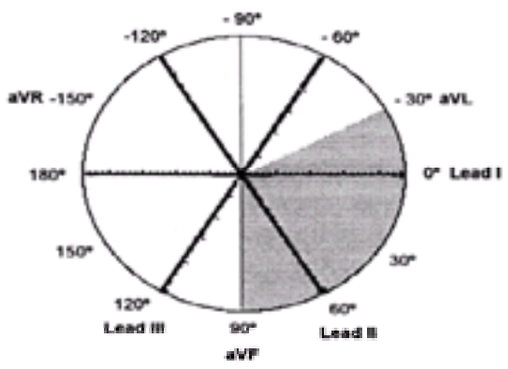


FIGURE 59.5 Frontal plane hexaxial reference system. The normal QRS axis in adults lies between –30 degree and +90 degrees (*area in gray*).

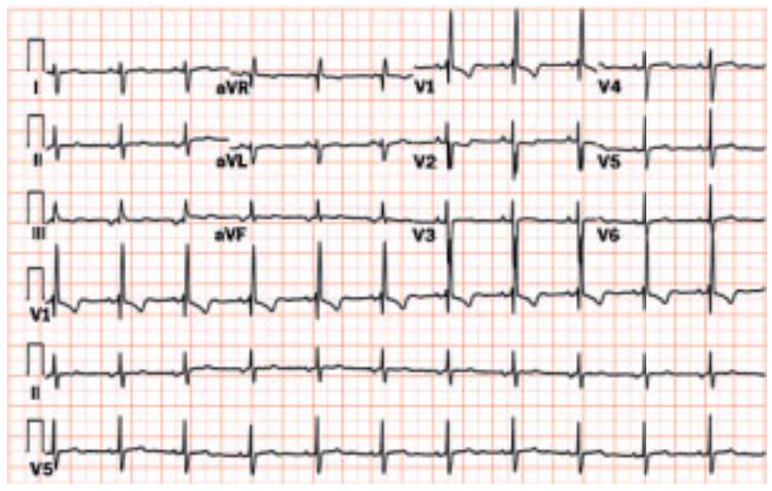
Deviations beyond –30 degrees are abnormal. The normal QRS complex is predominantly positive in both leads I (with its positive pole at 0 degrees) and II (with its positive pole at +60 degrees). If the QRS is positive in lead I but negative in II, the axis is deviated leftward between –30 and –120 degrees. If the QRS is negative in I but positive in II, however, the axis is deviated rightward between +90 and ±180 degrees. The axis is rarely opposite to normal (with a predominantly negative QRS orientation in both leads I and II).

Acute anterolateral myocardial infarction. Note ST segment elevation in the anterior precordial leads as well as leads I and aVL. New left anterior fascicular block suggests proximal left anterior descending infarct location.



Right ventricular hypertrophy. Note incomplete right bundle branch block pattern, right axis deviation, and ST-T–wave changes secondary to right ventricular hypertrophy.

The normal QRS axis is rightward in the neonate, moves to a vertical position during childhood, and then gradually moves to a more horizontal position during adulthood. In normal adults the electrical axis is almost parallel to lead II, but it is more vertical in thin individuals and more horizontal in heavy individuals.

Because the cardiac base is firmly attached to the intrathoracic structures, true (i.e., anatomical) rotation of the heart on its long axis is limited to superior or inferior shifts of the relatively mobile cardiac apex. Most QRS-axis deviations observed in the ECG in ventricular hypertrophies or fascicular blocks correspond, rather, to changes in the balance of epicardial versus endocardial activation forces, or to different routes taken by the activation forces.

ST Segment

The ST segment represents the time period in which the ventricular myocardium remains depolarized. The term *ST segment* is used regardless of whether the final wave of the QRS complex is an R or an S wave. At its junction with the QRS (i.e., J point), the ST segment forms a nearly 90-degree angle and then proceeds horizontally until it curves gently into the T wave.

The ST segment is normally isoelectric with the PR and TP segments. Slight upsloping (particularly in leads V_1 to V_3 and in V_4R to V_3R), downsloping, or horizontal depression of the ST segment may occur as normal variants. The length and appearance of the ST segment are influenced by factors that alter the duration of ventricular activation, such as exercise or bundle branch block.

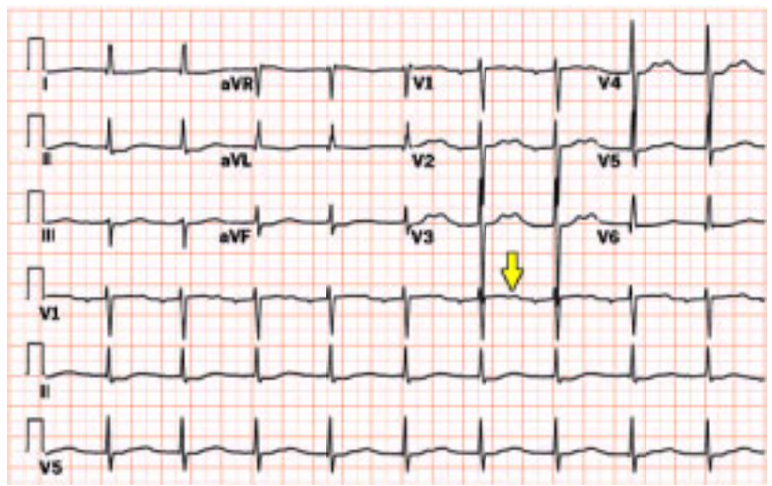
T Wave

The T wave represents exclusively uncancelled potential differences of ventricular repolarization; thus, it accounts for 8% or less of the total time-voltage product of the heart (46). The shape of the T wave is rounded but asymmetric, because the initial deflection is longer than the terminal deflection. The end of the T wave marks the completion of ventricular recovery, and it is not always easily identifiable. Slight “peaking” of the T wave is normal. The amplitude of the T wave does not normally exceed 0.5 mV in limb leads or 0.10 mV in precordial leads.

The direction of the T wave should be evaluated in relation to that of the QRS complex. The T wave is always positive in lead I, nearly always positive or isoelectric in lead II, and may have any polarity in leads III and aVF (27). In precordial leads the T wave is usually upright, except in 50% of women who present negative T waves in V_1.

U Wave

The U wave may be either absent or present as a small, rounded wave following the T wave. In a particular ECG lead, it shows the same direction as the T wave and it reaches approximately 10% of the amplitude of the latter. It is most prominent in leads V_2 through V_3. The origin of the U wave is uncertain. One theory attributes U-wave genesis to the repolarization of Purkinje fibers, and another to potentials generated during ventricular relaxation (47). Anatomic and electrophysiologic studies suggest that the U wave represents repolarization of the “M” cells, a population of subepicardial cells with unique activation properties, but this also has been questioned (48,49).



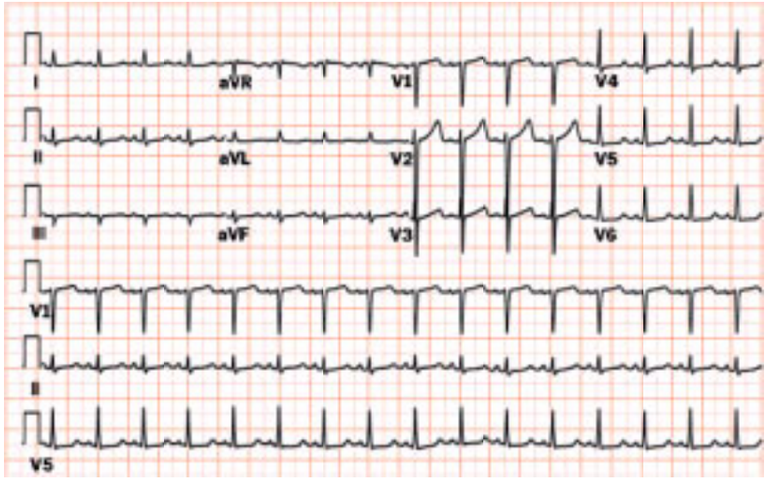
Hypokalemia. Prominent U waves are seen.

QT Interval

The QT interval measures the time from the beginning of the QRS complex until the end of the T wave. It estimates the duration of both ventricular depolarization and repolarization, but is mainly used as an estimate of ventricular recovery time. Repolarization measured as JT (i.e., the interval between the J point and the end of the T

wave) is significantly longer in women than in men (316 ± 31 ms vs. 262 ± 31 ms). Presumably, QT intervals are also shorter in men because of the modulating effect of testosterone on repolarization (50). Ethnic differences in the QT interval have not been demonstrated (51).

The value of the information provided by the QT interval is often limited by the difficulty in identifying the end of the T wave. The terminal portion of the T wave may be isoelectric, or a U wave may merge with the T wave. According to Lepeschkin, if the interval between two peaks in a notched T wave is 150 msec or more, the second peak is a U wave (47). The onset of the U wave should be considered the approximate end of the QT interval. At faster heart rates, the P wave may merge with the T wave and create a TP junction. The end of the QT interval in this instance is measured at the onset of the P wave. Considering these inherent limitations, the fact that methods for QT measurement vary among investigators and that efforts for standardization have not succeeded is not surprising (52,53 and 54). Recommended techniques include measuring the QT interval in leads with an initial Q wave, in leads in which the T wave is most distinct, in lead II or in aVL—in which the U wave is usually isoelectric—and in leads in which the QT is longest (usually V_2 or V_3) (52,55,56).



Hypocalcemia. Marked prolongation of the QT segment is appreciated in lead II.

A 30-year-old male patient with U waves secondary to hypokalemia.

Others advocate the use of a multichannel electrocardiograph with simultaneous recordings of limb and precordial leads, preferably at a paper speed of 50 mm per second (57,58). The QT interval should be measured in three or more consecutive beats (excluding those preceded by premature beats) and averaged to increase precision. Even when the QT interval can be measured with confidence, its reproducibility has been questioned. Intra- and interobserver variability is usually high (59,60). Automated QT analysis using computer programs to analyze digital ECG signals has not entirely resolved the problem (61,62).

The QT interval varies with rate, and normal QT values can be determined only by adjusting for the heart rate. Most automated ECG analyses include the corrected QT interval (QTc interval) in addition to the measured one. The inverse relationship between the RR and the QT intervals is not linear. With an increase in heart rate, a marked shortening of the QT interval occurs initially, followed by a more gradual shortening. Of several methods proposed for QT correction, the Bazett formula (QTc = QT/RR) is the most widely used (63). The normal value of QTc is up to 0.39 second in men and 0.44 second in women.

The Bazett formula has been criticized for several reasons. First, it was derived from observations made on only 34 subjects, some of them children, in a variety of physiologic states. Second, it does not properly adjust the QT at extreme rates. The QTc remains undercorrected (i.e., artificially shortened) during bradycardia, whereas it is paradoxically lengthened at faster rates (64). In a study of 1,300 normal subjects, Macfarlane and Lawrie found that the mean QTc was 0.434 second in persons with heart rates between 80 and 89 beats/min, and 0.446 second in those with rates between 90 and 99 beats/min (65). The upper limit of Bazett's QTc ranged from 0.463 second in young men to 0.506 second in older women, which thus suggests that 0.44 second is inadequately short as the upper limit of normality. Macfarlane and Lawrie proposed the equation QTc = QT + 1.75 (ventricular rate – 60) for QT correction.

Others have proposed alternative formulas to model the relationship between the RR and the QT intervals (64,66,67). Most of them function properly and produce nearly equivalent results for heart rates between 55 and 85 beats/min. The corresponding QTc values for this range are 350 to 420 ms, which in a study of over 14,000 subjects covered the distribution area of 50% of the paired QT/RR values. Outside this range, the discrepancies among investigators in the perceived usefulness of different correction formulas are marked (68,69). Conceivably, more than one formula is necessary to accurately describe the behavior of the QT interval over the entire range of heart rates (70).

Perhaps because no agreement has been reached regarding the ideal QT correction formula, the Bazett formula is still in use. The ultimate goal of the corrected QT is to serve as a prognostic indicator; thus, homogeneous databases including patients with a particular disease as well as information on age and sex are necessary to determine the boundaries of normality (71). Until a better correction method becomes available, both the corrected and the measured QT intervals should be reported.

An additional parameter, QT dispersion, has been proposed as a noninvasive marker of dispersion of refractoriness. It is calculated by subtracting the shortest from the longest QT interval, that is, $QT_{max} – QT_{min}$ (72). The QT dispersion may provide independent prognostic information regarding risk of ventricular tachyarrhythmias in patients with myocardial infarction, congenital and acquired long QT syndrome, hypertrophic cardiomyopathy, alcoholism, and congestive heart failure. Its poor reproducibility (73), however, which persists despite the use of magnifying techniques (74), and the fact that it may be only a surrogate for QT prolongation (75) suggest that the value of QT dispersion in scientific publications may have been exaggerated.

Normal Variants

ECGs as screening tests are requested daily by clinicians, surgeons, and cardiologists for a number of purposes. A normal ECG is a good predictor of normal left ventricular function, and it greatly reduces the need to request an echocardiogram to assess systolic function (76).

RSR'Pattern in Lead V_1

An RSR' (or rSr') pattern in lead V_1 with a QRS duration of less than 0.12 second is present in 2.4% of normal persons (77). The R' wave may correspond to relatively late activation of the crista supraventricularis (78).

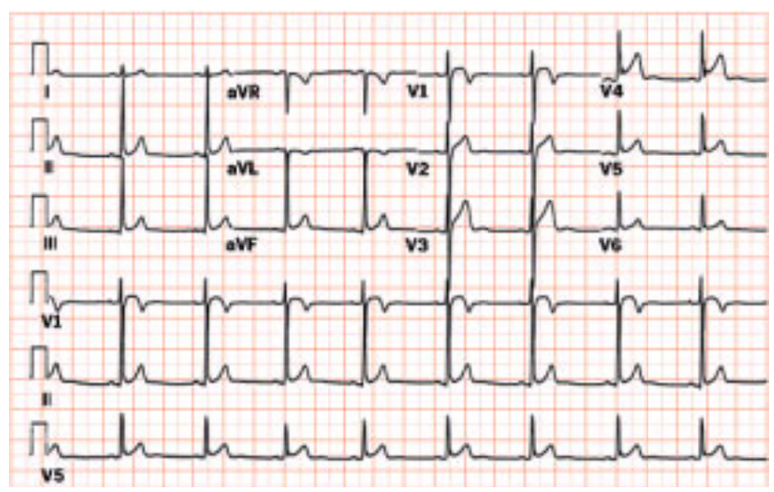
$S_1S_2S_3$ Pattern

The $S_1S_2S_3$ pattern has been observed in 20% of healthy subjects (77). The S waves in standard leads are inscribed when the terminal vector of the QRS complex originates in the outflow tract of the right ventricle or in the posterobasal septum and is directed rightward and superiorly. The typical $S_1S_2S_3$ pattern (with all S waves larger than their preceding R waves) is not as common as the case in which the amplitude of the S wave in lead I is smaller than that of the R wave.

Early Repolarization

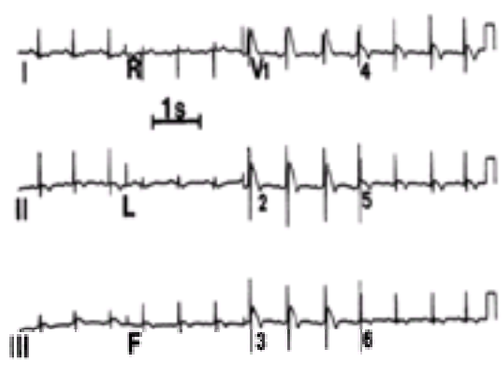
Some individuals show marked (i.e., more than 0.1 mV) ST-segment elevation, which may be present in all precordial leads (79) (Fig. 59.6). Normal young men (particularly African-Americans) may have ST elevation of up to 0.4 mV in leads V_1 through V_3, mimicking acute myocardial infarction or pericarditis (80). Possible causes are early ventricular repolarization or a mild intraventricular conduction delay in the right ventricle. A distinct notching on the downstroke of the R wave, an upward concavity of the ST segment, and symmetric, prominent T waves may also be present (80). Early repolarization appears to be an independent marker of enhanced aerobic condition (81).

FIGURE 59.6 Electrocardiogram of patient with early repolarization and sinus tachycardia (19-year-old African-American woman). ST elevation is present in both inferior and precordial leads.



Early repolarization. Note diffuse J-point elevation, early R-wave transition, with notched downstroke of R wave in lateral precordial leads. These changes are characteristic of early repolarization in this 28-year-old African-American male.

Differentiating early repolarization from an electrocardiographic pattern consisting of right bundle branch block (RBBB) and coved ST-segment elevation in right precordial leads may be difficult. This pattern (the Brugada syndrome) is associated with ventricular tachyarrhythmias and sudden death, and seems to be an autonomically transmitted condition (82,83 and 84) (*e*Fig. 59.6.1). An almost identical syndrome to the Brugada syndrome but with a pathologic substrate of right ventricular dysplasia has been reported (84,85). The possibility also exists that a common pathophysiologic ground might exist for Brugada syndrome and early repolarization (86).



***e*FIGURE 59.6.1** Electrocardiogram of patient with right bundle branch block and ST elevation in leads V_1 to V_4 (Brugada syndrome). (From Brugada P, Brugada J. Right bundle branch block, persistent ST segment elevation and sudden cardiac death: a distinct clinical and electrocardiographic syndrome. A multicenter report. *J Am Coll Cardiol* 1992;20:1391–1396, with permission.)

Unusual T Waves

Negative T waves, particularly in precordial leads (from V_6R to V_2, and sometimes through V_6) may be seen in young, usually African-American, vagotonic persons (87,88). These T waves may show intermittent changes in polarity, and in some cases follow a slightly elevated ST segment (early repolarization syndrome). Transient inverted T waves have been documented in normal subjects after meals (89) or after drinking cold water (90). Bifid T waves (i.e., T waves with two peaks different from a U wave) are present in 20% of children; their incidence decreases with age (91). Usually found in precordial leads, bifid T waves are more prevalent in V_1 and V_2 in younger groups, and shift toward V_5 and V_6 in older subjects. A likely mechanism producing bifid T waves is a delayed right ventricular repolarization; an asynchronous repolarization of the anterior and posterior walls would inscribe two separate peaks in the T wave. The probability of an underlying heart disease increases with age.

APPROACH TO ELECTROCARDIOGRAPHIC DIAGNOSIS

Sensitivity, Specificity, and Predictive Accuracy

The ECG is a highly valuable diagnostic tool. ECG diagnoses are made by inference, however, and are therefore subject to error (92). To obtain maximum benefit from electrocardiographic information, one must apply the principles of sensitivity, specificity, and predictive accuracy. Sensitivity is the number of persons with a condition who have a target ECG sign. A sign with perfect sensitivity is positive in all patients with the condition; the absence of the sign rules out the disorder. Specificity is the number of persons without a condition who do not have the target ECG sign. A sign with perfect specificity is negative in all persons free of the condition; the presence of the sign makes a positive diagnosis.

At the time an ECG is requested, when one does not know whether a particular disorder is present, the concept of predictive value is most helpful. The positive predictive value is the proportion of patients with positive test results who have the condition. The negative predictive value is the proportion of patients with negative results who do not have the condition. Predictive accuracy is the degree to which a positive or negative ECG sign represents what it is actually intended to represent, or

its ability to discriminate between two competing states. Accuracy can be assessed by comparison with reference techniques or gold standards (93).

Predictive values are a good measure of overall clinical usefulness in particular settings because they incorporate information on both the test (i.e., the ECG) and the population being tested (94). As postulated in the Bayes theorem, the presence of a sign (or a positive test result) is less informative in a clinically healthy population. An ECG abnormality detected during screening procedures is associated with a two to four times lower incidence of new cardiovascular events than an abnormality discovered during a clinical evaluation (95). Disorder prevalences between 40% and 60% result in the maximum drop or rise from pretest to posttest probability (96). Sensitivity and specificity, on the other hand, do not depend on the prevalence of the condition in the population, but they do depend on the spectrum of patients under study. Autopsy has too often been used as a gold standard in electrocardiography. This may potentially bias the spectrum of patients toward those with more severe manifestations. The increasing availability of noninvasive tests that provide accurate anatomical information (i.e., two-dimensional echocardiography, magnetic resonance imaging) has allowed for new correlations in living patients.

Choice of a Cutoff Point

Most ECG information relies on continuous values, and a decision must be made as to what constitutes a positive sign. For values that follow a normal distribution, abnormal results are defined as two standard deviations from the mean of the reference population. Thus, 5% of normal subjects have abnormal test results. Selecting a cutoff point involves trading a high sensitivity for a low specificity, or vice versa. Setting a cutoff point of ST-segment elevation of 0.4 mV in two ECG limb leads in patients with chest pain would provide a high specificity for acute myocardial infarction; however, it would also have poor sensitivity, because many patients with acute infarction do not have this much ST-segment elevation. Setting the cutoff at 0.05 mV identifies virtually all patients with acute infarction, but many persons without infarction would also be included.

The clinician must weigh the relative importance of the sensitivity and specificity of the sign selected for each patient and set the cutoff point accordingly. If false-positive results must be avoided, the cutoff point should be set to ensure a high specificity. When false-negative results are undesirable, the cutoff point should be set to ensure a high sensitivity. The role of these trade-offs needs to be clearly understood to prevent inadequate expectations regarding the diagnostic capabilities of the ECG—a problem not unusual among internal medicine doctors (97).

Receiver operating characteristic curves provide a graphic way to examine the relation between a test's sensitivity or specificity (96). The values of the test or sign are plotted along a curve, and their true-positive and false-positive rates (i.e., sensitivity and 1 – specificity, respectively) can be determined at each cutoff point. The upper-left-hand corner of the curve denotes an ideal electrocardiographic sign, with a true-positive rate of 0.1 and a false-positive rate of 0. A worthless electrocardiographic sign would follow the diagonal from the lower left to the upper right corners; each incremental gain in sensitivity would be matched with an equal loss in specificity. Receiver operating characteristic curves permit the formal comparison of different diagnostic signs (or set of signs). The better the sign, the closer its curve to the upper left corner.

THE ABNORMAL ELECTROCARDIOGRAM

QRS-Axis Deviation

Although QRS axes between 0 degrees and –30 degrees are sometimes called "left-axis deviations," they are truly a normal variant. Severe left-axis deviations (QRS axes between –30 degrees and –90 degrees) are considered abnormal; yet they are found in 2% of healthy adults (77,98).

Although the term *left-axis deviation* is often used interchangeably with left anterior fascicular block (LAFB), isolated left superior displacement of the QRS axis may occur in the absence of LAFB (in inferior myocardial infarction and other disorders). In some patients, the extent of left-axis deviation varies over short periods of time. The significance of this finding is uncertain; it may result from conduction delays affecting selectively different groups of fibers in the fan-like anterior division of the left bundle branch (27).

P-Wave Abnormalities

Abnormalities of the P wave reflect disorders of atrial pressure or volume, or an anomalous origin of the cardiac impulse.

Mitral stenosis. Left atrial enlargement and right ventricular hypertrophy have developed secondary to mitral stenosis, causing fixed pulmonary hypertension.

Right Atrial Abnormality

Right atrial enlargement has classically been diagnosed in the presence of (a) tall, peaked P waves in leads II, III, and aVF (0.25 mV or more in lead II) ("P pulmonale"), (b) a P-wave axis of 75 degrees or more, and (c) a positive deflection of the P wave in V_1 or V_2 of 0.15 mV or more (99). The correlation of these ECG signs with anatomic findings is poor, however. The amplitude of the P wave may paradoxically decrease as right ventricular hypertrophy progresses. Also, P-wave signs have relatively low sensitivity to detect "pure" right atrial enlargement. In a population with low prevalence of coronary disease, no associated chronic obstructive pulmonary disease, and no left heart pathology, QRS changes in lead V_1 (R/S of 1 or more; presence of Q) in the absence of RBBB were as specific and much more sensitive than a P-wave height of 0.25 mV or more in lead II. In addition, ST depression of 0.05 mV or more in II or aVF [probably representing a prominent atrial repolarization (Ta) wave] was almost 100% specific (100).

Left Atrial Abnormality

Left atrial enlargement is characterized by (a) a notched P wave with a duration of 0.12 second or more ("P mitrale"), best observed in leads II and V_1, and (b) a wide terminal negative deflection in lead V_1 (0.1-mV amplitude per 0.4-second duration) (Fig. 59.7). The terminal force of the P wave correlates better with left atrial volume than with pressure, which may also explain the moderate correlation of the P terminal force with the left atrial weight (101). Interestingly, no characteristics of the P wave correlate with atrial size. The left atrial enlargement pattern indicates an intraatrial conduction disturbance, and thus the term *left atrial abnormality* is preferred (102).

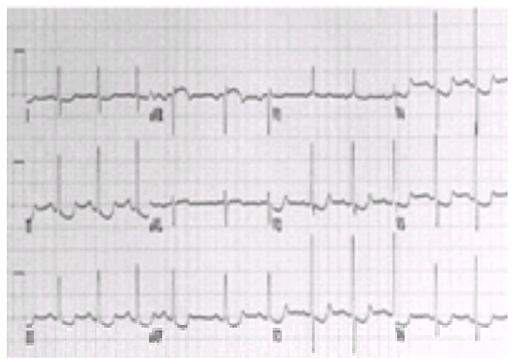


FIGURE 59.7 Left atrial abnormality. The P-wave duration is 0.125 second, and a prominent negative deflection is seen in V_1. Incomplete right bundle branch block and repolarization changes induced by digitalis are also present.

The term *pseudo–P pulmonale* denotes a prominent P wave in inferior leads that is caused by left atrial rather than right atrial abnormality. Detailed examination of the P wave reveals that its terminal portion is increased, whereas the initial portion is normal. Participation of the left atrium in the genesis of the pseudo–P pulmonale is confirmed by identifying a marked negative terminal component of the P wave in V_1.

Biatrial Enlargement

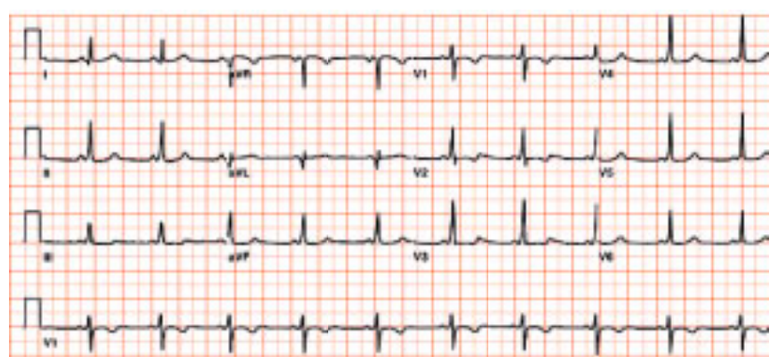
Biatrial enlargement is characterized by tall P waves in lead II, and notched and broad P waves in leads I and II with a terminal negative deflection in V_1.

Ta Wave

Ta waves may be prominent in atrial hypertrophy or infarction and during pericarditis. In the presence of atrial enlargement the Ta wave is prolonged and may displace the ST segment, which appears depressed.

PR Interval

A short PR interval in the presence of a normal P-wave axis suggests an abnormally rapid conduction pathway within the AV node or in its surroundings (i.e., a bundle of cardiac muscle connecting atria and ventricles, bypassing the AV node). Early activation of the ventricular myocardium (ventricular preexcitation) creates the potential for electrical impulse reentry into the atria, producing a tachyarrhythmia (Wolff-Parkinson-White, or WPW, syndrome). When a short PR interval is accompanied by an abnormal P-wave direction, the site of impulse origin has moved from the sinus node to a position closer to the AV node.



A 44-year-old female patient with Wolff-Parkinson-White syndrome.

A prolonged PR interval in the presence of a normal P-wave axis indicates a delay in impulse transmission at some point in the pathway between the atrial and ventricular myocardium. When a long PR interval is accompanied by an abnormal P-wave axis, the possibility that the P wave is associated with the preceding rather than the next QRS complex should be considered. This is a manifestation of retrograde activation from ventricles to atria, and the PR interval is usually longer than the preceding PR interval.

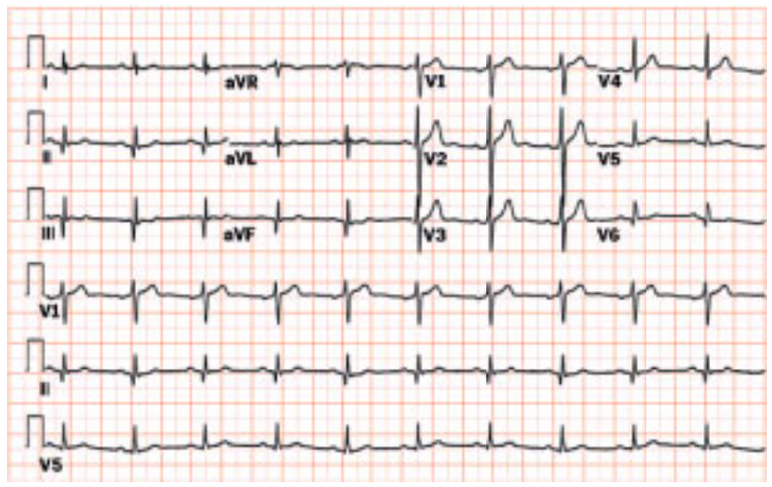
QRS Complex

Absence of R-wave progression from V_1 to V_5 may indicate left ventricular myocardial necrosis. The presence of notching and slurring of the QRS complex in the precordial leads is more sensitive than the presence of Q waves to detect anterior infarction, but is less specific (103). A rightward mediastinal shift in left pneumothorax may produce apparent loss of left precordial R waves (104). In dextrocardia, normal R-wave progression may be restored by recording leads V_1 to V_5R on the right side of the precordium.

Dextrocardia. Notable findings include a positive R wave in aVR and counterclockwise rotation in the precordial leads.

Q Wave

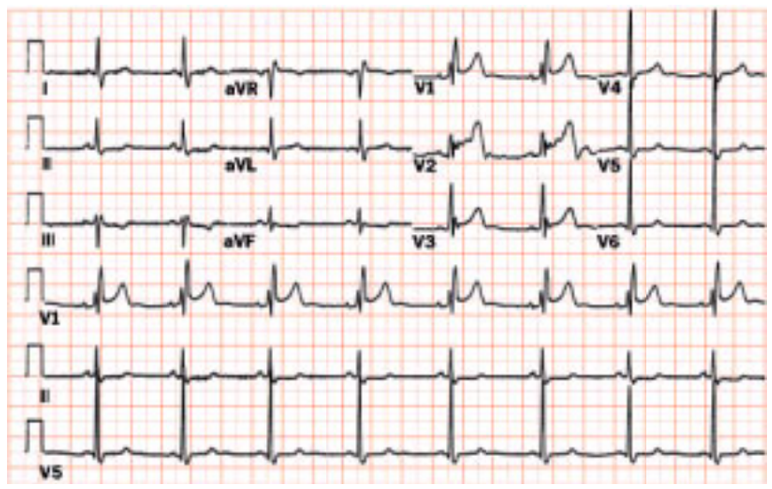
Conditions associated with abnormal Q waves include myocardial infarction or injury, ventricular hypertrophy or dilatation, and intraventricular conduction disturbances (LBBB, ventricular pacing, and WPW syndrome). Less frequent causes of Q waves include infiltrative myocardial disease, chronic obstructive pulmonary disease (in precordial leads), acute pulmonary embolism (in lead aVF), pneumothorax, and misplacement of precordial electrodes (105).



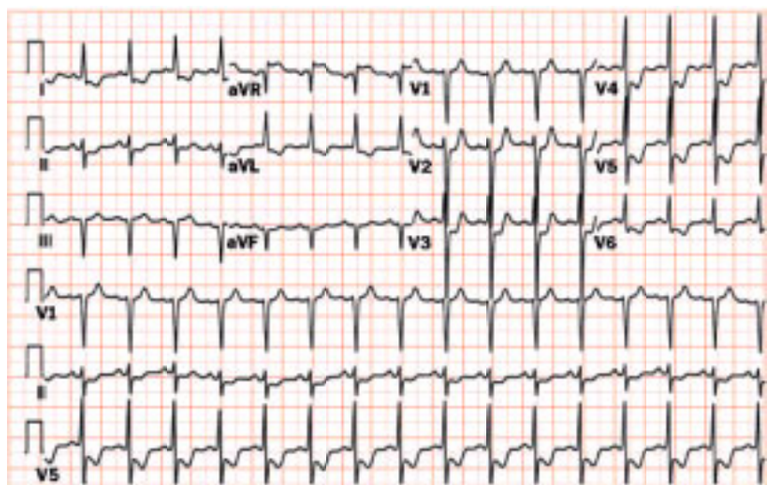
Inferior myocardial infarction. Prominent Q waves in the inferior leads are associated with T-wave inversions.

ST Segment

Alterations of the ST segment include elevation and depression. The most important cause of ST-segment elevation is transmural injury. Outside the acute setting, ST elevation can be found in combination with other signs of remote or recent infarction and is associated with ventricular asynergy, and can be seen in other pseudoinfarction patterns (106). Depression of the ST segment occurs when myocardial ischemia is present and when ventricular repolarization is altered.



Anterior myocardial infarction in setting of right bundle branch block. ST-segment elevation in the anterior precordial leads as well as primary T-wave changes support acute anteroseptal myocardial infarction.



Subendocardial ischemia. Anterolateral ST-segment depression is consistent with diffuse subendocardial ischemia versus non–Q-wave myocardial infarction.

QT Interval

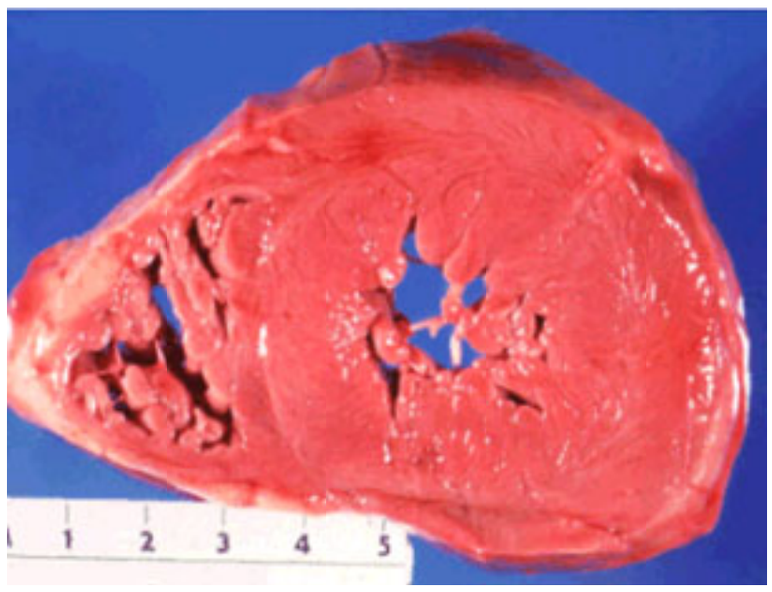
Causes of abnormal prolongation of the QT interval include myocardial ischemia, cardiomyopathies, hypokalemia, hypocalcemia, autonomic influences, drug effects, hypothermia, and congenital long QT syndrome. A prolonged QTc is a predictor of cardiovascular mortality even in the absence of overt heart disease (107).

Ischemia

Acute myocardial ischemia may induce an initial, transient QT shortening followed by extreme QT prolongation. Changes in the QT interval often accompany T-wave or U-wave inversion (108). The QT interval usually returns to its normal value within 72 hours of the acute coronary event, whereas inverted T waves may persist.

Hypertrophic Cardiomyopathy

The QTc is prolonged in patients with hypertrophic cardiomyopathy; a modest correlation is found between QTc and left ventricular wall thickness. QTc dispersion is also increased, which probably reflects the inhomogeneous ventricular refractoriness that predisposes to ventricular arrhythmias (109).



Massive left ventricular hypertrophy as well as concentric hypertrophic cardiomyopathy. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The

Cleveland Clinic Foundation.)

Hypothermia

Core temperatures of 35°C or less are associated with ECG manifestations that are probably induced by changes in ionic currents, an enhanced vagal tone, or both. Prolongation of the QT interval is usually related to the sinus bradycardia that accompanies hypothermia, but in some patients the QTc interval is also abnormal.

Autonomic Dysfunction

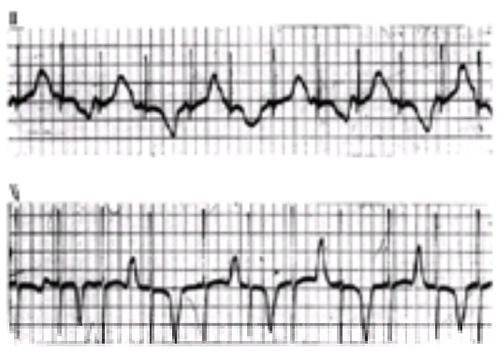
Patients with diabetes, alcoholism, and other disorders that cause autonomic dysfunction may show prolonged QT and QTc intervals (110).

Drugs

Antiarrhythmic drugs, the antibiotics erythromycin and ketoconazole, the antihistamine agents astemizole and terfenadine, the phenothiazines, and terodiline (a drug used for treatment of incontinence) have been associated with prolongation of the QT and QTc intervals, torsades de pointes, and sudden death (111). A continuously updated list of drugs associated with QT prolongation can be found on the Internet (112).

Congenital Long QT Syndrome

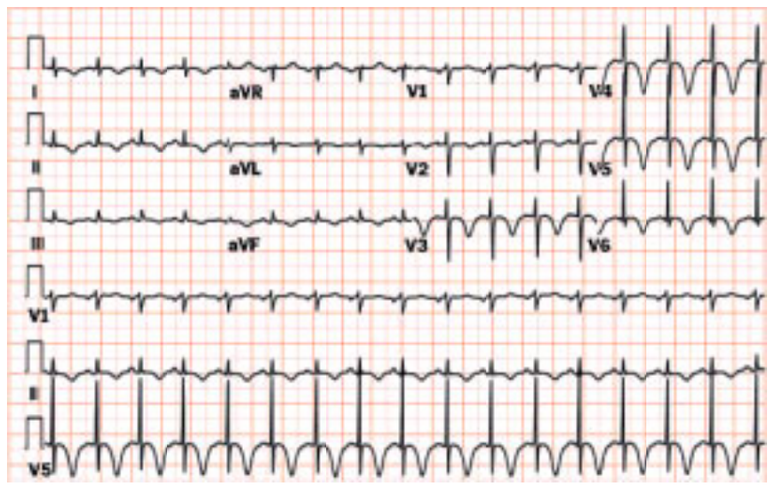
The congenital long QT syndrome is an autosomal dominant disorder in which the QTc interval measures longer than 0.46 second. Five percent to 10% of gene carriers for this disorder, however, have QTc durations within the normal range (113). Patients with this syndrome may also have marked sinus bradycardia and other repolarization abnormalities. The T wave is often notched or biphasic, or alternates its morphology or polarity (T-wave alternans; *e*Fig. 59.7.1) (114,115 and 116). Prominent U waves may also be present. The extreme prolongation of the QT interval can result in pseudo 2:1 AV block when every other P wave falls during or before the preceding T wave (114).



***e*FIGURE 59.7.1** Marked T-wave alternans in a patient with congenital QT prolongation. (From Sharma S, Nair KG, Gadekar HA. Romano-Ward prolonged QT syndrome with intermittent T wave alternans and AV block. *Am Heart J* 1981;101:500–501, with permission.)

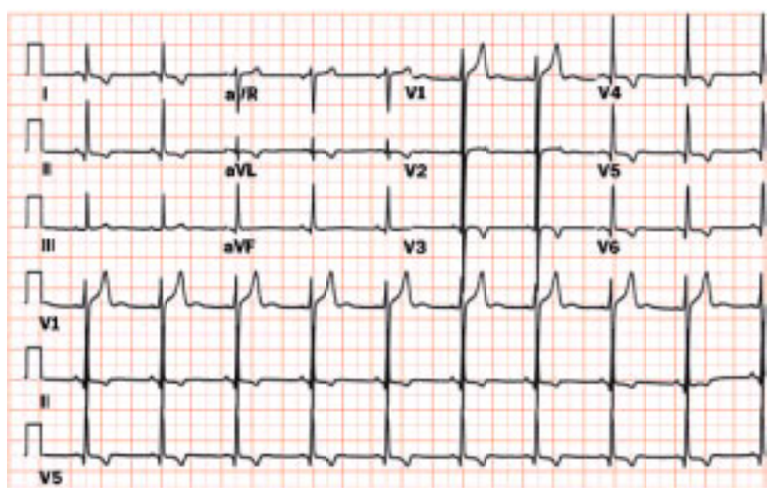
T Wave

Abnormalities of the T wave (usually consisting of inverted T waves) are seen in a number of conditions. Although the T wave is a sensitive detector of repolarization differences over the myocardium, the magnitude of T-wave changes is not proportional to the extent of myocardium with repolarization abnormalities (27,30). Negative T waves are considered “primary” when the preceding sequence of ventricular depolarization is normal, and “secondary” when it is altered. Primary T waves often accompany ST-segment changes and are observed during myocardial ischemia, myocarditis, pericarditis, and mitral valve prolapse, and are induced by some drugs (phenothiazines, class Ia antiarrhythmic agents, and amiodarone hydrochloride). Postprandial status, a recent paroxysmal tachycardia, and the injection of contrast into coronary arteries all may induce primary T-wave abnormalities (27,30). Research has shown that the negative T waves that develop in infarct-related ECG leads shortly after thrombolysis may be powerful markers for improved 30-day survival, which calls into question the name “T-wave abnormality” (117). However, such T waves must be dynamic (i.e., revert to positive with time, exercise, or dobutamine hydrochloride treatment) to predict myocardial viability and favorable outcome (118,119).



Neurogenic T waves. These deep, symmetric T-wave inversions developed after intracranial hemorrhage.

Secondary T waves are those associated with bundle branch block, ventricular pacing, ventricular hypertrophy, cardiomyopathies (120), and WPW syndrome. Less than 1% of ECGs recorded for any reason show giant, rather permanent negative T waves. The most frequent correlates are left ventricular hypertrophy and coronary artery disease (121).



Hypertrophic cardiomyopathy. Inverted precordial T waves associated with hypertrophic cardiomyopathy.

T-Wave Alternans

Electrical alternans of the T wave is a consequence of alternation of the duration or the shape of the action potential, or both. It has been documented in patients with the congenital long QT syndrome (*e*Fig. 59.7.1), in patients with hypocalcemia, and in patients treated with quinidine or amiodarone (122,123).

T-Wave "Memory"

The term *T-wave memory* describes the aspect of the T waves that seems to "remember" an abnormal activation pattern. The T-wave polarity follows the polarity of a preexistent ectopic QRS (124). Transient abnormal T waves are recorded in normally conducted beats after cessation of ventricular pacing or intermittent LBBB (124,125) (*e*Fig. 59.7.2). Also, in patients with WPW syndrome who undergo catheter ablation of the accessory pathway, the polarity of the T wave is that of the former delta wave. T waves appear negative in leads that showed a negative delta wave (126). Whether the memory T waves follow previous ectopic QRS complexes or delta waves, the magnitude and persistence of the T-wave changes increase proportionally with the duration of the abnormal ventricular activation.

***e*FIGURE 59.7.2** Memory T waves in a patient with complete atrioventricular block in whom a permanent pacemaker had been temporarily inhibited. The intrinsic rhythm shows a right bundle branch block pattern with deep, wide, negative T waves (positive in aVR) that follow the QRS morphology of the previously paced QRS complex.

U Wave

Positive, prominent U waves are usually induced by hypokalemia (127), but they may also be seen in patients taking digitalis or quinidine and in patients with the congenital long QT syndrome. Negative U waves are highly specific for the presence of heart disease (128). The three most common conditions associated with negative U waves are systemic hypertension, valve regurgitation, and ischemic heart disease.

Electrical Alternans

Electrical alternans is defined as alternation of the QRS complex or T-wave morphology, usually in a 2:1 ratio (*e*Fig. 59.7.1). The PR interval or the ST segment is affected more rarely. Causes of this phenomenon include myocardial ischemia, ventricular dysfunction, rapid tachycardias, significant pericardial effusion, and acute pulmonary embolism (129,130).

Pericardial tamponade. Low QRS voltage and electrical alternans are characteristic findings of tamponade.

The significance of electrical alternans varies with the underlying condition. The QRS alternans seen during pericardial effusion is a manifestation of mechanical alternans and suggests imminent tamponade. Alternans of the ST segment indicates transmural injury and probable coronary spasm. Overt repolarization alternans (affecting the ST segment, the QT interval, or the T wave) has been associated with ventricular arrhythmias and is relatively common in the congenital long QT syndrome (27).

VENTRICULAR HYPERTROPHY

Left Ventricular Hypertrophy

Left ventricular hypertrophy is a response to a pressure or volume overload. Because of the increase in myocardial mass, a longer time is required for the spread of the electrical activation from endocardium to epicardium. The intrinsicoid deflection, the R peak time, and the overall QRS duration are all prolonged (*e*Fig. 59.7.3). Because the thickness of the ventricular muscle correlates with the magnitude of the depolarization front, left ventricular hypertrophy exaggerates the normal ECG pattern of left ventricular predominance. An augmented mean QRS vector is oriented toward the left, posteriorly and superiorly, which thereby causes a positive deflection in leads I, II, aVL, V_5, and V_6. The precordial transitional zone is shifted to the left. An rS pattern is usually observed in V_1 and V_2, although sometimes the initial 'r' wave disappears.

***e*FIGURE 59.7.3** Left ventricular hypertrophy. Electrocardiograms recorded in two elderly women with left ventricular pressure overload due to aortic stenosis. Note the left ventricular conduction delay and intermittent ventricular premature beats in **A**, and left ventricular strain in **B**. (From Wagner GS, ed. *Marriott's practical*

electrocardiography, 9th ed. Baltimore: Williams & Wilkins, 1994:69, with permission.)

Several explanations have been proposed for the left-axis deviation observed in left ventricular hypertrophy (14). First, the prolonged epicardial activation separates in time the vectors generated in the last region of the left ventricle (i.e., superior and posterior) from the preceding vectors. This determines that the terminal vector (i.e., the last 0.06-second vector; Fig. 59.3) is more exclusively contributed from the superior and posterior regions. Second, in left ventricular hypertrophy the diameter of the mitral and aortic orifices remains normal. This causes the free wall to become more bowed superiorly and posteriorly, and the terminal vectors of the left ventricle move in that direction. Third, the increased magnitude of the terminal QRS vectors (oriented leftward and posteriorly) also causes left-axis deviation. Finally, intraventricular conduction defects could develop.

Left ventricular repolarization is also delayed in the presence of hypertrophy. The epicardial cells no longer repolarize early, which causes the spread of recovery to proceed from endocardium to epicardium. The reversal of the direction of the recovery process produces negativity of both the ST segment and the T wave in leads with leftward or posterior orientation. This is called *ventricular strain* (131). The development of strain correlates well with left ventricular mass as determined by echocardiography (132), although myocardial ischemia and intraventricular conduction delays may also contribute.

Left ventricular dilatation ("volume overload") secondary, for example, to aortic or mitral regurgitation enlarges the surface area of the left ventricle and displaces the myocardium closer to the precordium. This increases the amplitudes of leftward and posteriorly directed QRS waveforms (131). Volume overload may produce prominent but narrow Q waves in the leads facing the left side of the septum—that is, I, aVL, V_5, and V_6—and a reciprocal R wave in V_1 and V_2. The amplitude of the S wave is increased in leads V_2 and V_3 and that of the R wave is increased in leads V_5 and V_6. Thus, the suggestion has been made that the ECG cannot reliably distinguish between left ventricular dilatation and hypertrophy (133).

Electrocardiographic Diagnosis of Left Ventricular Hypertrophy

Classic electrocardiographic criteria for the detection of left ventricular hypertrophy are listed in eTable 59.0.3 (also see eFig. 59.7.3). These criteria are specific but not sensitive (134,135). The presence of obesity further decreases the sensitivity of the ECG for the detection of left ventricular hypertrophy (136). Of all criteria, high QRS voltage in precordial leads is the most sensitive, and the gender-specific Cornell voltage is the most closely correlated with left ventricular mass (137,138). The product of QRS duration and gender-specific Cornell voltage (the "Cornell product") seems to provide the best overall accuracy and is not significantly affected by the presence of bundle branch block (139). Left atrial abnormality is a strong independent predictor of increased left ventricular mass; each 0.1 mV per second of increase in left atrial abnormality predicts a 30-g increase in left ventricular mass (140).

***e*TABLE 59.0.3** CRITERIA FOR THE DIAGNOSIS OF LEFT VENTRICULAR HYPERTROPHY

Romhilt-Estes scoring system	
1. R or S in any limb lead ³0.20 mV	
or S in lead V_1 or V_2	
or R in lead V_5 or V_6 ³0.30 mV	3 points[a]
2. Left ventricular strain	
ST segment and T wave in opposite direction to QRS complex	
without digitalis	3 points
with digitalis	1 point
3. Left atrial enlargement	
Terminal negativity of the P wave in lead V_1 is ³0.10 mV in depth and ³0.04 second in duration	3 points
4. Left-axis deviation of ³–30 degrees	2 points
5. QRS duration ³0.09 second	1 point
6. Intrinsicoid deflection in lead V_5 or V_6 ³0.05 second	1 point
Total	13 points
Sokolow-Lyon criteria	
S wave in lead V_1 + R wave in lead V_5 or V_6 >3.50 mV	
Or	
R wave in lead V_5 or V_6 >2.60 mV	
Cornell voltage criteria	
Women, R wave in lead aVL + S wave in lead V_3 >2.00 mV	
Men, R wave in lead aVL + S wave in lead V_3 >2.80 mV	

[a]Left ventricular hypertrophy, 5 points; probable left ventricular hypertrophy, 4 points.
Modified from Romhilt DW, Bove KE, Norris RJ, et al. A critical appraisal of the electrocardiographic criteria for the diagnosis of left ventricular hypertrophy. *Circulation* 1969;40:185; Sokolow M, Lyon TP. The ventricular complex in left ventricular hypertrophy as obtained by unipolar precordial and limb leads. *Am Heart J* 1949;37:161; and Casale PN, Devereux RB, Alonso DR, et al. Improved sex-specific criteria of left ventricular hypertrophy for clinical and computer interpretation of electrocardiograms: validation with autopsy findings. *Circulation* 1987;75:565.

The ECG diagnosis of left ventricular hypertrophy is difficult regardless of physician training and testing conditions (40). Computers may not perform significantly better. In a comparison of several automated algorithms, left ventricular hypertrophy was correctly identified only 50% to 76% of the time (141). These difficulties may be explained by differences across populations in the prevalence of left ventricular hypertrophy (with better ECG correlations for white nonobese men) (142), distortion in the perceived prevalence of left ventricular hypertrophy by physicians (143), and variations in the spectrum of hypertrophy severity (144).

Left Ventricular Hypertrophy with Left Bundle Branch Block

Because most patients with LBBB also have anatomic left ventricular hypertrophy, determining the cause of increased QRS duration in a particular subject is difficult. The best correlation between QRS duration and ventricular mass is obtained at QRS widths of 135 ms or less (145). Criteria for left ventricular hypertrophy are more sensitive in the presence of left-sided intraventricular conduction disturbances, probably because patients with LAFB or LBBB tend to have more severe left ventricular hypertrophy than patients who do not.

Left atrial abnormality is a strong independent predictor of increased left ventricular mass in the presence of LBBB (140). A sum of the amplitudes of the S wave in V_2 and the R wave in V_6 of 4.5 mV or more has a sensitivity of 86% and a specificity of 100% for detection of left ventricular hypertrophy in patients with LBBB (146). Less useful criteria are S-wave amplitude in V_3 of 2.5 mV or higher (sensitivity, 56%; specificity, 90%) and R + S in any precordial lead of 4 mV or higher (sensitivity, 63%; specificity, 66%). A QRS duration of 0.16 second or higher is sensitive (75%) but not specific (34%); a QRS axis at –30 degrees or more, on the other hand, is highly specific (100%) although not sensitive (30%) (147).

Left Ventricular Hypertrophy with Left Anterior Fascicular Block

Left ventricular hypertrophy superimposed on LAFB increases the S wave in lead III and the R or S wave (or both) in precordial leads. An index that includes these changes [i.e., (R + S) maximal precordial ³3.0 mV + SIII] has 87% specificity and 96% sensitivity for left ventricular hypertrophy, with a positive predictive value of 89% and a negative predictive value of 95% (148).

Left Ventricular Hypertrophy with Right Bundle Branch Block

The presence of RBBB decreases the sensitivity of the ECG criteria for left ventricular hypertrophy, particularly for precordial signs. In nonobese patients with RBBB, a Sokolow index of 3.5 mV or above is 100% specific for left ventricular hypertrophy (149). Another useful sign when both disorders coexist is left atrial abnormality. The presence of a P-wave terminal force in lead V_1 increases the sensitivity for left ventricular hypertrophy to over 70%, with an approximate specificity of 80% (150). Each 0.1-mV increase in the P terminal force is associated with approximately 25 g of increase in left ventricular mass (151).

Right Ventricular Hypertrophy

Right Ventricular Hypertrophy and Right Bundle Branch Block

The right ventricle dilates either during compensation for a volume overload or after hypertrophy eventually fails to compensate for a pressure overload. This dilatation causes stretching of the right bundle branch, which courses from base to apex on the endocardial surface of the right side of the interventricular septum. When the impulse conduction within these right bundle and Purkinje fibers has slowed so much that electrical activation arrives at the right ventricle only after it has already been activated by impulses spreading from the left ventricle, RBBB has developed.

A 22-year-old Caucasian female patient with primary pulmonary hypertension.

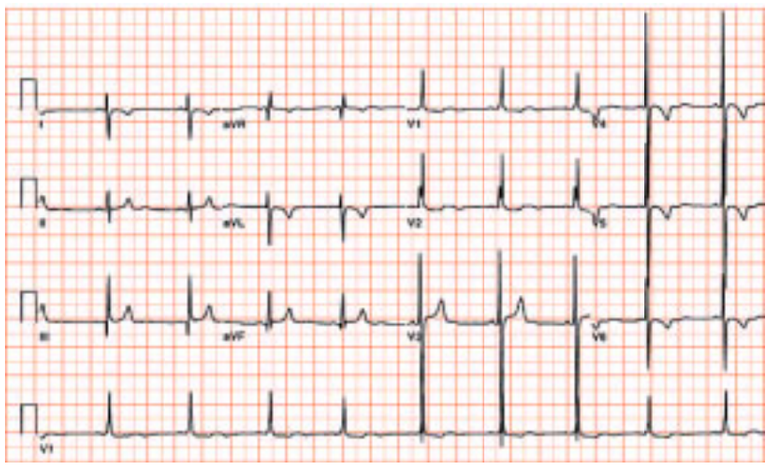
Electrocardiographic Diagnosis of Right Ventricular Hypertrophy

Right ventricular hypertrophy is normal in the neonate because during fetal development resistance is greater in the pulmonary than in the systemic circulation. Hypertrophy of the right ventricle persists during the first months of life. The QRS axis measures 100 degrees or more, and the QRS complex is predominantly positive in lead V_1 and predominantly negative in V_6. Such a highly specific pattern for neonatal right ventricular hypertrophy can rarely be found later in life. In adults, changes in response to right pressure overload are less typical because the right ventricular mass must be sufficiently large to overcome the left forces (152). Initially, the QRS complex in lead V_1 loses its negative predominance and a late positive R' wave may appear. With moderate hypertrophy the initial QRS forces move anteriorly (increased R wave in V_1), and the terminal QRS forces move rightward (increased S wave in lead I). Marked hypertrophy results in a predominantly positive QRS complex in V_1; the R wave is greater than 0.7 mV, the R/S ratio is greater than 1, and the S wave is less than 0.2 mV (153,154). Repolarization of the right ventricular myocardium is delayed, which produces negativity of both the ST segment and the T wave (ventricular strain).

The ECG criteria have poor sensitivity for detecting right ventricular hypertrophy. Right-axis deviation of 110 degrees or more identifies only 12% of cases, and the sensitivity of R-wave amplitude and R/S ratio in V_1 is lower than 10%. The specificity of all the criteria is moderate (155).

Biventricular Hypertrophy

Enlargement of both ventricles may lead to cancellation of opposite forces and result in a normal ECG. In some patients, tall R waves develop in all precordial leads with prominent, biphasic QRS complexes in midprecordial leads. Biventricular hypertrophy may also be considered when, coexisting with a pattern of left ventricular hypertrophy, the ECG shows (a) right-axis deviation to 90 degrees or more in the frontal plane, or (b) an R wave greater than the Q wave in aVR and an S wave greater than the R wave in V_5 (156).

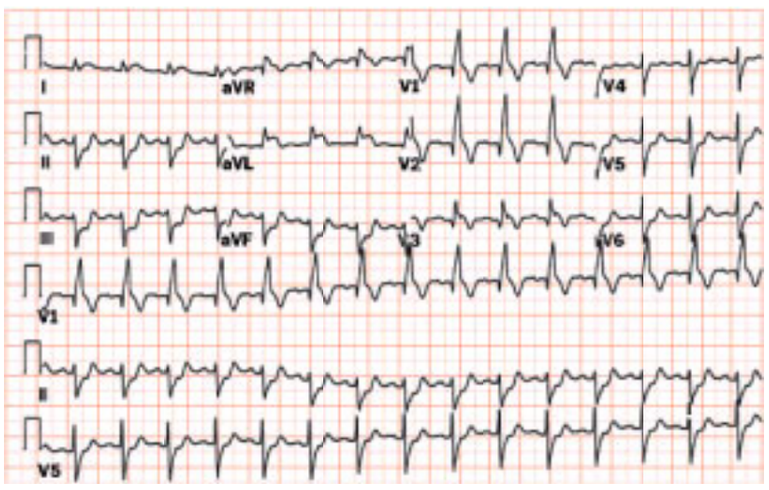


A 16-year-old male patient with biventricular hypertrophy secondary to ventricular septal defect and Eisenmenger's syndrome.

BUNDLE BRANCH AND FASCICULAR BLOCKS

An isolated conduction delay in the common bundle of His has a similar effect on activation of both ventricles; therefore, it does not alter the appearance of the QRS complex. The intraventricular conduction disturbances are termed *unifascicular blocks* when the ECG shows evidence of blockage of either the right bundle branch (RBBB), the left anterior fascicle (LAFB), or the left posterior fascicle (left posterior fascicular block, LPFB). The mildest manifestation of intraventricular conduction defects may be left-axis deviation. The normal conduction time (estimated when the QRS axis is at +90 degrees) increases linearly by a few milliseconds for each shift of the QRS axis toward the left (up to –90 degrees). At –30 degrees, the increase is 25 ms (157).

In *bifascicular blocks* the conduction is interrupted in two fascicles (i.e., LBBB, RBBB with LAFB, and RBBB with LPFB). The Purkinje system is not represented on the surface ECG, and conduction blocks at its level must be detected indirectly by their effects on myocardial activation and the QRS complex.



Acute anterolateral myocardial infarction complicated by conduction disturbance. ST-segment elevation in the anterior precordial leads as well as leads I and aVL is associated with right bundle branch block and left anterior hemiblock.

Conduction blocks vary in nature from anatomical lesions that interrupt impulse transmission in the specialized fibers to permanent or transient delays caused by nonuniformity of refractoriness, changes in membrane responsiveness, or decreased transmembrane action potential secondary to phase 4 of depolarization. These electrophysiologic conditions may result from ischemia, electrolyte imbalances, or cardioactive drugs. A stereotyped ECG pattern of bundle branch block develops regardless of the mechanism involved or the precise site of the conduction abnormality.

Electrocardiographic criteria for bundle branch and fascicular blocks are listed in *e*Table 59.0.4.

***e*TABLE 59.0.4** CRITERIA FOR THE DIAGNOSIS OF BUNDLE BRANCH AND FASCICULAR BLOCKS
Definition of ventricular conduction delays
A. Complete bundle branch blocks
Qualifying statements:
(S1) QRS duration ³0.120 sec (adults)
(S2) Supraventricular rhythm
(S3) Absence of WPW pattern
Criteria for a complete bundle branch block:
(a) S1 and S2 and S3
1. Complete RBBB
Qualifying statements:
(S1) R' or r' in V_1 or V_2
(S2) S duration >R duration in I and V_6
(S3) S duration >0.040 second in I and V_6
(S4) R peak time >0.050 second in V_1 or V_2
Criteria for RBBB:
(a) S1 and S2 or
(b) S1 and S3 or
(c) S4 and (S2 or S3)
2. Complete LBBB
Qualifying statements:
(S1) Broad and notched or slurred R in I and V_5 or V_6
(S2) Absence of Q wave in I and V_5 and V_6
(S3) R peak times ³0.060 sec in V_5 or V_6
Criteria for LBBB:
(a) S1 and S2 and S3
3. Nonspecific (unspecified) intraventricular block
All cases with QRS duration >0.12 sec that do not meet the criteria for LBBB or RBBB
B. Incomplete bundle branch blocks
1. Incomplete LBBB
Qualifying statements:
(S1) QRS duration ³0.100 sec and QRS duration <0.120 sec
(S2) Absence of Q waves in I and V_5 or V_6
(S3) R peak time >0.060 sec in V_5 or V_6
Criteria for incomplete LBBB:
(a) S1 and S2 and S3
2. Incomplete RBBB
Qualifying statements:
(S1) QRS duration <0.120 sec
(S2) r' or R' in V_1 or V_2
(S3) R' >R in V_1 or V_2
(S4) R peak time >0.050 sec in V_1 or V_2
Criteria for incomplete RBBB:
(a) S1 and S2 and S3 or
(b) S1 and S4
C. Fascicular blocks
1. LAFB
Qualifying statements:
(S1) QRS duration <0.120 sec
(S2) QRS axis £–45 degrees
(S3) QRS axis £–30 degrees and QRS axis >–45 degrees
(S4) rS pattern in II and III and aVF
(S5) qR pattern in aVL
(S6) R peak time ³0.045 sec in aVL
(S7) Slurred R downstroke in aVL
(S8) Slurred S in V_5 or V_6
Criteria for uncomplicated LAFB:
(a) S1 and S2 and S4 and S5 and S6 or
(b) S1 and S2 and S4 and S5 and S7 or
(c) S1 and S2 and S4 and S5 and S8
Qualifying statement:
(S4 is usually present with criteria a, b, and c above. If there is a QS in lead II, LAFB cannot be differentiated from interior myocardial infarction.
Criteria for possible uncomplicated LAFB:
(a) S1 and S3 and S4 and S5 and S6 or
(b) S1 and S3 and S4 and S5 and S7 or
(c) S1 and S3 and S4 and S5 and S8
2. LPFB
Qualifying statements:
(S1) QRS duration <0.120 sec
(S2) QRS axis >90 degrees and QRS axis <180 degrees
(S3) R in III > R in II (note that S3 is a consequence of S2)
(S4) qR pattern in III and aVF with Q duration £0.040 sec
(S5) absence of other causes of right-axis deviation
Criteria for LPFB:
(a) S1 and S2 and S3 and S4 and S5

LAFB, left anterior fascicular block; LBBB, left bundle branch block; LPFB, left posterior fascicular block; RBBB, right bundle branch block; WPW, Wolff-Parkinson-White syndrome.
From Willems JL, Robles Da Medina EO, Bernard R, et al. Criteria for intraventricular conduction disturbances and pre-excitation. *J Am Coll Cardiol* 1985;5:1261–1275, with permission.

Right Bundle Branch Block

The right ventricle contributes minimally to the normal QRS complex. Thus, RBBB produces little distortion during the time required for left ventricular activation; Figure 59.8 illustrates the slight changes of the early portion of the QRS complex contrasting with the marked distortion of its late portion. Late activation of the normal right ventricular myocardium via the spread of impulses from the left ventricle produces a late prominent R' wave in lead V_1 that follows the R wave produced by normal left-to-right activation of the septum. The presence of an RSR' configuration of the QRS complex is pivotal for the diagnosis of RBBB (*e*Table 59.0.4). However, this pattern may also be produced by a terminal conduction delay—vectorcardiographically dissimilar to either RBBB or LBBB—typical of posterior infarction (158). When the QRS duration is less than 0.12 second, the RSR' pattern may correspond to incomplete RBBB or a normal variant.

FIGURE 59.8 Right bundle branch block. The patient may also have right ventricular hypertrophy.

Fascicular Blocks

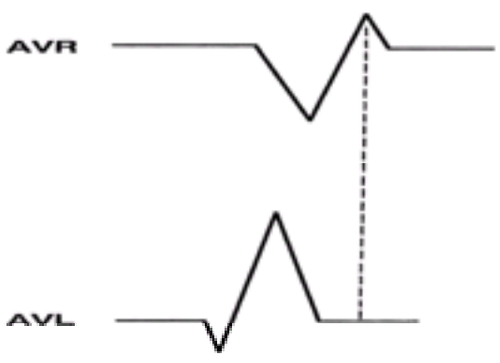
The anterior fascicle activates a portion of the left ventricle that is superior and to the left of that activated by the posterior fascicle. When both fascicles are intact, the impulse travels through them at the same time to depolarize the myocardium. The wavefronts from each fascicle then collide near the end of ventricular depolarization. An interruption or delay of impulse conduction in one fascicle results in asynchronous activation of the left ventricle.

LAFB is common and benign; LPFB is rare (159). Fascicular blocks are often associated with coronary artery disease. In autopsy studies, the most frequent finding underlying LAFB is anterior infarction with proximal left anterior descending (LAD) artery occlusion. Posterior infarction, however, is not usually associated with LPFB; autopsy examination in LPFB shows massive infarct of the septum (compromising both the anterior and posterior areas) and widespread damage to the left bundle branch (160).

Left Anterior Fascicular Block

In epidemiologic surveys, LAFB is the most common conduction abnormality, perhaps because the left anterior fascicle is located in the outflow tract and in apposition to the aortic ring; this makes it susceptible to increases in intraventricular pressure and disorders of the aortic valve (161). The initial ventricular activation in LAFB spreads inferiorly and rightward via the left posterior fascicle (13). Block in the anterior fascicle removes the competition from activation directed superiorly and leftward, and Q waves appear in leads with the positive electrode on the left arm (I and aVL) (Fig. 59.9). The impulse arrives at the inferior and apical myocardium retrogradely from the posterior fascicle with a minimal delay that prolongs the QRS by 0.02 second. The remainder of the left anterior ventricular wall is activated in a superior, leftward, and counterclockwise direction. These terminal forces are first represented in lead aVL and then in aVR. Thus, the peak of the terminal R in lead aVL precedes the peak of the terminal R wave in a simultaneous lead aVR (eFig. 59.9.1) (162). The R waves in leads I and aVL are prominent, and the large amplitude of the R wave in aVL may mimic left ventricular hypertrophy. Prominent S waves are seen in leads II, III, and aVF, causing a leftward shift of the QRS axis. This QRS-axis deviation is the major criterion for the diagnosis of LAFB (eTable 59.0.4). The original QRS-axis criterion proposed by Rosenbaum (and adopted by the World Health Organization/International Society and Federation for Cardiology Task Force) of –45 degrees has been considered highly specific but rather insensitive to detect LAFB (45); other authors use –30 degrees.

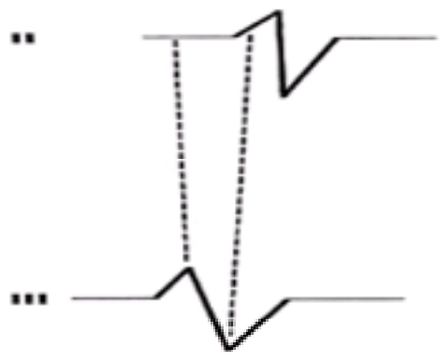
FIGURE 59.9 Left anterosuperior fascicular block. (From Wagner GS, ed. *Marriott's practical electrocardiography,* 9th ed. Baltimore: Williams & Wilkins, 1994:89, with permission.)



***e*FIGURE 59.9.1** Relation of the terminal QRS portion in leads aVR and aVL for the diagnosis of left anterior fascicular block. (From Warner RA. Recent advances in the diagnosis of myocardial infarction. *Cardiol Clin* 1987;5:381–392, with permission.)

The diagnosis of LAFB in the presence of inferior myocardial infarction is difficult because both entities produce left-axis deviation. In addition, inferior infarcts tend to produce a superior deviation of the initial depolarization forces, while LAFB directs them inferiorly, which thus counteracts the manifestations of inferior infarct. Warner and colleagues have proposed several criteria for the diagnosis of coexistent LAFB and inferior infarct, based on the correspondence of the QRS complex portions between simultaneous leads (162) (eTable 59.0.5, eFig. 59.9.2).

***e*TABLE 59.0.5** CRITERIA FOR THE DIAGNOSIS OF INFERIOR INFARCTION WITH LEFT ANTERIOR FASCICULAR BLOCK
Leads aVR and aVL both end in R waves, with the peak of the terminal R wave in lead aVR occurring later than the peak of the terminal R wave in lead aVL.
The points of maximum deflection of the QRS complex in lead III precede the points of maximum deflection of the corresponding portions of the QRS complex in lead II.
Q wave of any magnitude is seen in lead II.



***e*FIGURE 59.9.2** Relation of the initial QRS portion in leads II and III for the diagnosis of left anterior fascicular block in the presence of inferior infarct. (From Warner RA. Recent advances in the diagnosis of myocardial infarction. *Cardiol Clin* 1987;5:381–392, with permission.)

Left Posterior Fascicular Block

LPFB is usually associated with RBBB; its isolated form is rare. Rosenbaum and colleagues attributed the low incidence of LPFB to the fact that the posterior fascicle is short and thick and it is the first group of fibers to depart from the bundle of His. The posterior fascicle may also be protected by its dual blood supply from the anterior and posterior descending coronary arteries and because it lies in the less turbulent left ventricular inflow tract (13).

Aside from its association with coronary artery disease, LPFB has also been identified in cardiomyopathies, aortic valve disease, and calcification of the left ventricular skeleton (163). The initial activation of the left ventricular free wall when the left posterior fascicle is blocked occurs via the left anterior fascicle (13). The excitation front is directed superiorly and leftward. No forces travel inferiorly or rightward, and thus Q waves appear in leads with the positive electrode on the left leg (leads II, III, and aVF). Next, the activation wave spreads over the remainder of the left ventricular free wall in an inferior and rightward direction. This produces prominent R waves in leads II, III, and aVF and prominent S waves in leads I and aVL, which cause a rightward shift of the QRS axis to at least +90 degrees (164) (*e*Fig. 59.9.3). The QRS duration is slightly prolonged (by 0.02 second). The diagnosis of LPFB can only be made in the absence of right ventricular hypertrophy, because this condition itself can produce an LPFB pattern.

***e*FIGURE 59.9.3** Probable left posteroinferior fascicular block, suggested by extreme right axis deviation, in electrocardiogram of a 73-year-old woman. (From Wagner GS, ed. *Marriott's practical electrocardiography,* 9th ed. Baltimore: Williams & Wilkins, 1994:90, with permission.)

Midseptal Fascicle and Midseptal Fascicular Block

Application of the term *trifascicular* to the intraventricular conduction system alludes to the existence of two divisions (fascicles) of the left bundle branch in addition to the right bundle branch (33). The use of the term *trifascicular* by some authors to describe an additional subdivision of the bundle of His creates confusion (165). Histopathologic studies have identified discrete midseptal fibers in the anterior wall of the left ventricle (between the anterior and posterior fascicles), which stem separately from the bundle of His and may contribute to the propagation of the cardiac impulse (31,166,167). In this case, the intraventricular conduction system would comprise four fascicles, and the term *quadrifascicular* would apply (168).

Controversy exists regarding the existence of a distinct midseptal fascicle. Yet some investigators have reported clinical ECG observations compatible with midseptal fascicular block. A study of patients with no evidence of right ventricular hypertrophy described an ECG pattern mimicking posterior infarct with a narrow QRS complex shifted anteriorly in the horizontal plane but normally oriented in the frontal plane, with relatively tall R waves in lead V_1 and prominent R waves in leads V_2 through V_4. Angiography in these patients showed LAD artery (rather than right coronary) occlusion and akinesia of the left anterior ventricular wall, which suggests that the electrocardiographic pattern may have been caused by ischemic midseptal block.

The approximate incidence of anterior conduction delay with extreme QRS-axis deviation in the horizontal plane is 2% in normal subjects, but it may be much higher (e.g., approximately 25%) in patients with coronary artery disease or cardiomyopathy (167). Properly timed atrial extrastimuli in patients with normal QRS during sinus beats reproduce the QRS morphology of the conduction defect (169). Thus, anterior conduction delay has also been considered a borderline defect between a "true block" and a normal variant (which would result from a disproportion in the lengths of several fascicles of the left bundle branch, the left anterior fascicle being the longest and the anterior midfibers the shortest).

Other authors disagree with the notion that tall R waves in V_2 secondary to LAD occlusion represent midseptal block. The left midseptal fascicle receives its blood supply from midseptal perforator branches of the LAD (170). When an angioplasty balloon is inflated in the mid-LAD, the initial anterior vectors are reduced, with a *decrease* of the R wave in V_2 (171). The same result is obtained with properly timed extrastimuli (172). Thus, ischemically induced prominent R waves in V_2 may rather correspond to right septal conduction delay, reproducible with occlusion of the distal LAD (170).

Left Bundle Branch Block

LBBB produces marked distortion of the QRS complex (Fig. 59.10), and it may be caused by disease either in the main left bundle branch (predivisional) or in its fascicles (postdivisional). The presence of LBBB signs in a screening ECG correlates well with left ventricular systolic dysfunction (76).

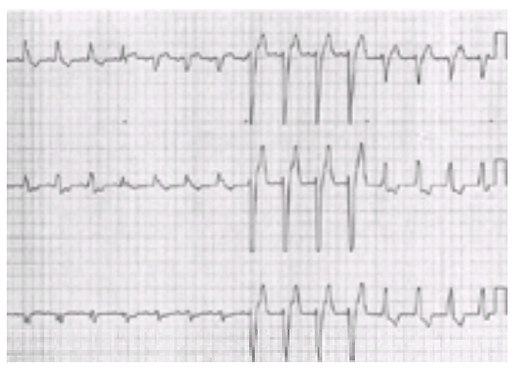


FIGURE 59.10 Uncomplicated left bundle branch block.

Left bundle branch block. Wide QRS complex, negative in lead V_1, is associated with secondary T-wave inversions.

The interventricular septum is normally activated from left to right. This produces an initial R wave in the right precordial leads and a Q wave in leads I and aVL as well as in the left precordial leads. During LBBB, the septum is activated from right to left. Initial Q waves are inscribed in the right precordial leads and the normal Q waves in V_5 and V_6 disappear. The ventricular activation front then proceeds from the left interventricular septum to the adjacent anterior superior and inferior walls, to the posterolateral free wall. This sequence of activation tends to produce monophasic QRS complexes: QS in lead V_1 and R in leads I, aVL, and V_6.

LBBB is characterized by secondary repolarization changes of opposing polarity to that of the main QRS deflection. For leads with a predominantly negative QRS complex, this results in an ECG pattern of ST-segment elevation with positive T waves, similar to the current of injury of acute coronary occlusion. Uncomplicated LBBB thus resembles anterior wall myocardial infarction (Fig. 59.10), and when left-axis deviation is also present, the repolarization pattern mimics that of inferior infarct.

The most important differential diagnosis of LBBB is the QRS pattern of the “corrected” transposition of the great vessels. In this condition, the initial QRS force shows the same direction as in LBBB because propagation of the impulse is inverted, but the QRS duration is normal.

Left Bundle Branch Block with Left-Axis Deviation

Several authors have reported a more severe organic heart disease and longer H-V intervals in patients with LBBB with left-axis deviation than in those with normal axis, which suggests a more diffuse pathologic compromise involving the left anterior fascicle (173,174). In most patients with intermittent LBBB and left-axis deviation, however, the QRS axis is normal during normally conducted beats (159,175). This suggests that left-axis deviation during LBBB results from a different septal activation pattern (i.e., site and extent of reengagement of the left-sided ventricular specialized conduction system after transseptal conduction) and not from a direct anatomical compromise of the left anterior fascicle.

Nonspecific Intraventricular Block

A QRS duration of 0.11 second or greater that does not satisfy the criteria for either RBBB or LBBB is considered a nonspecific intraventricular block (45).

Right Bundle Branch Block with Left Anterior Fascicular Block

LAFB not only appears as a unifascicular block much more commonly than LPFB, it also accompanies RBBB more often than does LPFB. The diagnosis is made by the late prominent R or R’ wave in V_1 typical of RBBB, and the initial R waves and prominent S waves in leads II, III, and aVF seen in LAFB. The QRS duration should be at least 0.12 second and the frontal plane axis should be between –45 degrees and –120 degrees (*e*Fig. 59.10.1).

***e*FIGURE 59.10.1** Right bundle branch block and left anterior fascicular block. The patient is a 66-year-old man with fibrosis of the conduction system. The markedly prolonged QRS duration (0.20 second) suggests underlying left ventricular hypertrophy. (From Wagner GS, ed. *Marriott’s practical electrocardiography,* 9th ed. Baltimore: Williams & Wilkins, 1994:94, with permission.)

Right Bundle Branch Block with Left Posterior Fascicular Block

The combination of RBBB with LPFB is less common than the combination of RBBB with LAFB. Even if ECG changes are typical, the diagnosis can be made only if no clinical evidence of right ventricular hypertrophy is present. The diagnosis of RBBB with LPFB should be considered when typical changes of RBBB are seen in V_1 and the initial R waves and prominent S waves of LPFB are present in I and aVL. The QRS duration should be at least 0.12 second and the frontal plane axis at 90 degrees or more (*e*Fig. 59.10.2).

***e*FIGURE 59.10.2** Combination of right bundle branch block and left posterior fascicular block. Electrocardiograms from a 71-year-old woman **(A)** and a 77-year-old man **(B)** with probable fibrosis of the conduction system. Note the prolonged PR interval in **B**, which suggests involvement of the left anterosuperior fascicle in addition. (From Wagner GS, ed. *Marriott’s practical electrocardiography,* 9th ed. Baltimore: Williams & Wilkins, 1994:95, with permission.)

Prognostic Significance of Bundle Branch Block

Isolated RBBB was found in 0.18% and LBBB in 0.1% of 110,000 subjects screened in Ireland. In the absence of clinically overt cardiac disease, bundle branch block was not associated with increased overall mortality. Isolated LBBB, however, carried a risk of development of cardiovascular disease and increased cardiac mortality (176). The most common abnormalities in patients with newly acquired LBBB are hypertension, cardiomegaly, and coronary artery disease. These entities have usually been diagnosed before the appearance of the conduction defect (174). In chronic coronary disease, the presence of LBBB is an independent predictor for mortality (177).

Trifascicular Blocks

Electrocardiographic documentation of trifascicular block during 1:1 AV conduction is rare and requires the presence of alternating RBBB and LBBB or fixed RBBB with alternating LAFB or LPFB (13). If both bundle branches are simultaneously affected by block, the ECG shows complete AV block. When the degree of block differs between the two bundle branches, ECG manifestations vary and include, for example, a shorter PR interval preceding either RBBB or LBBB, or a complete bundle branch block with prolonged PR interval (27). The combination of bifascicular block (RBBB + LAFB; RBBB + LPFB; or LBBB) with first-degree AV block on the surface ECG cannot be considered trifascicular block because the site of AV block can be either the AV node or the His-Purkinje system (178). His bundle electrocardiography may be necessary to evaluate conduction in the remaining fascicle in symptomatic patients with bifascicular block.

A 93-year-old male patient with trifascicular block.

ABERRANCY

Aberrant intraventricular conduction is the abnormal, asynchronous propagation of an impulse through the His-Purkinje system resulting in an altered QRS complex. This definition excludes conduction of supraventricular impulses via accessory pathways that bypass the AV node. Changes in the QRS complex may affect its duration, axis, or amplitude; successive aberrant beats may mimic ventricular tachycardia (179). The occurrence and extent of aberrancy are determined by (a) prematurity of the supraventricular impulse (i.e., excitation before completion of repolarization), (b) basic RR cycle and RR cycle preceding the premature beat, (c) velocity of AV nodal conduction, (d) refractoriness of the bundle branch, and (e) level of diastolic depolarization of the bundle branch system. The right bundle branch is more frequently involved in aberrant conduction than the left, probably because of its longer action potential duration at normal rates. Common manifestations of aberrancy include aberrant conduction of atrial premature beats, the Ashman phenomenon, acceleration-dependent (phase 3) aberrancy, deceleration-dependent (phase 4) aberrancy, concealed transseptal conduction (linking), and diffuse myocardial depression of conduction. “Pseudo–bundle branch block” was first demonstrated in patients by Castellanos and colleagues. It is induced by concealed premature impulses arising in the bundle branches (180).

Ashman’s phenomenon. Underlying rhythm is atrial fibrillation. QRS complex with right bundle branch block morphology after long-short coupling interval is diagnostic of Ashman’s phenomenon.

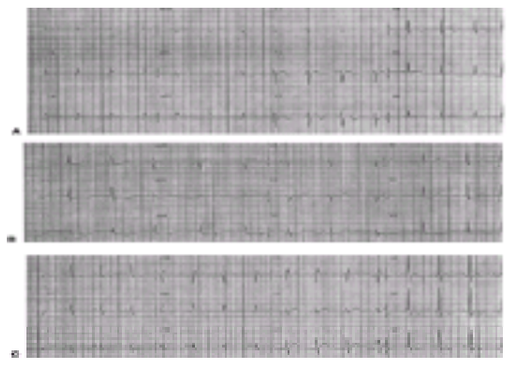
ISCHEMIC HEART DISEASE

Myocardial Ischemia and Injury: General Electrophysiologic Principles

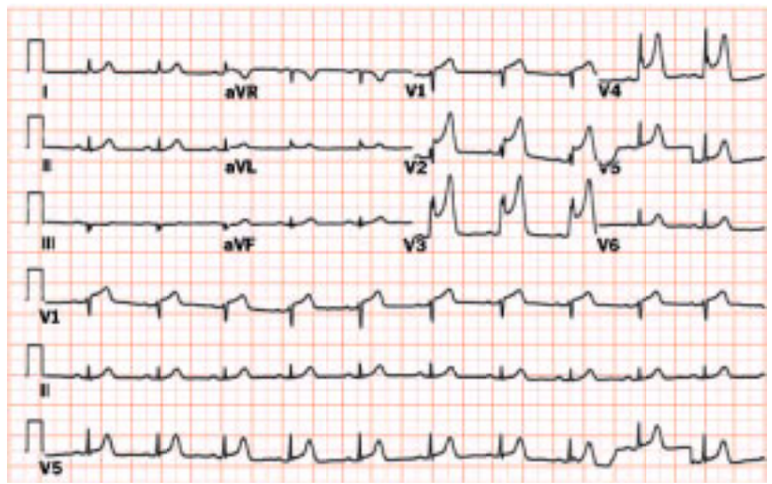
Myocardial ischemia results in two main electrophysiologic changes. First, myocytes partially depolarize and their membrane resting potential is reduced (i.e., becomes less negative). Second, the action potential duration and amplitude decrease. Local injury currents develop between ischemic and nonischemic cells that manifest in the ECG as ST-segment deviation toward the specifically involved area. During diastole, injury currents flow from ischemic to normal cells; during systole, injury currents flow in the opposite direction. Traditionally, ECG changes caused by an increase in myocardial metabolic demand or a decrease in coronary blood flow are called *ischemia* when changes affect only the T wave, and *injury* when changes affect the ST segment. Epicardial (or transmural) injury is characterized by ST-segment elevation and endocardial (“subendocardial”) injury by ST-segment depression.

Electrocardiographic Ischemia (T-Wave Changes)

The first ECG change during transmural ischemia is the development of peaked, tall T waves; this usually precedes ST-segment elevation (181). The ischemic zone is electrically more negative than its surrounding myocardial area during the recovery phase. Thus, while ST elevation is still present or after it has subsided, the T waves become inverted in relation to the QRS complexes (*e*Fig. 59.10.3). Normally the angle between the directions of the QRS complexes and the T waves is less than 45 degrees in the frontal plane and less than 60 degrees in the horizontal plane. When the angles are increased, the presence of myocardial ischemia should be considered. The T-wave inversion may regress within minutes or persist for several months (27). These primary T-wave changes are not specific or sensitive for the diagnosis of myocardial ischemia (181).



***e*FIGURE 59.10.3** Three resting electrocardiograms have various abnormalities in addition to T-wave inversion, which suggest ischemia in various areas of the left ventricle. **A:** Anteriorly in the distribution of the anterior descending artery. **B:** Inferiorly in the distribution of the posterior descending artery. **C:** Laterally and apically in the distribution of the diagonal branch of either the anterior descending or the circumflex artery. (From Wager GS, ed. *Marriott's practical electrocardiography,* 9th ed. Baltimore: Williams & Wilkins, 1994:131, with permission.)



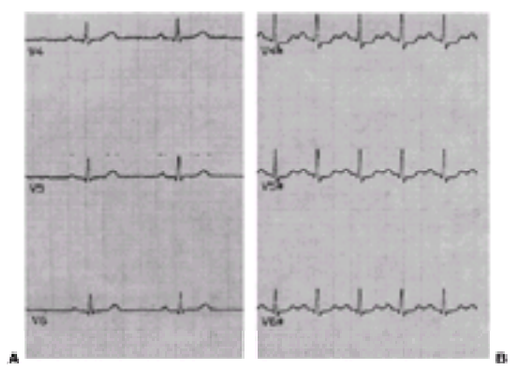
Acute anteroseptal myocardial infarction. Dramatic ST segment elevations in leads V_1 through V_5 with associated hyperacute T-wave changes are noted.

For some patients with chest pain presenting to the emergency room, negative T waves may be the first electrocardiographic finding observed—perhaps because ST elevation has already subsided. Biochemical changes may indicate acute or subacute (i.e., non–Q wave) myocardial infarction. These negative T waves and those observed after documented ST-elevation infarction have been labeled "postischemic" (27). Yet negative T waves that appear soon after ST-elevation infarction seem to be predictors of improved survival (117). Thus, other factors aside from ischemia (e.g., reperfusion) possibly may have a role in the genesis of such T waves (181,182).

Electrocardiographic Injury (ST-Segment Changes)

Subendocardial Injury (ST-Segment Depression)

Ischemia secondary to an increased metabolic demand affects initially the subendocardium, the area most vulnerable to ischemic damage. Changes involve mainly the ST-T waveforms (and much less the QRS complex), because myocytes are less susceptible to ischemia during electrical depolarization than during electrical recovery. Diastolic injury currents produce TQ segment elevation in the surface ECG that results in apparent ST-segment depression, whereas systolic currents produce "true" ST-segment depression. Initial changes include a depression of the J point of at least 0.10 mV and a horizontal or downward sloping of the ST segment toward the T wave (*e*Fig. 59.10.4). The T wave may or may not be altered in the same direction as the ST segment. T-wave inversion may be secondary to ST depression (i.e., the T wave is "dragged" by the ST segment), or it may change as a direct manifestation of delayed repolarization in the ischemic myocardium.



***e*FIGURE 59.10.4** The electrocardiographic recording of a 67-year-old woman has a normal resting appearance of leads V_4 to V_6 **(A)** but 0.1-mV ST-segment depression in lead V_4 during exercise **(B)**. (From Wagner GS, ed. *Marriott's practical electrocardiography,* 9th ed. Baltimore: Williams & Wilkins, 1994:129, with permission.)

The current of injury occurs at the time that the subendocardial cells complete their activation process, and therefore it affects the QRS complex. The QRS waveforms deviate in the same direction as the ST segment. This distortion affects the amplitude but not the duration of the QRS complex and alters its later part more than its initial part (183). The ST-segment depression of subendocardial injury resolves rapidly after removal of the cardiovascular stress. When the ST-segment depression persists in the absence of increased left ventricular workload, the diagnosis of subendocardial infarction should be considered.

Transmural or Epicardial Injury (ST-Segment Elevation)

Transmural injury is caused by interruption of the blood supply to the myocardium because of occlusion of one of the three coronary arteries or their branches. The first ECG change is tall, peaked T waves (181). Then the ST segment appears elevated in the ECG leads that face the ischemic area and may appear depressed in the opposite ECG leads.

One of the following criteria must be met for the diagnosis of transmural injury: (a) elevation of the origin of the ST segment at the J point of 0.10 mV or higher in two or more limb or precordial leads V_4 to V_6, or of 0.20 mV or higher in two or more precordial leads V_1 to V_3 (*e*Fig. 59.10.5, Fig. 59.11); or (b) depression of the origin of the ST segment at the J point of 0.10 mV or higher in two or more of leads V_1 to V_3, or ST-segment elevation greater than 0.10 mV in two or more of leads V_7 to V_9.

***e*FIGURE 59.10.5** Acute anterior myocardial infarction. Transmural injury is manifested by ST elevation of greater than 0.2 mV in leads V_1 to V_3.

FIGURE 59.11 A: Acute anterior myocardial infarction, with ST elevation in precordial leads (day 1). The presence of ST elevation in leads I and aVL, plus ST depression in leads III and aVF, suggests proximal left anterior descending artery occlusion. **B:** Subacute anterior myocardial infarction (day 2). ST elevation is regressing, and negative T waves and new Q waves are developing.

A highly specific marker of transmural injury is alternans of the ST segment. Electrical alternans consists of alternans of the degree of ST elevation and is secondary to variations in action potential duration or amplitude; alternating ST elevation and depression have not been reported (129).

Severe degrees of ischemia are associated with distortion of the later part of the QRS, which reverses after the acute phase (184). The ECG manifestations of transmural injury vary in duration. Those observed in patients during coronary angioplasty or in patients with coronary vasospasm disappear rapidly when the coronary occlusion is removed (171), whereas in patients with transmural injury secondary to coronary thrombosis they resolve gradually after spontaneous or therapeutic restoration of flow. When insufficient coronary blood flow persists after the myocardial metabolic reserves become depleted, the process of necrosis begins (185). In most patients, permanent new Q waves develop at some point after ST elevation or depression has occurred. In ECG leads in which rapid Q waves are normally present (eTable 59.0.2), they may become pathologically wide.

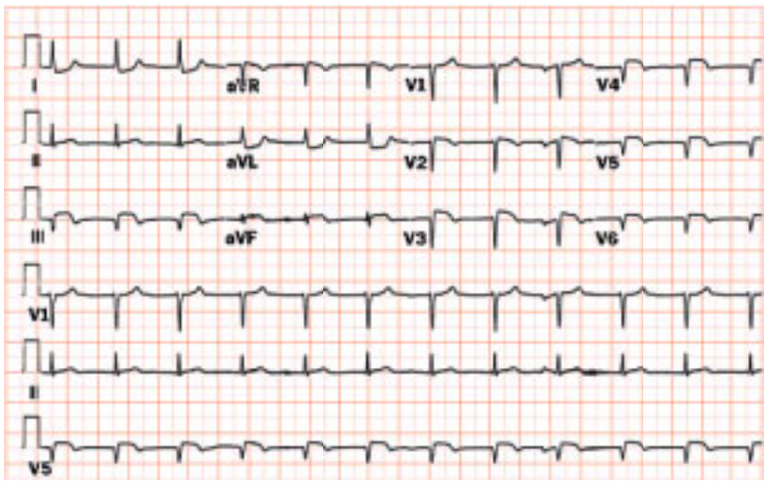
Acute Myocardial Infarction

The evolutionary changes during acute infarction include (a) ST elevation, often preceded by tall T waves, (b) abnormal Q waves, and (c) return of ST elevation to baseline with T-wave inversion. Tall or peaked T waves may be an early manifestation of transmural injury. The most typical change involves ST-segment elevation, which decreases significantly after the first 12 hours of chest pain (186) (Fig. 59.11). In some patients, multiple episodes of ST-segment elevation and resolution have been documented after thrombolytic therapy. A moderate ST elevation persists usually for several days; when observed beyond 2 weeks of the acute event, it suggests ventricular aneurysm. If coronary reperfusion is rapidly achieved, negative T waves usually develop and Q waves do not.

Lateral myocardial infarction. ST segment elevation in leads I and aVL associated with inferior reciprocal changes. Note preexisting anteroseptal myocardial infarction.

ECG DURING ACUTE MI

The diagnostic accuracy of the ECG depends on the extent and location of transmural injury or necrosis. In general, the 12-lead ECG is specific but only moderately sensitive for detection of acute myocardial injury (187,188). Systematically recording leads V_4R, V_8, and V_9 (i.e., a 15-lead ECG) increases the probability of detecting ST elevation from 47% to 59%, with no decrease in specificity (22). The infarction descriptors *anterior*, *inferior*, and *lateral* have classically been attributed to occlusions of the LAD, right coronary artery (RCA), and circumflex artery (LCX), respectively. Other terms such as *apical*, *septal*, *high lateral*, and *posterior* are also in use. The 12-lead ECG is only moderately accurate in determining the anatomic location of acute infarction, however, and the correspondence of some ECG terms with the pertinent site of infarction is rather poor (189). The ECG is most sensitive for detecting acute occlusion of the LAD and least sensitive for detecting involvement of the circumflex artery. Automated diagnoses of infarction (i.e., provided by the electrocardiographer) are specific but not sensitive; their most promising application is in the prehospital setting (190,191 and 192).



Right ventricular infarction. ST-segment elevation in leads V_4R and V_5R reveals right ventricular involvement complicating the inferior infarct.

Acute Anterior/Anteroseptal/Anterolateral Infarction (Left Anterior Descending Artery Occlusion)

During acute anterior injury, V_2 is the most sensitive lead for recording ST elevation (sensitivity, 99%) and for identifying the culprit lesion in the LAD. Other powerful predictors of proximal LAD occlusion include ST elevation in aVL and concomitant ST depression in inferior leads (193,194) (Fig. 59.11). ST elevation that extends to leads I and aVL often coexists with inferior ST depression. The magnitude of ST depression in inferior leads correlates better with that of ST elevation in leads I and aVL than with the ST elevation of precordial leads. The maximal ST elevation is best recorded in V_2 as well as V_3 (195) (eFig. 59.10.5; Fig. 59.11). Highly specific signs for occlusions at the level of the first septal perforator include ST elevation in aVR (196), disappearance of preexistent septal Q waves in lateral leads (197,198), and ST depression in V_5 (196).

Evolution of acute anterolateral myocardial infarction at 1 hour. Note "tombstoning" ST segments across the precordium as well as the lateral leads. Inferior reciprocal changes are seen.

Occasionally, ST elevation is also present in lead V_1. Lead V_1 captures electrical phenomena from the right paraseptal area, which is supplied by the septal branches of the LAD. In most patients the septum is additionally protected by a conal branch of the RCA (double circulation), and this explains why patients with anterior myocardial infarction usually have no ST elevation in V_1 (196). The presence of ST elevation in V_1 (eFig. 59.10.5) correlates strongly with ST elevation in V_3R and predicts the less common anatomical scenario in which a small conal branch of the RCA does not reach the interventricular septum (199).

Acute Inferior Infarction (Right Coronary or Circumflex Artery Occlusion)

The typical ECG pattern of inferior infarction consists of ST-segment elevation in leads II, III, and aVF (Fig. 59.12). In 80% to 90% of cases the culprit lesion is in the RCA (200); the remainder of the patients have LCX occlusion. Higher ST elevation in lead III than in lead II strongly suggests RCA occlusion (201,202). Because lead aVL faces the superior part of the left ventricle and directly opposes the inferior wall, ST-segment depression in aVL usually indicates RCA occlusion (sensitivity, 94%; specificity, 71%) (203). Precordial ST depression accompanying inferior injury is more likely to develop from LCX than from RCA occlusion (Fig. 59.13). Horizontal ST depression with initially negative then upright T waves in leads V_1 to V_3 or V_4 (Fig. 59.13) is associated with posterior wall motion abnormalities (204). Concomitant ST elevation in leads V_5 and V_6 also indicates posterolateral ischemia—triggered by either RCA or LCX occlusion (205). When this ST elevation is significant (more than 0.2 mV), it is likely a sign of infarction related to a "megaartery" (RCA or LCX), with a large ischemic burden (205).

FIGURE 59.12 Acute inferior myocardial infarction. Transmural inferior injury is accompanied by ST-segment depression in leads I, aVL, and V_1 to V_3.

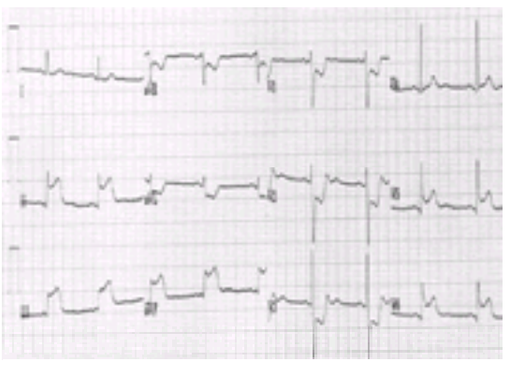


FIGURE 59.13 Acute inferior myocardial infarction produced by circumflex artery occlusion. ST elevation is present in leads V_5 and V_6 (suggesting "megaartery" occlusion), and ST depression with prominent U waves is seen in leads V_1 to V_3. The ST depression in aVL is unusual.

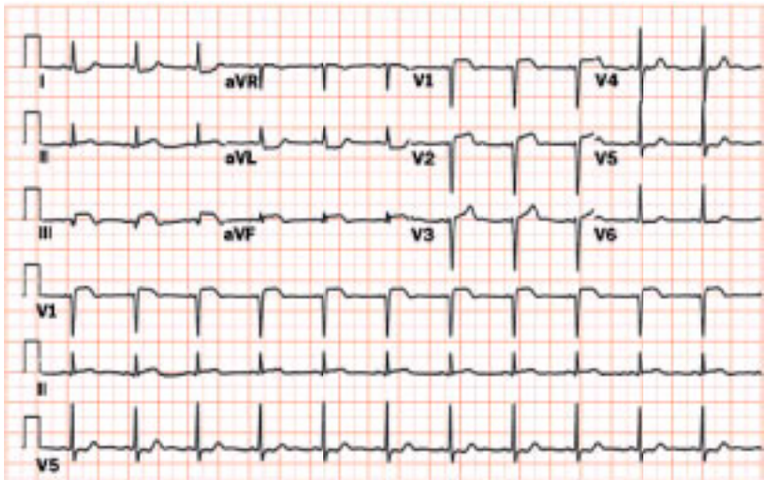
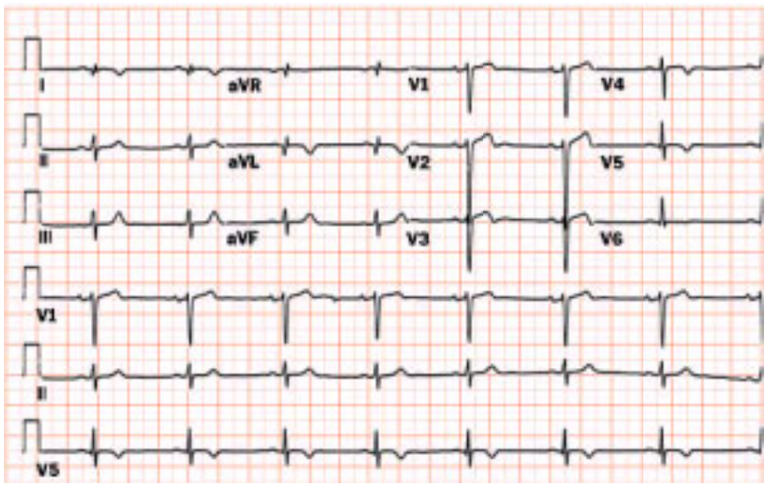


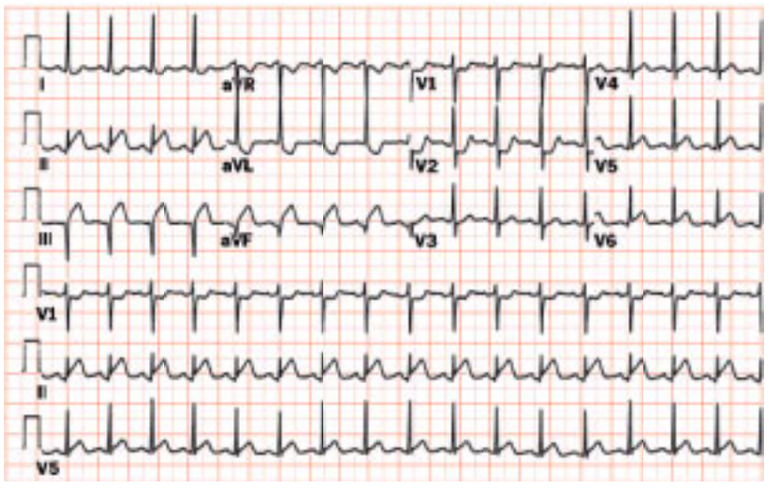
Acute inferior myocardial infarction with right ventricular involvement. Inferior ST-segment elevation associated with elevation in lead V_1. See right precordial leads.

Acute Lateral and Posterior Infarctions (Circumflex Artery Occlusion)

The vascular beds of the LCX show broad anatomic variability and supply a rather small ventricular area. This is why the standard 12-lead ECG displays ST-segment elevation in less than half of cases of LCX occlusion. When present, ST elevation is more often seen in leads II, III, and aVF, followed by leads V_5, V_6, and aVL (206). In some cases, a concomitant ST depression is seen in leads V_1 to V_3 (Fig. 59.13).



High lateral infarction, age unknown. Note prominent Q waves in leads I and aVL, associated with T-wave inversions.



Acute inferoposterior myocardial infarction. Note ST segment elevation in leads II, III and aVF with ST depression in leads V_1 and V_2.

One-third of patients with chest pain secondary to spontaneous LCX occlusion present with isolated ST depression. ST depression in V_1 and V_2 is a sensitive sign (203,206). Another one-third of patients present without any changes in the 12-lead ECG. In a study of 33 consecutively treated patients with LCX occlusion, however, ST elevation in V_7 through V_9 was always detected and was associated with posterior wall motion abnormalities (207). Leads V_7 to V_9 are more specific than precordial leads for detection of posterior infarction (84% vs. 57%), with similar sensitivity (approximately 80%) (208).

Acute Right Ventricular Infarction

Transmural injury of the right ventricle translates into ST-segment elevation of 0.1 mV or more in precordial leads. ST elevation in V_1 is highly specific for proximal RCA occlusion (202). In approximately 7% of patients, ST elevation extends to lead V_5, which suggests anterior infarction. This ST elevation decreases toward V_4, however, whereas in anterior injury from LAD occlusion, the ST segment is more elevated in V_2 and V_3 than in V_1 (209).

Right ventricular infarction is usually concurrent with infarcts of the inferior wall (eFig. 59.13.1). Half of patients with inferior injury have ST elevation in V_4R (sensitivity and predictive accuracy for right ventricular infarction are both 93%) (210). Isolated right ventricular infarction is rare and occurs mainly in patients with right ventricular hypertrophy (211).

***e*FIGURE 59.13.1** Inferior infarct with right ventricular compromise. Right-sided precordial leads V_2R to V_6R show ST elevation.

ST-Segment Depression in Patients with Acute Coronary Syndromes

Isolated ST-Segment Depression

In a study of 136 patients presenting with isolated ST-segment depression in the 12-lead ECG, evolution to infarction was observed in 54% of cases. One-year mortality was high for patients both with and without infarction (212). In general, ST depression is associated with older age, multivessel or left main coronary artery disease, multiple infarctions, or poor left ventricular function (213,214). A common cause of primary ST depression is the subocclusion of the left main coronary artery, and the ECG frequently shows a combination of ST depression in leads I, II, and V_4 to V_6 with ST elevation in aVR. A sum of ST changes of 18 mm is 90% sensitive for left main artery disease (215). A maximum ST depression in leads V_2 and V_3, on the other hand, indicates LCX occlusion (specificity, 96%; sensitivity, 70%). Recognizing this is important, because patients with isolated ST depression from LCX occlusion benefit from thrombolysis (216). Isolated ST depression in inferior leads may be caused by either inferior subendocardial ischemia or by a prominent atrial repolarization (Ta) wave during right atrial enlargement (100).

ST-Segment Depression Concomitant with ST Elevation

Many patients with acute chest pain present with “reciprocal” ST-segment depression, that is, ST depression concomitant with ST elevation in a different lead group. The mechanism underlying such ST depression is assumed to be mirroring, a phenomenon of electrical reflection of the transmural injury onto the opposite ventricular wall. The ST depression is captured by a lead placed at 180 degrees to the lead recording ST elevation, but the terms *reciprocal* and *mirror* are loosely applied to other recording points as well (217). For example, ST depression that is maximal in leads V_5 and V_6 may be related to acute ischemia of the right ventricle; it is the reciprocal of ST elevation in V_3R (181).

Another possible mechanism for ST depression is regional subendocardial ischemia or infarction. Although strictly speaking mirroring is also involved in the ST depression of subendocardial ischemia (because the ST elevation in the subendocardial layer is reflected onto the epicardial layer), most clinicians consider this ST depression “nonmirror” because it is a primary manifestation of artery occlusion, not secondary to ST elevation in a different territory (218). In patients with chest pain and predominant ST depression in any lead except aVR, ST depression of at least 0.4 mV is 97% specific (and 20% sensitive) for acute infarction (212). Several investigators have found that inferior ST depression during anterior injury is not accompanied by inferior ischemia (as assessed by perfusion imaging), which suggests that mirroring—rather than inferior subendocardial ischemia—is responsible for the ST depression (217,218). Over 85% of patients with ST depression in lead aVF have a culprit lesion in the proximal LAD. On the other hand, the significance of anterior ST depression accompanying inferior injury may depend on the leads involved. ST depression in leads V_1 through V_3 or I through aVL seems to correspond to mere mirroring, often from LCX occlusion. On the other hand, ST depression deeper in V_4 through V_6 than in V_1 through V_3 is associated with anterolateral or septal subendocardial injury from a severe lesion in the LAD or in the left main coronary artery (219) (Fig. 59.14).

FIGURE 59.14 Electrocardiogram recorded in a patient with ST elevation in inferior leads from acute right coronary thrombosis. The concomitant precordial ST depression, maximum in V_3 to V_6, probably corresponds to concurrent subendocardial injury. (From Wagner GS, ed. *Marriott’s practical electrocardiography,* 9th ed. Baltimore: Williams & Wilkins, 1994:140, with permission.)

Nonischemic ST Depression

The most important differential diagnosis in patients with ST depression and chest pain (with or without abnormal levels of creatine kinase) (220) is aortic dissection. As many as 50% of patients with dissection of the thoracic aorta may present with ECG abnormalities, mainly ST-segment depression (221), unless the origin of a coronary artery is involved in the dissection and signs of transmural injury develop.

Diagnosis of Acute Myocardial Infarction in the Presence of Confounding Factors

Right Bundle Branch Block

The diagnosis of evolving acute anterior infarction in patients with RBBB can be suspected when secondary T waves (opposite to the QRS complex) in leads V_1 to V_3 or V_4 are replaced by T waves of concordant polarity with the QRS (“pseudonormalization”). ST elevation is often easily detected (Fig. 59.15).

FIGURE 59.15 Acute anterior myocardial infarction with right bundle branch block (RBBB). Primary T waves have replaced the secondary T waves observed in RBBB.

Left Bundle Branch Block

In patients who present with acute chest pain and LBBB, ECG interpretation is difficult because the normal sequence of ventricular activation can be altered by both LBBB and acute myocardial injury. During either occlusion of a coronary artery by an angioplasty balloon or acute infarction, however, further ST-segment elevation does occur in LBBB (222,223 and 224). In a study that analyzed all published criteria for the diagnosis of acute infarction in the presence of LBBB, the ECGs of 131 patients who had LBBB and enzyme-confirmed acute infarction were compared with 131 ECGs of external controls who had chronic coronary artery disease and LBBB (*e*Table 59.0.6, Fig. 59.16). Criteria were validated in an independent sample of patients with acute coronary syndromes and LBBB. A scoring system suggested that a highly specific diagnosis of acute infarction could be made with a total score index of 3 points or higher (*e*Table 59.0.6). This score was associated with specificities of 90% or higher in both the derivation and the validation samples (225,226).

***e*TABLE 59.0.6** CRITERIA FOR THE DIAGNOSIS OF ACUTE MYOCARDIAL INFARCTION IN THE PRESENCE OF LEFT BUNDLE BRANCH BLOCK

Electrocardiographic criterion	**Score**
↑ ST ³1 mm concordant with QRS polarity	5
↓ ST ³1 mm in V_1, V_2, or V_3	3
↑ ST ³5 mm discordant with QRS polarity	2

↑, elevated; ↓, depressed.
From Sgarbossa EB, Pinski SL, Barbagelata A, et al. Electrocardiographic diagnosis of evolving acute myocardial infarction in the presence of left bundle branch block. *N Engl J Med* 1996;334:481–487, with permission.

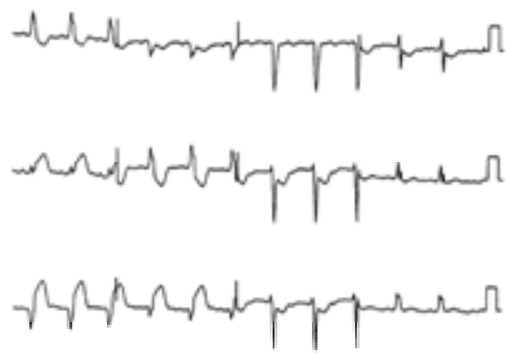


FIGURE 59.16 Electrocardiogram recorded in a patient with left bundle branch block and acute myocardial infarction. ST elevation greater than 0.3 mV is present in lead II (with concordant QRS polarity), ST elevation greater than 0.4 mV is present in leads III and aVF (with discordant QRS polarity), and ST depression is present in leads V_2 and V_3. (From Sgarbossa EB, Pinski SL, Barbagelata A, et al. Electrocardiographic diagnosis of evolving acute myocardial infarction in the presence of left bundle branch block. *N Engl J Med* 1996;334:481–487, with permission.)

Ventricular Pacing

In patients with permanent pacemakers and chest pain, the presence of ST elevation of 0.5 mV or more in leads with a negative QRS complex has a specificity of 88% and a sensitivity of 53% for the diagnosis of acute infarction. Two other criteria with high specificity but low sensitivity are ST elevation of 0.1 mV in leads with concordant QRS polarity and ST depression of 0.1 mV or more in lead V_1, V_2, or V_3. No criteria involving the QRS complex or isolated T waves is highly specific (227).

Nondiagnostic Electrocardiograms

As many as 15% to 18% of acute myocardial infarctions do not produce changes in the initial ECG, and an additional 25% produce nonspecific changes (228). Recording serial ECGs increases the probability of detecting acute infarction (229). Maximizing the information provided by the *admission* ECG is ideal, however, because reperfusion therapies are more effective when administered early. A 15-lead ECG that includes leads V_4R, V_8, and V_9 should be obtained in all patients without ST elevation in the 12 standard leads; this increases the detection rate of ST elevation from 47% to 59% with no decrease in specificity (22). In patients with nondiagnostic ECGs at admission, the most frequent culprit artery is the circumflex (230). Once patients with acute infarction and normal admission ECGs have undergone angiographic evaluation and survived hospitalization, the frequency of involvement of the infarct-related artery is similar for the three major arteries. Patients who never develop ECG changes have lesions in branch vessels (231). In the absence of confounding factors, nondiagnostic ECGs in patients with suspected acute infarction are associated with a low incidence of in-hospital events and mortality (232).

Individuals who present to the emergency department with chest pain and signs of left ventricular hypertrophy in the ECG may pose a particular diagnostic challenge because secondary T waves and ST-segment changes act as confounders. Remarkably, a multicenter study concluded that patients with both acute chest pain and electrocardiographic signs of left ventricular hypertrophy are four times less likely to have acute myocardial infarction and one-third less likely to have ischemia than patients who do not show ECG signs of left ventricular hypertrophy (233).

ESTABLISHED MYOCARDIAL INFARCTION

Q-Wave Infarction

Although the ST segment is still elevated during ongoing transmural injury, abnormal Q waves begin to develop as a consequence of both the loss of electrical forces in the necrotic area and the predominant effect of the resultant force directed away from the area (Fig. 59.11). The deviation of the ST segments may confound the capability to measure the amplitudes of the QRS waveforms. Pathologic Q waves are recorded from all myocardial regions that depolarize early during the cardiac cycle. The posterobasal area depolarizes late, which thereby produces a positive QRS waveform in the precordial leads opposing this zone (i.e., V_1 and V_2).

In most patients, necrotic Q waves persist indefinitely after the acute event, but in 15% to 30% of cases they disappear or become nonsignificant. These regression changes are similar for patients with anterior and inferior infarcts (234,235). Small, rapid ‘r’ waves may also result from recovery of electrical activity in a necrotic area when QS complexes developed immediately after the acute episode. The presence of an initial ‘r’ wave of less than 20 ms in lead V_2, for example, is an excellent discriminator between presence and absence of anterior infarction (236).

Non–Q-Wave Infarction

After an episode of cardiac chest pain, even if accompanied by biologic markers of cardiac necrosis, some patients do not develop pathologic Q waves. Only small ‘q’ waves or ‘r’ waves of diminished amplitude appear. The labeling of these alternative ECG changes as Q-wave or non–Q-wave infarctions varies among authors (237).

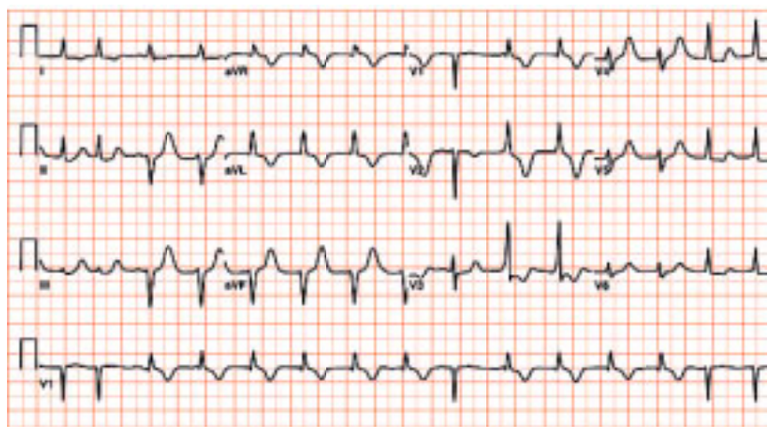
The most conspicuous changes of non–Q-wave infarction involve repolarization. Patients may present with ST elevation, depression, or both, or with isolated negative T waves (238). Early ECG changes cannot accurately predict evolution to non–Q-wave infarction. Also, approximately 9% of “non–Q-wave” infarctions result indeed from transmural injury of the left inferoposterior wall. These patients present with isolated ST depression in leads V_1 to V_4. A distinctive feature of anterior non–Q-wave infarction is a downsloping ST depression (as opposed to a horizontal ST depression in posterior infarcts) with precordial T-wave inversion (181).

The underlying angiographic finding in many patients with non–Q-wave infarction is a recanalized vessel (239). When a culprit vessel is identified, in 60% of cases it is the circumflex (240). The absence of Q waves does not seem to correlate anatomically with nontransmural necrosis (241). The prognosis of non–Q-wave infarction among patients treated with thrombolysis is better than that of Q-wave infarction, and it is markedly predicted by the repolarization changes in the admission ECG (242). Changes restricted to the T wave predict much lower morbidity and mortality than changes consisting of ST depression (243,244 and 245).

Unstable angina versus non–Q-wave myocardial infarction. ST-segment depression in leads V_2 through V_5 supports acute ischemic syndrome.

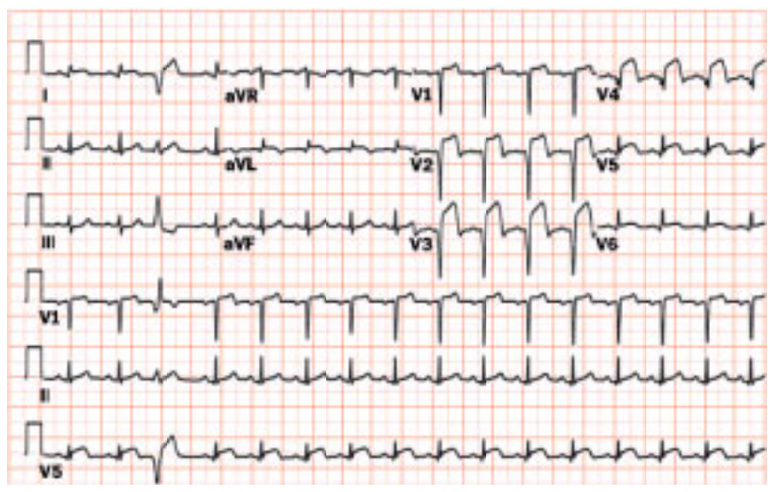
Electrocardiogram during and after Thrombolysis

Thrombolytic therapy accelerates the ECG evolutionary changes of acute infarction. Early T-wave inversion and a rapid resolution of ST-segment elevation have been associated with patency of the infarct-related artery (244,245). Additional elevation of the ST segment within the first hour of thrombolytic therapy occurs in 59% of patients, usually preceding a subsequent rapid decline of the ST elevation (246). Reperfusion obtained through primary coronary angioplasty is associated with additional ST elevation in only 12% of cases (246). Achieving a steady-state ST deviation within 100 minutes of thrombolysis is highly sensitive and specific for patency of the infarct-related artery (247). The second most common electrocardiographic change during effective reperfusion is the presence of accelerated idioventricular rhythm (246).

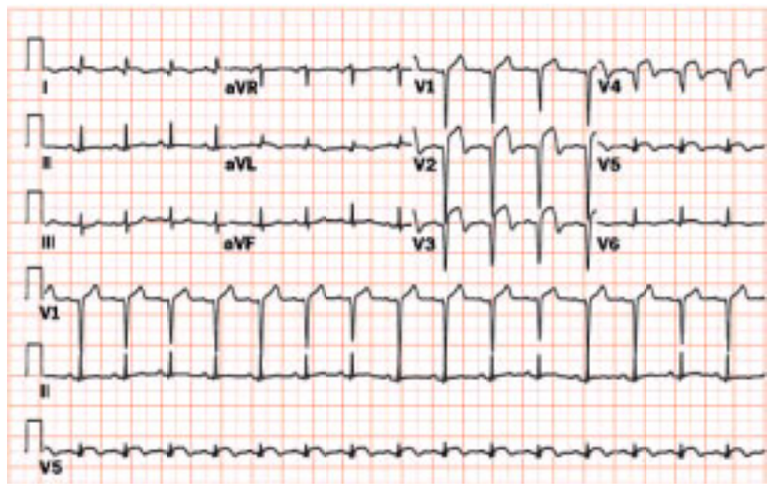


A 51-year-old patient with reperfusion accelerated idioventricular rhythm after thrombolytic therapy. Prior electrocardiogram documented ST elevation in leads II, III, and AVF, which resolved with thrombolytic therapy.

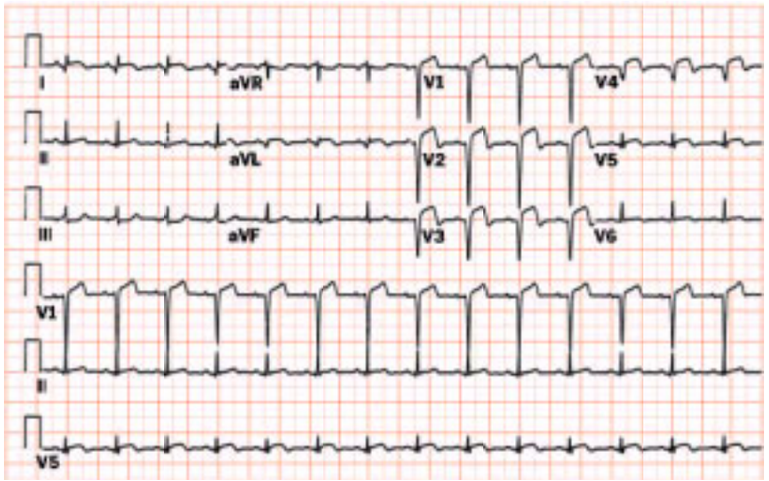
Subsequent evolution of infarction after thrombolysis is characterized by decrease in R-wave amplitude and by Q-wave development of smaller magnitude than that observed among patients not receiving thrombolysis (248); non–Q-wave infarctions are also common (242).



Evolution of acute anterolateral myocardial infarction at 3 hours. Tombstoning is less prominent with the onset of T-wave inversions in the anterior precordium. Reciprocal changes are resolving.



Evolution of acute anterolateral myocardial infarction at 24 hours. Prominent Q waves have developed across the anterior precordium and leads I and aVL. ST segment elevation persists, however.



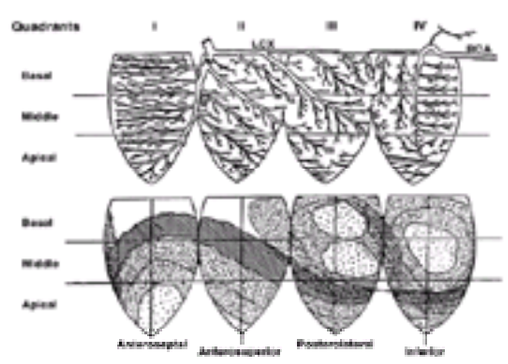
Evolution of acute anterolateral myocardial infarction at 72 hours. Q-wave pattern in the anterolateral leads is well established. Persistent ST-segment elevation suggests complication by aneurysm or pericarditis.

ECG IN ESTABLISHED MI

Autopsy, echocardiographic, and angiographic studies have shown that the 12-lead ECG has a limited capability to diagnose established myocardial infarction (249,250). The accuracy of the ECG depends on both the location and size of the infarct, and may be hampered by the presence of intraventricular conduction defects, LAFB, Q-wave regression, multiple infarctions (e.g., an anterior infarct may reduce tall R waves in V_1 and V_2 from a previous posterior infarct), and left ventricular hypertrophy.

Infarct Location

The presence of abnormal Q waves in two or more leads of a lead group permits the identification of the particular infarcted ventricular region (eFig. 59.16.1). Studies of wall motion dynamics have suggested that the classic electrocardiographic designation of certain infarct areas may not be accurate. For example, abnormal Q waves in leads I, aVL, V_5, and V_6 are often associated with apical, rather than lateral, wall motion abnormalities in ventriculograms (251). Anteroseptal infarct has classically been defined by the presence of Q waves in leads V_1 to V_3 (252). Echocardiographic and angiographic examination of patients with ST-segment elevation in these leads, however, has shown anteroapical infarcts and normal septa (253,254). Anatomically defined septal infarcts result instead in disappearance of septal Q waves in inferior leads and in leads I, V_5, and V_6. These changes are preceded by ST depression in the same leads during the acute phase, or, if the infarction was inferoseptal, by precordial ST depression. Initial R waves may be reduced in V_1 to V_3 (198,255).



***e*FIGURE 59.16.1** The 12 sectors of the left ventricular myocardium are defined by the four quadrants and the three levels. The distributions of the coronary arteries (*top*) are related to the distributions of infarctions that result from their occlusions (*bottom*). The four grades of shading from light to dark indicate infarct size as small, medium, large, and very large, respectively. LCX, left circumflex coronary artery; RCA, right coronary artery. (From Califf RM, Mark DB, Wagner GS. *Acute coronary care in the thrombolytic era*. Chicago: Year Book, 1988:20–21.)

Prominent right precordial R waves have been classically attributed to posterior infarct (Fig. 59.17), which may be a misnomer, because the term *posterior* applies better to the thoracic wall facing these areas of the left ventricle than to the left ventricle itself. Prominent R waves in V_1 (duration 0.04 second or more, R/S greater than 1) are nearly 100% specific and have a 91% positive predictive value for basal *lateral* asynergy of the left ventricle (sensitivity, 36%) (256). Specificity and positive predictive value drop slightly for prominent R waves in V_2, but the sensitivity increases to 61%. Asynergy of adjacent inferior and lateral segments is common in these patients. Abnormal R waves in V_1 in patients with chest pain are 96% specific for circumflex artery occlusion (206), and in autopsy studies 50% of lateral infarctions are associated with tall precordial R waves (257). The coronary artery more severely involved in posterior or inferoposterior infarcts is the circumflex, usually in association with significant disease of the RCA (258). In some patients, a taller R wave in V_1 and frankly prominent R waves in V_2 and V_3 may develop after LAD occlusion (259). Prominent R waves in this case do not correspond to posterior infarction but may rather represent a functional conduction disturbance (i.e., right conduction defect or midseptal block) (170,260).

FIGURE 59.17 Inferoposterior infarction.

The amplitude and duration of R waves may also be used for the diagnosis of established infarction (251). Because the electrical activation of the right ventricular free wall is insignificant in comparison with that of the left ventricular myocardium, infarction of the right ventricle rarely induces significant alteration of the QRS complex. Usually, only a slight voltage reduction occurs (261). When present, Q waves in both V_3R and V_4R are specific markers for right ventricular infarction (specificity, 100%; sensitivity, 78%) (42).

Diagnosis of Established Infarction in the Presence of Left Bundle Branch Block or Ventricular Pacing

The presence of Q waves in lead I is a highly specific sign for anterior infarction in patients with LBBB (262). A late notching of the S wave in V_3 to V_5 (Cabrera sign) was found to be both sensitive (91%) and specific, but this finding was not consistent in all studies (263,264). A 100% specificity for anterior infarction is reached by a

combination of two Q waves (in leads I, aVL, V_5, or V_6), with R wave regression in V_1 to V_4. For inferior infarcts, the presence of Q waves or R-wave notching in two inferior leads has poor sensitivity but high specificity (265).

In patients with heart pacing, the pacemaker can often be inhibited to disclose the underlying activation pattern, but sometimes this is not a viable resource. Examination of the QRS complex in precordial leads may show a qR morphology, which indicates anterior infarct. Initial 'q' waves in leads I, aVL, V_5, and V_6 are 100% specific for the diagnosis of anterior infarct (266). Although a QS pattern in inferior leads is normal during uncomplicated pacing, the presence of a qR or QR pattern has a 100% specificity for inferior infarcts (266).

Initial studies of pacing and infarction, however, may be biased toward patients with larger infarcts who required ventricular pacing (267). In patients without pacemakers who underwent apical pacing during electrophysiologic evaluations, only the sign of Cabrera was associated with previous infarction (268). This sign and QRS notching in inferior leads had a specificity of 92%.

Limitations to the electrocardiographic diagnosis of remote infarction during right ventricular pacing include variations in the position of precordial electrodes between recordings and slight displacement of the catheter away from its original implant site.

Infarct Size

Selvester and coworkers developed a method for estimating the total percentage of the left ventricle infarcted using a weighted scoring system (269) (eFig. 59.16.1). Computerized simulation of the sequence of electrical activation of the normal left ventricle formed the basis for a 32-point scoring system, with each point accounting for 3% of the ventricle.

The Selvester QRS scoring system includes 54 criteria from 10 of the 12 standard leads with weights ranging from 1 to 3 points per criterion. Criteria are defined in precordial leads V_1 and V_2 for both anterior and posterior infarct locations. This system for size estimation also contains criteria relating to the S wave. Satisfaction of only a single Selvester criterion may represent either a normal variant or an extremely small infarct.

ATRIAL INFARCTION

Atrial infarction is rarely recognized in the ECG. Atrial infarction is most unlikely in the absence of ventricular compromise, but it may occur in 1% to 17% of patients with acute myocardial infarction (270). The injury current affects atrial repolarization and results in elevation of the Ta wave with reciprocal changes in opposite leads. This produces displacement of the PR segment, better appreciated in patients with AV block (271).

PSEUDOINFARCTION PATTERNS

Conditions that suggest the ECG diagnosis of acute myocardial injury include severe hyperkalemia (Fig. 59.18), pericarditis, uncomplicated LBBB (Fig. 59.10), primary and secondary cardiac tumors (eFig. 59.18.1), acute pulmonary embolism, and ventricular aneurysm (272,273,274 and 275).

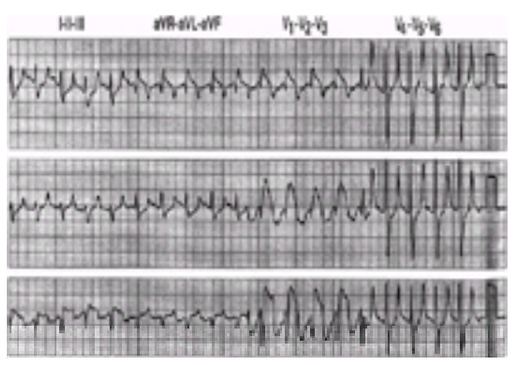


FIGURE 59.18 Pseudo–acute myocardial infarction mimicked by hyperkalemia. Peaked T waves are best seen in this case in leads V_4 to V_6. (From Kamimura M, Hancock W. Acute myocardial infarction in diabetic ketoacidosis. *Hosp Pract* 1992;27:28–30, with permission.)

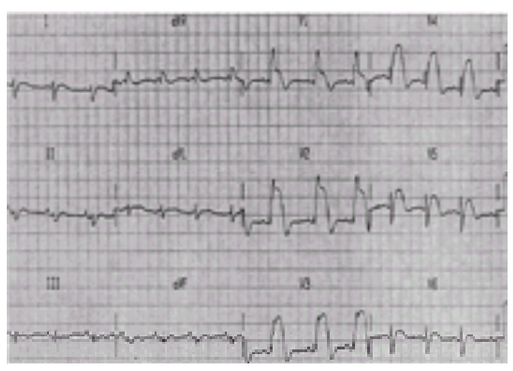


***e*FIGURE 59.18.1** Pseudo–acute myocardial infarction mimicked by a cardiac tumor. (From Houghton JL, Sinden JR, Gross CM. Acute presentation of pseudo–myocardial infarction secondary to metastatic cancer. *Am J Med Sci* 1992;303:170–173, with permission.)

An 83-year-old female patient with hyperkalemia.

A 9-year-old male patient with hyperkalemia and QRS widening.

The presence of myocardial necrosis with pathologic Q waves or decrease in R-wave amplitude may be mimicked by left ventricular hypertrophy, fascicular blocks, ventricular preexcitation, infiltrative heart disease, lead misplacement, pulmonary emphysema, pleural effusion (276), and epicardial implantable defibrillator systems (277). LBBB and ventricular pacing may mimic the electrocardiographic appearance of either acute or remote myocardial infarction (278).

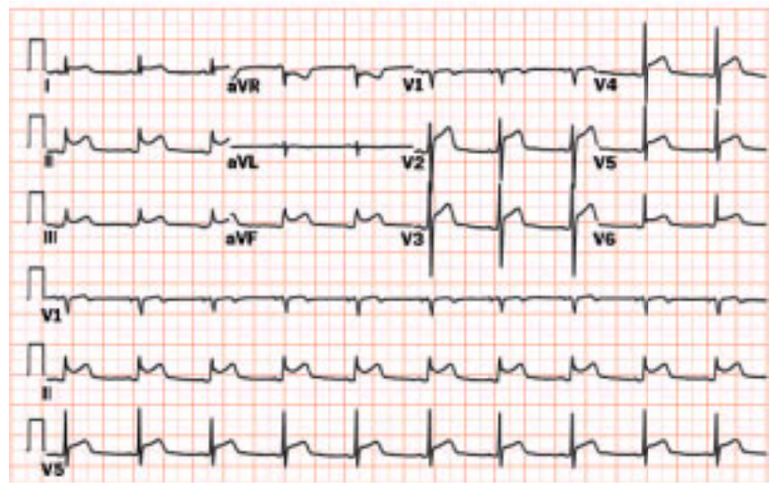
A 65--year-old male patient with a ventricular pacemaker.

MISCELLANEOUS CAUSES OF ELECTROCARDIOGRAPHIC ABNORMALITIES

Acute Pericarditis

Early ECG abnormalities during acute pericarditis include diffuse ST-segment elevation and upright T waves. Because the myocardial area injured by the inflammation is only partially depolarized, new ST vectors develop, directed away from the ventricular cavity and toward the apical epicardium. Thus ST-segment elevation may be seen in all leads except aVR, which shows ST depression. Lead V_1 may also record ST depression because it faces the right atrium. Although the P wave is usually not affected, PR (STa)-segment depression may develop (80).

Acute pericarditis persists for 3 or 4 weeks. When the ST segment normalizes, the T waves become inverted. In some patients, the T-wave inversion may be the only documented ECG change.



Acute pericarditis. Note diffuse, marked ST-segment elevation with PR-segment elevation in lead aVR.

The ECG changes of pericarditis may need to be differentiated from those of acute myocardial infarction, myocarditis, early repolarization syndrome, acute pulmonary embolism, pneumothorax, and pneumomediastinum. One must consider that pericarditis can complicate both acute myocardial infarction and myocarditis. The T-wave changes in postinfarction pericarditis may consist of persistently positive deflections after 48 to 72 hours or gradual, premature reversal of initially inverted T waves. The premature restoration of the concordance of the ST segment and T wave is a pivotal ECG manifestation (sensitivity, 100%; specificity, 77%). This evolution of the T wave after infarction is deceptive because it renders the ECG appearance more “normal” (245).

Electrolyte Abnormalities

Because the cardiac action potential results from transmembrane ionic movements, changes in electrolyte concentration may alter cardiac depolarization, repolarization, and conduction properties.

Hyperkalemia

Potassium is a depressant of cardiac activation. In general, the sinus node and the bundle of His tolerate hyperkalemia better than the ventricular myocardium (27). The correlation between serum potassium levels and ECG changes is poor. The earliest manifestation of hyperkalemia consists of symmetrical, peaked (“tented”) T waves, best seen in leads II, III, and V_2 to V_4 (Fig. 59.18). This typical change, however, is seen in only 22% of patients. As potassium levels increase, the P wave decreases its amplitude and increases its duration. The PR interval also prolongs, which reflects AV conduction delay. More severe hyperkalemia induces complete flattening of the P wave and widening of the QRS complex. A pattern resembling RBBB, LBBB, or nonspecific conduction defects may develop; the R-wave amplitude is reduced, the S wave becomes prominent, and ST-segment depression follows. The QRS complex in hyperkalemia usually differs from the bundle branch block or preexcitation patterns because the QRS is uniformly wide (27).

A 41-year-old with hyperkalemia.

Sinoatrial block (either Wenckebach or Mobitz II) is not uncommon. Sometimes the ST segment deviates from the baseline and mimics an acute infarction pattern. If hyperkalemia remains untreated, sinoventricular conduction, AV block, or ventricular fibrillation occurs.

Hypokalemia

Low plasma potassium levels are common in patients with acute myocardial infarction, after out-of-hospital cardiac arrest, and during treatment with diuretics. Hypokalemia prolongs repolarization. The initial ECG signs are T-wave flattening or inversion, ST-segment depression, and prominent U waves; the latter is the most characteristic change (27,127). As potassium levels decrease, the T wave fuses with the U wave, so that the ending of the QT interval is obscured (27).

More severe hypokalemia is manifested by a slight increase in the QRS complex and P-wave amplitudes and by prolongation of the PR interval. Ectopic atrial and ventricular beats are not unusual at potassium concentrations lower than 3.3 mEq per liter because automaticity is increased. Severe hypokalemia is associated with atrial tachycardia with block and with AV dissociation, and finally with ventricular arrhythmias (torsades de pointes). Patients taking digitalis are especially prone to arrhythmias in the presence of hypokalemia.

Hypokalemia is often found in hypertensive patients treated with diuretics. In these patients, a positive Sokolow-Lyon index could represent a false-positive finding, as the index correlates better with hypokalemia than with left ventricular mass (279).

Hypercalcemia

A high concentration of calcium increases the excitability threshold and has an inotropic effect. Hyperkalemia shortens both the ST segment and the QT interval and prolongs the PR interval and the QRS complex. Severe hypercalcemia may be associated with second- or third-degree AV block (27).

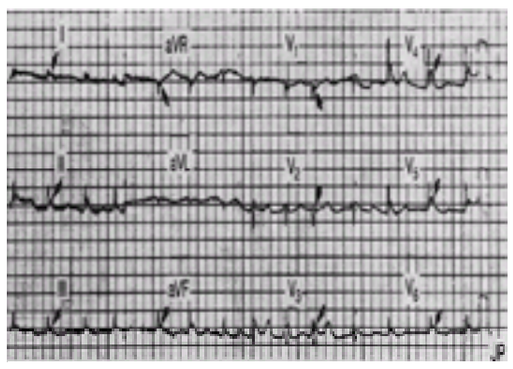
A 54-year-old male patient with hypercalcemia.

Hypocalcemia

Hypocalcemia prolongs the ST segment and the QT interval. The duration of the ST segment is inversely related to the calcium blood level. The T wave remains relatively normal (27).

Hypothermia

The electrocardiographic changes of hypothermia include bradycardia, flattening of P waves, and prolongation of the PR, QRS, and QT intervals. Irregularities of the isoelectric line may be seen as a consequence of muscular tremor or atrial fibrillation. A typical sign—observed in approximately 80% of patients with hypothermia—is the appearance of a J wave. The J (or Osborn) wave is a deflection that distorts the QRS-ST junction and is more commonly observed in leads II, III, aVF, V_5, and V_6 (eFig. 59.18.2). The J wave disappears with normothermia. Prolonged QT intervals may persist after the body temperature and the QRS complex have normalized (280).



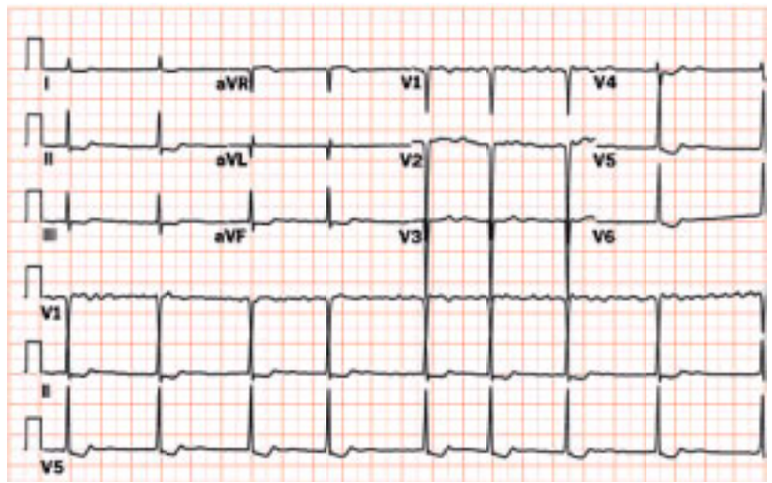
***e*FIGURE 59.18.2** Electrocardiogram obtained in a patient with hypothermia. The J waves are marked by arrows. (From Patel A, Getsos JP, Moussa G, et al. The Osborn wave of hypothermia in normothermic patients. *Clin Cardiol* 1994;17:273–276, with permission.)

Drug Effects

Therapeutic or toxic cardiac effects of various medications may be detected on the ECG.

Digitalis

Digitalis accelerates ventricular repolarization, particularly in the subendocardium. This manifests on the ECG first by a T-wave flattening and by prominent U waves with a shorter QT interval. The most typical change, however, consists of a coved ST depression (Fig. 59.7). The T wave appears biphasic, with its first portion negative and merging with the ST segment. These repolarization changes do not correlate well with therapeutic or toxic blood levels of the drug.



Digitalis effect. Note controlled ventricular rate with short, scooped ST segments in the lateral leads.

Digitalis intoxication is often manifested by arrhythmias similar to those seen in severe hypokalemia (i.e., atrial tachycardia with block and AV dissociation). However, no particular arrhythmia is pathognomonic of digitalis intoxication (281).

Characteristics of digitalis-induced atrial tachycardia include atrial rate between 140 and 250 per minute, inferior-to-superior direction of atrial activation, and 2:1 AV block. During 2:1 AV conduction, the PP interval including a QRS complex is usually shorter than the one not including a QRS complex. This resembles the ventriculophasic arrhythmia of complete AV block and is probably caused by comparable changes in the autonomic tone during the cardiac cycle (281). Nonparoxysmal junctional tachycardia at a rate between 70 and 130 beats/min (generally with AV dissociation) is frequent (271).

Quinidine and Class Ia Antiarrhythmic Drugs

Quinidine blocks the fast sodium channel in the cell membrane, and it prolongs both the action potential duration and the repolarization. The effects of quinidine include narrowing and then inversion of the T waves, prominent U waves, and prolonged QT interval (282). Quinidine effects are exaggerated by the presence of digitalis. Prolongation of the QRS complex by 25% to 50%, AV block, ventricular arrhythmias (torsades de pointes), and sick sinus syndrome are toxic effects of quinidine. The psychotropic agents phenothiazines, tricyclic antidepressants, and lithium produce ECG changes similar to those of quinidine.

Propafenone and Class Ic Antiarrhythmic Drugs

Propafenone hydrochloride, flecainide acetate, and encainide prolong the AH and HV intervals and the atrial and ventricular refractory periods. The QRS duration is increased. All class Ic drugs may induce ventricular arrhythmias (proarrhythmic effect). The JT interval is not prolonged.

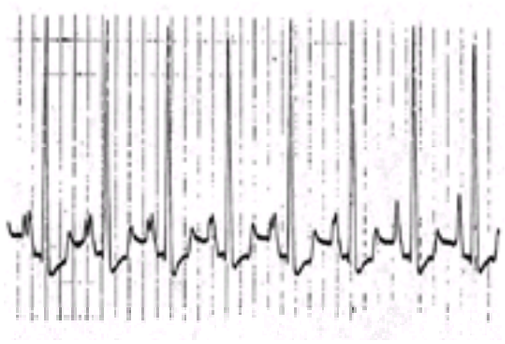
The Transplanted Heart

Incomplete or complete RBBB is the most prevalent abnormality in transplanted patients, but it is unrelated to pre- or intratransplantation hemodynamic factors or to ischemia (283,284). The PR and QT intervals are shorter and the precordial transitional zone is displaced to the left in the transplanted patients in comparison with the last recorded ECGs in the donors. The shift in the transitional zone and the conduction delay of the right bundle would indicate a clockwise rotation of the heart on its vertical axis. The increased prevalence of RBBB during follow-up, however, may be associated with mildly increased pulmonary pressures (285).

A 55-year-old African-American male patient status post cardiac transplant. Note the accessory atrial rhythm as evidenced by the extra P waves in the inferior leads.

Soon after transplantation, supraventricular arrhythmias are common and self-limited (284). The sudden appearance of first-degree AV block, however, should suggest acute cardiac rejection (286).

A curious finding soon after transplantation is that of remnant recipient atrial activity (*e*Fig. 59.18.3), which usually decreases with time (285). Modern surgical techniques, however, provide for a complete excision of the recipient atria, which will probably abolish their electrocardiographic manifestations in future transplant recipients.



***e*FIGURE 59.18.3** Electrocardiogram strip from a patient with heart transplantation showing a progressive change from an apparent P mitrale configuration to an apparent P pulmonale at the end of the strip. The illusion is produced by imposition of both the remnant (recipient) and the donor atrial activity. (From Malcolm I. P mitrale–P pulmonale variation [Letter]. *Am Heart J* 1996;132:1322, with permission.)

Pulmonary Abnormalities

Acute Cor Pulmonale

The ECG changes in acute cor pulmonale (*e*Table 59.0.7) reflect acute pulmonary hypertension with dilatation of the right chambers and perhaps myocardial ischemia. The classic “right heart strain” patterns, $S_IQ_{III}T_{III}$ and S_IQ_{III} (probably secondary to clockwise rotation), are not constant.

***e*TABLE 59.0.7** ELECTROCARDIOGRAPHIC MANIFESTATIONS OF ACUTE PULMONARY EMBOLISM

Incomplete or complete right bundle branch block, usually with ST-segment elevation and positive T wave in V_1
S waves >0.15 mV in leads I and aVL
Rightward shift of the QRS axis to >90 degrees or an indeterminate axis
Shift in the transition zone in the precordial leads to V_5 (clockwise rotation)
Q waves in lead III and less commonly in aVF, but not in lead II
Low-voltage QRS complex of <0.5 mV in the limb leads
T-wave inversion in leads III and aVF or leads V_1 to V_4
Atrial fibrillation or atrial ectopy

Several studies have found that the only ECG signs that are significantly more frequent among consecutively treated patients with confirmed acute pulmonary embolism than among those with suspected pulmonary embolism are sinus tachycardia and incomplete RBBB (287). A diagnosis of acute pulmonary embolism can be considered probable when three or more of these changes coexist in the admission ECG (288). Interestingly, the degree of right QRS-axis deviation, the presence of incomplete or complete RBBB, and the rate of sinus tachycardia correlate with the extent of embolization (289).

Pulmonary Emphysema

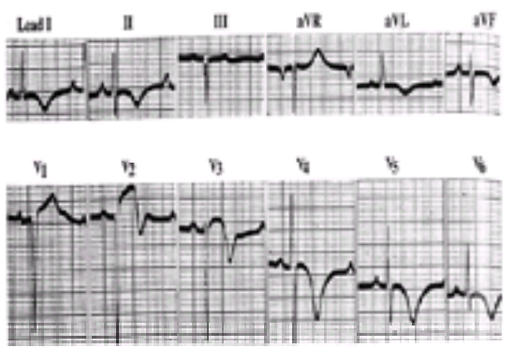
The overinflated lungs in pulmonary emphysema produce anatomic changes. The diaphragm is lowered and the cardiac electrical axis becomes more vertical and rotates clockwise. In the ECG, the most typical findings include prominent P waves [more than 0.25 mV; indeed, a P pulmonale predicts pulmonary emphysema or low diaphragm position better than it does right atrial enlargement (155)] and exaggerated atrial repolarization (Ta) waves producing more than 0.10 mV of ST-segment depression in inferior leads; a rightward shift of the QRS axis to 90 degrees or more in the frontal plane; decreased progression of the R-wave amplitudes in precordial leads; and low voltage of the QRS complexes, especially in the left precordial leads (290).

None of these criteria is highly specific for pulmonary emphysema. The degree of QRS-axis deviation is related to the degree of airway obstruction, but only 8% of patients present deviations to 90 degrees or more. Frontal-plane axes of 60 degrees or greater are more common but nonspecific (291). Other patients show indeterminate axes.

Autopsy studies indicate that right ventricular hypertrophy is present in 60% to 70% of cases of chronic cor pulmonale, but it can be detected only in one-fourth of living patients.

Neurogenic Manifestations on the Electrocardiogram

Patients with acute or chronic diseases of the nervous system may show repolarization changes in the ECG. Negative T and U waves, ST-segment changes, and QT prolongation may appear during subarachnoid hemorrhage (*e*Fig. 59.18.4), ischemic stroke, radical neck dissection, spinal cord trauma, and electroconvulsive therapy (90,292,293 and 294).



***e*FIGURE 59.18.4** Electrocardiogram recorded in a patient with subarachnoid hemorrhage showing T-wave changes mimicking myocardial ischemia. (From Chou TC, Susilavorn B. Electrocardiographic-pathological conference: electrocardiographic changes in intracranial hemorrhage. *J Electrocardiol* 1969;2:193–196, with permission.)

Certain localizing factors are constant throughout different patient groups. Subarachnoid hemorrhages associated with negative T waves and QT prolongation are usually left-sided (292), and tumors of the limbic system are associated with QT and QTc prolongation three times more often than tumors in other areas (295).

Misplacement of Electrocardiographic Leads

Misplacement of ECG leads is common. A study of 11,432 ECGs detected reversals involving the left arm and foot or adjacent precordial electrodes in 2% of the recordings (296). Estimates are that of the 300 million ECGs recorded annually in the world, approximately 6 million contain a lead reversal. The proportion may be higher when other combinations of lead reversals are considered.

Reversal of the Right and Left Arm Cables

When the electrodes attached to the arm cables are reversed, “lead I” shows negative P and T waves, and a predominantly negative QRS complex. “Lead II” is indeed lead III, and “lead aVR” is indeed lead aVL, and vice versa (297). Thus, the limb leads suggest the diagnosis of dextrocardia. The precordial leads, however, show the normal progression of R waves through V_6.

Limb lead reversal. Note upright QRS complex and P wave in lead aVR with inverted QRS in leads I and aVL.

Reversal of Each Arm Cable with Its Corresponding Leg Cable

When the arm cables are switched with the leg cables, “lead I” shows a flat line that records the potential difference between both legs. “Lead II” is an inverted (upside-down) lead III, because the positive electrode is now in the left arm. “Lead III” mirrors its image, because the polarity of its two components is inverted. “Lead aVR” is a replica of “lead aVL,” because both leads now record potentials derived from comparing each leg (aVF) with the same central terminal.

Misplacement of Precordial Lead Electrodes

In a prospective study in which precordial leads were deliberately misplaced, 2-cm changes in electrode position (too high or too low) resulted in significant ECG abnormalities (298). Variations included changes in R-wave amplitude, ST segments, Q waves, and the transition zone. The most important differential diagnosis when precordial lead electrodes are misplaced in a high position is anterior infarction, because QS complexes or low-voltage R waves may appear. The use of device-guided lead placement improves accuracy and reproducibility in interpretation of precordial waveforms (298).

HIGH-RESOLUTION ELECTROCARDIOGRAPHY

Standard recording techniques cannot detect low-amplitude bioelectric potentials from the body surface. Potentials generated by the His-Purkinje system and by depressed ventricular myocardium ("late potentials") are difficult to identify because their signals are smaller than the electrical noise produced by various sources (299). Two techniques have been developed to overcome this problem: (a) temporal averaging (usually referred to as "signal averaging"), which is applicable only to repetitive electrocardiographic signals; and (b) spatial averaging, which can record the His-Purkinje signal and late potentials on a beat-to-beat basis. Signal averaging (the most frequently used technique) can analyze potentials in either time domain, frequency domain, or a combination of both. Results of these analyses in patients with acute or remote myocardial infarction have shown an increased incidence of low-amplitude, high-frequency components within the QRS complex. These components are attributed to fragmentation of the depolarization front by fibrous tissue and to a decrease in electromotive force (300). The risk of ventricular arrhythmias in postinfarction patients and of cardiac death in patients with coronary artery disease or hypertrophic cardiomyopathy who have nonsustained ventricular tachycardia can be stratified on the basis of signal-averaging information (301). Although signal-averaged ECG is an interesting research tool, its clinical applications are currently limited.

BODY SURFACE MAPPING

Body surface mapping records cardiac electric events with numerous electrodes (from 16 to 200) and thus contributes additional information to that of the standard ECG. Cardiac field mapping provides details on the spatial and temporal sequence of cardiac excitation and recovery. Local intraventricular conduction disturbances, preexcitation, premature ventricular beats, and repolarization disorders can be precisely located (302). After a discriminant analysis of body torso maps derived from 120 leads in patients with various types of infarcts, the conclusion was that six torso sites accounted for a specificity of 96% and a sensitivity of 94%. Unfortunately, these sites did not coincide with any of the conventional 12-lead positions (303). Visual inspection of the ECG maps does not suffice for diagnostic purposes; sophisticated statistical and deterministic models are necessary. The difficulty in interpretation and the cumbersome recording and acquisition processes explain why the cost-effectiveness ratio for this technique is still unfavorable and confine it to the research arena.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Proficiency and Accuracy in Electrocardiographic Recording and Interpretation

Perhaps because the ECG is widely available and easy to obtain, its recording and interpretation are regarded as minor tasks (92). The responsibility of ECG recording has shifted from physicians to nurses, technicians, or medical students, and cardiologists are rarely present at the time of a patient's initial evaluation. This is conducive to suboptimal ECG data collection. First, lead misplacements and noise are common (304). Second, in most acute clinical settings, only 12 ECG leads with few QRS complexes per lead are obtained. Special ECG leads and prolonged rhythm strips (other than in lead II) are underused in daily practice (305). The need to change the patient from the supine position or to use equipment beyond the standard provided with current ECG machines may be a deterrent to the addition of posterior or esophageal leads. Thus, acute myocardial infarctions, arrhythmias, and intermittent bundle branch block may remain inadequately documented.

In addition to these shortcomings of the ECG recording, interpretation may also be limited. The ever-increasing competition between electrocardiography and other procedures for the attention of the young physician may conspire against acquisition of a high level of individual competence in ECG principles and diagnosis (92). Even experienced physicians usually examine only 11 leads of the 12 available; lead aVR (and the information it may provide) is ignored (24).

The self-perception of proficiency in ECG interpretation may be overly optimistic. In a study of 100 consecutively treated cases of fatal myocardial infarction, 47% were missed throughout hospital evaluation (306). Residents in family practice programs missed acute infarctions in 21% of ECG recordings, and their expertise did not improve with the year of residence (307). General practitioners performed better in identifying normal ECGs (82% specificity) than in recognizing acute infarction (33% to 61% sensitivity) (308). Emergency physicians participating in a multicenter study classified as normal 41% of abnormal ST segments. Misreading was related to suboptimal triage and unnecessary cardiac care unit admissions (309). A study using electrocardiographer judgment as the gold standard found a 67% accuracy for family physicians versus a 91% accuracy for cardiologists (310). Because cardiologists perform better than internists (311), the specific medical training of the interpreter may play a role in diagnostic accuracy. Although obvious ST-segment or Q-wave changes are absent in most cases of missed infarctions, approximately one-fourth of missed infarctions could be diagnosed with adequate competence in ECG reading (228,312). Fisch has suggested that the inevitable use of automated diagnoses "may be, in fact, an obstacle to the acquisition of ECG skills" (313).

Reproducibility

High variability within or between readers may put into question the validity of ECG analyses. Unfortunately, intra- and interobserver agreement rates are seldom tested or reported. Studies that systematically evaluated the reproducibility of ECG interpretations found approximately 80% intraobserver and 30% interobserver agreement rates (314,315 and 316). Discrepancies in ECG interpretation are related to the ECG waveform or interval under analysis, to variability in consecutive ECG recordings, and to the interpreter. For example, measurements of the ST segment are highly reproducible from beat to beat, but those of QT interval are not (59,226). The limb leads III, aVF, and aVL may be responsible for most intraobserver variation in the diagnosis of established infarction (314). For precordial recordings, variability is often a consequence of differences in lead placement (298). Day-to-day variability of the 12-lead ECG has been documented within normal persons and is associated with circadian influences and meal consumption (41). The role of expertise in the reproducibility of ECG interpretation is uncertain. At least among internal medicine residents, experience may be more important for intraobserver than for interobserver agreement; the latter rates may not improve after observers undergo training programs in electrocardiography (314). Comparative reproducibility between cardiologists and other physicians has been scrutinized only in limited settings and has been found to be acceptable (317).

Role of Computerized Electrocardiogram Interpretation

Computer-assisted ECG interpretation is now widely available. Ideally, automated measurements of ECG waveforms and intervals can significantly reduce physician time in ECG analysis while providing readings that are precise at the microvolt and millisecond level. In general, however, computer-derived intervals are longer than those determined visually. Reasons for the discrepancy include examination of multiple-lead versus single-lead measurements (in automated versus visual readings, respectively), and paper speed and amplification. Manual measurements performed with an amplification factor of 10 or 20 produce significantly wider intervals, similar to computer-derived results (45). Many computer programs apply longer-than-standard upper and lower normal limits for ECG intervals (e.g., minimum PR = 130 ms; maximum QRS complex = 0.126 ms) (318). Additional limitations of computerized readings include minute-to-minute variability, inability to determine the anteroposterior direction of electrical forces, and discrepant measurements among programs (319,320 and 321). Automated diagnoses (e.g., "left ventricular hypertrophy") may be less reliable and accurate than automated raw measurements, because the rapid expansion of ECG digital technology during the 1980s outpaced most efforts to evaluate the quality of the product (53). Many diagnostic programs in electrocardiographs are now 25 years old (313). An investigation of commonly used ECG software found a variety of systematic errors. The accuracy rate for clinically validated ECG diagnoses of myocardial infarction or left ventricular hypertrophy was 70% for computer analysis versus 76% for visual readings by cardiologists (315,321).

Further refinement in automated ECG interpretation is expected in the near future. At present, computer-analyzed ECGs require overreading by an experienced cardiologist.

THE FUTURE

The clinical use of the ECG has withstood the passage of time, and the contribution of ECG information to the care of cardiac patients remains unique. Despite the development of more sophisticated and expensive noninvasive diagnostic and prognostic techniques, the ECG is still the initial (and sometimes the only) test demonstrating cardiovascular abnormalities. Medical education must emphasize the value of the ECG, however. Systematic instruction and supervised practice in ECG diagnosis are fundamental to maintain proficiency in ECG interpretation.

Current emphasis in ECG research is on the study of dynamic patterns inherent in certain parameters (especially ventricular repolarization) with the aid of ambulatory recordings and newer, potent digital storage and analysis techniques. Correlation of findings from the ECG with those from emerging techniques such as electromechanical left ventricular mapping (which displays a color-coded map of the activation process) may help to further understanding of newly described ECG patterns (322).

Attempts to improve the resolution of standard electrocardiography have relied on an increase in the number of recording electrodes (body surface mapping) and on an improvement in the signal-to-noise ratio of the higher-frequency signals by averaging and filtering (signal-averaged ECG). Initial results with these techniques are promising, but their roles in clinical practice are still unclear.

The advent of effective myocardial reperfusion therapies has renewed the interest in the ECG manifestations of the acute ischemic syndromes. More recently, wireless technology is allowing the transmission of 12-lead ECG waveforms from remote locations to cardiologists' hand-held computers. Because intraobserver agreement among cardiologists is high when interpreting both paper ECGs and their liquid-crystal–displayed counterparts, remote interpretation may become widely adopted and contribute to decreased time to treatment for patients in need of reperfusion or those with complex arrhythmias (26).

Overall, the standard 12-lead ECG will continue to expand in clinical importance and will remain an integral part of the evaluation of all cardiac patients, particularly those with ischemic heart disease or rhythm disturbances.

OVERVIEW

By using information provided by intracardiac recordings and programmed cardiac stimulation, diagnosing correctly the site of origin and the mechanism of an arrhythmia on a 12-lead electrocardiogram (ECG) has markedly improved in recent years. This chapter reviews how to use a 12-lead ECG in patients with supraventricular tachycardia (SVT), ventricular tachycardia (VT), and preexcitation.

A systematic approach to ECGs is essential for optimal interpretation. Correctly diagnosing an arrhythmia is important not only to prognosis and the selection of appropriate antiarrhythmic drugs, but also because of the possibility of completely curing an arrhythmia by radiofrequency catheter ablation.

INTRODUCTION AND HISTORY

This chapter is intended to serve as an introduction to the chapters in this textbook that cover supraventricular and ventricular arrhythmias (see Chapter 64, Chapter 65, Chapter 66, and Chapter 67). The ECG is a valuable tool to diagnose these arrhythmias, and the major features that differentiate key supraventricular and ventricular arrhythmias are reviewed in this chapter. Although the chapters that follow provide an in-depth discussion of each arrhythmia, this chapter relies heavily on graphic examples to illustrate rapid and accurate diagnosis of these important rhythm disturbances.

The electrical impulse that is responsible for normal cardiac rhythm originates in the sinus node, spreads over the atrium, passes from atria to ventricles only by way of the atrioventricular (AV) node–His pathway, and spreads over the ventricles through the bundle branches and the Purkinje system. The ECG recording of this regularly occurring event characteristically shows a P-QRS-T complex with each of the components well defined as to its width, height, axis, and interrelation (Fig. 60.1).

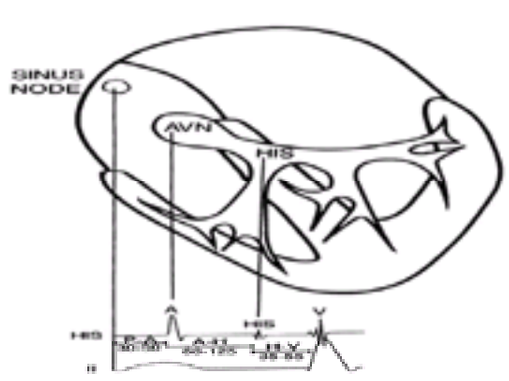

FIGURE 60.1 Time relations between the electrical activation of the different parts of the heart during sinus rhythm. A bundle of His electrogram and lead II are shown to illustrate the different time intervals. AVN, atrioventricular node.

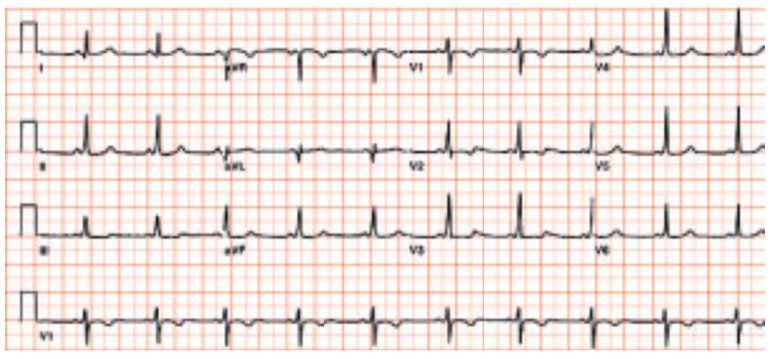
Ventricular Preexcitation

In the normal heart, the AV node–His pathway is the only connection between the atria and the ventricles. However, some people are born with an extra connection between the atrium, AV node, and ventricle (1). Conduction over these pathways after a supraventricular beat results in earlier activation of the ventricle (*preexcitation*) than during conduction over the AV node–His pathway only. The most common type of preexcitation is caused by a direct connection between the atrium and ventricle. In this situation, described by Wolff et al. in 1930 (2), arrhythmias are often present.



A 44-year-old female patient with Wolff-Parkinson-White syndrome.

Electrocardiogram in Preexcitation

When two AV pathways [the AV node–His pathway and the AV accessory pathway (AP)] are present, the conduction properties of the two pathways and the location of the AV AP determine the configuration of the QRS complex during sinus rhythm. This is shown in Figure 60.2. The typical picture of a short PR interval, a delta wave (representing ventricular activation over the AP) and a broad QRS complex, is present when there is a major contribution to ventricular activation by AV conduction over the AP. When contribution to ventricular activation over the AP is small because of the AP location or rapid transmission of the sinus impulse over the AV node, the ECG shows minimal changes pointing to ventricular preexcitation. Figure 60.3 illustrates a 12-lead ECG during sinus rhythm in the two situations shown in Figure 60.2.

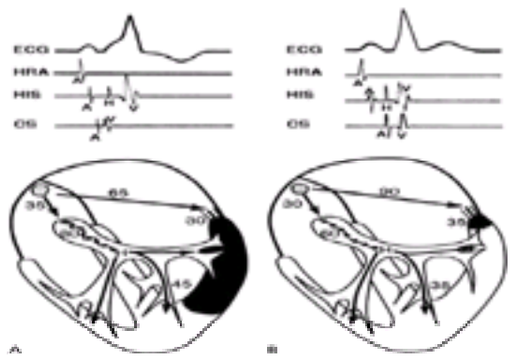


FIGURE 60.2 Factors determining the degree of ventricular preexcitation during sinus rhythm in a patient with Wolff-Parkinson-White (WPW) syndrome during sinus rhythm. The corresponding electrocardiographic (ECG) and intracavitary recordings from the high-right atrium (HRA), bundle of His region (HIS), and coronary sinus (CS) are shown in the upper part of the figure. In the heart in **A**, atrioventricular (AV) conduction time from the sinus node over the normal AV nodal–His pathway is 160 ms. The time required to travel from the sinus node to the atrial insertion of the AP is 65 ms, and the left-sided accessory pathway (AP) conduction time is 30 ms (total of 95 ms). Because of the shorter conduction time over the AP, an important part of the ventricle is preexcited, resulting in a short PR interval, a distinct delta wave, and a widened QRS complex. In the heart in **B**, there is longer conduction time from the sinus node to the atrial insertion of the AP, a longer conduction time over the AP itself, and a shorter conduction time over the AV node. Thus, the impulse arrives in the ventricles simultaneously through the AV node and the AP, producing a normal PR interval and a narrow QRS complex.

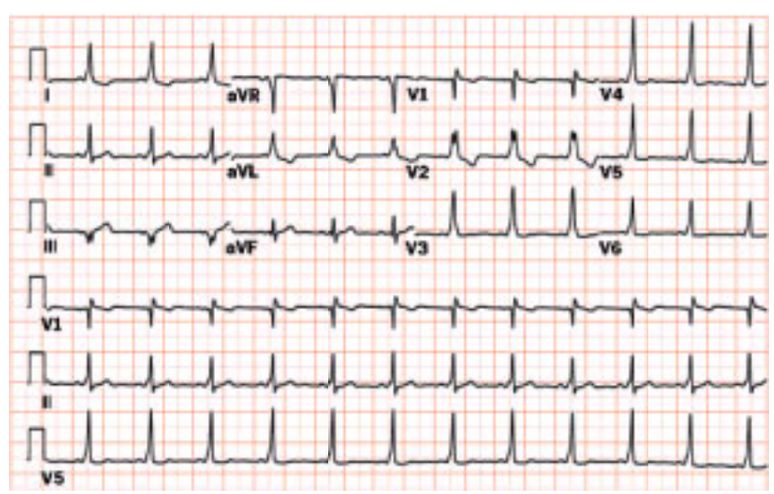
FIGURE 60.3 Electrocardiographic examples of the two diagrams shown in Figure 60.2. **A** and **B** in this figure correspond to **A** and **B**, respectively, in Figure 60.2. Note the prominent delta wave in **A**, indicating that a much larger area of the ventricle is preexcited than is shown in **B**.



Wolff-Parkinson-White syndrome. Note short PR interval with classic delta wave due to accessory pathway conduction.

As is discussed elsewhere (see Chapter 66), APs may not only be present as connections between atrium and ventricle, but also as fibers connecting the AV node with the ventricle (Mahaim fibers or nodoventricular fibers) (3) or the atrium with the bundle of His (atriofascicular fibers). It is also important to know that accessory connections may conduct anterogradely and retrogradely, only anterogradely, or only retrogradely. When conduction over the accessory connection is possible only in the retrograde direction, the term *concealed accessory conduction* is used.

Localizing accessory connections is important, because it is possible to interrupt conduction in these connections by the application of radiofrequency energy. As is pointed out elsewhere, exact localization requires catheter mapping of cardiac activation. However, the ECG can be very useful in identifying the atrial and the ventricular ends of an accessory AV connection.

Figure 60.4 provides a schematic representation of the four zones of AV AP locations along the AV ring; Figure 60.5 gives representative examples. Although this is an oversimplification, it helps in understanding how to use the delta-wave axis (during preexcited sinus rhythm or preexcited tachycardia) or the P-wave axis [during tachycardias with ventriculoatrial (VA) conduction over the AV AP] for localizing the ventricular end and the atrial end of the AV AP.

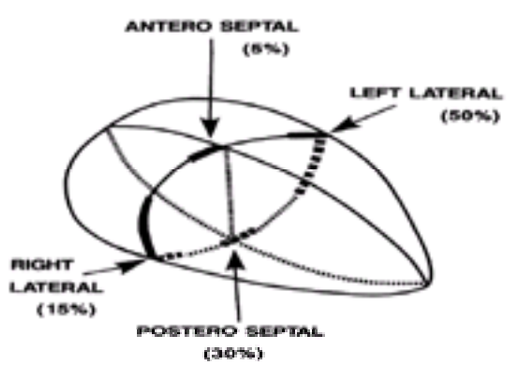


FIGURE 60.4 Frontal look at the heart, depicting the localization and incidence of the four most common types of accessory atrioventricular pathways. This drawing helps to explain how in the frontal plane the ventricular end (the delta wave) and the atrial end (the P wave during orthodromic circus-movement tachycardia) of the accessory pathway can be localized using the 12-lead electrocardiogram.

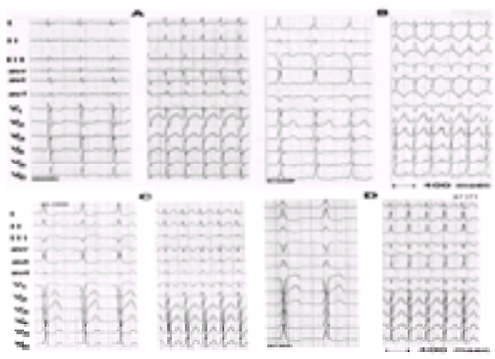

FIGURE 60.5 Twelve-lead electrocardiogram during sinus rhythm and orthodromic circus-movement tachycardia in a left free wall **(A)** and a posteroseptal accessory pathway (AP)**(B)**. Twelve-lead electrocardiogram is depicted during sinus rhythm and orthodromic circus-movement tachycardia in a right free wall**(C)** and anteroseptally located accessory pathway **(D)**.

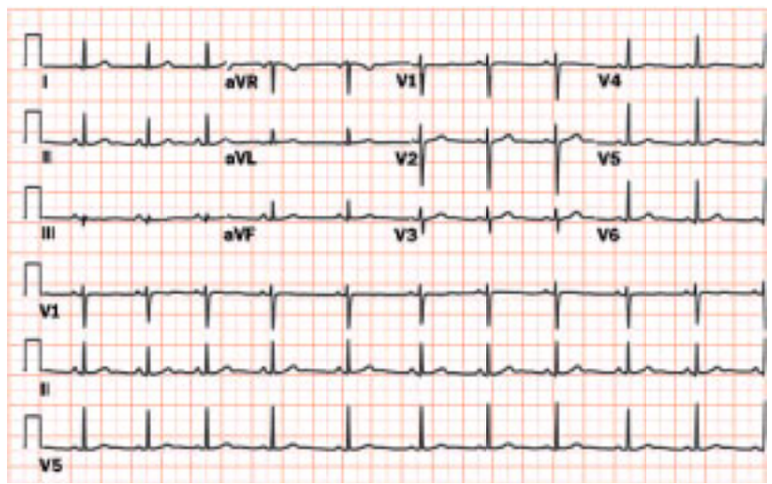
Diagnosing an Arrhythmia

An arrhythmia is characterized on an ECG as a deviation from the normal sinus rhythm in rate [i.e., too fast (tachycardia) or too slow (bradycardia)], regularity (one or more heartbeats occurring earlier or later than expected), or a different pattern of activation of the cardiac muscle. These changes can be registered on the ECG, allowing clinicians not only to make the diagnosis of an arrhythmia but frequently to recognize its site of origin and mechanism. These aspects are important to prognosis and selection of therapy.

Normal sinus rhythm is regular or shows slight respiration-related rate changes, referred to as *sinus arrhythmias*. The rate of sinus rhythm is determined by several factors, such as activity of the autonomic nervous system (vagal vs. sympathetic stimulation), hormones, body temperature, and so forth. A sinus rate of greater than 100 beats/min is referred to as a *sinus tachycardia*; a sinus rate of less than 60 beats/min is known as a *sinus bradycardia*.



Sinus arrhythmia. Young female patient with sinus rhythm characterized by irregular RR intervals.

When impulse formation occurs outside the sinus node during a regular sinus rhythm, it is termed a *premature beat* if such impulse formation occurs earlier than the expected beat of the basic rhythm (Fig. 60.6); an *escape beat* refers to an impulse formation that occurs outside that of the basic rhythm and terminates an interval longer than the preceding basic rhythm (Fig. 60.7).

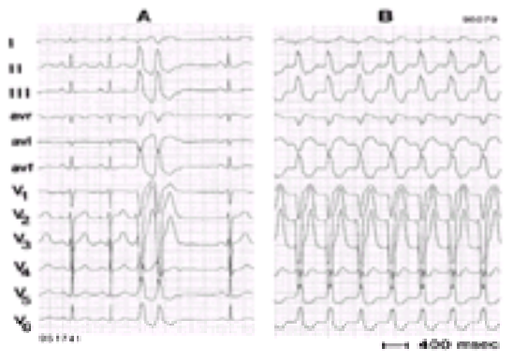


FIGURE 60.6 A: Two consecutive premature ventricular beats. The second one shows retrograde conduction to the atrium.**B:** A monomorphic ventricular tachycardia is present coming from the same area as the premature beats in **A** (the outflow tract of the right ventricle).

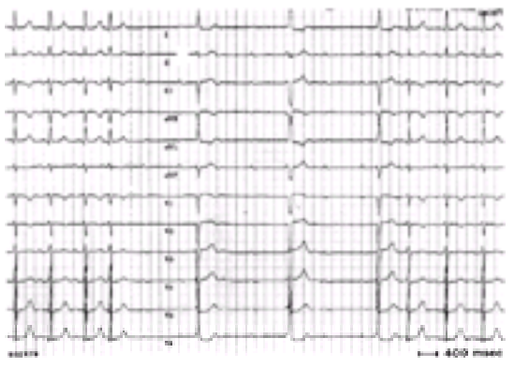

FIGURE 60.7 Escape beats terminating a pause that is longer than those of the QRS intervals of the preceding conducted sinus beats.

Premature or ectopic beats may arise anywhere in the heart. They may occur individually, two or three in a row [i.e., doublets (Fig. 60.6) or triplets], or continuously, resulting in a tachycardia.

When premature beats have a fixed time relation to the previous normal depolarization, they are referred to as *coupled* premature beats. If they have no fixed relation to normal beats but occur at fixed interectopic intervals, they may arise in a *parasystolic* focus (Fig. 60.8). Such a focus is completely or partially protected from other impulses. Partial protection may result in slight changes in interectopic intervals, known as *modulated parasystole* (4).

FIGURE 60.8 Atrial parasystole. Apart from sinus rhythm, there is ectopic impulse formation at the atrial level. Ectopic impulse formation is totally independent of the basic sinus rhythm. As shown, depending on the prematurity of the atrial ectopic beat, the QRS differs in configuration because of different degrees of aberrant conduction.

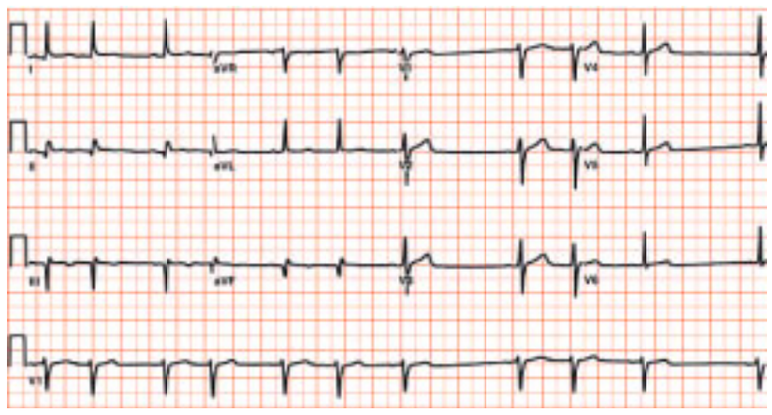
A tachycardia may show a regular or an irregular rhythm. The regularity or irregularity may be at the atrial level, at the ventricular level, or at both levels. When all complexes of a tachycardia show the same configuration, the tachycardia is termed a *monomorphic* tachycardia (Fig. 60.6). When the tachycardia complexes show marked differences in configuration, the tachycardia is referred to as a *polymorphic* tachycardia. If a tachycardia stops spontaneously within 30 seconds, it is defined as a *nonsustained* tachycardia; when the tachycardia persists for more than 30 seconds or does not stop spontaneously, it is termed a *sustained* tachycardia.

Site of Origin of an Arrhythmia

Arrhythmias may arise anywhere in the heart. For practical purposes, they are divided into those arising in the atrium, the AV nodal region, and the ventricle and those that use extra connections between the atrium and ventricle in their arrhythmic mechanism. Identification of the site of origin is based on (a) the relation between the P wave and QRS complex; (b) the width and configuration of the P wave, which indicate how the atria are activated during the arrhythmia; and (c) the width and configuration of the QRS complex, which indicate how the ventricles are activated during the arrhythmia.

Aberrant Conduction

Figure 60.8 illustrates the occurrence of *premature atrial beats* during sinus rhythm due to a parasystolic atrial focus. It should be noted that these beats occur earlier and have a P-wave configuration that differs from that of the P waves during sinus rhythm. Conduction of the premature atrial beat from atrium to ventricle depends on the prematurity of that beat. A very early atrial beat is not conducted to the ventricle because of refractoriness of the AV conduction system. When conducted to the ventricle, the QRS configuration of the premature atrial beat depends on the time of arrival in the ventricle and, therefore, on the degree of refractoriness of the bundle branches. The amount of change (aberrancy) of the QRS complex following the premature atrial beat is related to the prematurity of that beat and the refractory state of the bundle branches, which, in turn, is related to the length of the RR interval that precedes the premature atrial complex (Fig. 60.8).



A 56-year-old male patient with nonconducted premature atrial contractions.

Aberrant conduction is quite common during the sudden rate change at the onset of an SVT, because the supraventricular impulse arrives at the bundle branches at such an early time that one of the bundle branches is still refractory (Fig. 60.9). The mechanism of aberrant conduction is thus termed a *phase 3*– or *tachycardia-dependent aberrancy*. Another cause of persistent aberrant conduction during SVT is retrograde invasion into one of the bundle branches (5). An example is given in Figure 60.10.

FIGURE 60.9 Aberrant conduction follows the onset of a supraventricular tachycardia (phase 3 aberrancy). Note that the right bundle branch block aberrancy disappears after 15 tachycardia complexes.

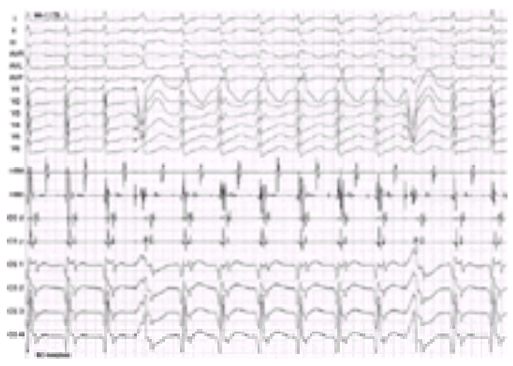


FIGURE 60.10 Supraventricular tachycardia with aberrant conduction due to retrograde invasion into the right bundle branch. Retrograde invasion was produced by an electrically induced right ventricular premature beat and persists until another induced right ventricular premature beat restores normal conduction over the right bundle branch. Apart from the 12-lead electrocardiogram, several intracardiac leads are shown. CS, coronary sinus; HBE, bundle of His electrogram; HRA, high-right atrium.

TACHYCARDIAS

Atrial Tachycardia

During atrial tachycardia, impulse formation is in the atrium, outside the sinus node. The P wave precedes the QRS complex. The polarity of the P wave indicates the site of origin in the atrium. Two types of atrial tachycardias must be distinguished. *Paroxysmal* atrial tachycardia is the most common and is characterized by a sudden onset and cessation of the arrhythmia (Fig. 60.11). A rare, but more serious, type of atrial tachycardia is a *permanent* or *incessant* atrial tachycardia, with the arrhythmia being present for more than 50% of the day (Fig. 60.12). In these patients, the rate of impulse formation in the atrium frequently increases during sympathetic stimulation (e.g., during exercise). Administration of antiarrhythmic drugs usually fails to prevent 1:1 AV conduction during exercise in these patients. The incessant nature of the arrhythmia and the difficulty in controlling the ventricular rate may lead to dilated (tachycardia-induced) cardiomyopathy (6). A fuller discussion of atrial tachycardia can be found in Chapter 65.

FIGURE 60.11 Paroxysmal atrial tachycardia. The tachycardia shown here starts after three sinus beats.

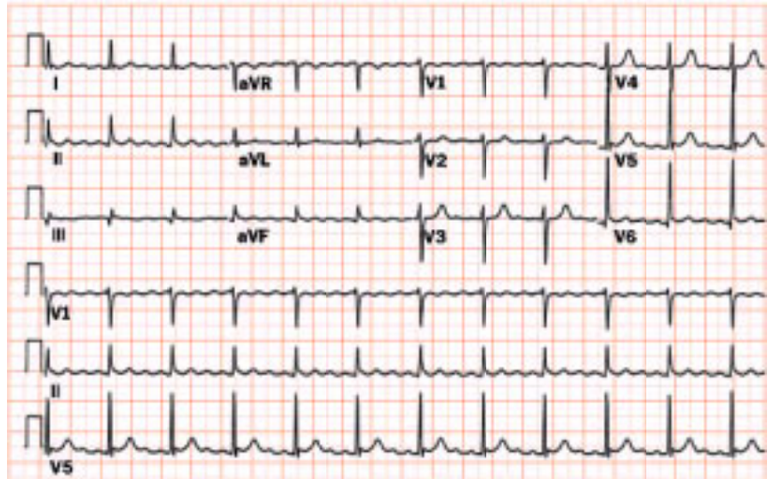
FIGURE 60.12 Incessant atrial tachycardia. Atrioventricular conduction of 2:1 is present in the left panel, changing into 1:1 atrioventricular conduction. The origin of the arrhythmia is low in the intraatrial septum.

A 57-year-old female patient with atrial tachycardia and 2:1 atrioventricular conduction.

Atrial Flutter

Atrial flutter is typically characterized by a regular atrial rhythm, a rate of 250 to 350 beats/min, and an atrial activity with a sawtooth pattern. Identifying atrial activity during atrial flutter can be facilitated by carotid sinus massage (CSM) (Fig. 60.13). Depending on the pattern of atrial activation during flutter, the shape and polarity of the flutter waves may differ. The ventricular rate during atrial flutter depends on the conduction characteristics of the AV conduction system and usually varies from a 2:1 AV relation to higher degrees of AV block. A fuller discussion of atrial flutter can be found in Chapter 65.

FIGURE 60.13 Atrial flutter. Shown here is an atrioventricular conduction of 2:1, changing in the middle to 4:1 atrioventricular conduction during carotid sinus massage.



Atrial flutter. Atrial rate of 300 beats/min with upright P waves inferiorly. This is consistent with atypical atrial flutter.

Atrial flutter. Inverted "saw-tooth" waves in the inferior leads suggest typical atrial flutter.

Atrial Fibrillation

During atrial fibrillation (AF) atrial activity is characteristically rapid, with a rate of 350 to 500 beats/min, and shows an irregular rhythm that varies continuously in shape (Fig. 60.14). Depending on the shape and duration of the fibrillatory waves, one can distinguish coarse from fine AF. The underlying mechanism cannot be identified by such ECG characteristics of AF. The ventricular rate during AF depends on the electrophysiologic properties of the AV conduction system. The refractory period of AV nodal and subnodal tissue and concealed conduction in the AV node determine the ventricular frequency during AF, which, in the absence of a refractory period prolonging drugs, is from 130 to 180 beats/min.

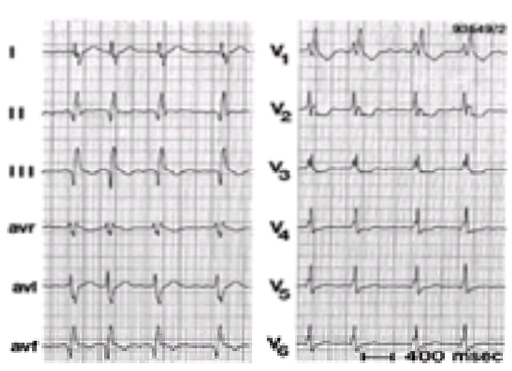


FIGURE 60.14 Atrial fibrillation. Characteristic of atrial fibrillation are the changes in atrial activation pattern and the irregularity of the RR intervals.

When two connections between the atrium and ventricle are present and are able to conduct the impulses from the atrium to the ventricle during preexcitation, the ventricular rate during AF relates to the duration of the refractory period of the two connections (7). When the AV AP has a short anterograde refractory period, a very high ventricular rate may occur during AF (Fig. 60.15). This high ventricular rate may deteriorate into ventricular fibrillation and may result in sudden cardiac death. The characteristic ECG feature of AF in the presence of ventricular preexcitation is a rapid, irregular ventricular rhythm with wide QRS complexes. The QRS configuration changes according to the contribution of the two AV pathways to ventricular activation. A fuller discussion of AF can be found in Chapter 64.

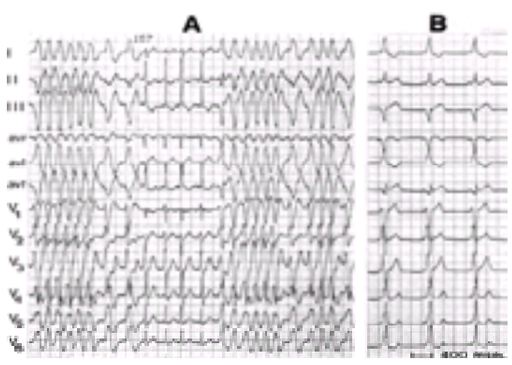

FIGURE 60.15 A: Atrial fibrillation in a patient with the Wolff-Parkinson-White syndrome. Note atrioventricular (AV) conduction over the accessory pathway (AP) on the left and right sides of the panel, with AV conduction over the AV node in the middle. As shown, the ventricular rate can become very high during AV conduction over the AP. **B:** Posteroseptal location of the AP is shown during sinus rhythm.

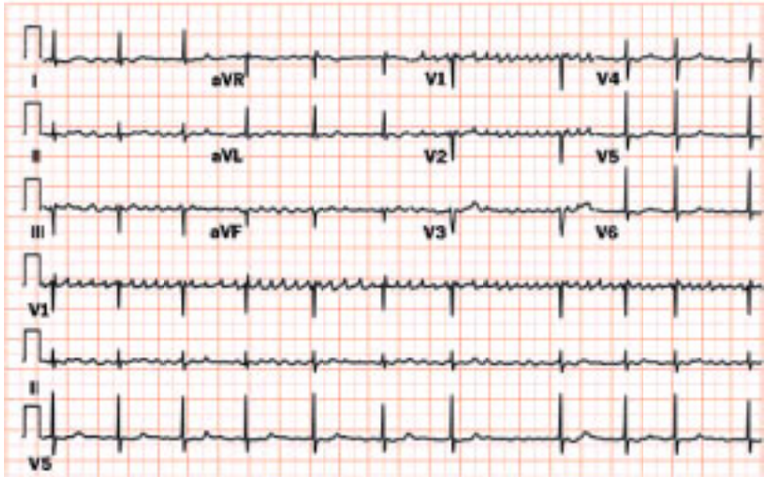

Atrial fibrillation. Narrow complex QRS with irregular RR intervals. Ventricular rate is controlled.

Tachycardias Located in the Atrioventricular Nodal Region

During these arrhythmias, there is usually 1:1 conduction from the AV nodal region to the atrium and to the ventricle (see Chapter 66), and because of the simultaneous activation of the atrium and the ventricle, the P waves are generally hidden within the QRS complex, or they may fall in the terminal part of the QRS complex, mimicking S waves in leads II, III, and aVF and a pseudo-incomplete right bundle branch block (RBBB) pattern in lead V_1 (Fig. 60.16); this is the *common* form of AV nodal tachycardia. The P wave rarely follows the QRS complex with an RP interval longer than the PR interval; this is an *uncommon form* of AV nodal tachycardia. In contrast to the common form of AV nodal tachycardia, the uncommon form is usually short lived and self-terminates within seconds to minutes.

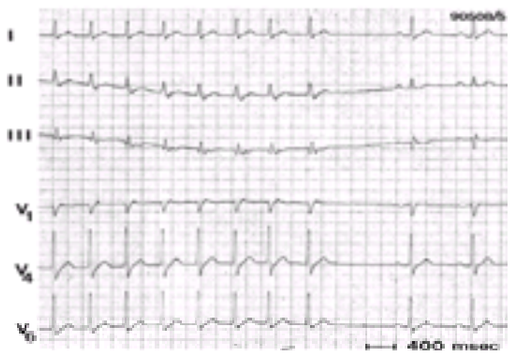

FIGURE 60.16 Common form of atrioventricular nodal tachycardia. Note the pseudo-S wave in leads II and III and the pseudo, incomplete right bundle branch block pattern in lead V_1caused by the P wave during tachycardia.

Atrioventricular nodal reentrant tachycardia. Note retrograde P wave buried within the ST segment.

Occasionally, 2:1 block develops between the AV node and the ventricle. The P wave typically is exactly in the middle between two QRS complexes. Because atrial activation starts low in the intraatrial septum, the P wave is narrow and negative in leads II, III, and aVF (Fig. 60.17). A fuller discussion of these tachycardias can be found in Chapter 66.

FIGURE 60.17 Atrioventricular (AV) nodal tachycardia with 2:1 block between the AV node and the ventricle and 1:1 conduction from the AV node to the atrium. As shown in the bundle of His recording (HIS), the 2:1 block is located in the distal part of the AV node. RA, right atrium; RV, right ventricle.

Tachycardias Using Extra Connections between Atrium and Ventricle: Circus-Movement Tachycardia

The presence of more than one connection between the atrium and ventricle creates a possible pathway for a reentry circuit resulting in a tachycardia. During tachycardia, AV conduction occurs over one AV connection, and VA conduction occurs over the other. Depending on the pathway used for AV conduction, the tachycardia may show (a) a narrow QRS complex or a typical RBBB or left bundle branch block (LBBB) configuration when AV conduction occurs over the AV node–His pathway or (b) a preexcited QRS complex when AV conduction occurs over the accessory connection (Fig. 60.18).

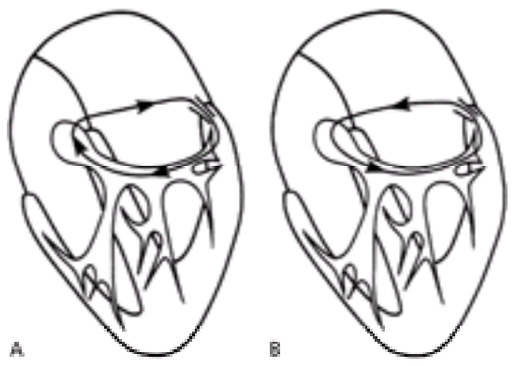

FIGURE 60.18 The two types of circus-movement tachycardias (CMT) in a patient with an accessory atrioventricular (AV) pathway. **A:** Orthodromic CMT with AV conduction over the AV node and ventricular conduction over the accessory pathway. **B:** CMT in the reverse direction—antidromic CMT.

In the first type of tachycardia, termed *orthodromic circus-movement tachycardia* (*CMT*), the AP is the retrograde limb in the tachycardia circuit. If the AP rapidly conducts the impulse, a short RP interval results. Less frequently, an AP has slower conduction properties and the RP interval is long (Fig. 60.19 and Fig. 60.20). In the second type of tachycardia, referred to as an *antidromic CMT*, AV conduction occurs over the accessory connection, resulting in a wide QRS complex that shows pronounced slurring of its initial portion; such a wide QRS complex with pronounced slurring is due to ventricular activation starting outside the intraventricular conduction system (Fig. 60.21). VA conduction during this tachycardia may occur either by way of the His–AV node axis or by way of a second accessory connection. A fuller discussion of CMTs can be found in Chapter 65.

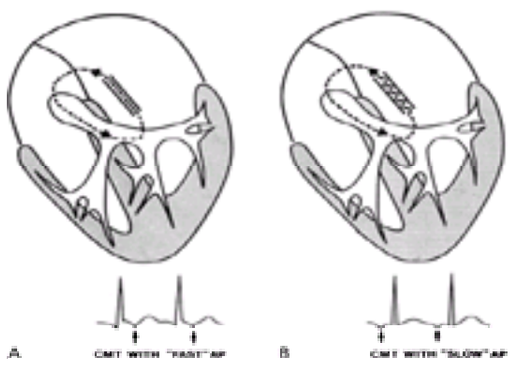

FIGURE 60.19 Two types of accessory pathways (AP) and their effect on the RP interval during circus-movement tachycardia (CMT). **A:** Rapidly conducting AP resulting in a short RP interval during orthodromic CMT. **B:** Slowly conducting AP leads to a long RP interval during tachycardia.

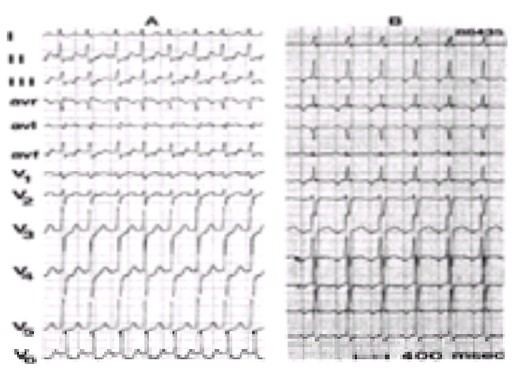

FIGURE 60.20 Examples of the two types of tachycardias for which the tachycardia circuit is shown in Figure 60.19. **A:** Ventriculoatrial conduction over the rapidly conducting accessory pathway. **B:** Conduction over a slowly conducting accessory pathway.

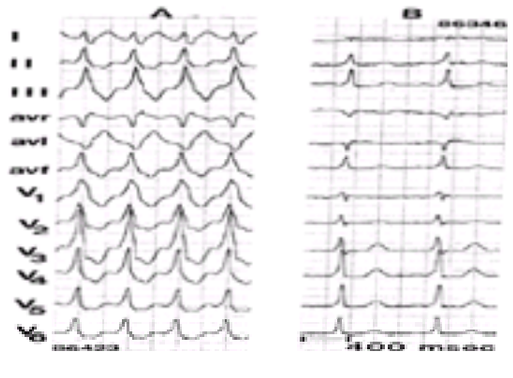

FIGURE 60.21 A: Antidromic circus-movement tachycardia with atrioventricular conduction over a left posterior accessory pathway. **B:** Same patient during sinus rhythm.

Additional Features That Are Helpful in Differentiating Supraventricular Tachycardias

Electrical Alternans

During a regular SVT, the QRS configuration and the T wave may alternate in height (Fig. 60.22). This phenomenon is more common in orthodromic CMT than in atrial or AV nodal tachycardia (8). It especially occurs during high rates of the tachycardia and can only be considered suggestive of orthodromic CMT when alternation occurs for longer than 5 seconds after the beginning of the tachycardia.

FIGURE 60.22 Electrical alternans of the QRS complex during a circus-movement tachycardia using a “concealed” atrioventricular accessory pathway. The tachycardia terminates when block occurs in the atrioventricular nodal part of the circuit.

Effect of Bundle Branch Block on the Tachycardia Rate

When one of the bundle branches is incorporated into the tachycardia circuit, block in that bundle branch during tachycardia usually slows the tachycardia rate (9). As shown in Figure 60.23 and Figure 60.24, this can only occur in *orthodromic* CMT.

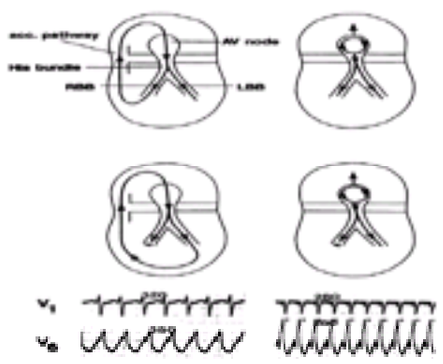

FIGURE 60.23 Effect of a bundle branch block during circus-movement tachycardia using an accessory (acc.) pathway that is on the same side of the heart as the bundle branch block. As shown, the circuit becomes longer when right bundle branch block (RBB) develops in a patient with a right-sided accessory pathway. Nothing happens to the tachycardia rate when bundle branch block develops during atrioventricular (AV) nodal reentrant tachycardia (measurements are in ms). LBB, left bundle branch block.

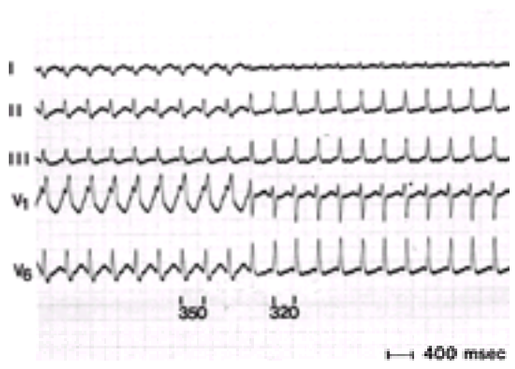

FIGURE 60.24 Example of rate change during right bundle branch block in a patient with an orthodromic circus-movement tachycardia using a right-sided accessory pathway. During right bundle branch block, the RR interval is 30 ms longer compared with the RR interval during nonaberrant conduction.

Value of Carotid Sinus Massage

CSM can be very helpful in differentiating regular from irregular tachycardias. This is illustrated in Table 60.1. Table 60.2 summarizes the ECG features of the most common types of regular SVTs.

Type of supraventricular tachycardia	Effect of carotid sinus massage
Sinus tachycardia	Gradual and temporary slowing of the heart
Atrial tachycardia	
Paroxysmal	Cessation of tachycardia or no effect
Incessant	Temporary slowing of ventricular rate (because of AV block) or no effect
Atrial flutter	Temporary slowing of ventricular rate (because of AV block) or no effect
AVNRT	Cessation of tachycardia or no effect
CMT	Cessation of tachycardia or no effect

AV, atrioventricular; AVNRT, AV nodal reentry tachycardia; CMT, circus-movement tachycardia (using an AV accessory pathway and the AV node).

TABLE 60.1 EFFECT OF CAROTID SINUS MASSAGE ON SUPRAVENTRICULAR TACHYCARDIA

ECG signs	AT	CMT	AVNRT
AV block (spontaneous or by CSM)	If present, may not only be useful for diagnosing AT but also for differentiating atrial flutter (atrial rate >250/min) from AT	Rules out CMT	Unusual, but 2:1 block is possible
Electrical alternans	Rare	Common (especially at high tachycardia rates)	Rare
P-wave location in relation to QRS complex	Present between R waves; PR length varies with atrial site of origin and AV nodal conduction time	Present between R waves: RP<PR in fast AP, RP>PR in slow AP	Hidden in QRS or distorting the distal portion of the QRS
P polarity	Varies with the location of atrial impulse formation	Varies according to location of atrial end AP	Always negative in leads II, III, and AVF
Aberrant conduction	Rare	Common	Rare

AP, accessory pathway; AT, atrial tachycardia; AV, atrioventricular; AVF, atrioventricular fibrillation; AVNRT, atrioventricular nodal reentry tachycardia; CMT, circus-movement tachycardia incorporating AP; CSM, carotid sinus massage; ECG, electrocardiogram.

TABLE 60.2 SUMMARY OF ELECTROCARDIOGRAPHIC FEATURES OF THE MOST COMMON TYPES OF REGULAR SUPRAVENTRICULAR TACHYCARDIAS

Wide QRS Tachycardia

Correctly identifying the site of origin of a wide QRS tachycardia is not only important to proper treatment of the arrhythmia but also to the prognosis. VT usually has a more ominous prognosis than does SVT.

Table 60.3 and Figure 60.25 illustrate the possible causes of a wide QRS tachycardia. To correctly diagnose such a tachycardia, it is essential to use a 12-lead ECG. This should be used systematically, checking for independent atrial and ventricular activity (AV dissociation) and for characteristics of a QRS tachycardia such as its width, axis, and configuration.

A supraventricular tachycardia (SVT) with preexisting or functional bundle branch block; this includes sinus tachycardia, atrial tachycardia, atrial flutter, atrial fibrillation, and atrioventricular (AV) nodal reentry tachycardia
Orthodromic circus-movement tachycardia (CMT) using the AV node in the anterograde direction and an accessory pathway (AP) in the retrograde direction with preexisting or functional bundle branch block
An SVT with conduction over an AP
Antidromic CMT using an AP in the anterograde direction and the AV node or another AP in the retrograde direction
A reentry tachycardia using a nodoventricular fiber in the anterograde direction and the bundle branch–His pathway or another AP in the retrograde direction
A ventricular tachycardia

TABLE 60.3 POSSIBLE CAUSES OF A WIDE QRS TACHYCARDIA

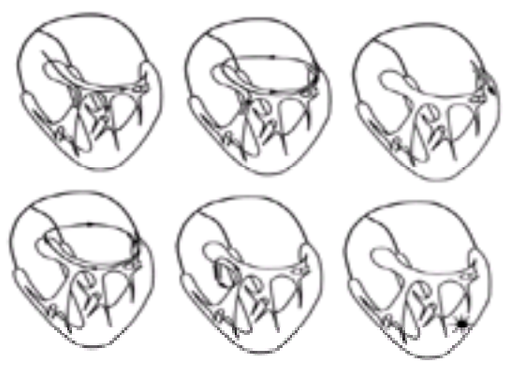

FIGURE 60.25 Six possible causes of a wide QRS tachycardia. See Table 60.3 for a full description.

Wide complex tachycardia. Atrioventricular dissociation confirms ventricular origin.

Atrioventricular Dissociation

Independent atrial and ventricular activity during a wide QRS tachycardia has been correctly considered a hallmark of VT. However, during VT some form of VA conduction may be present, especially when the VT rate is relatively slow (10). When AV dissociation is present during VT, the atrial rate is usually slower than the ventricular rate, except in atrial tachycardia, atrial flutter, or AF. During VT, part or all of the ventricle may occasionally be activated by a supraventricular impulse (e.g., a sinus beat), which is conducted through the AV conduction system and arrives in the ventricle when the ventricle is partly or completely excitable. This typically occurs when the VT rate is relatively slow. This phenomenon results in capture or fusion beats (Fig. 60.26).

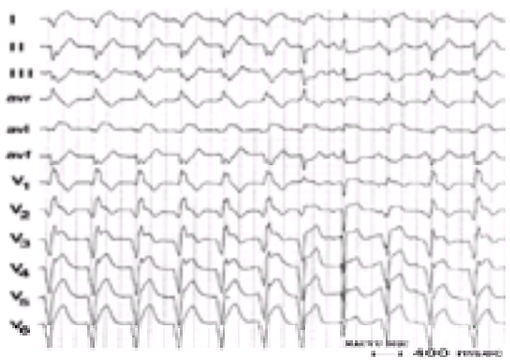

FIGURE 60.26 Ventricular tachycardia with a relatively slow rate, allowing the occurrence of capture and fusion beats. The tracing was recorded in a patient with a recent anterior wall myocardial infarction. Note the QR pattern in several leads during ventricular tachycardia.

Width of the QRS Complex

Absence or delay in RBB conduction during a supraventricular rhythm results in an RBBB configuration and a QRS complex with a width of 120 ms. When conduction

in the LBB is blocked, the width of the QRS complex may become as long as 140 ms. These facts are of value in distinguishing an SVT from a VT. The wider the QRS complex, the more likely that the tachycardia is ventricular in origin. This is typically the case when ectopic ventricular impulse formation occurs in the free wall of the right or left ventricle and when activation of the two ventricles occurs sequentially rather than simultaneously. This finding prompted Wellens et al. (10) to evaluate the role of the width of the QRS complex in distinguishing an SVT from a VT complex. For several reasons, however, an SVT has a QRS width of greater than 140 ms. They include (a) SVT in the presence of BBB with additional intramyocardial conduction delay, (b) SVT with AV conduction over an AV, and (c) marked QRS widening during SVT because of the use of antiarrhythmic drugs that prolong intraventricular conduction.

An 81-year-old male patient with ventricular tachycardia.

VT may have a QRS width of less than 140 ms. Such is the case for VTs that originate in or close to the specific conduction system of the left ventricle (Fig. 60.27).

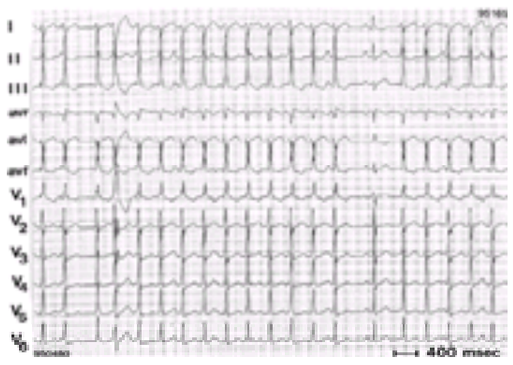

FIGURE 60.27 Idiopathic ventricular tachycardia arising in or close to the anterior fascicle of the left bundle branch. Note atrioventricular dissociation during ventricular tachycardia. Note also that the QRS width during ventricular tachycardia is only 120 ms.

QRS Axis in the Frontal Plane

When impulse formation originates in the ventricle, the frontal plane axis is frequently abnormal. This axis depends on the site of origin of the VT. In 1976, Wellens et al. (10) observed that a frontal plane axis to the left of –30 degrees during tachycardia was suggestive of a VT. This observation still holds true in VT with an RBBB configuration but remains questionable in VT with an LBBB shape (11).

The etiology of VT with an LBBB shape is usually either (a) an anterior or inferoposterior scar from a previous myocardial infarction (MI) in or close to the interventricular septum, (b) an idiopathic VT arising from the outflow tract of the right ventricle, or (c) a VT in arrhythmogenic right ventricular (RV) dysplasia. Whereas in the first and third etiologies the exit point of the VT and, therefore, of the QRS axis may vary, in idiopathic VT from the RV outflow tract the frontal plane axis is typically vertical or to the right. In general, in a patient with a wide LBBB-shaped tachycardia, marked left-axis deviation (i.e., to the left of –60 degrees) or marked right-axis deviation (i.e., to the right of +90 degrees) suggests a ventricular arrhythmia.

Configurational Characteristics of the QRS Complex

Right Bundle Branch Block–Shaped QRS Complex

In SVT with RBBB, leads V_1 and V_6 usually have a triphasic pattern (10,12). Lead V_1 has an rSR' pattern, with the initial r reflecting normal septal activation, the S wave reflecting left ventricular activation, and the R' wave reflecting delayed activation of the right ventricle. Lead V_6 shows a narrow q wave resulting from normal septal activation, an R wave representing left ventricular activation, and an S wave reflecting delayed RV activation. In lead V_6 the R:S ratio is typically greater than 1:1.

In VT with an RBBB shape, lead V_1 shows a monophasic or biphasic QRS complex (i.e., R, qr, rs). The presence of a deep S wave in lead V_6 with an R:S ratio of less than 1:1 supports a diagnosis of VT (10). This is typically the case when left-axis deviation is present. In the case of right-axis deviation, the R:S ratio in lead V_6 is usually greater than 1:1 (Fig. 60.28).

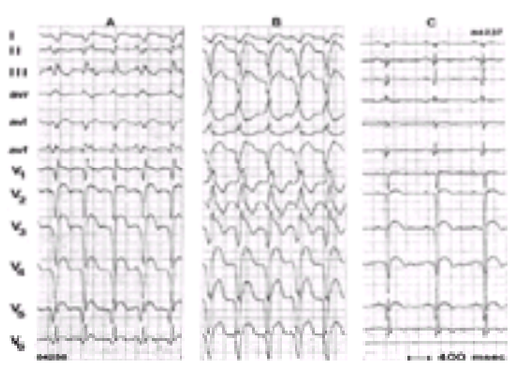

FIGURE 60.28 Two types of ventricular tachycardias in a patient with an old anteroseptal and apical myocardial infarction **(A)**. In **B** and **C**, a right bundle branch block pattern is present, with a QR and a monophasic R, respectively, in lead V_1. QRS negativity or positivity in lead V_6 is related to the frontal plane axis. A QS complex during left-axis deviation is shown in **B**, and a QR complex during right-axis deviation is shown in **C**. During ventricular tachycardia, atrioventricular dissociation is clearly present in **B** and in **C**.

Left Bundle Branch Block–Shaped QRS Complex

Leads V_1, V_2, and V_6 are the important ECG leads to use in distinguishing a VT from an SVT with LBBB (11). If an r wave is present in either lead V_1 or V_2, it is narrow (i.e., <0.04 second) in SVT with LBBB. Moreover, the downstroke of the S wave is fast, without slurring or notching, and the distance from the beginning of the QRS to the nadir of the S wave is 0.06 second or less. If in lead(s) V_1 or V_2, or both, the r wave is greater than 0.04 second and the downstroke of the S wave is slurred and

delayed, a diagnosis of VT is likely (Fig. 60.29). A Q wave in lead V_6 is diagnostic of VT (11).

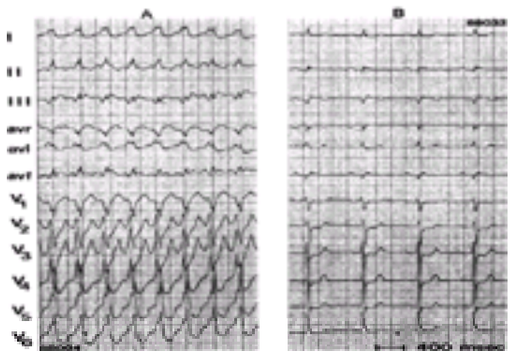

FIGURE 60.29 A: Ventricular tachycardia with a left bundle branch block shape. Note initial positivity of the QRS in lead V_1 (>0.04 second), slurring of the S wave in leads V_1 and V_2, and a distance from the beginning of the QRS to the nadir of the S wave of 120 ms in leads V_1 and V_2. **B:** An old inferior myocardial infarction.

Concordant Pattern in the Precordial Leads

Leads V_1 through V_6 may all show positive or negative QRS complexes, referred to as *positive* and*negative concordancy*. Negative concordancy is diagnostic of VT (Fig. 60.30). Positive concordancy occurs not only in VT originating in the posterobasal area of the left ventricle but may also be seen in tachycardias with AV conduction over an AP inserting into the posterobasal left ventricle (Fig. 60.21).

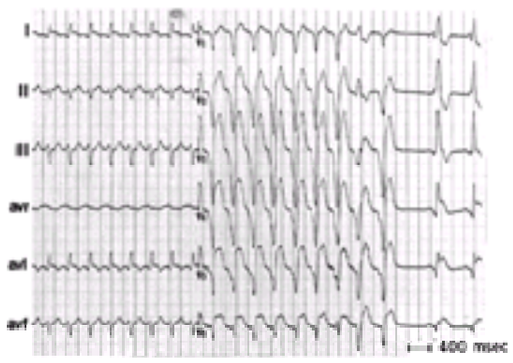

FIGURE 60.30 Ventricular tachycardia (VT) shows a negative concordant pattern in the precordial leads. This is diagnostic of VT. The QRS following termination of VT shows an old anteroapical myocardial infarction.

Presence of Q Waves during Tachycardia

As a rule, QR complexes during a wide QRS tachycardia are highly suggestive of VT (Fig. 60.26, Fig. 60.28, 60.29) unless identical QR complexes are present in the same leads during sinus rhythm (13). However, Qr complexes may occur, although rarely, during tachycardia and sinus rhythm in the same leads in the presence of a bundle branch reentrant tachycardia (14) (Fig. 60.31). As is shown in Table 60.4, in patients with VT following MI, approximately 40% have a QR complex in one or more of the ECG leads. QR complexes during VT typically occur in patients with a localized ventricular scar, as in those with a previous MI or localized infiltrative or inflammatory myocardial disease.

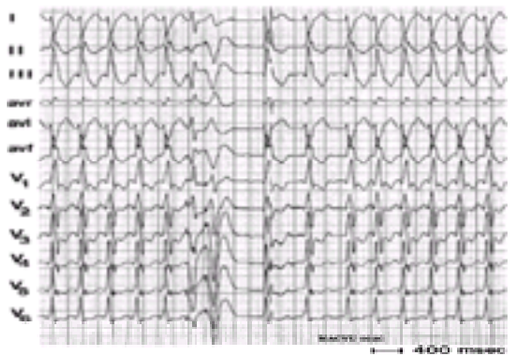

FIGURE 60.31 Ventricular tachycardia based on bundle branch reentry. After two electrically induced premature ventricular beats, the tachycardia terminates in the middle of the recording. However, it resumes after three conducted sinus beats. QRS is identical during sinus rhythm and tachycardia. During electrophysiologic study, the tachycardia was found to be based on bundle branch reentry, with the right bundle branch as the retrograde pathway. The tachycardia was cured by radiofrequency ablation of the right bundle branch.

	LBBB morphology (n = 58) (%)	RBBB morphology (n = 75) (%)
Presence of a QR in any lead except aVR during VT	25/58 (43)	28/75 (37)
Correlation between the site of QR pattern during VT and site of myocardial infarction during sinus rhythm (in ≥1 lead)	21/25 (84)	20/28 (71)

LBBB, left bundle branch block; RBBB, right bundle branch block; VT, ventricular tachycardia.

TABLE 60.4 INCIDENCE OF QR COMPLEXES IN PREVIOUS MYOCARDIAL INFARCTION AND THE CORRELATION BETWEEN QR PATTERN DURING VENTRICULAR TACHYCARDIA AND SITE OF MYOCARDIAL INFARCTION DURING SINUS RHYTHM

Interval from Onset of QRS to Nadir of the S Wave in Precordial Leads

As already indicated in Left Bundle Branch Block–Shaped QRS Complex, the interval from the onset of QRS to the nadir of the S wave in precordial leads is increased

in VT. Brugada et al. (15) have suggested that an RS interval of greater than 100 ms in one or more precordial leads is highly suggestive of VT. The clinician must be careful, however, because such a duration may occur in SVT with AV conduction over an AP, SVT during the administration of drugs that slow intraventricular conduction, and SVT with preexistent BBB, especially LBBB.

ECG INWIDE QRS TACHYCARDIAS

It is essential to follow a systematic approach when analyzing ECGs in patients with wide QRS tachycardias. Table 60.5 reviews the different signs that should be systematically checked for when analyzing a regular wide QRS tachycardia. Correctly diagnosing the tachycardia is imperative, because incorrectly diagnosing an SVT may lead to selecting inappropriate antiarrhythmic drugs and to deleterious results (16,17). Such an error is one of the most frequent mistakes made in treating arrhythmias; hence, familiarity with the criteria described herein should almost invariably prevent such a misdiagnosis.

Atrioventricular (AV) dissociation suggests ventricular tachycardia	(VT), but ventriculoatrial conduction may be present during VT.
A *QRS width* of ≥160 ms suggests VT, but one needs to rule out	(a) preexistent bundle branch block (BBB, especially left BBB (LBBB), (b) supraventricular tachycardia (SVT) with AV conduction over an accessory pathway (AP), and (c) use of drugs that slow intraventricular conduction delay (class IA, IC, amiodarone).
Keep in mind: VT arising close to or in the intraventricular con-	duction system may have a width of ≤140 ms.
Left-axis deviation (to the left of −30 degrees) suggests VT but is	not helpful in (a) LBBB-shaped QRS, (b) SVT with conduction over a right-sided or posteroseptal AP, and (c) SVT during use of class IC drugs.
Right-axis deviation (to the right of +90 degrees) suggests VT in	LBBB-shaped QRS.
QR complexes in leads other than aVR suggest VT unless the	same QRS configuration is present in the same leads during sinus rhythm (unless bundle branch reentry is present).
Concordant pattern in precordial leads suggests VT, but positive	concordancy may occur during SVT with AV conduction over a left posterior AP.
R-nadir ≥100 ms in one or more precordial leads suggests VT	but may be found in (a) SVT on drugs that slow intraventricular conduction, (b) SVT with AV conduction over an AP, and (c) preexistent BBB (especially LBBB).
In the presence of capture or fusion beats, rule out (a) fusion	with a contralateral premature ventricular beat and (b) fusion with a ventricular echo beat.

TABLE 60.5 VALUE AND LIMITATIONS OF SIGNS IN DIAGNOSING REGULAR WIDE QRS TACHYCARDIA

THE FUTURE

Requirements in catheter ablation techniques will make it possible to cure an increasing number of different types of arrhythmias in the future. Additional improvements in ECG interpretation will facilitate rapid identification of the most appropriate treatment in patients with arrhythmias.

OVERVIEW

Ambulatory electrocardiography (ECG) records a patient's ECG during routine activities, when the effect of autonomic tone, exercise, emotion, and other stresses can be evaluated. The technique assesses cardiac rhythm, myocardial ischemia, QT interval duration, signal-averaged ECG, and heart-rate variability. Newer solid-state recording systems digitize the ECG signal and all QRS complexes recorded during the 24 hours are available for analysis. These systems are replacing previously used tape systems. Intermittent and memory-loop ambulatory recorders are helpful for documenting symptoms that occur too infrequently to be assessed by 24-hour ambulatory ECG. The implantable memory-loop recorder is useful in assessing patients with symptoms that occur infrequently and are technically difficult to record with an intermittent or memory-loop recorder.

Ambulatory ECG monitoring in persons without apparent heart disease has identified a wide range of arrhythmias, a finding that must be kept in mind when patients are evaluated. Monitoring results must be placed in context with the patient's clinical condition and associated symptoms. Ambulatory monitoring is helpful when assessing patients with cardiogenic syncope, although memory-loop recorders are proving to be of more benefit. Ventricular arrhythmias recorded by 24-hour monitoring after myocardial infarction identify patients at risk for further cardiac events and can be helpful in combination with other prognostic tests to identify high-risk patients in whom intervention may improve survival.

Evaluating therapy using ambulatory monitoring must be done with the knowledge that a significant spontaneous variation occurs in the frequency and complexity of ventricular arrhythmias. For an antiarrhythmic drug to demonstrate efficacy, the frequency of ventricular ectopy should be suppressed by 80% to 90% with all repetitive forms eliminated. Ambulatory ECG monitoring is an important test that is useful in the evaluation of patients with arrhythmia or ischemia, and in assessing factors associated with increased risk of sudden death.

Signal-averaged ECG averages multiple QRS complexes, minimizing the level of noise that contaminates the periodic ECG signal, thereby exposing signals at the microvolt level that are normally hidden within noise. These signals at the end of the QRS complex are termed *late potentials* and represent delayed conduction through diseased myocardium and a potential physical substrate for reentry ventricular tachycardia. Late potentials usually arise from the border zone surrounding the scar of a previous myocardial infarction, but they can also be present in patients with hypertrophic cardiomyopathy, dilated cardiomyopathy, arrhythmogenic right ventricular dysplasia, myocarditis, and infiltrative heart disease. The use of time-domain analysis to identify late potentials and to predict risk for ventricular arrhythmias has been validated in numerous studies and is the method used in commercial equipment. Frequency-domain analysis is less widely used, and diagnostic end points have not been standardized. Signal-averaged ECG using time-domain methods is not reliable in patients with prolonged QRS duration because of ventricular conduction delay.

Criteria to define the presence of late potentials depend on the lead configuration, filter, and processing algorithm; they need to be defined individually for each commercial system. The peak incidence of late potentials occurs in the first week after myocardial infarction and slowly decreases during follow-up, with 50% of patients having late potentials before being dismissed from the hospital and 25% at 5 years after infarction. Fewer than 5% of patients who do not have late potentials after myocardial infarction develop late potentials during long-term follow-up in the absence of another myocardial infarction. Late potentials are an independent risk factor for the development of ventricular arrhythmias after myocardial infarction, with a positive predictive accuracy of 20% and a negative predictive accuracy of 95%. Patients at high risk for serious arrhythmic events after myocardial infarction are best identified by combination of the results of signal-averaged ECG with other clinical and laboratory risk factors. Similarly, signal-averaged ECG in patients with cardiogenic syncope and a history of myocardial infarction is predictive of inducible ventricular tachycardia at electrophysiologic testing. The frequency of late potentials is decreased after thrombolytic therapy for acute myocardial infarction. The efficacy of antiarrhythmic drugs cannot be assessed using signal-averaged ECG.

T-wave alternans (TWA) is an ECG pattern characterized by changing morphology of the T wave on an every-other-beat basis. TWA is rarely seen on the ECG, but, when seen, is associated with pathophysiologic conditions that may give rise to ventricular arrhythmias, including Prinzmetal's angina, electrolyte abnormalities, acute ischemia, and long QT syndrome. With the advent of advanced signal-processing methods, TWA can now be measured at the microvolt level, even though visual inspection of the ECG shows no abnormality. Animal studies have demonstrated that microvolt-level TWA is a predictor of susceptibility to ventricular arrhythmias. TWA is caused by local alteration in the duration of the action potential as documented during electrophysiologic mapping studies. The development of reentrant ventricular arrhythmias, including ventricular tachycardia and ventricular fibrillation, is hypothesized to be caused by local action potential alternans, which leads to spatial dispersion of recovery and the fractionation of depolarizing wavefronts, allowing reentry. Recent literature has supported the use of microvolt-level TWA to identify patients at risk for life-threatening ventricular arrhythmias and sudden cardiac death.

GLOSSARY

Complex ventricular ectopy: Nonsustained ventricular tachycardia, more than 10 premature ventricular complexes per hour.

Continuous ambulatory ECG: ECG recording for 24 to 48 hours that stores every heartbeat.

Delayed ventricular potentials: Another term for late potentials.

FQRSD: Filtered QRS duration. The total duration of the QRS complex is measured after filtering to determine whether late potentials are prolonging the QRS complex.

Frequency-domain signal-averaged ECG: A method of assessing late potentials by mathematical methods to measure frequency content of the QRS waveform.

High-resolution ECG: Another term for signal-averaged ECG.

Intermittent ambulatory ECG: ECG recording in which ECG data is stored only when the device is activated. Data is stored after the device is activated.

k: The alternans ratio used to define whether TWA is present.

LASD: Low-amplitude signal duration. The terminal QRS below 40 µV is measured to assess whether low-level late potentials are present.

Late potentials: Low-level electrical signals at the end of the QRS complex that represent slow conduction through abnormal myocardium.

Modulating factor: Variable that interacts with triggers and substrate to initiate an arrhythmia. Modulating factors include electrolytes, ischemia, and autonomic tone.

Memory-loop ambulatory ECG: ECG recordings taken for several days to weeks with ECG data stored to permanent memory only when the device is activated. The ECG preceding and following device activation is stored.

RMSV: Root mean square voltage. The last 40 ms of the QRS complex is assessed to determine whether a late potential is present.

Signal-averaged ECG: The standard ECG is filtered, and multiple QRS complexes are averaged, allowing identification of late potentials.

Time-domain signal-averaged ECG: A method of assessing late potentials by measuring their duration and amplitude.

Trigger: Cardiac events that initiate a sustained arrhythmia. Triggers include premature atrial and ventricular extrasystoles and alteration in cycle length.

TWA: T-wave alternans.

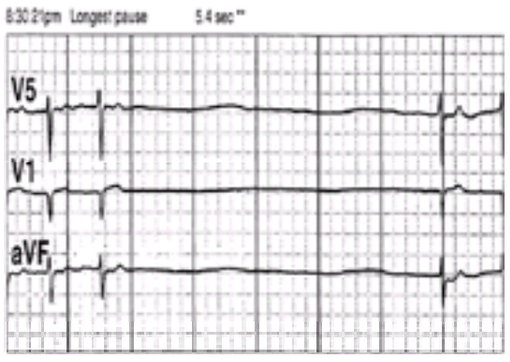
V*alt*: The alternans voltage used to define whether TWA is present.

AMBULATORY ELECTROCARDIOGRAPHY

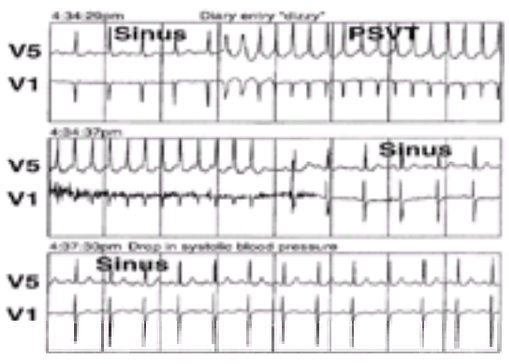
Historical Perspective

Ambulatory ECG was introduced by Holter and Gengerelli in 1949 (1); they used radiofrequency transmission with large, cumbersome equipment. Recording techniques improved, leading to the magnetic tape recording unit in 1961 (2). During the subsequent four decades, extensive clinical experience has developed, and ambulatory ECG monitoring has demonstrated that the test is useful for the diagnosis and management of cardiac arrhythmias and for assessing prognosis in populations of patients at high risk for life-threatening cardiac arrhythmias (3). The ambulatory ECG allows recording of a patient's ECG during routine activities, when the effect of 24-hour variation in autonomic tone, exercise, emotion, and other stresses on cardiac rhythm can be evaluated. Such effects may not be present during continuous monitoring in the hospital.

The ambulatory ECG was initially used to assess patients for the presence of tachycardia or bradycardia (*e*Fig. 61.0.1 and *e*Fig. 61.0.2). The technique evolved to be used for evaluation of myocardial ischemia by recording changes in the ST segment, of the QT interval duration as a prognostic factor for serious ventricular arrhythmia, of signal-averaged ECG to identify late potentials and substrate for serious ventricular arrhythmias, and of changes in the RR interval, reflecting heart-rate variability, a strong prognostic indicator for serious cardiac events.



***e*FIGURE 61.0.1** A 24-hour ambulatory electrocardiographic (ECG) recording in a patient with episodes of near syncope. The ECG demonstrates a 5.4-second sinus pause that occurred when the patient was resting and that was not associated with symptoms.



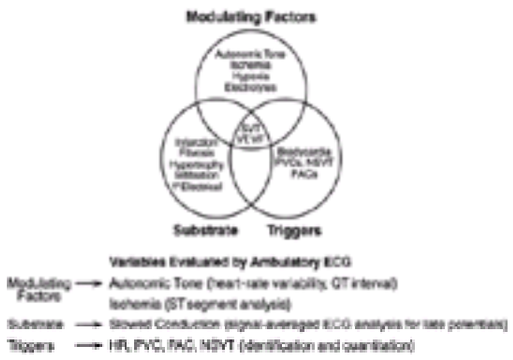
***e*FIGURE 61.0.2** A 24-hour ambulatory electrocardiographic (ECG) recording in a patient with episodes of "dizziness" and orthostatic hypotension. A 24-hour ambulatory ECG and a blood pressure recording were obtained. The ECG demonstrates an episode of paroxysmal supraventricular tachycardia (PSVT) associated with a complaint of feeling "dizzy." The patient was asymptomatic during decreases in systolic blood pressure at a time when the rhythm remained sinus.

The equipment used to record the ambulatory ECG has also evolved, with improved recording fidelity, reduction in size and weight, improved data acquisition using solid-state technology, and use of computer-enhanced analysis systems. In addition, patient-activated event recorders allow intermittent ECG recording at the time that infrequent symptoms occur. Recently, an implantable automatic and patient-activated ECG recording system was developed to document the cardiac rhythm during

symptomatic episodes that may occur as infrequently as every 12 months.

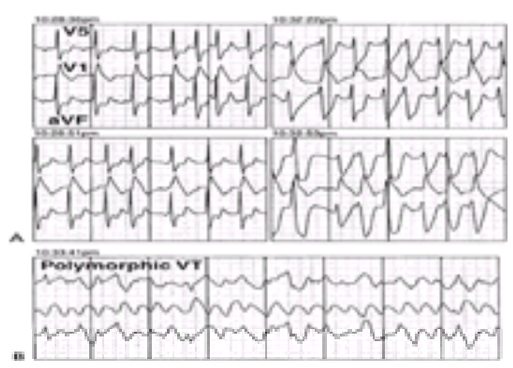
Pathophysiology of Cardiac Arrhythmias

The ambulatory ECG records the effect of changing autonomic tone and environmental factors on the development of cardiac arrhythmias. Sustained tachycardia is dependent on the interaction of triggers, substrate, and modulating factors (4) (eFig. 61.0.3). Triggers include premature atrial complexes and premature ventricular complexes (PVCs), nonsustained ventricular tachycardia (NSVT), and alterations in cardiac cycle length produced by ectopic beats and bradycardia. Arrhythmia triggers interact with a substrate: ischemic heart disease with either a fixed area of scar or transient abnormal conduction due to ischemia; hypertrophy in patients with advanced hypertrophic cardiomyopathy, hypertensive heart disease, or aortic stenosis; myocardial dilatation associated with cardiomyopathy; and inflammation and infiltration of the myocardium. Modulating factors interacting with substrate and triggers may be required before an arrhythmia occurs. Modulating factors include changes in sympathetic and parasympathetic tone, electrolytes, and ischemia (5).



***e*FIGURE 61.0.3** Pathophysiologic interactions resulting in arrhythmia. Venn diagram of the interaction of modulating factors, triggers, and substrate for the genesis of cardiac arrhythmias. The 24-hour ambulatory electrocardiogram (ECG) evaluates several of the interacting factors accounting for arrhythmias. HR, heart rate; PAC, premature atrial complex; PVC, premature ventricular complex; NSVT, nonsustained ventricular tachycardia; SVT, sustained ventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

The ambulatory ECG is extremely helpful in identifying substrate, triggers, and modulating factors that interact to cause cardiac arrhythmias (eFig. 61.0.4). At first, the ambulatory ECG assessed triggers of cardiac arrhythmias, including PVCs, NSVT, and premature atrial complexes. The technique now also identifies late potentials by signal-averaged ECG, a marker of substrate capable of supporting a reentrant arrhythmia, and heart-rate variability, a modulating factor reflecting sympathetic tone.



***e*FIGURE 61.0.4** A 24-hour ambulatory electrocardiographic (ECG) recording in a patient with coronary artery disease and episodes of lightheadedness. **A:** At 10:28:36, the ECG records ST depression in leads aVF and V_5, with ST elevation in lead V_1. Over the next 4 minutes, the changes of acute injury progress. **B:** The rhythm degenerates into polymorphic ventricular tachycardia, from which the patient was resuscitated. This demonstrates the interaction of myocardial ischemia and subsequent ventricular arrhythmia. VT, ventricular tachycardia.

Individuals with symptomatic palpitations and symptoms suggestive of an arrhythmia often relate that their spells occur at different times of the day or are associated with different activities. The ambulatory ECG allows for assessment of bradycardia- or exercise-induced arrhythmias. Such rhythms include torsades de pointes with prolongation of the QT interval, atrial fibrillation that is dependent on enhanced vagal tone and heart-rate slowing, and cardiac arrhythmias that follow sympathetic tone increases during exercise.

Technical Aspects of Ambulatory Electrocardiographic Monitoring

Ambulatory ECG monitoring includes continuous and intermittent ECG recording. Continuous ambulatory ECG recording is performed for periods of 24 to 48 hours and allows assessment of cardiac rhythm on a continuous basis. Intermittent ambulatory ECG recordings can be obtained over longer periods of observation using a memory-loop recorder.

Continuous Ambulatory Electrocardiographic Monitoring

The two common recording systems are *tape-based* and *solid-state*. The tape-based system is a battery-powered device that records at an extremely slow tape speed, with two or three ECG amplifiers and an analog tape recorder. The typical analog amplifier records ECGs at frequencies similar to the standard 12-lead ECG (.05 to 100 Hz). Not all ambulatory ECG recording devices have this full-frequency response; a narrower response may limit fidelity, reducing the accuracy of recording dynamic changes in ST segments. The recording accuracy depends on the quality of the tape-drive motor and gearing. Irregularities in the tape drive can create artifacts that simulate tachycardia or bradycardia; this effect can be lessened or more easily identified with systems that record a simultaneous timing signal on an additional channel. Ambulatory ECG recorders have an event marker that allows patients to document the times at which they are feeling their typical symptoms, which can then be correlated with the ECG during playback. The recorders cannot be immersed in water.

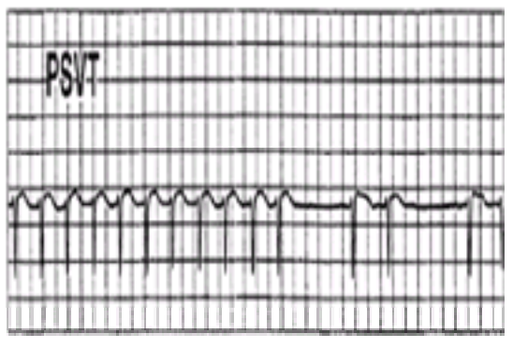
With the conventional tape-based system, recorded data is processed by a scanner, where it is digitized and analyzed with close interaction by an experienced operator. Abnormalities are then quantitated, and sample ECG rhythm strips or full-disclosure pages are recorded for subsequent review and documentation. In addition, the more sophisticated systems allow for assessment of RR interval and heart-rate variability, ST segment deviations, QT interval changes during 24 hours, and signal averaging to detect late potentials. The simplest scanner will not do data processing or tabulation, only full disclosure of the entire ECG recording. This system allows for identification of significant rhythm abnormalities but is inaccurate for quantitating abnormalities or performing any sophisticated processing. Using a system that does not incorporate computer-assisted analysis, the operator can miss as many as one-third of ventricular or supraventricular arrhythmias (6). Computer-assisted analysis systems significantly improve the sensitivity and specificity of ECG monitoring, increasing accuracy for quantitating ectopic complexes to approximately 95% (7,8). In the preferred system, experienced operators use computer-based analysis. Although this approach increases costs, it improves accuracy.

Solid-state recording systems digitize the incoming ECG signal from two or three channels and then store this data in the solid-state memory. The digital signal is assessed by intricate algorithms to determine whether the QRS complex is normal or represents an ectopic beat or part of a run of tachycardia. Older systems did not store every beat recorded during the 24 hours, but only samples of what were considered to be normal and abnormal complexes as determined by the algorithm. Such systems had problems with artifact being misinterpreted and stored as abnormal rhythm, or of ECG being stored if a patient felt symptoms at a time when the system interpreted the ECG as normal (9). Newer solid-state systems are capable of recording every heartbeat during a 24-hour period. This allows the ECG to be analyzed in a manner similar to analysis of the data from a tape-based system. Such systems combine the advantages of the tape-based system, in which all ECG complexes are recorded and analyzed, with the advantages of a smaller, quieter, and easier to maintain solid-state system. Solid-state devices are dependent on efficient and accurate coding algorithms. As the algorithms for cardiac arrhythmia, heart-rate variability, and tabulation of ectopic complexes improve (10,11), the ability to analyze and process incoming data in real time will simplify subsequent analysis after the recording is obtained. The increased cost of the recorder is a disadvantage of a

solid-state system.

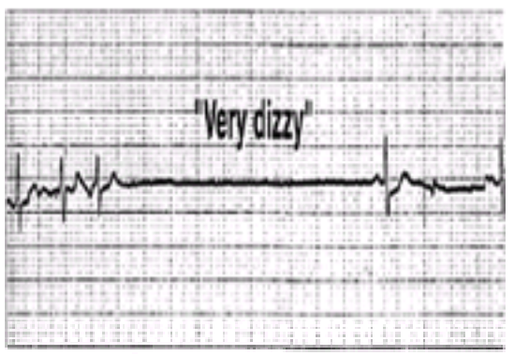
Intermittent and Memory-Loop Ambulatory Electrocardiographic Recording

Intermittent recorders are capable of storing only a limited number of short, patient-activated ECG recordings (12) (eFig. 61.0.5). These devices are lightweight, and some are as small as a thick credit card. Their advantage over continuous ambulatory systems is that the ECG is more likely to be obtained while the patient is experiencing clinical symptoms, thus allowing a direct correlation between the patient's symptoms and the ECG recorded at that instant (13,14,15,16 and 17). Current devices use solid-state technology that allows recording of 1 to 5 minutes of ECG for three to five occasions on which the patient is feeling symptoms. The ECG is stored in the solid-state memory of the device and transmitted by telephone to the base station at a time that is convenient for the patient.



***e*FIGURE 61.0.5** Intermittent memory-loop electrocardiographic (ECG) recording of a patient with palpitations. The rhythm strip documents an pisode of paroxysmal supraventricular tachycardia (PSVT) that terminates spontaneously, converting to sinus rhythm. The patient's symptoms occurred once every 2 to 3 weeks and were too infrequent to be recorded during 24-hour ambulatory ECG monitoring.

Development of this technology led to memory-loop circuitry, which is a hybrid between the ambulatory ECG monitor and the solid-state event recorder. With the memory-loop recorder, electrodes are applied to the patient and the device is worn on a continuous basis. When the patient activates the device, a permanent recording of stored ECG data is obtained that includes periods from 1 to 4 minutes before and 30 to 60 seconds after the recording button is pressed (*e*Fig. 61.0.6). The data can then be transmitted by telephone at the patient's convenience. This device has the disadvantage that it must be worn on a continuous basis, but the clear advantage that it obtains ECG data recorded before the patient presses the button and, thus, documents the rhythm at the onset of the patient's palpitations and the initiating event. Memory-loop devices are extremely helpful for documenting events that are associated with significant symptoms but occur on an infrequent basis. Ninety-five percent of symptomatic calls for suspected transient cardiac arrhythmias occur within 4 weeks of use of this device, and serious arrhythmia is documented in 52% of patients (18). Approximately 25% of patients who have recurrent syncope obtain diagnostically useful information using this device. Memory-loop recorders are limited by malfunction and by the inability of 20% of patients to properly use the device (19).



***e*FIGURE 61.0.6** Event recorder. Memory-loop electrocardiographic recording in a patient with symptoms of near syncope and palpitations. The recording documents an episode of atrial fibrillation, converting to sinus rhythm with an intervening pause. The patient had symptoms at the time of the pause that were similar to typical spells.

The most recent development in this technology is a small implantable memory-loop recorder that is placed subcutaneously in the left upper chest, allowing continuous ECG recording using a loop-based memory system capable of recording for up to 18 months (20). The device can be activated by the patient or set to automatically record an arrhythmia that is below or above a predetermined heart rate. Information is stored before the device is activated to record the onset of an arrhythmic or symptomatic event. The data is then downloaded into a computer for analysis and review. This system has the unique advantage of not being dependent on patient interaction, avoiding problems caused by patients who are unable to activate the device or place the recording leads. The device can be used for extended periods of time, as opposed to the standard memory-loop recorder, which is less practical after 3 to 4 weeks because of skin irritation from the patch electrodes. The implantable memory-loop recorder also allows the ECG to be recorded while the patient is exposed to water, when other systems cannot be used. A report of 85 patients who had syncope and negative ambulatory monitoring, tilt-table, and electrophysiologic testing showed that 58 patients (68%) had recurrent syncope at a mean of 10.5 months after implantation (21). The diagnosis of the syncopal mechanism included bradycardia in 18 patients and tachycardia in three patients; normal rhythm was recorded at the time of syncope in the remaining patients, suggesting a vasodepressor mechanism.

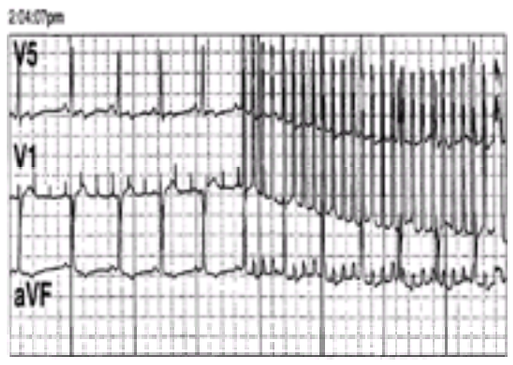
Selection of 24-hour continuous ambulatory versus intermittent ECG recording depends on the patient and the symptoms (22). Both recording systems are most useful when a patient has typical symptoms while the ECG is being recorded. The absence of any significant rhythm abnormality while symptoms are occurring is helpful in patient management, because it eliminates arrhythmia as a possible cause of the symptoms. An abnormal rhythm that occurs without symptoms may be a cause of the patient's clinical symptoms, or it may be only a spontaneous arrhythmia that could be recorded in a normal, asymptomatic individual. Monitoring does not help patient management in this situation.

Continuous 24-hour ambulatory ECG is helpful and provides the most useful, direct approach to documenting the ECG in patients with daily symptoms. Patients with infrequent symptoms are more likely to benefit from the intermittent or memory-loop recorder. An intermittent recorder is useful for a patient who has several minutes of arrhythmia that occur too infrequently to justify the continuous application of ECG electrodes required by the memory-loop recorder. The memory-loop recorder is most useful for patients who are expected to have symptoms within 4 weeks after they begin using the device and in whom symptoms are brief and not expected to last long enough to find, apply, and record with the intermittent recorder. The implantable memory-loop recorder is helpful for patients who have syncope or near syncope of unknown etiology despite standard evaluation, but who have spells too infrequently to justify a standard memory-loop recorder. A study of 43 patients with palpitations showed the event recorder to be superior to 24-hour ambulatory monitoring for diagnosing the mechanism of the palpitations. Event recorders detected clinically important arrhythmia in 19% of the patients, whereas ambulatory monitoring failed in all patients (23). Kus and coworkers (24) reported that continuous and intermittent recordings were complementary and that combined use increased the diagnostic yield for arrhythmia. Clinical judgment and experience are important in selecting the best diagnostic test for an individual patient; cost per management decision based on ambulatory ECG findings ranges from $550 for assessing drug therapy to $14,000 for assessing stroke (25).

Recording Artifact

Experienced operators are aware that artifact can simulate arrhythmia. Ambulatory ECG artifacts are important to recognize and can occur with tape slippage, excessive damping, inappropriate calibration, or saturation of the amplifier (26,27). The P-wave, QRS, and T-wave morphology may change in relation to body position and respiration (*e*Fig. 61.0.7). Electrical artifacts (*e*Fig. 61.0.8) can simulate pacemaker malfunction, and tape distortion or slippage may result in prolonged intervals that simulate sinus pauses or tachycardia. These problems occur less often with digital solid-state systems.

***e*FIGURE 61.0.7** Ambulatory electrocardiographic monitoring demonstrating a change in the QRS morphology in lead V_5 when the patient stands.



***e*FIGURE 61.0.8** Electrical artifact recorded during 24-hour ambulatory electrocardiographic monitoring demonstrating the value of recording different electrocardiography leads.

Ambulatory Electrocardiographic Findings in Normal, Asymptomatic Persons

Ambulatory ECG monitoring in persons without apparent heart disease has identified a wide range of arrhythmias (*e*Table 61.0.1). Brodsky and colleagues (28) reported heart rates for healthy male medical students that ranged from 37 to 180 beats/min during waking periods and 33 to 115 beats/min during sleep. Twenty-four percent of the subjects had heart rates below 40 beats/min during sleeping periods, and sinus pauses of more than 1.75 seconds were noted in 28% of subjects. When comparing healthy young males and females, females had a higher average heart rate while awake and asleep, less bradycardia below 40 beats/min, less junctional escape rhythm, and similar frequency of arrhythmia (29). Transient second degree atrioventricular (AV) block has been documented in 2% to 6% of trained athletes and young, otherwise healthy males and females (28,29 and 30). These arrhythmias often occur during sleep and are vagally mediated (31). Supraventricular and ventricular premature complexes are found in healthy control subjects, although the absolute number is low (28,32). The frequency of arrhythmias increases with age (33,34 and 35). In the Framingham Heart Study, Bikkina and associates (36,37), using 1-hour ambulatory monitoring in 2,727 men and 3,306 women with no history of heart disease or symptomatic arrhythmia, reported that complex ventricular arrhythmias increased with age. Approximately 5% of men younger than 60 years, 18% aged 60 to 69 years, and 35% older than 70 years had complex ventricular arrhythmias. In contrast, approximately 7% of women younger than 60 years, 12% aged 60 to 69 years, and 25% older than 70 years had asymptomatic complex ventricular ectopy. Manolio and associates (38) reported cardiac arrhythmias in 234 women and 158 men older than 65 years who had no evidence of coronary artery disease, hypertension, or diabetes. They identified ventricular arrhythmias in 11% of men and 20% of women, supraventricular arrhythmias in 54% of women and 63% of men, and bradycardia or conduction block in 0.9% of women and 55.1% of men. In athletes (39,40), 24-hour ambulatory ECG monitoring, in comparison to controls, identified a significantly lower average minimum heart rate (38 vs. 45 beats/min), more sinus pauses that were longer than 2 seconds (37% vs. 6%), more episodes of Mobitz I block (23% vs. 6%), and more junctional rhythm (20% vs. 0%), but no significant difference in the number of PVCs (33% vs. 43%). The finding of arrhythmia in asymptomatic healthy individuals must be kept in mind when patients are evaluated. The results of ambulatory ECG monitoring should be placed in context with the patient's clinical condition and associated symptoms.

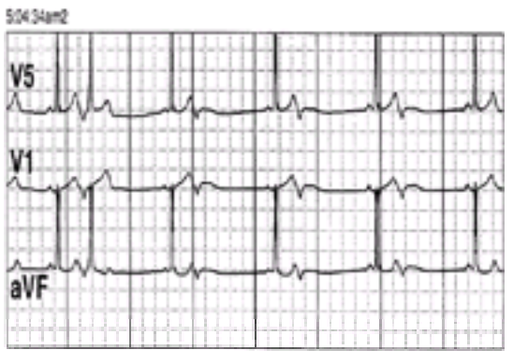
Ambulatory Recordings in Specific Clinical Syndromes

Cardiogenic Syncope

Patients who experience sudden loss of consciousness are best evaluated with techniques other than ambulatory monitoring because of the severity of their symptoms. Such patients are often admitted to the hospital for long-term ECG assessment and then considered for electrophysiologic testing, tilt-table testing, or exercise assessment to identify the cause of their spells. Patients with syncope who undergo ambulatory ECG monitoring experience lightheadedness, presyncope, or syncope during the recording 25% of the time (41,42 and 43). Approximately 2% to 15% are identified as having an associated cardiac arrhythmia when the symptoms occurred, and 35% have no associated ECG abnormality (32,42,44). Extending the recording to 3 days increases the number of patients who experience symptoms to 50%, and extending the recording to 5 to 21 days increases the number of patients who experience symptoms to 75% (43). Bass and coworkers (45) identified ECG abnormalities in 27% of 95 patients with syncope, using 72 hours of ambulatory ECG monitoring. Twenty-four hours of ambulatory monitoring often is not enough to identify potentially important arrhythmias in patients with syncope. Monitoring may need to be extended to 48 hours if recordings from the first 24 hours are normal (45) (*e*Fig. 61.0.9 and *e*Fig. 61.0.10).



***e*FIGURE 61.0.9** A 24-hour ambulatory electrocardiographic (ECG) recording in a patient with symptomatic bradycardia. The ECG demonstrates nonconducted atrial premature complexes occurring in bigeminy, resulting in bradycardia, which was asymptomatic at the time of this recording.

***e*FIGURE 61.0.10** A 24-hour ambulatory electrocardiographic (ECG) recording in a patient with near-syncope. The ECG demonstrates right bundle branch block with a premature ventricular complex followed by four nonconducted P waves. This high-grade atrioventricular block occurred during sleep and was not associated with symptoms.

The criteria for determining a significant arrhythmia in the absence of associated symptoms are difficult to establish. For example, many authors indicate that a sinus pause of 2.0 to 2.5 seconds is abnormal, but other authors have shown that sinus pauses of 3 seconds or longer may not cause symptoms and do not predict an adverse prognosis (46,47). Therefore, a sinus pause should be correlated with symptoms before intervention is considered.

Ambulatory ECG monitoring can be useful in identifying patients who would benefit from the use of electrophysiologic studies to assess unexplained syncope. Linzer and associates (48) evaluated a model of clinical characteristics for its usefulness in predicting outcome of electrophysiologic studies in 141 patients with unexplained syncope (49). They demonstrated that a combination of clinical, ECG, and ambulatory ECG findings can predict outcome of electrophysiologic testing. Patients who have cardiogenic syncope and associated heart disease, cardiac arrhythmia on ambulatory ECG monitoring, or abnormal 12-lead ECG results should be considered for electrophysiologic testing. Patients without these abnormalities are generally considered for tilt-table testing. Thirty percent of patients with negative electrophysiologic and tilt-table studies continue to have syncope and may benefit from use of a memory-loop recorder. The implantable memory-loop recorder should prove to be uniquely beneficial in this group of patients.

Atrial Fibrillation

In patients with paroxysmal atrial fibrillation, 24-hour ambulatory ECG monitoring can help identify the onset of the arrhythmia and potential approaches to treatment. Patients with vagal-dependent atrial fibrillation typically demonstrate a slowing of the sinus rhythm with the onset of atrial fibrillation (50). This arrhythmia occurs most commonly when patients are sedentary or sleeping and is aggravated by medications that slow sinus rhythm, such as beta-adrenergic blockers or digoxin. Atrial fibrillation may occur after an episode of supraventricular reentrant arrhythmia. Patients with a manifest or concealed accessory pathway or reentry within the AV node may initially develop their usual reentrant arrhythmia, which then disorganizes into atrial fibrillation. Atrial fibrillation can be successfully eliminated by preventing the reentrant arrhythmia.

The 24-hour ambulatory recording system is also helpful in assessing a patient's rate control during atrial fibrillation. Patients may demonstrate adequate rate control while they are sedentary but experience a rapid heart rate and symptoms when they are active. A treadmill exercise test can assess the heart-rate response to exercise, but 24-hour ambulatory monitoring is often more useful because it identifies heart-rate response during a patient's more usual activities, which include both physical and emotional stresses. Finally, 24-hour ambulatory monitoring may be helpful in identifying patients in whom a pulmonary vein focus is the cause of atrial fibrillation.

Atrial fibrillation. Narrow complex QRS with irregular RR intervals. Ventricular rate is controlled.

Ventricular Arrhythmias after Myocardial Infarction

The role of complex ventricular ectopy in predicting mortality after myocardial infarction has been confirmed in several multicenter trials (51,52). The definition of complex ventricular ectopy has included NSVT, multiple morphologies, and PVC frequency. PVC frequencies of more than 3 and of more than 10 per hour (51,52) have been found to be predictors of myocardial events and are independent of ejection fraction and heart rate (eTable 61.0.2). These studies were performed before the widespread use of thrombolysis, which has significantly decreased the mortality associated with acute myocardial infarction.

***e*TABLE 61.0.2** FREQUENCY OF PVCS AND RELATIONSHIP TO MORTALITY IN PATIENTS WITH MYOCARDIAL INFARCTION

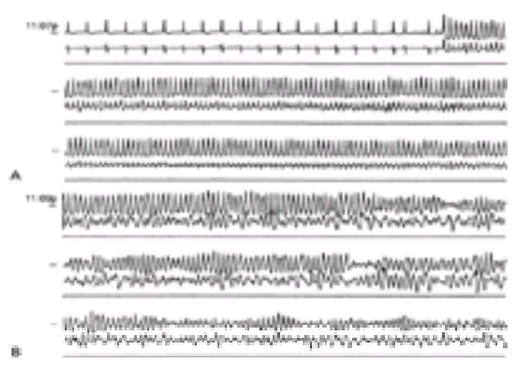
[b]Includes sudden death and sustained ventricular tachycardia.
Adapted from Shen WK, Hammill SC. Survivors of acute myocardial infarction: who is at risk for sudden death? *Mayo Clin Proc* 1991;66:950–962.

A 1996 study by Statters and associates (55) reported that PVCs continue to be an independent predictor of mortality after myocardial infarction in patients who undergo thrombolytic therapy. They assessed 680 patients who underwent 24-hour ambulatory ECG monitoring 6 to 10 days after myocardial infarction, 379 of whom received thrombolytic therapy. At a sensitivity level of 40%, the positive predictive accuracy of PVCs to predict cardiac mortality and arrhythmic events in patients receiving thrombolytic therapy was 19.4% and 25.8%, respectively, compared to 16% and 16%, respectively, for patients who did not receive thrombolytic therapy. The PVC frequency for dichotomizing patients into high- and low-risk groups was 25 PVCs per hour after thrombolytic therapy and 10 PVCs per hour without thrombolytic therapy. In the study, PVC frequency was more highly predictive of prognosis after myocardial infarction in patients who had undergone thrombolytic therapy than in those who had not, using this higher frequency of dichotomy. Maggioni and colleagues (56) identified similar findings in patients receiving thrombolytic therapy in the GISSI-2 trial (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico), which included 8,878 patients.

Studies of this nature emphasize the importance of PVC triggers associated with structural heart disease in the development of life-threatening ventricular arrhythmias after myocardial infarction (57). Risk factors that can be assessed by 24-hour ambulatory monitoring, including PVC frequency, abnormal autonomic tone assessed by reduced heart-rate variability, and ischemia monitoring of ST segment changes, further delineate the dynamic relationship between PVC trigger, substrate, and modulating factors that can converge to create a life-threatening arrhythmic event (eFig. 61.0.11). The optimum duration of recording to risk-stratify patients who have experienced infarction is not clear. Most studies use 24 hours of monitoring. However, some studies have reported that more than 1 hour of monitoring was unnecessary (58,59). NSVT with reduced ejection fraction has been used to identify postinfarction patients who are at potential risk for a cardiac event and would benefit from further evaluation by means of electrophysiologic testing (3).



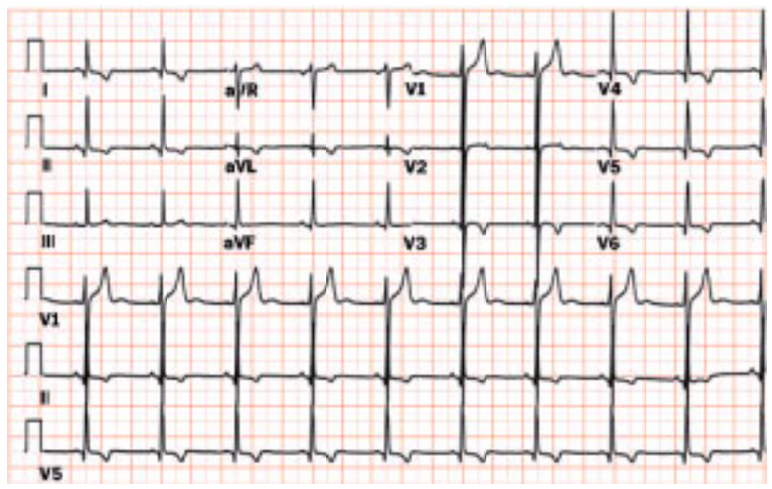
***e*FIGURE 61.0.11** A 24-hour ambulatory electrocardiographic recording in a patient with coronary artery disease. **A:** The patient has a premature atrial complex, a pause, and then a normal complex, followed by a premature ventricular complex, which initiates a run of sustained monomorphic ventricular tachycardia. **B:** The monomorphic ventricular tachycardia degenerates into polymorphic ventricular tachycardia.

The suppression of asymptomatic PVCs after myocardial infarction was postulated to decrease mortality; however, recent clinical trials have not borne this out (60,61,62 and 63). Although antiarrhythmic medication may reduce the frequency with which arrhythmias are triggered, it may also increase the susceptibility of the myocardium to more serious arrhythmia. This does not negate the usefulness of PVCs in identifying high-risk patient groups for selection for other treatments (55).

Dilated and Hypertrophic Cardiomyopathy

Ventricular arrhythmias recorded by 24-hour ambulatory ECG monitoring independently predict subsequent death in patients with dilated cardiomyopathy (64). DeMaria and coworkers (65) evaluated 88 patients who did not have PVCs, 63 who had PVC pairs, and 67 who had NSVT on ambulatory monitoring with associated dilated cardiomyopathy. Survival at 24 months was approximately 95% in patients without PVCs and 80% in patients with PVC pairs and NSVT (p <.05). The use of angiotensin-converting enzyme inhibitors has significantly increased survival in patients with moderately symptomatic congestive heart failure and reduced ventricular function. Nonetheless, approximately 25% to 50% of deaths in patients with congestive heart failure are related to cardiac arrhythmias, despite the use of angiotensin-converting enzyme inhibitors (66,67). As with patients who have ischemic heart disease, ambulatory monitoring in patients with dilated cardiomyopathy identifies patients at increased risk for sudden death.

In 1981, NSVT recorded during 24-hour ambulatory monitoring was reported to be associated with sudden death (68,69), with an 8% annual mortality rate in patients with hypertrophic cardiomyopathy. A subsequent study by Spirito and associates (70) reviewed 151 asymptomatic patients with hypertrophic cardiomyopathy in whom the finding of NSVT on ambulatory monitoring was associated with a relative risk of sudden death of 2.4, compared with patients without NSVT. Although the risk of sudden death was slightly higher in the presence of NSVT, these authors did not recommend that a finding of NSVT should lead to the initiation of antiarrhythmic therapy. Chang and coworkers (71) and Fananapazir and colleagues (72) reported the results of ambulatory ECG monitoring, electrophysiologic testing, and cardiac catheterization in 230 patients with hypertrophic cardiomyopathy, with 115 patients having NSVT on ambulatory monitoring. The only two independent predictors of subsequent death or arrhythmic events were sustained ventricular tachycardia on electrophysiologic study and a history of cardiac arrest or syncope. NSVT was associated with a worse prognosis only in patients with symptoms of impaired consciousness, and, thus, it was not recommended that asymptomatic patients with NSVT undergo further testing. The finding of NSVT on ambulatory monitoring should not automatically lead to antiarrhythmic therapy, but it should alert the physician that further evaluation of the patient is needed (73).



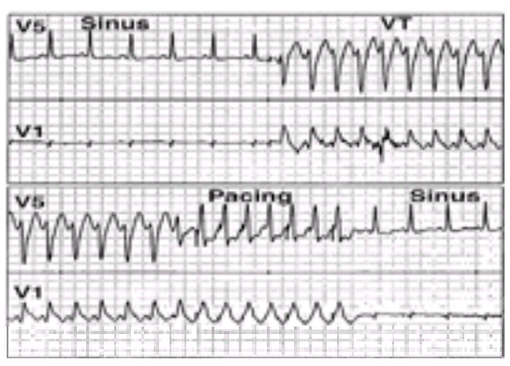
Hypertrophic cardiomyopathy. Inverted precordial T waves associated with hypertrophic cardiomyopathy.

Evaluating Therapy

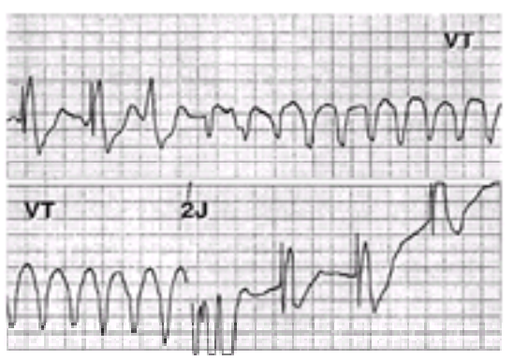
Twenty-four-hour ambulatory ECG monitoring is useful in assessing the response to antiarrhythmic therapy, the performance of a permanent pacemaker, and the causes of shocks from an implantable defibrillator.

Generally, 24-hour ambulatory monitoring is used in conjunction with electrophysiologic and treadmill exercise testing to assess the response of serious ventricular arrhythmias to antiarrhythmic drug therapy. Response to antiarrhythmic therapy can be judged using serial ambulatory monitoring in patients who have a high density of spontaneous ventricular arrhythmias and in whom a ventricular arrhythmia is not induced at electrophysiologic testing (74,75). This approach should be used with caution because of the spontaneous variation that occurs in the frequency of cardiac arrhythmias during 24-hour ambulatory monitoring. Multiple studies have emphasized the importance of long-duration recordings (76,77,78,79,80,81 and 82) to help diminish the effect of spontaneous variability. It is not uncommon for arrhythmias to diminish during sleep and increase with activity. Statistically significant reduction in PVC activity is observed only when a 90% reduction in PVCs occurs over the course of 24 hours. Spontaneous variability in complex ventricular arrhythmias, including runs of ventricular tachycardia, is significantly higher in patients with coronary artery disease (77,78). Ambulatory monitoring may be less effective in predicting clinical outcome with amiodarone (83). Ambulatory monitoring is useful in patients with atrial fibrillation, atrial flutter, and atrial tachycardia to determine whether adequate rate control is achieved with AV nodal–blocking drugs during activity and periods of emotional stress, while avoiding prolonged pauses during periods of inactivity or sleep.

Questions of pacemaker function are often assessed with 24-hour ambulatory monitoring. Failure to sense or pace that is not easily detected during a brief interrogation of the pacemaker may be apparent during 24-hour monitoring. Finally, older implantable cardioverter defibrillators lack the ability to record intracardiac electrograms to identify the mechanism of an arrhythmia that initiated antitachycardia therapy or defibrillation (eFig. 61.0.12 and eFig. 61.0.13). Such patients may present with frequent shocks but without symptoms that suggest cardiac arrhythmia. Shocks may be inappropriate, and sinus tachycardia or atrial fibrillation may be misinterpreted as ventricular tachycardia. In addition, lead problems can result in oversensing and inappropriate shocks from the device. Twenty-four-hour ambulatory monitoring and memory-loop event recording are useful to identify the rhythm that initiates device therapy. Newer implantable cardioverter defibrillators have monitoring as part of their solid-state circuitry that allows recording and displaying of the intracardiac electrogram to confirm that the device is functioning appropriately.



***e*FIGURE 61.0.12** A 24-hour ambulatory electrocardiographic recording in a patient with an implantable cardioverter defibrillator who is experiencing multiple episodes of palpitations and occasional shocks. The ambulatory recording documents sinus rhythm, then the onset of ventricular tachycardia (VT) that is appropriately detected and terminated with antitachycardia pacing.



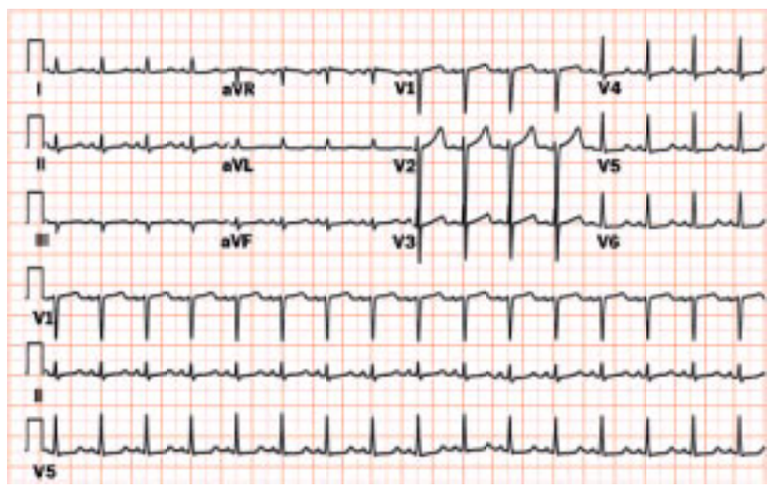
***e*FIGURE 61.0.13** Memory-loop electrocardiographic recording in a patient using an implantable cardioverter defibrillator for management of ventricular tachycardia (VT) who is now experiencing shocks without any additional symptoms. A recording during one of the shocks documents an episode of VT, appropriately converting to sinus rhythm after a 2-J shock.

Heart-Rate Variability, ST Segment Changes, and QT Interval

Ambulatory ECG monitoring has proved helpful for assessing autonomic tone, through measurement of RR intervals and assessment of heart-rate variability (seeChapter 77), and for ascertaining the frequency of silent and symptomatic myocardial ischemia through ST segment analysis (seeChapter 16). QT interval prolongation is a marker of repolarization changes associated with malignant ventricular arrhythmia, termed *torsades de pointes* (84).

A 51-year-old female patient with torsades de pointes.

Twenty-four-hour ambulatory monitoring identifies dynamic changes in the QT interval (85). Formulas used to correct the QT interval for heart rate introduce distortion that may cause abnormal values to appear at slow and rapid heart rates (86). Preliminary evaluation of healthy patients shows a longer corrected QT interval (QTc) during ambulatory monitoring (445 ± 12 ms) than is seen on the resting ECG, with women having a longer QTc than men. The QTc is longest immediately after awakening. Molnar and associates (87), assessing 21 healthy patients, reported that peak prolongation in QTc and maximum variability occurred shortly after patients woke up, reflecting increased autonomic instability during early waking hours that corresponds with the peak period for increased vulnerability to ventricular tachycardia and sudden death. A study by Algra and colleagues (88) evaluated the effects of variability in the duration of the QT interval on the occurrence of sudden death, comparing ambulatory recordings in 104 patients who died suddenly with 201 patients randomly drawn from a cohort of 6,693 consecutive patients undergoing 24-hour monitoring. Both prolonged mean QTc and shortened mean QTc over the course of 24 hours were associated with a more than twofold risk of sudden death, compared with intermediate mean QTc values.



Hypocalcemia. Marked prolongation of the QT segment is appreciated in lead II.

Personal Perspectives

Ambulatory ECG is useful for stratifying a patient's risk for malignant ventricular events after acute myocardial infarction. Use of ambulatory ECG to assess rhythm abnormalities as a cause of intermittent symptoms will decrease and be replaced by use of memory-loop recorders that are either worn externally or implanted. These devices are better than ambulatory monitoring for assessing infrequent but worrisome symptoms that suggest cardiac arrhythmia.

Conclusions

Ambulatory ECG monitoring is an established clinical test that demonstrates increasing usefulness for evaluating patients who have arrhythmia and ischemia and for assessing factors associated with increased risk of sudden death. Technological advances will continue to enhance ambulatory ECG, making reductions in the size of recorders, longer recording periods, and more rapid and accurate analysis possible. The technique increasingly will be used to assess predictors of sudden cardiac death, including prolongation of the QT interval and assessment of autonomic tone with heart-rate variability. These risk factors will be used in combination to better select patients at the highest risk who will benefit from the implantable cardioverter defibrillator. Enhancement of algorithms used to measure QT interval, heart-rate variability, and signal-averaged ECG will make ambulatory recording an integral part of risk-stratification after myocardial infarction. Memory-loop recorders will play an increasingly important role in assessment of patients who have intermittent symptoms that suggest cardiac arrhythmia. The implantable memory-loop recorder will be used commonly in patients who have infrequent episodes of near syncope and syncope.

SIGNAL-AVERAGED ELECTROCARDIOGRAPHY

Historical Perspective

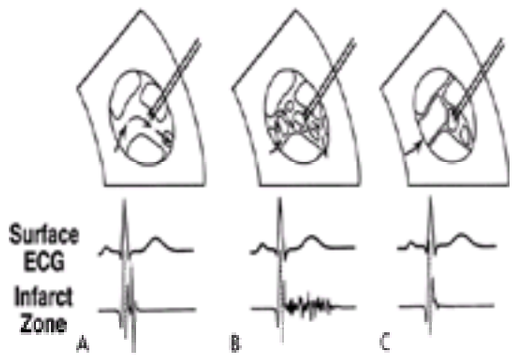
Signal averaging of the surface ECG is a noninvasive computerized method of analyzing standard ECGs that identifies patients who are at risk for ventricular tachycardia (89,90,91,92 and 93). This high-resolution ECG technique averages multiple QRS complexes, minimizing the level of noise that contaminates the periodic ECG signal, thereby exposing signals at the microvolt level that are normally hidden within noise (92). The technique identifies electrical signals at the end of the QRS complex, termed *late potentials*, that represent delayed conduction through diseased myocardium and thus a potential physical substrate for reentrant ventricular tachycardia. Late potentials have been correlated with clinical ventricular tachycardia, ventricular tachycardia inducibility at the time of electrophysiologic testing, and arrhythmic events after myocardial infarction (93).

Signal averaging was first used in ECG to noninvasively record a bundle of His electrogram (94,95). Han and associates (96) then demonstrated in 1969 that electrical activity may persist beyond the QRS complex after myocardial infarction in the canine heart. These potentials were referred to as *delayed ventricular potentials* and were later recorded by Durrer and coauthors in 1971 (97). The relationship of late potentials to the genesis of ventricular arrhythmias was subsequently demonstrated in the early 1970s (98,99,100,101 and 102). Simson (103) reported methods for recording and analyzing late potentials in patients. These technical advances introduced time-domain analysis of the signal-averaged ECG and subsequent correlation of late potentials with ventricular arrhythmias.

Pathophysiology of Late Potentials

In 1973, Boineau and Cox (102) demonstrated that electrograms recorded from ischemic regions of the canine myocardium were fractionated and delayed beyond the QRS complex and into the ST segment. Delayed activation is the substrate for reentrant ventricular tachycardia in patients with acute or remote myocardial infarction (98,99,101,104). Josephson and associates (105) described intracardiac recordings of low-level diastolic electrical activity during ventricular tachycardia, representing reentry within the border zone of the infarction. The low-level late potentials recorded directly from the heart can also be recorded from the body surface using a method of high amplification, band-pass filtering, and signal averaging (106).

Late potentials are usually found in border zones surrounding the scar of a previous myocardial infarction. Fibrosis forms an insulating boundary between muscle bundles and Purkinje tissue that slows and fragments the wave of electrical depolarization as it sweeps through the ventricular myocardium, constituting the substrate for reentry. Endocardial recordings of electrical depolarization from a border zone demonstrate conduction delay and fragmentation (eFig. 61.0.14). The border zone is both the source of late potentials and the substrate for reentrant ventricular tachycardia. Signal-averaged ECG has subsequently been demonstrated to record delayed electrical activation through the myocardium in several pathologic conditions in addition to myocardial ischemia. Abnormal conduction and delayed potentials are present in patients with hypertrophic cardiomyopathy, dilated cardiomyopathy, arrhythmogenic right ventricular dysplasia, myocarditis, and infiltrative heart disease. The technique has been extended to the atrium, where measures of atrial conduction delay correlate with the development of atrial fibrillation.



***e*FIGURE 61.0.14** Late potentials occurring in the border zone of experimental myocardial infarction in the canine model. **A:** No conduction delay with a normal QRS complex recorded by both the surface electrocardiogram (ECG) and the electrode from the infarct zone. **B:** Conduction delay through myocardial cells that are surrounded by areas of infarction. The surface ECG continues to be normal, because the mass of myocardium affected by the conduction delay is too small to generate a complex that can be recorded by the surface ECG. In contrast, the electrode recording from the infarct zone demonstrates delayed conduction, or late potentials, as the impulse traverses through the abnormal myocardium. It is this area of delayed conduction that is recorded by the signal-averaged ECG, which amplifies the low-level signal and reduces the associated noise. **C:** Conduction block and inability of the electrical impulse to penetrate or conduct through the infarct zone. (Adapted from El-Sherif N, Scherlag BJ, Lazarr R, et al. Reentrant ventricular arrhythmias in the late myocardial infarction period. I: Conduction characteristics in the infarction zone. *Circulation* 1977;55:686.)

Technical Aspects of Signal-Averaged Electrocardiography

Commercially available equipment for performing signal averaging includes ECG leads, an amplifier, an analog-digital converter, and a personal computer with software that can be used to average the QRS waveforms and store data. Signal-averaged ECG originally required dedicated equipment but now may be included as part of a standard ECG machine. The patient interface and front-end electronics are of primary importance for data acquisition and analysis.

The patient's skin must be cleansed and mildly abraded before attachment of the electrode to help reduce noise generated by artifact from the electrode-skin interface. A significant clinical problem with recording low-level bioelectrical signals from the heart is extraneous noise; reduction of such noise is necessary, because the amplitude of delayed ventricular activity is usually smaller than the amplitude of electrical noise produced by the patient or environmental sources. The noise in ECG recording generally ranges from 8 to 10 mV and primarily has three origins: (a) skeletal muscle, principally from respiratory muscles; (b) 50 or 60 Hz from electrical equipment; and (c) electrical feedback from amplifiers and electrodes (92). The purpose of signal averaging is to improve the signal-to-noise ratio to allow the detection of low-amplitude bioelectrical signals (107).

Bipolar XYZ leads are most commonly used to obtain a signal-averaged ECG, with each lead amplified from 1 × 104 to 2.5 × 104 and converted in a digital format at a sampling frequency of 1,000 to 2,000 times per second. Effective signal averaging requires that the signal of interest remain constant and unchanging so that it can be separated from the more random signal generated by noise. Only identical QRS complexes are averaged, because complexes with noise or aberrant conduction mask low-level late potentials. Typically, systems analyze a set number of QRS cycles or until the noise has been reduced to a satisfactory level. The resulting waveform appears smooth and continuous, and the noise, because it is random, is reduced by the averaging technique. In general, noise is proportional to the square root of the number of averaged cycles and is reduced to less than 1 mV by proper signal averaging techniques.

Signal averaging is the first of several electronic signal processing steps used to detect late potentials (108). High-pass filtering is used to remove the ST segment and the T wave; both are slowly changing, low-frequency signals relative to the late potential and QRS complex, and they may obscure the small low-level late potentials. The high-pass filters most commonly used are 25, 40, and 80 Hz. The 40-Hz filter is used most frequently.

Time-Domain Methods

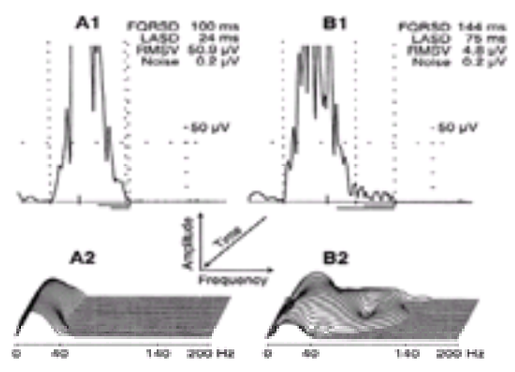
Commercially available signal-averaged ECG systems use time-domain analysis to detect late potentials either with uncorrected bipolar XYZ lead signals processed by a bidirectional Butterworth filter (109,110,111,112,113,114 and 115), with bipolar XYZ leads and a bispectral filter, or with Frank XYZ leads and a spectral filter (116,117). The bidirectional Butterworth and spectral filters both have merits and drawbacks, and neither method of filtering is superior (118). Used bidirectionally, the Butterworth filter is excellent for detecting the end of the QRS complex, but it is not suitable for obtaining accurate measurements of the root mean square amplitude or energy of the major waves of the QRS (118). The spectral filter can be designed so that is has a well-defined frequency response and can attenuate the ST segment, but it will prolong the duration of the QRS complex and P wave (119). Whichever signal-averaged ECG system is used, the criteria used to identify late potentials must be developed specifically for that recording system (109).

Frequency-Domain Methods

Time-domain analysis of the signal-averaged ECG has several limitations: It may be difficult to define the end of the QRS complex; high-pass filters may attenuate or abolish late potentials; and late potentials may be difficult to distinguish from random noise. Frequency-domain analysis of the signal-averaged ECG has the advantage that it does not require complex high-pass filtering. Fast Fourier transform analysis is an analytical method used for signal processing in the frequency domain that avoids some of the limitations of high-gain amplification and signal filtering that come with time-domain analysis (120).

The QRS complex is a periodic signal that may be represented by the mathematical summation of a series of sine waves of different frequencies and amplitudes (120). The lowest-frequency sinusoidal component of the QRS complex is called the *fundamental*, and it has a repetition rate equal to that of the periodic signal under evaluation. All higher sinusoidal components of the signal in question have frequencies that are multiples of this fundamental frequency. Fast Fourier transform analysis is a computer-based mathematical algorithm that allows determination of the amplitudes of the various harmonic components that comprise a complex periodic waveform, such as the QRS complex. For each time-domain signal, there is one and only one frequency-domain presentation (120). Frequency-domain analysis evaluates the terminal QRS complex and has the advantage that it does not require decisions about the optimal choice of high- and low-pass filters, and thus it reduces the risk that the late potential will inadvertently be removed from the analyzed signal (121). The likelihood of distorting the underlying signal by amplification and filtration is also reduced using fast Fourier transform analysis.

Other frequency analysis methods that can be used to evaluate the terminal portion of the QRS complex include time-window techniques, such as spectral temporal mapping (122,123) and spectral turbulence analysis (124), and autoregressive methods, such as maximal entropy (125) and adaptive frequency determination (126) (*e*Fig. 61.0.15). Frequency-domain analysis using a window function is not suitable if specific frequency peaks are required, but it is suitable if identification of frequency bands is optimal (91). If spectral peaks, in addition to timing information, are required for signal analysis, then the moving time-window and autoagressive methods must be used. These techniques have been reported (127,128) to overcome the need to use different criteria in patients with bundle branch block and conduction defects and are less dependent on noise levels occurring during signal-averaged ECG recording. Satisfactory end points of spectral analysis have not been standardized.



***e*FIGURE 61.0.15** Time-domain and spectral temporal mapping recordings from a patient without (A1 and A2) and a patient with (B1 and B2) ventricular tachycardia. In the patient without ventricular tachycardia, the time domain (A1) is normal, and the corresponding spectral temporal map (A2) is normal, with no frequency content

between 40 and 140 Hz. In the patient with ventricular tachycardia, clear late potentials are recorded by time-domain analysis (B1), and the corresponding spectral temporal map (B2) demonstrates high-frequency components between 40 and 140 Hz. FQRSD, QRS duration after filtering; LASD, low-amplitude signal duration; RMSV, root mean square voltage. (Adapted from Kulakowski P, Malik M, Poloniecki J, et al. Frequency versus time domain analysis of signal averaged electrocardiograms. II: Identification of patients with ventricular tachycardia after myocardial infarction. *J Am Coll Cardiol* 1992;20:135–143.)

Comparison of Time- and Frequency-Domain Methods

The value of time-domain analysis for the identification of late potentials and selection of patients at risk for ventricular arrhythmias has been confirmed in numerous studies. Similarly, several studies have shown that differences in the frequency content of the QRST segment help to identify patients with ventricular tachycardia (120,127,129). Cain and associates (120) reported that 15% of patients without and 8% of patients with sustained ventricular tachycardia showed an increase in the amplitude of the high-frequency components in the terminal QRS complex. In a subsequent study, the same authors (129) demonstrated that the terminal 40 ms of the QRS complex and the ST segment contained ten- to 100-fold greater amplitude of components in the 20- to 50-Hz range in patients with ventricular tachycardia compared to those without tachycardia. Similar findings were reported by Haberl and coauthors (127). However, there has been controversy as to the value and reproducibility of frequency-domain analysis (121,130,131,132 and 133). Worley and associates (121) reported that the results of frequency analysis depended on the length of the analyzed segment and that only magnitude area ratios in the intervals starting 60 ms after the onset of the QRS complex differentiated patients with and without ventricular tachycardia. Kelen and associates (134) reported that a 3-ms change in the length of the analyzed segment resulted in marked changes in area ratio and that frequency-domain analysis could not distinguish patients with ventricular tachycardia or late potentials from patients without ventricular tachycardia or late potentials.

Spectral temporal mapping has been reported to be a possible solution to some of the technical difficulties in attaining reproducibility with frequency-domain methods (135,136). Haberl and associates (123) reported that spectral temporal analysis of the terminal QRS complex, including the ST segment, correlated well with the diagnosis of late potentials using criteria based on time-domain analysis, and that this technique performed better than time-domain analysis in identifying patients with ventricular tachycardia. These findings were challenged by Odemuyiwa and coworkers (133), who reported that time-domain analysis was superior to spectral temporal mapping in predicting arrhythmic events in postinfarction patients. Malik and associates (131) compared the reproducibility of frequency-domain and time-domain analysis of signal-averaged ECGs in 40 subjects and found that reproducibility was significantly higher for the time-domain method than for spectral temporal mapping. Kulakowski and coauthors (132) compared the results of time-domain, frequency-domain, and spectral temporal mapping analysis of the signal-averaged ECG in 30 postinfarction patients with and 30 postinfarction patients without spontaneous sustained ventricular tachycardia. They concluded that, compared with time-domain analysis, frequency-domain analysis and spectral temporal mapping did not improve the identification of postinfarction patients with ventricular tachycardia. Similar results were reported by Mittleman and colleagues (137) in a study including 50 patients who had histories of coronary disease and ventricular tachycardia and 25 normal subjects. Time-domain analysis was superior to spectral temporal mapping, including in patients with bundle branch block. Spectral temporal mapping analysis has a significant problem with false-positive results and less favorable reproducibility.

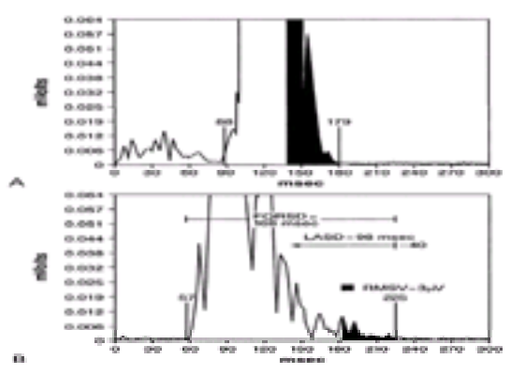
At this time, it must be concluded that spectral temporal mapping and frequency-domain analysis of the ECG are less useful than time-domain analysis for predicting arrhythmic events in postinfarction patients. It is still not clear if frequency-domain analysis of patients with bundle branch block may have a role in risk-stratification. The remainder of this chapter will deal with time-domain analysis of the signal-averaged ECG.

Recordings Using Ambulatory Electrocardiography

Signal-averaged ECG has been applied to 24-hour ambulatory ECG monitoring in an attempt to gain additional diagnostic information from the ambulatory ECG (138). Ambulatory signal-averaged ECG monitoring has several technical differences from signal-averaged ECG obtained at the patient's bedside. The signal-averaged ECG uses XYZ recording leads, and the ambulatory method uses V_1, V_5, and aVF. The diagnostic criteria for signal averaging has been developed with XYZ data and, therefore, may not be directly applicable to data obtained by different lead sets. Other significant differences include the recording bandwidth, the sampling rate, and the filter used (138). Ambulatory signal-averaged ECG requires more cardiac beats—more than 1,000—to be averaged to allow adequate noise reduction. Despite technical differences, clinical studies have described close correlation of signal-averaged ECG parameters in standard and ambulatory signal-averaged ECG (139). The 24-hour monitoring period has the potential advantage of evaluating individuals under various conditions, including physical and emotional stress that may not be present when the standard signal-averaged ECG is obtained. However, ambulatory signal-averaged ECG needs to be restricted to quiet activities that do not induce skeletal-muscle myopotential artifact or noise.

Late Potential Criteria

After the signals are averaged and filtered, three methods are used to identify the presence or absence of late potentials at the terminal QRS (eFig. 61.0.16). The first method is to assess the total QRS duration after filtering (FQRSD). Because late potentials are continuous with the end of the QRS, they increase the overall QRS duration. The second method is to calculate the root mean square voltage (RMSV) of the last 40 ms of the vector magnitude QRS complex. Late potentials are low-amplitude signals, and the measurement is much smaller when late potentials are present. The third method is to calculate how much of the terminal vector magnitude complex lies below the 40-µV level, the low-amplitude signal duration (LASD). Once the computer software program determines the baseline noise level, it moves backward in time to identify the offset of the QRS complex and then the point at which the QRS complex increases to the 40-µV level. That point in time is marked, and a calculation is made to determine how much of the terminal vector magnitude QRS complex in ms lies under the 40-µV level. Averaging to lower noise levels results in longer QRS duration and affects reproducibility (140).



***e*FIGURE 61.0.16 A:** Normal signal-averaged electrocardiogram (ECG) showing a QRS duration after filtering (FQRSD) of 91 ms, a root mean square voltage (RMSV) of 96 µV, and a low-amplitude signal duration (LASD) of 18 ms. **B:** A signal-averaged ECG obtained in a patient with a prior anterior myocardial infarction and ventricular tachycardia. The QRS demonstrates a prolonged FQRSD of 168 ms, a reduced RMSV of 3 µV, and a prolonged LASD of 98 ms. This signal-averaged ECG meets the criteria for the presence of late potentials, whereas **(A)** does not. See text for details.

Commercially available signal-averaging systems use different lead configurations, filters, and processing algorithms. Therefore, criteria to define the absence or presence of late potentials and establish a normal range (eTable 61.0.3) need to be developed for each system (109). The important, pioneering work of Simson (103) set out criteria developed with a bidirectional 25-Hz Butterworth filter and uncorrected bipolar XYZ leads. Since this initial work, further studies have indicated that the 40-Hz filter is preferable to the 25-Hz filter, because it provides improved sensitivity and reproducibility (112,113,114 and 115). Gomes and associates (141), using a 40-Hz bidirectional Butterworth filter with uncorrected bipolar XYZ leads, determined optimal criteria for identifying late potentials in 25 normal subjects: FQRSD >114 ms, LASD >38 ms, and RMSV <20 µV. Denes and colleagues (112), using a system with a 40-Hz Butterworth filter and uncorrected bipolar XYZ leads in 42 normal subjects, determined that late potentials were identified by FQRSD >120 ms, LASD >38 ms, and RMSV <20 µV.

***e*TABLE 61.0.3** NORMAL LIMITS FOR SIGNAL-AVERAGED ELECTROCARDIOGRAPHY PARAMETERS

	FQRSD (ms)	LASD (ms)	RMSV (µV)
Butterworth filter, bipolar XYZ leads, 40- to 250-Hz filtering			
Gomes (141)[a] (n = 25)	114	38	20
Danford (142)[a](n = 32)	119	47	NA
Raineri (143)[a](n = 63)	115	48	2

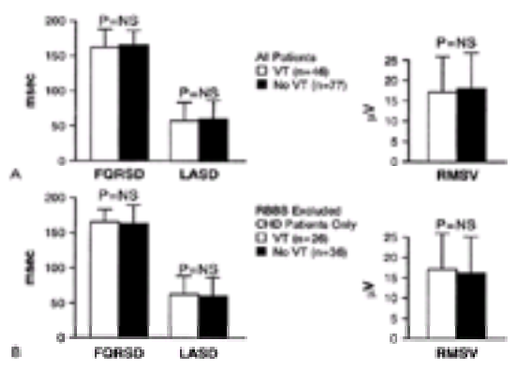
Fourier transform filter, frank XYZ leads			
Timmermans (116)[b]			
Men (n = 100)	122	41	20
Women (n = 85)	115	41	20

FQRSD, filtered QRS duration; LASD, low-amplitude signal duration (<40 µV); NA, not applicable; RMSV, root mean square voltage terminal 40 ms.
[a]Mean ± 2 standard deviations for FQRSD; low 5% confidence limits for RMSV.
[b]Ninetieth percentile for FQRSD, LASD; lower tenth percentile for RMSV.

A system using a 40-Hz high-pass filter, Frank XYZ leads, and fast Fourier transform filter was evaluated by Timmermans and coworkers (116) in a study of 185 patients without heart disease. The study included 85 women and 100 men and took into account information on gender and body-size differences in the definition of late potentials. They reported the following gender-specific normal values: in men, FQRSD <122 ms; in women, FQRSD <115 ms; and in both genders, LASD <41 ms and RMSV >20 µV. Other authors (142,143) have reported similar gender differences for FQRSD, with women having shorter FQRSD. Separate FQRSD criteria should be used for men and women. Signal-averaged ECG criteria are different in children and adolescents because of the shorter QRS duration (144).

Signal-averaged ECG criteria were reported in 182 patients with known coronary artery disease and previous myocardial infarction who underwent programmed ventricular stimulation (117). The signal-averaged ECG variables that best characterized control subjects and separated patients with and without inducible ventricular tachycardia were an FQRSD <120 ms, an LASD <38 ms, and an RMSV >20 µV. El-Sherif and coworkers (145) evaluated 1,158 patients in the Cardiac Arrhythmia Suppression Trial and reported that an FQRSD >120 ms was the most predictive criterion for arrhythmic events.

Evaluation of the signal-averaged ECG using time-domain variables has excluded patients with conduction defects. A conduction defect, including bundle branch block or intraventricular conduction delay, with late depolarization of a large muscle mass may mask diagnostic late potentials. This difficulty was reported by Buckingham and associates (146) when they used altered criteria (longer FQRSD and LASD and lower RMSV) to maintain sensitivity and specificity in patients with conduction defects. Although they attained good results with their model, other investigators have found the signal-averaged ECG to be of limited value in patients who show conduction defects (100,109). Ommen and coauthors (147) reported 123 patients with a standard QRS >118 ms who underwent signal-averaged ECG and subsequent electrophysiologic testing (*e*Fig. 61.0.17). No signal-averaged ECG variables differed significantly between patients with and patients without inducible ventricular tachycardia. The study concluded that signal-averaged ECG time-domain variables cannot be used to predict inducibility of ventricular tachycardia during electrophysiologic testing in patients who display conduction defects. Frequency-domain analysis may improve the predictive accuracy in patients who show bundle branch block (148), although the findings have been difficult to reproduce.

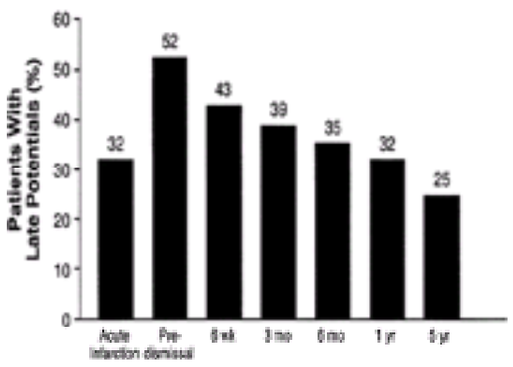


***e*FIGURE 61.0.17** Signal-averaged electrocardiography (ECG) in patients with conduction defects. **A:** One hundred twenty-three patients were evaluated, and 46 patients had ventricular tachycardia (VT) induced at electrophysiologic testing. Using multivariate analysis, no signal-averaged ECG criteria separated patients with ventricular tachycardia from patients without ventricular tachycardia. **B:** No signal-averaged ECG criteria separated the 26 patients with ventricular tachycardia from the 36 patients without ventricular tachycardia, despite the exclusion of right bundle branch block and the inclusion of only those patients who had known coronary heart disease. FQRSD, QRS duration after filtering; LASD, low-amplitude signal duration; NS, not significant; RMSV, root mean square voltage. (Adapted from Ommen SR, Hammill SC, Bailey KR. Failure of signal-averaged electrocardiography with use of time-domain variables to predict inducible ventricular tachycardia in patients with conduction defects. *Mayo Clin Proc* 1995;70:132–136.)

Signal-Averaged Electrocardiography in Specific Clinical Syndromes

Late Potentials after Myocardial Infarction

Late potentials increase during the initial days after myocardial infarction and slowly decrease over subsequent months (*e*Fig. 61.0.18) (148). McGuire and associates (149) studied the natural history of late potentials after myocardial infarction, obtaining serial signal-averaged ECGs early after admission and at the time of hospital dismissal. Early after the onset of myocardial infarction, approximately 30% of patients have late potentials that increase to 50% at the final predischarge study (150). A subsequent study by Kuchar and associates (151) followed 234 patients after myocardial infarction and reported that 18% of patients who had late potentials at hospital discharge no longer had an abnormal signal-averaged ECG at 6 weeks, 39% had lost late potentials by 12 months, and 52% of 5-year survivors demonstrated a resolution of late potentials. Importantly, fewer than 5% of patients without late potentials at the initial recording subsequently developed late potentials in the absence of another myocardial infarction.



***e*FIGURE 61.0.18** Natural history of late potentials after myocardial infarction. Fifty-two percent of patients have late potentials at the time of dismissal after myocardial infarction. This incidence slowly decreases during follow-up, with only 32% having late potentials at 1 year and 25% at 5 years. Fewer than 5% of patients who do not have late potentials before hospital dismissal will develop late potentials during follow-up in the absence of an intervening myocardial infarction.

Late potentials are an independent risk factor for developing ventricular arrhythmias after myocardial infarction (*e*Table 61.0.4) (149,150,151,152,153,154,155,156,157,158,159,160,161,162,163,164,165,166 and 167) and have been detected in 39% to 93% of patients who subsequently develop a ventricular arrhythmia or experience sudden cardiac death (101). Among patients with late potentials, between 8% and 48% develop sustained ventricular tachycardia or sudden death, and fewer than 5% of patients without late potentials will have arrhythmic complications. The negative predictive accuracy ranges from 88% to 99%, and the positive predictive accuracy ranges from 8% to 29% (101). The majority of studies show a positive predictive accuracy of approximately 20% for the ability of signal-averaged ECG to identify risk for malignant ventricular arrhythmias in patients recovering from myocardial infarction. It is this low-positive predictive accuracy that makes the test less useful as a single diagnostic study for identifying patients at risk of ventricular arrhythmia. Typically, the signal-averaged ECG results are combined with ejection fraction, ventricular arrhythmia on ambulatory monitoring, or heart-rate variability to improve predictive accuracy (*e*Table 61.0.5).

The use of thrombolytic therapy has had a significant effect on the presence and prognostic implications of late potentials identified by the signal-averaged ECG (168). The presence of an open artery after reperfusion therapy reduces the incidence of late potentials (168,169,170 and 171) (*e*Fig. 61.0.19). Late potentials are present in

25% to 65% of patients with a closed infarct-related artery, whereas an open infarct-related artery reduces the incidence of late potentials to 6% to 34%. Thrombolytic therapy is associated with an incidence of late potentials of 5% to 17%. The use of thrombolytic therapy has significantly reduced the incidence of death after myocardial infarction, and this reduced event rate has negatively affected the predictive value of the signal-averaged ECG.

The signal-averaged electrocardiogram and ventricular arrhythmias after thrombolysis for acute myocardial infarction. *J Am Coll Cardiol* 1990;15:1270–1276.)

Malik and coworkers (171) reported 331 survivors of acute myocardial infarction, 130 of whom were receiving thrombolytic therapy, who were followed for 10 months. An arrhythmic event occurred in 8.5% of patients without and 6.2% of patients with thrombolytic therapy. The usefulness of late potentials to predict subsequent arrhythmic events was substantially worse in the patients who were receiving thrombolytic therapy than in those who were not receiving thrombolytic therapy, with a threefold lower positive predictive accuracy. McClements and Adgey (165) evaluated 301 survivors of myocardial infarction, of whom 68% received thrombolytic agents. The signal-averaged ECG and ejection fraction were independent predictors of subsequent events. Steinberg and associates (172) reported the results of signal-averaged ECG in 159 patients who were receiving thrombolytic therapy 6 to 24 hours after myocardial infarction and 151 patients who did not receive thrombolytic therapy. Thrombolytic therapy reduced the frequency of an abnormal FQRSD >120 ms from 19% to 12%. This change was confined to the subgroup of patients who showed ST elevation on their presenting ECG.

Similar results were reported by Hohnloser and colleagues (173) in 173 patients with acute myocardial infarction, of whom 51% were treated with thrombolytic therapy. An open infarct-related artery was documented in 136 patients. When multivariate analysis was performed, an occluded infarct-related artery and the presence of regional wall motion abnormalities were the strongest independent predictors for the development of late potentials, which occurred in 24% of patients. During a mean follow-up of 12 months, the mortality rate was 4.1%; seven patients died suddenly or experienced ventricular fibrillation, and two patients had sustained monomorphic ventricular tachycardia. Multivariate analysis revealed that only an occluded infarct-related artery was an independent predictor of arrhythmic complications, and that late potentials were less helpful in identifying patients at risk for sudden death. Signal-averaged ECG should be combined with other prognostic tests to improve its predictive accuracy in identifying patients at risk for an arrhythmic event after thrombolytic therapy.

Sustained Ventricular Tachycardia with Ischemic Heart Disease

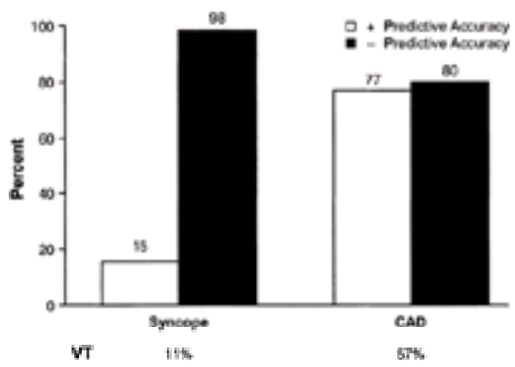
The majority of patients who have documented ventricular tachycardia and ischemic heart disease also have late potentials; the incidence ranges from 52% to 90% (91) (*e*Table 61.0.2). Late potentials are identified in 21% to 65% of patients who present with ventricular fibrillation (174,175). The test is less useful in these two populations, because they have already presented with cardiac arrhythmia. The signal-averaged ECG is most useful for predicting which patients are at risk for subsequent arrhythmia, rather than in patients who have already presented with clinical arrhythmia, because treatment is dependent on the arrhythmia and not on the

presence or absence of late potentials.

The value of detecting late potentials by signal-averaged ECG to predict ventricular tachycardia during electrophysiologic testing in patients with ischemic heart disease is well accepted (113,114 and 115). A study of 182 patients with coronary artery disease who were undergoing electrophysiologic testing for multiple reasons, including a history of syncope, NSVT, and sustained ventricular tachycardia, showed a sensitivity of 87%, a specificity of 65%, and a positive predictive value of 77% for identifying patients at risk for inducible ventricular tachycardia (117).

Predictive Power of Late Potentials Depends on the Prevalence of Coronary Artery Disease

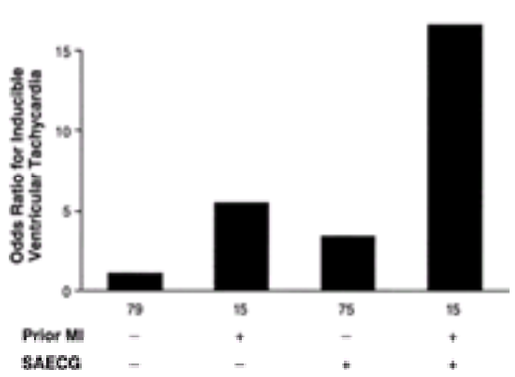
The negative predictive accuracy of signal-averaged ECG is noted to be 95% to 99% in patients with syncope and in patients after myocardial infarction. These patients have a low incidence of ventricular events and, therefore, a high-negative predictive accuracy would be expected. The signal-averaged ECG has a low-positive predictive accuracy of 15% to 20% for identifying patients at risk for subsequent malignant ventricular arrhythmia. In patients with known coronary artery disease and suspected ventricular tachycardia who subsequently undergo electrophysiologic testing, the negative predictive accuracy decreases to 80%, and the positive predictive accuracy improves to 77% (*e*Fig. 61.0.20) because of the increased disease prevalence. A lower-negative predictive accuracy is expected in testing these patients. When the suspicion for ventricular arrhythmia is high, the signal-averaged ECG should not be used to exclude further testing.



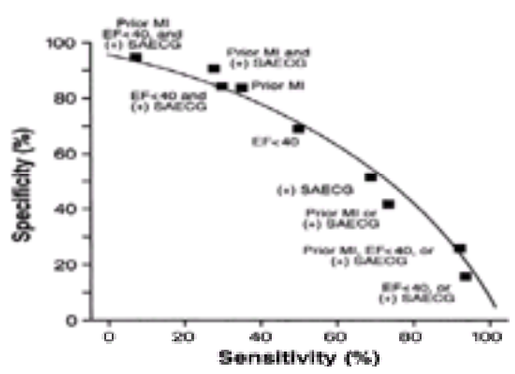
***e*FIGURE 61.0.20** The predictive accuracy of the signal-averaged electrocardiogram (SAECG) for identifying patients who will subsequently have ventricular tachycardia (VT) induced at electrophysiologic testing depends on the frequency of VT in the population studied. Patients with syncope have a low incidence of inducible VT (11%), a low-positive predictive accuracy (15%) and a high-negative predictive accuracy (98%). In contrast, patients with coronary artery disease (CAD) who are suspected of having VT have a higher inducibility (57%) and a higher-positive predictive accuracy (77%), but a lower-negative predictive accuracy (80%). Patients in whom there is a strong suspicion for VT should not be eliminated from electrophysiologic testing based solely on the results of the SAECG. (Adapted from Vatterott PJ, Bailey KR, Hammill SC. Improving the predictive ability of the signal-averaged electrocardiographic with a linear logistic model incorporating clinical variables. *Circulation* 1990;81:797–804; and Hammill SC, Tchou PJ, Kienzle MG, et al. Establishment of signal-averaged electrocardiographic criteria with Frank XYZ leads and spectral filter used alone and in combination with ejection fraction to predict inducible ventricular tachycardia in coronary artery disease. *Am J Cardiol* 1992;70:316–320.)

Syncope

Patients with syncope may undergo electrophysiologic testing to assess whether they have sustained ventricular tachycardia that is inducible and is a presumed cause of their clinical event. A negative signal-averaged ECG may preclude the need for electrophysiologic testing in such patients (176). Lacroix and associates (177) evaluated 100 patients who presented with syncope and underwent electrophysiologic testing. They reported that the signal-averaged ECG had a positive predictive value of 39% for predicting sustained monomorphic ventricular tachycardia. Kuchar and associates (178) reported on 150 consecutive patients who were evaluated for syncope by signal-averaged ECG and electrophysiologic testing, with late potentials identified in 29 patients, 16 of whom subsequently had inducible ventricular tachycardia. In their study, the signal-averaged ECG had a positive predictive value of 55% and a negative predictive value of 94%. Steinberg and associates (179) reported a multicenter study of 189 patients who were evaluated for unexplained syncope. Ventricular tachycardia was induced in 15% of the patients, and the signal-averaged ECG was the most sensitive test but had poor specificity. By multivariate analysis, the signal-averaged ECG and a history of a previous myocardial infarction were independently predictive of ventricular tachycardia, with the risk increasing 17-fold in patients with both abnormalities (*e*Fig. 61.0.21). In patients with no history of previous myocardial infarction, no additional testing was useful in identifying those at risk for inducible ventricular tachycardia. They concluded that the signal-averaged ECG was the most sensitive noninvasive test available for predicting sustained monomorphic ventricular tachycardia in patients with syncope, but that it yielded false-positive results in many patients, with a specificity of 55%. These authors stress the importance of combining different tests to improve predictive accuracies (*e*Fig. 61.0.22).



***e*FIGURE 61.0.21** The signal-averaged electrocardiogram (SAECG) is extremely helpful when it is combined with a history of myocardial infarction (MI) in predicting inducible ventricular tachycardia at electrophysiologic testing in patients with cardiogenic syncope. Patients with both a history of myocardial infarction and an abnormal SAECG have an odds ratio of 17 for inducible ventricular tachycardia. (Adapted from Steinberg JS, Prystowsky E, Freedman RA, et al. Use of the signal-averaged electrocardiogram for predicting inducible ventricular tachycardia in patients with unexplained syncope: relation to clinical variables in a multivariate analysis. *J Am Coll Cardiol* 1994;23:99–106.)



***e*FIGURE 61.0.22** Patients at risk of atrial fibrillation (AF) have a prolonged P-wave duration by signal averaging. The P-wave duration in patients without AF measured 116 ms, in contrast to the P-wave duration in patients with AF, which measured 162 ms. (Adapted from Guidera SA, Steinberg JS. The signal-averaged P-wave duration: a rapid and noninvasive marker of risk of atrial fibrillation. *J Am Coll Cardiol* 1993;21:1645–1651.)

Dilated, Hypertrophic, and Arrhythmogenic Right Ventricular Cardiomyopathy

Information in the literature is in conflict considering the usefulness of signal-averaged ECG in patients with dilated cardiomyopathy (180,181 and 182). Mancini and colleagues (183) reported on 114 patients with dilated cardiomyopathy and a mean ejection fraction of 22%. The 1-year survival rate was 50% in 54 patients with an abnormal signal-averaged ECG and 100% in 66 patients with a normal signal-averaged ECG. This report conflicts with the study by Turitto and coworkers (184), who reported on 80 patients who had NSVT, a mean ejection fraction of 20%, and dilated cardiomyopathy. Neither electrophysiologic testing nor signal-averaged ECG predicted arrhythmic events, total death rate, or survival rate.

Few studies have evaluated the usefulness of signal-averaged ECG in patients with hypertrophic cardiomyopathy (71,185). Cripps and associates (185) reported on 64 patients with hypertrophic cardiomyopathy, compared with 50 age- and gender-matched control subjects. An abnormal signal-averaged ECG was present in 20% of patients and only 4% of control subjects, with a significant correlation between the presence of NSVT on 48-hour ambulatory monitoring and an abnormal signal-averaged ECG. There was no association between an abnormal signal-averaged ECG and a family history of premature sudden death, syncope, maximum left ventricular wall thickness, or symptomatic status. This study included only a few patients who had experienced a significant cardiac event, and definite recommendations on the use of signal-averaged ECG in patients with hypertrophic cardiomyopathy cannot be made at this time.

Nava and associates (186) evaluated the signal-averaged ECG in 138 patients with arrhythmogenic right ventricular cardiomyopathy compared to 146 healthy control subjects. A high correlation was seen between patients who had the disease and the presence of ventricular tachycardia (94%; p <.02). Overall, the signal-averaged ECG was abnormal in 57% of patients and 4% of subjects.

Effect of Interventions on Late Potentials

Surgical procedures that remove the area of myocardium responsible for ventricular arrhythmia are associated with a reduction in the incidence of late potentials (187,188). The majority of patients have late potentials before surgery, and 56% continue to have late potentials after surgery. In patients who do not show late potentials after surgery, 90% will have no inducible ventricular tachycardia, whereas 85% to 100% of patients who do show late potentials will have sustained ventricular tachycardia that remains inducible after surgery.

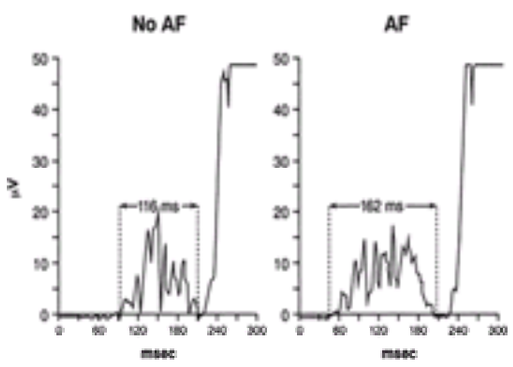
Angioplasty during acute myocardial infarction (189) reduces the incidence of late potentials. Reports are inconsistent as to whether signal-averaged ECG abnormalities are improved after the angioplasty procedure in patients with chronic coronary artery disease (190,191). In patients with coronary artery disease who are undergoing coronary artery bypass grafting, the signal-averaged ECG after surgery rarely detects abnormalities in patients without a history of myocardial infarction, but in patients with a history of myocardial infarction, abnormalities may resolve or improve after surgery (192). Twidale and coauthors (193) reported that radiofrequency ablation had no effect on late potentials in four patients in whom ablation of ventricular tachycardia was successful.

Cardiac Transplantation

The use of the signal-averaged ECG to identify patients who are experiencing cardiac transplant rejection has been reported in a few studies (194,195). Keren and associates (194) reported that temporal analysis of the signal-averaged ECG demonstrated a sensitivity of 65%, a positive predictive accuracy of 92%, and a negative predictive accuracy of 68% for identifying acute rejection. Lacroix and associates (195) reported that an 11% decrease in the RMSV using a 70-Hz high-pass filter provided a sensitivity of 88% and a specificity of 78% for the presence of rejection.

P-Wave Signal Averaging

Preliminary reports have evaluated the usefulness of signal averaging of the P wave in predicting patients at risk for atrial fibrillation (196,197,198,199 and 200) (eFig. 61.0.23). Both time- and frequency-domain analysis are helpful in assessing abnormal P waves (200). Increased P-wave duration and magnitude are associated with paroxysmal atrial fibrillation in patients after cardiac surgery (196) and in patients with hyperthyroidism (197). Steinberg and associates (196) reported on 133 patients who underwent P-wave signal averaging after cardiac surgery, of whom 33 developed atrial fibrillation at a mean of 2.6 days after surgery. A P-wave duration of more than 140 ms predicted atrial fibrillation with a positive predictive accuracy of 37% and a negative predictive accuracy of 87%. Standard technique and definition for identifying an abnormal P wave by signal-averaged ECG have not been established, although this does appear to be a promising method for identifying patients at risk for subsequent atrial fibrillation.



***e*FIGURE 61.0.23** Patients at risk of atrial fibrillation (AF) have a prolonged P-wave duration by signal averaging. The P-wave duration in patients without AF measured 116 ms, in contrast to the P-wave duration in patients with AF, which measured 162 ms. (Adapted from Guidera SA, Steinberg JS. The signal-averaged P-wave duration: a rapid and noninvasive marker of risk of atrial fibrillation. *J Am Coll Cardiol* 1993;21:1645–1651.)

Personal Perspectives

Signal-averaged ECG is proving to be less helpful as a single technique to risk-stratify patients. The low-positive predictive accuracy reduces the test's sefulness. The negative predictive accuracy is only high in a population of patients who are at low risk for an arrhythmic event. As the risk for an arrhythmic event increases (as determined by other factors, such as reduced ventricular function, presence of coronary artery disease, and complex ventricular arrhythmias), the negative predictive accuracy decreases. Therefore, a negative result of signal-averaged ECG should not preclude electrophysiologic testing in patients who are strongly suspected of having a ventricular arrhythmia. Signal-averaged ECG should be used in conjunction with other tests and clinical parameters to identify high-risk patients. Little further development will take place in time-domain analysis methods and diagnostic criteria. Frequency-domain analysis methods will continue to improve and, hopefully, will allow detection of delayed conduction in parts of the heart that are now obscured, either because they occur early in the QRS complex, as in anteroseptal infarction, or because they are masked by a ventricular conduction delay. Frequency-domain analysis is difficult to reproduce and to perform reliably outside of research institutions. Signal-averaged ECG has a minimal role in the evaluation of patients with dilated or hypertrophic cardiomyopathy and in assessing rejection in cardiac transplantation. P-wave signal averaging identifies patients at risk for atrial fibrillation, but it has little benefit for clinical management at this time.

Future Directions

The signal-averaged ECG identifies delayed conduction that represents the substrate for ventricular arrhythmia. Time-domain methods of analysis are used with criteria to define late potentials developed for each recording system. The test is not clearly useful in patients with conduction defects. Recommendations for use of the signal-averaged ECG have been published (*e*Table 61.0.6). The presence of late potentials after myocardial infarction identifies patients at risk for arrhythmic events, although the predictive accuracy is reduced after thrombolytic therapy. The signal-averaged ECG, combined with other prognostic tests and with patient history, identifies patients with syncope who are at risk for induced ventricular tachycardia on electrophysiologic testing. Signal-averaged ECG is less helpful in patients with dilated and hypertrophic cardiomyopathy and is not useful for predicting antiarrhythmic drug efficacy. New methods of analyzing the signal-averaged ECG may improve the test's predictive accuracy. The test is most useful for identifying patients at risk for ventricular tachycardia when combined with other prognostic tests. Research and development efforts will continue to focus on using frequency-domain analysis to identify delayed conduction that may not be observed using time-domain analysis, such as late potentials occurring early in the QRS complex in patients who have an acute anteroseptal myocardial infarction or late potentials masked by ventricular conduction defects.

***e*TABLE 61.0.6** RECOMMENDATIONS FOR USE OF SIGNAL-AVERAGED ELECTROCARDIOGRAM

Established value
Stratification of risk of development of sustained ventricular arrhythmias in patients recovering from myocardial infarction who are in sinus rhythm without electrocardiographic evidence of bundle branch block or intraventricular conduction delay (QRS complex >120 ms)
Identification of patients with ischemic heart disease and unexplained syncope who are likely to have inducible sustained ventricular tachycardia
Valuable in clinical care, further supportive evidence desirable
Stratification of risk of development of sustained ventricular arrhythmias in patients with nonischemic cardiomyopathy
Assessment of success of operation for sustained ventricular tachycardia
Promising but currently unproved
Detection of acute rejection of heart transplants
Assessment of efficacy or proarrhythmic effects of antiarrhythmic drug therapy in patients with ventricular arrhythmias
Assessment of success of pharmacologic, mechanical, or surgical interventions to restore coronary artery blood flow
Not indicated
Patients with ischemic heart disease and documented sustained ventricular arrhythmias
Stratification of risk of development of sustained ventricular arrhythmias in asymptomatic patients without detectable heart disease

From Cain ME, Anderson JL, Arnsdorf MF, et al. Signal-averaged electrocardiography. *J Am Coll Cardiol* 1996;27:238–249, with permission.

Spectral temporal mapping, spectral turbulence analysis, and autoregressive methods, including maximal entropy and adaptive frequency determination, may prove to be more useful than time-domain analysis in identifying delayed conduction. Models that incorporate clinical factors and results of noninvasive testing, including signal-averaged ECG, will increasingly be used to identify patients at highest risk for sudden death. Signal averaging of the P wave will gain importance as it becomes commercially available and is more commonly used to identify patients at risk for atrial fibrillation.

T-WAVE ALTERNANS

Historical Perspective

Electrical alternans must be distinguished from mechanical alternans, which occurs in the setting of pericardial effusion when the entire heart moves in an alternating pattern, resulting in a change in QRS amplitude. This is often diagnosed as electrical alternans when the heart rotates on its cardiac electrical axis on an every-other-beat basis. In contrast, true electrical alternans represents alternation in the intrinsic cardiac electrical activity. Described as early as 1909 (201,202), electrical alternans has been associated with Prinzmetal's angina (203), acute ischemia (204), electrolyte abnormalities (205), and the long QT syndrome (206). These conditions are associated with increased risk for ventricular arrhythmias, and TWA can be visible on the surface ECG, particularly in patients with long QT syndrome while they are experiencing emotional or exercise stress (eFig. 61.0.24). In general, TWA that is visible on the surface ECG is rare and is generally considered an ECG curiosity not specifically associated with arrhythmic risk.

***e*FIGURE 61.0.24** Electrocardiogram from a 44-year-old woman with acquired long QT syndrome. The electrocardiogram demonstrates T-wave alternans before the onset of torsades de pointes.

Pericardial tamponade. Low QRS voltage and electrical alternans are characteristic findings of tamponade.

Pathophysiology of T-Wave Alternans

Electrical alternans is believed to be a marker of increased susceptibility to reentry arrhythmias (207), owing to the dispersion of refractoriness and to some areas of the myocardium having the ability to conduct only on an every-other-beat basis. This alternation in conduction is reflected as electrical alternans on the ECG. TWA is caused by an alternation in the duration of the action potential that occurs in diseased tissue with a well-described cellular and ionic basis (208,209). Experimental studies (209,210) suggest that TWA is caused by localized alternation in action-potential duration that then leads to the development of reentrant arrhythmias.

Technical Aspects of Measuring T-Wave Alternans

Because TWA involves microvolt-level changes in T-wave morphology, it is not detected by visual inspection of the surface ECG. The spectral method (211) was developed for the detection of microvolt-level TWA and allows sampling of a series of T-wave amplitudes, with subsequent assessment of the power spectrum of these beats using fast Fourier transform analysis techniques. A composite power spectrum is developed by averaging separate spectra for different points in the T wave. Two numerical indices of alternans are determined: V*alt*, the alternans voltage, which corresponds to the square root of the amplitude of the alternans peak above the background noise levels, representing the magnitude of the alternating variation in T-wave morphology compared to the mean T wave; and *k*, defined as the alternans ratio, which is the amplitude of the alternans peak above the background noise level measured in units of the standard deviation of the noise. Using these two indices, levels have been developed to define normal and abnormal.

Clinical Evaluation of T-Wave Alternans

Rosenbaum and associates (212) assessed 83 patients who underwent invasive electrophysiologic study for a variety of clinical indications. At 20 months of follow-up, 81% of the patients with a positive TWA experienced a ventricular event (defined as sudden death, cardiac arrest, sustained ventricular tachycardia, or ventricular fibrillation), whereas only 6% of patients with a negative TWA experienced such an event. Testing for TWA was equivalent to invasive electrophysiologic testing as a predictor of ventricular tachyarrhythmic events in this study. Hohnloser and colleagues (213) evaluated ten measures of arrhythmic risks in 95 patients who received an implantable cardioverter defibrillator for clinical indications. The implantable defibrillator served as the monitor for documenting ventricular tachyarrhythmic events. Among the various measures of predicting ventricular events, only TWA and left ventricular ejection fraction were statistically significant univariate predictors of

implantable cardioverter defibrillator discharge. Adachi and associates (214) assessed the ability of TWA to predict the occurrence of spontaneous ventricular tachycardia or fibrillation in 58 patients with nonischemic dilated cardiomyopathy. TWA was highly correlated with the occurrence of spontaneous ventricular tachycardia or fibrillation (p <.001) in this population, in whom invasive electrophysiologic testing is generally not regarded as a useful predictor of spontaneous ventricular arrhythmias. Ikeda and colleagues (215) reported on 102 patients who were assessed with TWA, signal-averaged ECG, and left ventricular ejection fraction after myocardial infarction. TWA was a significant predictor of a tachyarrhythmic event (p <.006), with the highest relative hazard (16.8) compared to signal-averaged ECG (5.7) and left ventricular ejection fraction (4.7). At the end of 12 months of follow-up, 28% of the patients with TWA had experienced a clinical event. Klingenheben and associates (216) assessed 107 patients with New York Heart Association class II and III congestive heart failure but no history of ventricular arrhythmia. TWA was a highly significant predictor of ventricular arrhythmic events (p <.0036); none of the other predictors were statistically significant, including left ventricular ejection fraction, the presence or absence of NSVT, baroreceptor sensitivity, measures of heart-rate variability, and signal-averaged ECG. In this study, no ventricular arrhythmic events occurred in patients who had a negative TWA.

Personal Perspectives

TWA testing joins an increasing list of techniques used to identify patients at high risk for ventricular arrhythmia and sudden cardiac death who potentially may benefit from use of the implantable cardioverter defibrillator. At this time, no definitive clinical data have demonstrated benefits of treatment that is based on TWA status, but the technique does appear to have promise as an aid in risk-stratifying these patients. Prospective clinical trials are required to determine the exact role of TWA in guiding patient management.

Conclusions

Microvolt-level TWA testing is a promising technique that appears to be an effective, noninvasive predictor of risk for ventricular arrhythmias and sudden death in the studies published to date. This test appears to be comparable to invasive electrophysiologic testing but needs to be assessed in controlled clinical trials to determine whether management based on TWA findings improves the survival of patients at risk for life-threatening ventricular arrhythmias.

OVERVIEW

An electrophysiologic study (EPS) provides a safe and effective method for evaluation, risk stratification, and treatment of known and suspected arrhythmias. This chapter emphasizes EPS indications, techniques, and normal findings.

An EPS permits assessment of individual portions of the cardiac electrical system. These assessments include evaluation of spontaneous function, responses to stresses, and vulnerability to induced tachyarrhythmias. Indications and guidelines for EPS have been established for a broad range of situations and clinical problems (1) (*e*Table 62.0.1).

***e*TABLE 62.0.1** MAJOR INDICATIONS FOR ELECTROPHYSIOLOGIC TESTING

ACC/AHA/NASPE 1995	Class I	Class II	Class III
Sinus node function	Symptomatic patients: sinus node dysfunction is suspected but unproved.	Patients with documented sinus node dysfunction in whom evaluation of AV or ventriculoatrial conduction may aid choice of pacer	Symptomatic patients with documented association between rhythm and symptoms, therapy would not change with EPS
		Sinus brady: intrinsic vs. autonomic or drug effects	Asymptomatic sinus brady only with sleep, including sleep apnea
		Symptomatic patients with sinus brady, to rule out other causes	
Acquired AV block	Symptomatic patients with HV block suspected but unproved.	Patients with second- or third-degree AV block where site of block or response to measures (e.g., drugs) could affect therapy	Symptomatic patients with symptoms and AV block correlated with ECG
	Paced patients with AV block who are still symptomatic.	Suspected concealed junctional depolarizations causing pseudo-AV block	Asymptomatic patients with transient AV block associated with sinus slowing (e.g., nocturnal type I second-degree AV block)
Chronic intraventricular conduction defects	Symptomatic patients, cause unknown.	Asymptomatic patients with bundle branch block in whom pharmacologic therapy that could cause block is contemplated	Asymptomatic patients with intraventricular conduction defects
			Symptomatic patients in whom symptoms correlate with or are excluded by ECG
Narrow QRS complex tachycardia	To choose treatment for patients with poorly tolerated tachy that does not respond adequately to drugs.	Patients with frequent episodes to be treated with drugs, but there is concern about proarrhythmia, or drug effects on sinoatrial node or AV conduction	Patients well controlled by vagal maneuvers or drugs and not candidates for nonpharmacologic treatment
	Patients who prefer ablation.		
Wide QRS complex tachycardias	Correct diagnosis is needed for treatment, but is unclear on ECG.	None	Diagnosis of supraventricular tachycardia or VT certain from ECG
			However, EPS data may be useful in guiding subsequent treatment
Prolonged QT intervals	None.	To identify proarrhythmic effects of a drug in a patient with cardiac arrest on the drug	Manifest long QT, with or without arrhythmias
		Patients with syncope and with or without long QT or TU waves, to unmask abnormal QT, for example, with a catecholamine	Acquired long QT syndrome with identifiable cause
Wolff-Parkinson-White syndrome	Patients being evaluated for catheter ablation.	Asymptomatic patients with family history of sudden death; or who engage in high-risk activities (insurance?)	Asymptomatic patients not covered above
	Patients with deltas who have had arrest or SUO.	Patients with deltas undergoing other cardiac surgery	
	Symptomatic patients in whom EPS data could affect treatment.	Asymptomatic patients not covered above	
Ventricular premature contractions, couplets, and VT-NS	None.	Patients with other risk factors (e.g., low ejection fraction, abnormal sinoatrial ECG, VT-NS on Holter, if EPS will be used to guide treatment if sustained VT is induced	Patients with syncope of known cause whose treatment will not be altered by EPS findings

		Highly symptomatic patients considered for catheter ablation	
SUO	Patients with suspected structural heart disease and SUO.	Patients with recurrent SUO, without structural heart disease, and with a negative tilt test result	Patients with syncope of known cause whose treatment will not be altered by EPS findings
Cardiac arrest survivors	Survivors without new Q-wave MI. Arrest >48 h after acute MI.	Arrest caused by bradyarrhythmia Arrest possibly due to congenital long QT syndrome	Arrest in first 48 h after acute MI Arrest from clear cause (e.g., acute ischemia, aortic stenosis, or long QT syndrome)
Unexplained palpitations	Rapid pulse felt by medical personnel, without ECG. Palpitations followed by syncope.	"Significant" palpitations where EPS may help in diagnosis, risk assessment, or treatment	Palpitations documented to be due to noncardiac cause (e.g., hyperthyroidism)
Guiding drug therapy	Patients with sustained VT or arrest, especially if prior MI. Patients with AV nodal reentry tachycardia, AV reentrant tachycardia, or atrial fibrillation with an accessory pathway in whom drug therapy is planned.	Sinoatrial node reentry tachycardia, A-tachy, atrial fibrillation, or atrial flutter, without deltas Patients with arrhythmias not inducible at baseline EPS	Isolated atrial premature contractions or ventricular premature contractions Ventricular fibrillation with a clearly identified reversible cause
Related to implantable devices	Before and during implant, and before discharge to confirm performance. After implant to determine if a factor has altered the performance of the device. Test interactions if two devices are to be used.	In patients with documented indications for pacing, to optimize pacing mode and sites	Patients who are not device therapy candidates

GLOSSARY

AH interval: The interval from the first rapid deflection of the atrial electrogram on the bundle of His lead to the first inscription of the bundle of His depolarization.

Cycle length: Interval in milliseconds. During EPS, cycle lengths or intervals often change from beat to beat, so that these measures are more relevant than an overall rate that is expressed in beats per minute (beats/min). The use of rates in beats/min is retained mostly to facilitate communications with physicians who are more comfortable with this terminology.

Effective refractory and conduction periods: Measurements of impulse propagation at various levels in the heart (see text for detailed definitions).

Functional refractory and conduction periods: Measurements of impulse propagation at various levels in the heart (see text for detailed definitions).

HV interval: The interval from the first inscription of the bundle of His potential to the first evidence of ventricular depolarization on the surface electrocardiogram or the bundle of His lead.

PA interval: The interval from the first evidence of sinus node depolarization whether on the intracardiac or surface electrocardiogram, to the atrial deflection as recorded in the bundle of His lead.

S_1, S_2, S, . . ., N: S_1 refers to the baseline or drive stimuli in a series, with each of the series of S_1s being of equal intervals. S_2 is the first extrastimulus, with the S_1–S_2 interval almost always shorter than the S_1–S_1. S_3, S_4, S, . . ., N are the second, third, Nth extrastimulus. See text for details.

HISTORICAL PERSPECTIVE

The leap from the experimental animal laboratory to the clinical arena and clinical cardiac electrophysiology was made possible by the development of cardiac catheterization and transvenous pacing techniques. Intracardiac recordings from the right atrium, bundle of His region, and right ventricle allowed direct rather than inferential analysis of normal and abnormal rhythms (2,3). Electrophysiologic testing was quickly established as the definitive method for diagnosis and subsequently for treatment of cardiac rhythm disorders.

INTRODUCTION

A complete EPS consists of a series of tests that are designed to evaluate the heart from top to bottom (i.e., from the sinus node to the ventricle, with steps in between). Depending on the purpose of the EPS for a given patient, all or only some of these regions may be tested, in an à la carte fashion.

The testing techniques used to evaluate each region are remarkably similar. Pacing at increasing rates and programmed electrical stimulation form the core of testing at each level, supplemented by various pharmacologic probes and physical maneuvers.

This chapter emphasizes the indications for EPS; matters related to patient preparation, vascular access, stimulation, and recording techniques; and an outline of EPS related to the major parts of the heart's electrical system. Other chapters in this text cover the details of specific arrhythmias.

Indications for Electrophysiologic Study

The earliest practical application of EPS was assessment of the conduction system. This was followed in rapid succession by EPS for characterization of various tachycardias; as a guide for antiarrhythmic drug efficacy; identification of the cause of syncope of undetermined origin; arrhythmia mapping before and during open heart surgery; and as an integral part of the procedure for catheter ablation of tachycardias. Guidelines on the indications for EPS have been published from time to time by the American College of Cardiology together with the American Heart Association, and by the North American Society for Pacing and Electrophysiology (1) (eTable 62.0.1). An update of these guidelines is due in the near future.

Patient Preparation

Education and Consent

Patients are often quite anxious about the prospect of an invasive study. Most diagnostic EPSs involve only venous access and are, therefore, safer than coronary angiography. The latter is a procedure that many patients are familiar with and tend to take for granted. Electrophysiologists often have patients referred to them who have been told by the referring physician that EPS is a minor, low-risk procedure. These patients may be alarmed to learn that no procedure is risk free, and that EPS may require several hours. Therefore, it is important for realistic patient education to begin with the referring physician. The electrophysiologist should put the various risks in context. Patients can understand analogies, such as the risks versus the benefits of walking across a busy street. Patients should also have a realistic idea of the benefit they may derive from undergoing EPS, including the possibility that the study result may be negative or equivocal.

Preprocedure Preparations

Traditionally, diagnostic EPS was performed in the postabsorptive, nonsedated state. There are of course some problems with this idea. There is great variation among patients in the anxiety experienced during invasive procedures. As EPSs became longer and more complex, it became clear that sedation would be required for many

of these subjects.

Twelve-Lead Electrocardiography

It is helpful to have a 12-lead electrocardiography (ECG) available, particularly when tachyarrhythmias are expected during the procedure, or in patients for whom ischemia is an issue. It is desirable for the 12 leads to be recorded simultaneously, or in just a few seconds, in case the arrhythmia is fast, slow, or transient.

Defibrillator Pads

Using preapplied adhesive defibrillator pads avoids the need to disrupt the sterile field in the event that electrical defibrillation or cardioversion is needed during the procedure.

Arterial Line

Arterial lines are used routinely in a *minority* of EPS laboratories, except in unstable patients or for certain ablation procedures. Automated cuff blood pressure devices are usually adequate.

Sedation

Many patients benefit from minimal sedation. Longer procedures and ablations are now routinely performed using intravenous conscious sedation. Guidelines are published by the North American Society for Pacing and Electrophysiology (4).

Urinary Problems

Urinary retention may occur in both genders during lengthy EPSs, particularly if combined with sedation and a tachycardia-related diuresis. When this situation is anticipated, it is useful to insert a Foley catheter before the procedure. Lubrication and topical anesthesia of the urethra using a commercially available lidocaine jelly injector system makes catheterization both acceptable and well tolerated by the patient.

Oxygen and Carbon Dioxide Monitoring

Monitoring of O_2 saturation has become virtually routine in many laboratories and is of particular value in sedated patients. If patients are receiving supplemental oxygen, the O_2 saturation may be misleadingly high. Expired CO_2 monitors are useful in preventing hypercapnia in such situations and are recommended in the guidelines for conscious sedation.

Universality of Stimulation Techniques

There is a relatively small menu of stimulation techniques useful in the study of both bradycardias and tachycardias.

Stimulus Amplitude and Pulse Duration (Pulse Width)

Most EPS laboratories use outputs at two to four times diastolic threshold. Twice threshold is more common. In general, refractory periods (see Conduction and Refractory Periods, later in this chapter) are somewhat longer when determined using twice threshold, and this may reduce the incidence of induction of nonclinical tachyarrhythmias. At four times threshold, one is at the beginning of the more vertical portion of a strength-interval curve, which may have several advantages (5,6).

A pulse duration of 1 or 2 ms is most commonly used. This dates from the early days of clinical EPS when implanted pacemakers had similar pulse durations, as do current temporary pacemakers. This pulse duration is now out of synchrony with those used in implantable devices, but it has been retained for the sake of consistency in EPS protocols done over long periods of time.

Most commercial EPS stimulators emit constant current pulses. Initially, this too was in keeping with the norm for implantable pacemakers. The latter are now nearly universally constant voltage devices. Testing of patients with and without clinical tachycardias with both constant voltage and constant current stimulation, all at four times diastolic threshold, produced no significant difference in any of the results.

Incremental versus Decremental

Both terms are in regular use and have opposite meaning depending on whether one is considering *rate* in beats/min or *cycle length* in milliseconds. In the paragraphs that follow, the most conventional usage is employed.

Straight Pacing

The pacing rate or cycle length is maintained throughout the duration of the stimulation. There are several common applications for straight pacing.

1. *Rate incremental pacing.* After pacing at a given rate for a predetermined number of stimuli or seconds, the rate is then increased (with or without intervening pauses) in a series of steps until predetermined end points are reached. Rate incremental pacing terminology is derived from stimulators controlled by an analog dial. Digitally controlled devices often increase the rate by choosing a sequence of cycle length *decrements*, but the term *incremental pacing* may still be used.
2. S_1–S_1 *drive stimuli*. The heart is paced, or driven, at a specified rate and duration (typically eight beats) after which a premature extrastimulus is delivered (see Extrastimulus Technique). The eight drive beats are each termed S_1 *stimuli*. These S_1s may be followed by first, second, third, and *N*th premature extrastimuli and are designated S_2, S_3, S_4, and S_N. When extrastimuli follow a series of sinus beats, the latter may also be designated as S_1s. S_1–S_1 drive stimuli are sometimes called *trains*, but this can be confused with ultrarapid train stimulation (see Ultrarapid Train Stimulation, later in this chapter), which are also referred to as *trains*.
3. *Burst pacing for tachycardia induction.* Stimuli are delivered at a constant rate for a relatively short duration, but at successively faster rates with each burst until a predetermined maximum rate or minimum interval (i.e., cycle length) has been reached.
4. *Bursts for termination of tachycardia*. Bursts for termination of tachycardia is similar to the technique used for induction. The initial pacing rate is faster than that of the tachycardia.
5. *Underdrive pacing for tachycardia termination.* Underdrive pacing is pacing at a rate slower than the tachycardia at a constant rate. Therefore, stimuli fall at differing points in the tachycardia cycle.

Ramps

Ramp pacing implies a smooth change in the interval between successive stimuli. Ramps, too, can be incremental or decremental as defined by either rate or cycle length. Several applications for ramps are presented here.

1. As a test for conduction, long ramps with small cycle length decrements between successive stimuli provide results comparable with stepwise rate incremental pacing (7).
2. For tachycardia induction, the ramp is decreased in duration, but the steepness of the slope is increased (i.e., interstimulus intervals are decreased more rapidly). Successive ramps go to higher and higher rates (shorter intervals) up to a predetermined limit.
3. Tachycardia termination is somewhat similar to tachycardia induction. It is commonly used in antitachycardia pacing algorithms in implantable cardioverter defibrillators (ICDs). Programmed rate incremental ramps are also known as *autodecremental pacing*.

Extrastimulus Technique

One or more extrastimuli (designated S_2, S_3, and S_N) are introduced at specific coupling intervals based on previous drive S_1s, or spontaneous beats. Thereafter, the S_1–S_2 interval is altered, usually in 10- to 20-ms steps, until an end point is reached, such as tissue refractoriness or termination or induction of a tachycardia. It is

usual to begin late in diastole and successively decrement the S_1–S_2 interval. When the physician is satisfied with the results of S_1–S_2 testing, a second extrastimulus (S_3) may then be introduced with the S_2–S_3 interval altered in a fashion similar to that used for S_1–S_2.

Two methods are in common clinical use for decrementing the S_1–S_2 and S_3–S_4 intervals (8,9). In the *tandem method*, the S_1–S_2 is decremented until S_2 does not capture, and then the S_1–S_2 interval is increased by 40 to 50 ms and held there. S_3 is then introduced, and the S_2–S_3 interval decremented until S_3 fails to capture. At that point, the S_1–S_2 interval is decremented, and S_3 retested to see if it captures. From that point on, the S_1–S_2 and S_2–S_3 are decremented in tandem until refractory, so that they and the S_3–S_4 interval are altered in a fashion similar to that used for S_2–S_3. In the *simple sequential method*, the S_1–S_2 interval is decremented until it no longer captures, and then incremented until it does (usually 10 ms). The S_1–S_2 interval is then held constant, while the S_2–S_3 interval is decremented in a similar fashion to that used for S_1, and then the same for S_3–S_4. The tandem method can be looked on as more conservative, because it favors relatively longer intervals and gives a larger number of stimulation runs before moving on to the next extrastimulus. Prospective studies comparing the two methods have shown no differences between the two methods in any of outcomes assessed (8). The choice of the simple sequential or tandem method therefore remains a matter of investigator's choice.

Ultrarapid Train Stimulation

Stimuli are delivered at short intervals (10 to 50 ms) for a duration sufficient to result in a desired number of captures (10,11). The technique has long been used experimentally (with sequentially increasing stimulus amplitudes) for induction of ventricular fibrillation. It is now used clinically for that purpose with ICDs. Shorter trains have also proved useful in termination of tachycardias (10) and in induction of monomorphic tachycardias (11). Of all the techniques described, ultrarapid trains are the least universally employed, except for ventricular fibrillation induction with ICDs.

Stimulation Protocols

Adequacy is more important than universality. Bodies such as the North American Society for Pacing and Electrophysiology have published guidelines on the minimum standards for an acceptable protocol (12). In addition to suggesting reasonable ranges of stimulation sites, drive cycle lengths, numbers of extrastimuli, and amplitudes and pulse durations of the extrastimuli, the guidelines also suggest outcome criteria. For example, the protocol used should be able to induce sustained monomorphic ventricular tachycardia in at least 90% of patients with coronary artery disease who present with such a rhythm.

Signal Filtering and Interelectrode Distance

The surface ECG is usually filtered at 0.1 to 100.0 Hz. The bulk of the energy is in the 0.1- to 20.0-Hz range. Because of interference from alternating current (AC), muscle twitches, and similar relatively high-frequency interference, it is sometimes necessary to record the surface ECG over a lower frequency range or to use notch filters. Timing of events with respect to QRS onset is often important during EPS, but it is cumbersome to display all 12 leads of the regular surface ECG. Orthogonal lead systems (X,Y,Z) are logical but not commonly used. It is more typical to use mutually perpendicular leads (I, AV_F, and V_1), often supplemented by lead II, which gives an indication as to the presence of abnormal left-axis deviation. Many electrophysiologists have their own personal favorite lead selections.

Intracardiac leads can be placed strategically at various positions within the heart. Therefore, it is desirable to record *local* events in the region of the lead, rather than far field events. This is accomplished by filtering intracardiac electrograms, typically at 30–40 to 500 Hz. Note that this eliminates the spectrum with the greatest energy that reaches the surface ECG. The higher frequency waves carry much less energy and may be difficult to detect more than a centimeter away from the recording lead. Bipolar electrograms are generally used, and smaller interelectrode distances record increasingly local events.

Timing of Local Events

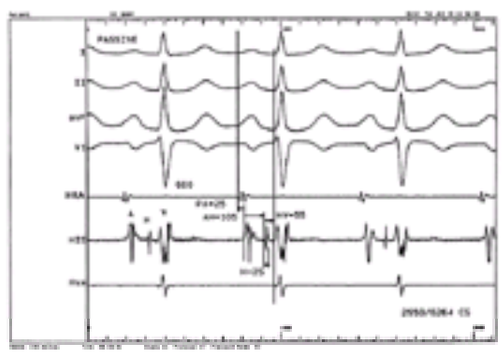
With an "unfiltered" bipolar lead, an approaching wavefront creates a positive deflection that quickly reverses itself as the lead passes directly under the electrode. This rapid reversal constitutes the "intrinsic deflection" of the electrogram and represents the timing of the most local event (i.e., at the site of the bipole) (13). Electrograms are filtered at 30–40 to 500 Hz and have a much more jagged appearance. When recorded simultaneously with an unfiltered electrogram, the midpoint of the intrinsic deflection of the unfiltered electrogram occurs at the same time as a similar deflection on the filtered electrogram, or at the peak positive or negative deflection of the filtered electrogram. The slew rate or dV/dT of the filtered electrogram is so rapid in normal heart tissue that the difference between the peak and the nadir of the deflection is 5 ms or less. Identification of the local event is therefore easy with either filtered or unfiltered electrograms in normal tissue. However, diseased myocardium may conduct very slowly with fractionated electrograms that make local events harder to identify. The electrophysiologist must then decide whether to use onset rather than local criteria for timing of events. Even in normal tissue, onset deflections are usually less crisp than the local deflection. Tradition plays a large role in the choices of deflections used for timing of events (see Baseline Intervals, later in this chapter). At times, there may be a deflection that is of particular interest, such as a His or bundle branch deflection that is small relative to the size of surrounding electrograms. This is particularly true when the gain must be markedly increased to produce a measurable deflection. In such instances, a "limiter" or "clipper" option on the amplifier and recorder system can eliminate the highly amplified surrounding signals to allow concentration on the deflection of interest. However, limiters also eliminate the ability to determine the timing of the intrinsic deflection (local timing) of the signals being limited.

Catheterization Techniques

The percutaneous technique is used almost exclusively. The bundle of His electrogram (HBE) is most commonly recorded using a lead inserted via a femoral vein and advanced through the right atrium across the tricuspid into the right ventricular inflow area. Some other areas are more easily reached through the superior vena cava. Insertion sites can also include the antecubital, jugular, and subclavian veins.

Choices of Surface and Intracardiac Signals

A classic display would include three or four surface ECGs; a recording from the high right atrium (HRA); the HBE, which includes the low medial right atrium, the bundle of His deflection, and the right ventricular inflow deflection; and a recording from the right ventricular apex. Depending on the type of study and the information sought, stimulation and recording from other sites may be appropriate (eFig. 62.0.1).



***e*FIGURE 62.0.1** Normal intracardiac electrograms. This is a "passive HBE" (i.e., a bundle of His electrogram and accompanying recordings during sinus rhythm with no ongoing manipulations, stimuli, or intentional stresses). Semiorthogonal leads 1, AV_F, and V_1 are used together with lead 2, which is helpful in determining axis. The measurement of intervals is demonstrated. HRA, high right atrium; RVA, right ventricular apex.

ELECTROPHYSIOLOGIC STUDY

Baseline Intervals

Using intracardiac electrograms, the PR interval of the surface ECG can be further subdivided (eFig. 62.0.1). During sinus rhythm, the earliest atrial activity is identified using the HRA electrogram from the sinus node region at the junction of the superior vena cava and the right atrium. The P wave is then timed from the earliest

evidence of such atrial activity, whether first seen in the HRA lead or in the surface ECG. Next, conduction through the right atrium to the region of the atrioventricular (AV) node and bundle of His is then measured as the PA interval. This is defined as the interval from the P wave as just defined, to the *first rapid* depolarization of the atrium recorded on the HBE lead. AV node conduction is measured by the interval from the *first rapid* deflection of the A wave in the HBE lead to the*first evidence* of bundle of His depolarization on the HBE lead; this is designated the AH interval. Conduction through the bundle of His and bundle branches is then measured as the timing from the *first evidence* of the bundle of His deflection to the *first evidence* of ventricular deflection on the HBE lead *or* on the surface ECG, whichever comes first. Normal values for these intervals based on a compilation of sources (14,15,16,17,18,19,20,21 and 22) are found in eTable 62.0.2. Note that the traditional use of *first rapid* deflections can be quite subjective compared with *first evidence* or the local or *intrinsic deflection*.

***e*TABLE 62.0.2** NORMAL CONDUCTION INTERVALS (±2 SD)

	PA intraatrial	AH atrioventricular node	His HV, His to V	P-LA interatrial
Passive/baseline	10–45	55–130	<2530–55	40–130
Atrial paced	10–75	[a]	<2530–55	65–150

***e*FIGURE 62.0.5** The AH interval during normal sinus rhythm (NSR) and during high right atrial pacing. Mean and standard deviations (SD) are shown for subjects without evidence of atrioventricular nodal disease. [From Fisher JD. *Primer of cardiac electrophysiology*. Armonk, NY: Futura (*in press*); modified from Fisher JD. Role of electrophysiologic testing in the diagnosis and treatment of patients with known and suspected bradycardias and tachycardias. *Prog Cardiovasc Dis* 1981;24:25, with permission.]

A minority of authors use the HQ interval rather than the HV interval. The HQ interval is the interval from the onset of the bundle of His potential to the onset of the QRS and the surface ECG. Logically, one might also use information from the right ventricular apical lead or other intracardiac leads (14,23), but these are not part of the conventional measurements. The bundle of His potential itself should be crisp and distinct and less than 25 ms in duration. *Interatrial* conduction is measured from the HRA to the left atrium. Normal values appear in eTable 62.0.2.

Influences on the Timing of Cardiac Intervals

Sympathetic and parasympathetic tone can influence the heart rate and timing of cardiac intervals (24,25 and 26). Changes in neurohumoral tone can result from anxiety, sedation, exercise, sleep, ischemia, metabolic state, pharmacologic agents, and maneuvers such as carotid sinus massage (CSM). Some of these are discussed further in relevant sections of the EPS.

Carotid Sinus Massage

In most patients, cardioinhibitory effects on the sinus node are most apparent with right CSM, whereas the AV node is more likely to be affected by left CSM, but this distinction is by no means universal (15,27,28,29,30,31 and 32). Sinus node inhibition results in sinus bradycardia or sinus arrest. Inhibition of the AV node can result in prolongation of the AH interval or in block at the AH level. If CSM results in sinus arrest, concurrent *atrial* pacing will determine whether there is block at the AV node level as well.

CSM may be particularly revealing in patients who have the Wenckebach phenomenon at the time of their EPS. In one of those “paradoxical responses” of medical lore, Wenckebach at the HV level sometimes seems to improve with CSM. This is because the sinus node may be slowed, giving the bundle of His and bundle branches (which are much less affected by vagal tone) time to recover and resume conduction. In a patient with the Wenckebach phenomenon, therefore, CSM that produces worsening of the block is “good” because such a block is usually at the AV node level. This is more benign than block at the HV level, which leaves the patient with an idioventricular escape rhythm. Improvement of block with CSM may therefore be bad.

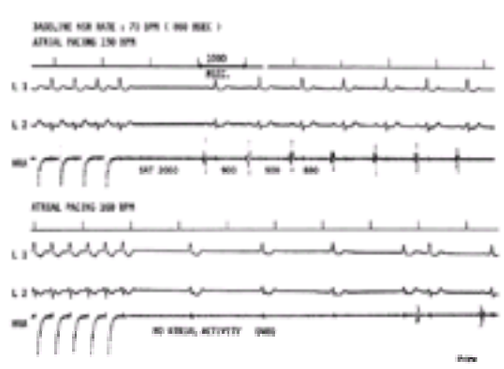
Carotid Sinus Massage Normal Values

Sinus pauses of 3 seconds or more in response to CSM are considered abnormal. In a control group of 98 patients without a history of AV block, bradycardia, or syncope (32), the mean sinus interval with firm right or left CSM was 1,252 ms, and +2 SD was 2,364 ms. Only 1% of patients had pauses of 3 seconds or more, and 2% had second- or third-degree AV block.

Sinoatrial Node Function Tests

Sinus Node Recovery Times

The sinus node is the archetype of an automatic focus. Automatic rhythms are characterized by spontaneous depolarization, overdrive suppression, and postoverdrive warm-up or return to baseline cycle length (15,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51, 52,53,54,55,56,57,58 and 59). Pacing at rates in excess of the spontaneous rate of an automatic focus results in temporary inhibition of spontaneous depolarization, with gradual return to the original cycle length over several beats following cessation of pacing (eFig. 62.0.2).



***e*FIGURE 62.0.2** Prolonged sinus node recovery times. This patient had a baseline sinus rate of 70 beats/min (860 ms). After pacing the high right atrium (HRA) at 130 beats/min, the sinus recovery time (SRT) was 2,060 ms, which is markedly prolonged. In the bottom panel, after pacing at rate 160, there is no SRT for 6,480 ms, although there is a junctional escape rhythm at approximately 40 beats/min. NSR, normal sinus rhythm.

Importance of Multiple Pacing Rates

Clinically, the sinus node recovery time (SNRT) is used to test sinus node automaticity. Pacing at rates near the baseline cycle length causes no overdrive suppression so that the interval between the last paced beat and the next sinus beat is comparable with the baseline cycle length. If the SNRT after pacing at 500 ms is shorter than after 600 ms, or there is marked variation (greater than 250 ms) in the SNRTs if multiple tests are performed after pacing at 500 ms, this may imply that some impulses have not penetrated the sinus node (i.e., that some degree of sinoatrial block exists). At pacing cycle lengths shorter than 500 ms, there is usually little further prolongation of the SNRT; on the contrary, changes in neurohumoral tone may result in shorter SNRTs. In patients with sinus node disease, faster pacing rates may result in marked prolongation of the SNRT.

Pacing durations beyond 15 seconds usually have little effect on the SNRT in *healthy* subjects. Patients with sinus node disease may have marked suppression after longer pacing durations. It is best to perform multiple SNRTs at multiple paced cycle lengths, and to use pacing durations of 1 to 2 minutes in some of these trials.

Sinus Node Recovery Time

Normally, the SNRT is less than 1,500 ms, with a scatter on multiple tests of less than 250 ms. SNRTs tend to be shorter with shorter sinus cycle lengths, and therefore a variety of “corrections” have been introduced. Values derived from such tests are then called the SNRTC or CSNRT.

$$\text{CSNRT} = \text{SNRT} - \text{sinus cycle length}$$

This is the most common correction. Normal values have been reported from 350 to 550 ms, with 500 ms being most commonly used.

$$\text{CSNRT} = \text{X\% of sinus cycle length}$$

P>Normal values range up to 160%.

$$\text{CSNRT} = 1.3\ (\text{mean sinus cycle length in ms}) + 101\ \text{ms}$$

Beware of the use of corrections at slow sinus rates because results can be absurd. For example, a patient with symptomatic bradycardia at 1,400-ms cycle length and an SNRT of 1,800 ms = CSNRT 400 ms with the first method. In this case, the abnormal uncorrected SNRT of 1,800 is more accurate; in fact, one does not need an SNRT to make the clinical diagnosis.

Recovery Beats (Total Recovery Time)

After the SNRT, the pattern of subsequent beats returning to the basic sinus cycle length should also be analyzed. A variety of such patterns exist. One helpful measure is the total recovery time (i.e., how long it takes to return to the basic sinus cycle length) (14,15,56,60).

Secondary Pauses

Secondary pauses are identified when there is an initial shortening of the cycle length after the SNRT, followed by an unexpected lengthening of the cycle length (44). In some instances, this is a sign of sinus node disease. In others, it can be a normal reflex following hypotension induced by pacing at rapid rates, or in response to pressure overshoot in the first recovery beat because of the prolonged filling time.

Overview of Sinus Node Recovery Time

The previous discussion should make it clear that a phrase such as “the SNRT was normal” is too simplistic. The number provided for “the” SNRT is most often the maximum or longest SNRT of several runs. Others may report the average SNRT. Sometimes, only a single SNRT is done as part of a superficial study. A full interpretation requires all the information from several runs at different paced rates, together with data from subsequent beats. The sensitivity of a *single* SNRT is approximately 35% in patients with sinus node disease. This rises to greater than 85% when multiple SNRTs at different rates are recorded, along with scatter and total recovery time, with a specificity of greater than 90%.

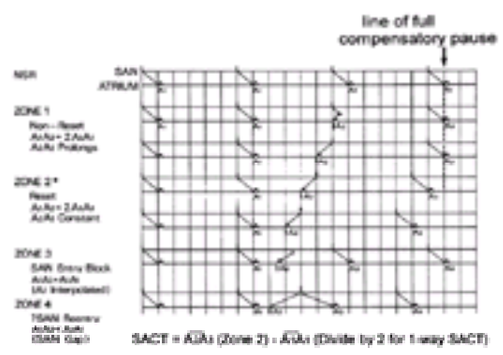
Sinoatrial Conduction Time

Direct Recordings

The sinus node atrial depolarization can be recorded directly in some patients, using high-gain unfiltered electrograms (54,55,61,62,63,64,65 and 66). Signal-averaging techniques have also been used to measure the sinoatrial conduction time (SACT) noninvasively (67).

Strauss Technique

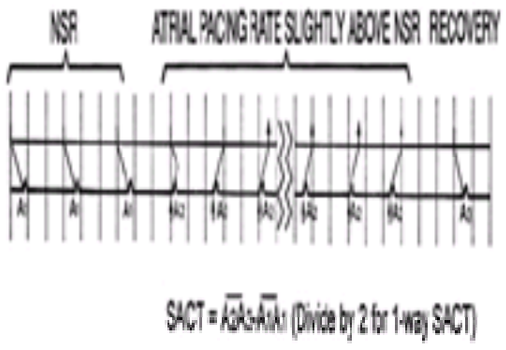
The Strauss technique (15,39,41,49,51,52,53,54 and 55,59,65,68,69,70,71 and 72) uses the extrastimulus technique to assess SACT (eFig. 62.0.3). Baseline sinus beats are designated A_1. The premature beats (A_2) are delivered after every eighth A_1, and the timing of the recovery beat (A_3) is measured. Very long A_1–A_2 intervals generally do not affect the timing of the A_3 (i.e., A_1–A_3 = 2 A_1–A_1, a complete compensatory pause, designated *zone 1*). Shorter A_1–A_2 intervals result in penetration of the sinus node with resetting so that the resulting pause is less than compensatory. This is termed *zone 2*, and the SACT is calculated as the mean of several zone 2 A_2–A_3 intervals minus the corresponding mean of A_1–A_1 intervals (SACT = A_2–A_3 – A_1–A_1). This value is often divided by 2 to estimate the one-way SACT, although it is understood that conduction times into and out of the sinoatrial node may be different. The upper limit of normal (one-way) is approximately 145 ms. Reducing the A_1–A_2 interval further finally results in peculiar responses indicating sinus node entry block (zone 3) or reentry (zone 4). This technique had been anticipated in analyses of ECGs (73) and earlier clinical electrophysiologic studies (74).



***e*FIGURE 62.0.3** Sinoatrial conduction time (SACT): Strauss method. See text. The sinoatrial node (SAN) depolarizes unseen and results ultimately in atrial depolarization, designated here as A_1. Premature atrial beats (A_2) are introduced with increasing prematurity, and the timing of the return cycle (A_3) is analyzed. The dashed line near the right of the figure indicates the line of complete compensatory pause. The SACT is calculated from zone 2 responses. NSR, normal sinus rhythm. [From Fisher JD. *Primer of cardiac electrophysiology*. Armonk, NY: Futura (*in press*); modified from Fisher JD. Role of electrophysiologic testing in the diagnosis and treatment of patients with known and suspected bradycardias and tachycardias. *Prog Cardiovasc Dis* 1981;24:25, with permission.]

Narula Method

The Narula method (75) for measuring the SACT is simpler. This assumes that pacing the atrium at rates of 10 beats/min or less above the sinus rate will not result in significant overdrive suppression of the sinus node, but that the pacing beats will gradually penetrate and reset the sinus node (*e*Fig. 62.0.4). The calculation of the SACT is the same as for the Strauss method.



***e*FIGURE 62.0.4** Sinoatrial conduction time (SACT) by Narula method. As in the previous illustration, the sinoatrial node depolarizes unseen and ultimately results in atrial depolarization (A_1). Instead of premature beats, atrial pacing at a rate slightly above that of the sinus rate is used as A_2. It is assumed that such atrial pacing will depolarize the sinus node without significant overdrive suppression. The SACT is then calculated using the same formula as the Strauss method. NSR, normal sinus rhythm. [From Fisher JD. *Primer of cardiac electrophysiology*. Armonk, NY: Futura (*in press*); modified from Fisher JD. Role of electrophysiologic testing in the diagnosis and treatment of patients with known and suspected bradycardias and tachycardias. *Prog Cardiovasc Dis* 1981;24:25, with permission.]

Kirkorian-Touboul Method

Kirkorian, Touboul, and their colleagues (76) developed a method designed to determine the SACT independently of baseline sinus cycle length, which can normally be somewhat variable. It is less widely used than the other methods.

Comments on Sinoatrial Conduction Time Methods

The Strauss method is useful as part of an overall EPS when information is also sought on conduction system refractoriness or possible dual or accessory pathways during sinus rhythm. The Narula method is the quickest and easiest to perform, but gives only the SACT. The Kirkorian-Touboul method may have several advantages, but has not yet reached the level of use of the other methods.

The SACT appears to be *directly* related to sinus cycle length (55,65), and the sinoatrial node refractory period is *directly* related to drive cycle length (76).

Autonomic Effects and Manipulations (Intrinsic Heart Rate)

The sinus node is the archetype of the automatic rhythm, but it is subject to a wide variety of neurohumoral influences. To eliminate these, chemical denervation of the sinus node on a temporary basis can be achieved by injection of 0.2 mg per kg of propranolol (or 0.22 mg per kg of atenolol) in divided doses followed by 0.04 mg per kg of atropine (38,49,52,54,77,78). The normal intrinsic heart rate is age related, according to the formula: intrinsic heart rate = 118.1 – (0.57 × age); normal values are ±14% for age less than 45, and ±18% for age greater than 45.

Testing of SNRTs and SACT may yield improved results after autonomic blockade (36,49,51,52,54).

Atrioventricular Conduction and Refractoriness

Impulses traveling from the atrium to the ventricle must traverse the atrium, AV node, bundle of His, and bundle branches (His-Purkinje system). The AV node and the His-Purkinje system are considered separately. The discussion of the sinus node touched briefly on the concepts of conduction and refractoriness. These concepts require further attention for understanding of impulse propagation from atrium to ventricle.

Conduction and Refractory Periods

Capture of the heart by a pacer stimulus and propagation of the wavefront to other points can be assessed using tests of conduction and of refractoriness (7,79,80,81,82,83,84,85,86,87,88 and 89). Conduction is assessed by observing the propagation of wavefronts during pacing at progressively incremental rates (decremental cycle lengths). Refractoriness is tested by pacing at designated cycle lengths followed by introduction of increasingly premature extrastimuli. Results from the two methods are closely correlated, but not interchangeable. For example, with incremental pacing, block usually occurs at the AV node level, whereas the extrastimulus method may result in block at any of several different levels or noncapture at the site of stimulation.

Conduction

Rate incremental pacing is delivered to a selected site in the heart, and propagation to a selected distal point is assessed. During tests of conduction, it is usual for capture to be maintained at the site of stimulation and block to occur at a distal point (7,81). As an example, stimulation of the HRA may be used for assessment of AV conduction. The stimulated wavefront traverses the right atrium, passes through the AV node, the bundle of His, and the bundle branches. As the pacing rate increases, there is normally a slight increase in the intraatrial conduction time, a progressive increase in the AV node conduction time (the AH interval), and little change in the HV interval, with block usually at the AV node level.

The following examples continue with the model of HRA pacing in the assessment of AV conduction.

Stepwise Rate Incremental (Cycle Length Decremental) Pacing (Straight Pacing)

Pacing is delivered to the HRA at a constant rate. The ability of tissue to conduct is affected by the baseline rate or cycle length of the preceding beats. Therefore, the initial stimuli at any given rate may produce different effects from those observed several seconds later. This is called the *period of accommodation* (90) and may last up to 45 seconds, although 10 seconds is usually sufficient. For clinical testing, 15 seconds at any given rate is the minimum time at which intervals should be analyzed; 45 to 60 seconds is preferable, and mandatory if intervals have not stabilized by 15 seconds.

The stepwise, straight pacing method can be used simultaneously for the assessment of SNRTs as described earlier.

During straight atrial pacing at a constant rate, look for block at the HV level at a point at which the AH interval is not prolonging at that paced rate (i.e., before the development of AV nodal Wenckebach). This is an abnormal finding, except in some children and adults with very short AH intervals or others able to conduct through the AV node at higher rates than usual.

There are disadvantages to the straight pacing method. The prolonged pacing required at each rate is time consuming. Rapid pacing may provoke sensations or hypotension in patients who produce neurohumoral responses that can alter results.

Rate Incremental Ramp Pacing

Ramps for assessment of conduction are often an attractive alternative to the stepwise method (7,87,88 and 89). The pacing rate is slowly increased at 2 to 4 beats/min per second until block occurs. This method avoids prolonged rapid pacing and is particularly suitable when multiple assessments of conduction are planned (e.g., after therapeutic interventions) and in the assessment of retrograde conduction. Because each successive paced interval differs from its predecessor by only a few milliseconds, the interval at which block occurs can be determined more precisely using the ramp method.

Comparative studies of the ramp and stepwise incremental pacing methods in assessment of anterograde and retrograde conduction have shown them to be comparable (7,87,89).

Conduction Periods

At pacing rates below those causing conduction block, there is a 1:1 relationship between stimulus and response at a distant site. Conduction time may be prolonged, so that the stimulus to response time is prolonged. For symmetry with the terminology used for refractory period testing, the comparable terminology has sometimes been used (81).

Refractory Periods

Refractory periods are determined by assessing the effects of extrastimuli (S_2, S_3, S_N) delivered decrementally after a series of spontaneous or paced beats (S_1). Many variables are considered in the assessment of refractory periods. These include the stimulus amplitude and the drive rate or cycle length. Longer cycle lengths are generally associated with longer refractory periods, but refractory periods of different parts of the conducting system do not respond comparably with changes in drive cycle lengths (15,79,91).

1. The *relative refractory period* is the drive to extrastimulus interval (S_1–S_2) that produces slowing in conduction (an increase in stimulus to distal response time). Conduction is slowed when a wavefront encounters tissue that is not completely repolarized.
2. In the *absolute refractory period* the tissue cannot be depolarized, even by an extrastimulus of great amplitude.
3. The *effective refractory period* (ERP) is the longest S_1–S_2 at a *designated stimulus amplitude* (usually two to four times diastolic threshold) that fails to capture.
4. The *functional refractory period* (FRP) is the shortest interval at which a specified (usually distal) site can be depolarized by any S_1–S_2 interval.

It is helpful to think of the ERP as a stimulus-to-stimulus measurement, and the FRP as a response-to-response measurement (91).

The anterograde ERP and FRP of the AV conduction system are defined in the following ways:

1. Atrial ERP is the longest S_1–S_2 interval that fails to achieve atrial capture.
2. Atrial FRP is the shortest A_1–A_2 interval recorded at a designated site (often the bundle of His region) before failure of S_1–S_2 to capture the atrium.
3. AV node ERP is the longest A_1–A_2 not propagating to the bundle of His. Although often based on HRA stimulation, the A_1–A_2 *should* be measured at the His region to avoid the confounding effects of changes in atrial conduction times.
4. AV node FRP is the shortest H_1–H_2 in response to any A_1–A_2. Patterns of AV nodal conduction and refractoriness are often complex (91), based on Wit et al. (82).
5. His-Purkinje System ERP is the longest H_1–H_2 not propagating to the ventricles.
6. His-Purkinje System FRP is the shortest V_1–V_2 interval before reaching the ERP of the His-Purkinje system.
7. Bundle branch ERP and FRP are as for the His-Purkinje system, but based on production of right or left bundle branch block or fascicular block.

It is important to note that atrial conduction may materially affect determination of refractory periods. Note that *refractory periods should not be timed from the site of stimulation, but from the point in the conduction cascade that is being assessed*. For example, if the HRA is stimulated in a patient with a left lateral Kent bundle, an early extrastimulus may encounter the relative refractory period of the atrium, so that intraatrial conduction time is prolonged. Thus, the timing of the S_1–S_2 stimuli in the HRA would be shorter than the timing of the propagated impulse when it arrives at the region of the Kent bundle as the local A_1–A_2 interval.

Limitations of Tests of Conduction and Refractoriness

It is *unusual* to be able to collect a complete set of numbers (81,82,83,84 and 85). With conduction testing, block most commonly occurs at the AV node level. With refractory period testing, the ERP of the atrium is often longer than the ERP of the AV node so that one encounters atrial refractoriness before AV nodal refractoriness, obviating the possibility of assessing the latter (81,82,83,84 and 85).

An atrial stimulus cannot be used to test the His-Purkinje system if the impulse is blocked at the AV node level. This is a limitation that applies to the majority of patients undergoing either conduction or refractory period testing. One implication is that patients whose His-Purkinje system conduction periods or refractory periods *can* be tested are unusual, and therefore the data may be suspect. This should be kept in mind when reading literature or protocols that involve reporting of refractory periods at various levels of the conduction system.

It is possible to assess anterograde conduction and refractoriness distal to the AV node by direct pacing of the bundle of His (92,93). This is not part of the routine EPS evaluation, however, and is reserved for instances when the information is particularly desired.

Atrium

Passive Recordings

During normal sinus rhythm, earliest atrial depolarization occurs in the region of the sinus node at the junction of the superior vena cava and the high lateral right atrium (18,21,94,95,96,97,98,99,100,101,102,103,104,105,106,107 and 108). Normal *intraatrial* conduction (PA interval) and *interatrial* conduction intervals appear in eTable 62.0.2.

Histologically distinct pathways comparable with bundle branches do not occur in the atrium. The “internodal pathways” are physiologic manifestations related to fiber orientation and thickness (94,95,96 and 97). Intraatrial conduction may be slow, but block rarely occurs (100,103,104 and 105).

Rate Incremental Atrial Pacing (Stepwise or Ramp)

The PA interval may prolong gradually, as does the interatrial conduction time (eTable 62.0.2). It is usually possible to maintain 1:1 capture with incremental pacing techniques to 250 to 300 beats/min. At such pacing rates, precipitation of atrial fibrillation is not rare and is not necessarily an abnormal response. Pacing threshold normally tends to increase at faster rates (21).

Extrastimulus Testing

This technique is used for assessment of atrial refractory periods and for induction of arrhythmias. As with incremental pacing, there is prolongation of intraatrial and interatrial conduction, which is more pronounced in patients with a history of atrial arrhythmias (19,101,102). Development of a fractionated atrial electrogram is more often seen in patients who have a history of atrial fibrillation (101,102,107,108). Intraatrial blocks in response to extrastimuli are unusual (103).

Occasionally, double or triple extrastimuli induce atrial fibrillation in patients with no history of atrial rhythm disorders. Such episodes usually terminate spontaneously and are not clinically relevant in the absence of a history of known or suspected atrial arrhythmias.

Autonomic and Pharmacologic Effects

Vagal tone and medications such as adenosine and edrophonium may slow the sinus rate, but they tend to shorten the refractory period of the atrium. This makes the atrium more vulnerable to induction of atrial fibrillation. Patients with vagal-dependent atrial fibrillation typically have episodes during sleep and the condition may be

worsened by the vagotonic effects of digitalis therapy.

Atrioventricular Junction

The *AV junction* is not synonymous with the *AV node*. The junction is defined as that portion of the conduction system from the proximal portion of the AV node to the distal portion of the bundle of His before its bifurcation.

Junctional Recovery Times

Some individuals have what appears to be a stable junctional rhythm in the absence of a conducted atrial rhythm (109). If these patients are asymptomatic, the question of the need for pacing arises, and the junctional recovery time (JRT) (analogous to the SNRT) helps in the assessment. Following atrial or ventricular pacing, a corrected JRT (CJRT = JRT – basic cycle length) of 200 ms or less, either in the baseline state or after 2.0 to 2.5 mg of atropine, is typical in asymptomatic patients with junctional pacemakers located *either* in the AV node or the bundle of His. Patients with longer CJRTs, if symptomatic, may require pacing.

Atrioventricular Node

Normal ranges for the AH interval, which reflects AV nodal conduction times, are shown in eTable 62.0.2. AV nodal anatomy and physiology are too complex to review here in detail (110). From a clinical electrophysiologist's viewpoint, the node has several pathways entering from the atrium, whose characteristics have been estimated by subtraction (i.e., by assessing function after catheter ablation of alternative pathways) (111,112). A *slow posterior pathway* arises near the coronary sinus ostium and proceeds anteriorly near the tricuspid annulus to the compact node. Use of this pathway is associated with slow conduction velocity (long AH and PR intervals) but ability to conduct at rapid rates in beats/min (shorter ERP and conduction limit). The *fast anterior pathway* is near to the His recording site and has properties that are the opposite of the slow pathway. There is also a presumed transseptal or left-sided input, and many variations on all of these. Within the node itself there is a network of many potential pathways that normally merge to cause synchronous input at the nodal bundle of His junction (113). It is clear that there is a wide spectrum of normal AV nodal physiology (114,115 and 116).

Rate Incremental Atrial Pacing

The AH interval normally prolongs smoothly with incremental pacing until just before block when there may be a marked increase (15) (eFig. 62.0.5) that can be graphed as a smooth curve. AV block at the AV node level occurs normally over a broad range of pacing rates, from approximately 100 to 200 beats/min (15). This range encompasses two standard deviations, but there is a continuum of possible normality that may extend somewhat below 100 beats/min or above 200 beats/min. Age is also a factor, with younger individuals often having shorter AH intervals at a given pacing rate, and Wenckebach at higher rates.

Atrioventricular Node: Extrastimulus Testing and Refractoriness

Extrastimulus testing may produce evidence of longer refractory periods at shorter pacing cycle lengths (eTable 62.0.3). However, this may hold true only for adults (80) and at relatively low pacing rates. Patterns of AH and AV curves in response to increasingly premature extrastimuli can be complex (82).

[d]p <.05 between adult and pediatric values.
From Denes P, Wu D, Dhingra R, et al. The effects of cycle length on cardiac refractory periods in man. *Circulation* 1974;49:32; Dubrow IW, Fisher EA, Amat-Y-Leon F, et al. Comparison of cardiac refractory periods in children and adults. *Circulation* 1975;51:485, with permission.

The alternative *Rosenbleuth hypothesis* is that there is a one-step delay in a refractory barrier (117,118 and 119), and that AV nodal refractoriness actually shortens with shorter drive cycle lengths if calculations are made based not on overall conduction delay but at a single layer in the AV node.

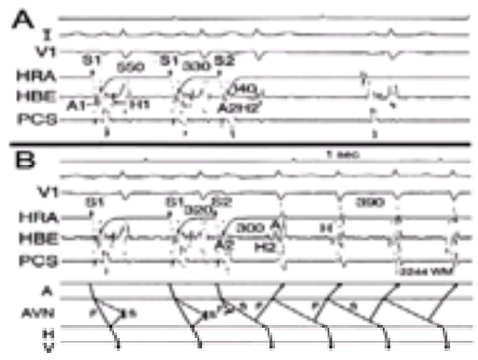
The site of atrial pacing may also affect AV nodal conduction, with shorter AH intervals associated with pacing from the coronary sinus (119,120,121,122 and 123). The AH interval is similar with high and low right atrial pacing (123,124).

Echo Beats

The AV node is not a single pipeline from the atrium to the bundle of His, but rather a network of many potential pathways, with mostly similar conduction and refractory characteristics. Even in healthy individuals, a premature beat or extrastimulus may encounter refractoriness in one pathway. Conduction in one pathway may allow recovery of the previously refractory pathway, so that it is then able to conduct in a retrograde direction. This then emerges into the atrium as an AV nodal echo beat.

Dual Atrioventricular Node Physiology

Rate incremental pacing, or the extrastimulus technique, generally results in a smooth prolongation of the AH curve. If shortening of the paced cycle length by 10 ms (14) or shortening of the S_1–S_2 extrastimulus interval by 10 ms (14,126) results in an increase of 50 ms or more in the AH interval, this is diagnostic of dual AV node pathway physiology (125) (eFig. 62.0.6). Dual pathway physiology is the hallmark of AV node reentry tachycardia, but can also be encountered in some patients with no history of such an arrhythmia. Sometimes, there will be evidence of multiple AH jumps, triple or quadruple pathway physiology.



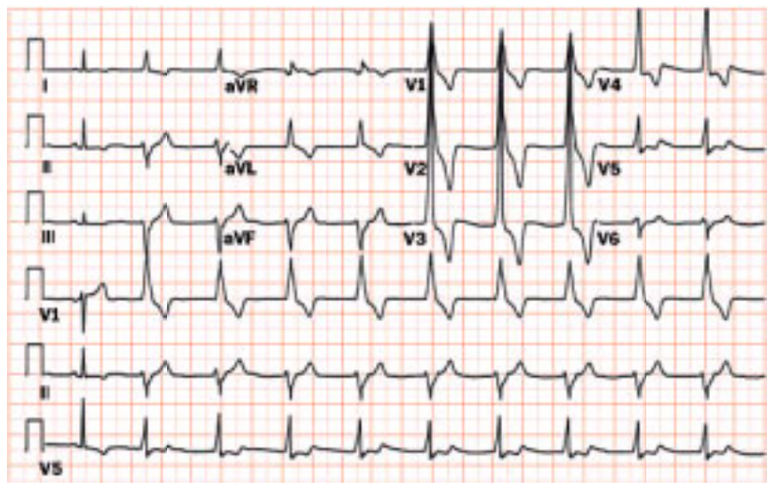
***e*FIGURE 62.0.6** Dual atrioventricular node physiology and induction of atrioventricular nodal (AVN) reentrant tachycardia. **A:** Surface leads 1 and V_1 are displayed together with tracings from the high right atrium (HRA), bundle of His electrogram (HBE), and proximal coronary sinus (PCS). During HRA pacing at a cycle length of 550 ms, an extrastimulus (S_2) is introduced at 330 ms. This produces an A_2–H_2 interval of 140 ms. **B:** When the S_1–S_2 interval is reduced from 330 to 320 ms, the A_2–H_2 "jumps" to 300 ms, indicating the effective refractory period of the fast pathway, and engagement of the slow pathway, initiating AVNRT. This is also shown on the ladder diagram at the bottom, where *F* is fast pathway and *S* is slow pathway.

Atrioventricular Node Responses to Exercise versus Pacing

The PR and AH intervals change little in response to exercise and may in fact decrease somewhat due to a decrease in parasympathetic tone and increase in circulating catecholamines. With incremental atrial pacing in a recumbent patient, autonomic tone is changed only indirectly in response to factors such as anxiety or hypotension. The AH interval, therefore, prolongs markedly with atrial pacing (eFig. 62.0.5), and this is normal.

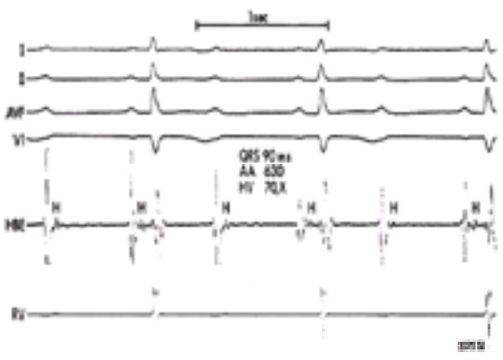
His-Purkinje System (Infranodal Conduction, HV Interval)

Measurement of the HV interval has been discussed in Baseline Intervals and elsewhere in this chapter. Complete heart block at the HV level leaves the patient with an idioventricular rhythm. This may be slow enough to cause syncope or worse. Block at the infranodal HV level is an important diagnosis to make in a patient with unexplained syncope or heart block at a previously undetermined level (3).

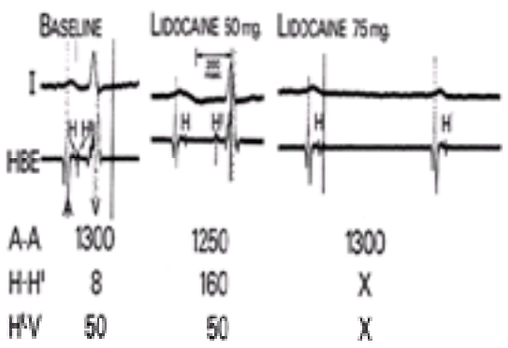


Idioventricular rhythm. Note wide complex QRS with absence of P waves and slow ventricular rate.

Beware the conventional rule of thumb that AV block in the presence of a narrow QRS implies disease at the AV node level, and block in patients with a wide QRS complex or bundle branch block implies that the block is at the His-Purkinje level. The rule of thumb is approximately 85% accurate. It may not matter if one does not pace a patient with a wide QRS who has block at the AV node level (127), but it may be quite important if one does not pace a patient with block at the HV level because the QRS complex is narrow (128). The latter situation can occur with intra-Hisian block or with balanced first-degree bundle branch block (127,128 and 129) (eFig. 62.0.7 and eFig. 62.0.8).



***e*FIGURE 62.0.7** HV block in a patient with a narrow QRS interval. There is 2:1 HV block, with conducted HV intervals prolonged at 70 ms. The prolonged HV interval together with a narrow QRS may indicate balanced bilateral 1-degree HV block (see eFig. 62.0.8). HBE, bundle of His electrogram; RV, right ventricle.



***e*FIGURE 62.0.8** Intra-Hisian block confirmed with lidocaine. Elderly woman with recurrent syncope and a normal 12-lead electrocardiogram. Brief periods of complete heart block were documented, but without accompanying symptoms. The baseline bundle of His electrogram (HBE) revealed a multiphasic or ragged bundle of His potential. After administration of 50 mg of lidocaine (*middle panel*), there was little change in the heart rate, but the multiphasic bundle of His potential split into two deflections labeled *H* and H^1. After an additional 25 mg of lidocaine, there was complete atrioventricular block following the proximal component of the bundle of His potential. (From Fisher JD. Role of electrophysiologic testing in the diagnosis and treatment of patients with known and suspected bradycardias and tachycardias. *Prog Cardiovasc Dis* 1981;24:25, with permission.)

Incremental Atrial Pacing and Conduction Analysis

The HV interval normally remains constant at all paced rates (eTable 62.0.2). HV block that occurs unexpectedly during straight pacing at a rate not producing AV node Wenckebach is usually abnormal (130) and may be grounds for implantation of a permanent pacemaker (131). HV block and bundle branch block can be observed or induced by myriad mechanisms (14,126), summarized in the previous and following sections. The physician must differentiate abnormal from physiologic responses.

Programmed Extrastimuli and Refractory Periods

The HV interval usually remains constant with increasingly premature extrastimuli, because the refractory period of the AV node is usually longer than that of the His-Purkinje system. However, with closely coupled extrastimuli that are conducted through the AV node, refractoriness may be encountered in the bundle of His or the right or left bundle branch. In such cases, determination of the ERP and FRP of these structures is possible. At times, extrastimulus testing produces block that disappears with further prematurity of the extrastimuli. This “gap phenomenon” is discussed in a later section (see Gap Phenomenon).

Pharmacologic Agents

Lidocaine (132,133), procainamide (133,134 and 135), and ajmaline (136,137) have all been used as pharmacologic stresses to the His-Purkinje system. Typical doses of lidocaine (75-mg bolus given twice at 30- to 45-second intervals) produce little alteration of the HV interval. Block within or below the His is an abnormal finding (eFig. 62.0.8). Procainamide (133,134 and 135) 10 mg per kg over 15 to 20 minutes can normally prolong the HV interval by up to 30%. Prolongation beyond that point and block in response to pacing are abnormal responses. HV block in response to lidocaine or procainamide is unusual in patients without suspected conduction disease, or even in patients with bifascicular block who do not have a history of AV block or unexplained syncope (132,133,134 and 135).

Clinical Significance of the HV Interval

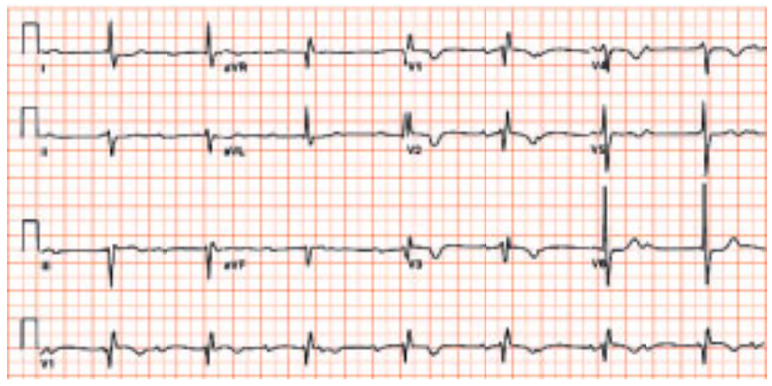
After two decades, this has remained a matter of lively dispute (138,139,140,141,142,143 and 144). Asymptomatic patients with prolonged HV intervals may enjoy a favorable prognosis, although pacing is usually recommended for HV intervals longer than 100 ms (131). In patients with unexplained syncope and no abnormal findings other than an HV interval between 60 and 100 ms, there is a broad range of opinion regarding whether syncope should be attributed to probably intermittent HV block. Analysis is complicated by the fact that many patients with syncope may have had several other plausible causes for syncope. In addition, the HV interval may normally be longer in patients with left branch bundle block (145), due to the longer course of the right branch bundle before ventricular insertion. Bundle of His pacing may be able to differentiate proximal from peripheral left branch bundle block (146,147), which may have different prognostic implications.

Catheter Bumping

The right bundle is particularly vulnerable to block due to mild trauma from the bundle of His recording catheter. This can produce a right branch bundle block pattern or (in patients with left branch bundle block) marked prolongation of the HV interval or even complete block at the HV level. Such blocks are almost always transient.

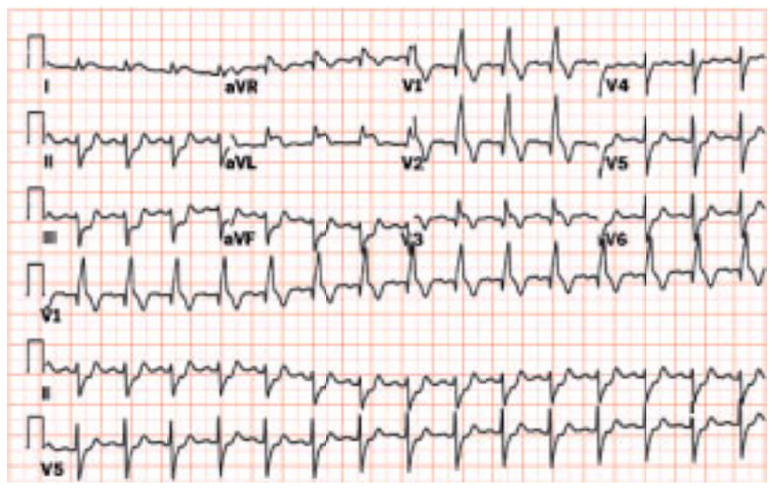
Conduction System in Acute Myocardial Infarction

High-degree AV block, new bundle branch block, and a prolonged HV interval are all associated with an unfavorable prognosis (148,149,150,151,152 and 153). Many such patients succumb to tachyarrhythmias or pump failure rather than AV block, so that the role of permanent pacing remains uncertain, unless the patient has had transient or sustained complete heart block associated with bifascicular or trifascicular disease (131,150). EPS performed during the course of hospitalization for acute myocardial infarction often reveals disease that is more widespread or even in a different location than suggested by the ECG (153,154). Serial changes in the HV interval during the course of hospitalization for an acute infarction suggest that the outcome is more favorable for when initially prolonged HV intervals subsequently normalize (151). These studies, together with prospective trials such as the Multicenter Automatic Defibrillator Implantation Trial (MADIT) and the Multicenter Unsustained Tachycardia Trial (MUSTT), underscore the value of EPS for risk stratification in high-risk postinfarction patients.



An 83-year-old patient with complete heart block, junctional escape rhythm, left anterior hemiblock, and complete right bundle branch block.

Trifascicular block. Note right bundle branch block, left anterior hemiblock, and associated first-degree atrioventricular block.



Acute anterolateral myocardial infarction complicated by conduction disturbance. ST-segment elevation in the anterior precordial leads as well as leads I

and aVL is associated with right bundle branch block and left anterior hemiblock.

Retrograde Conduction (Ventriculoatrial Conduction)

Absence of ventriculoatrial (VA) conduction at any paced rate is both common and normal (155,156,157,158,159 and 160). When present, normal VA conduction uses the normal AV conduction system, with the first atrial depolarization usually in the septal region in proximity to the AV node. In some instances, the slow posterior pathway is preferentially engaged so that first atrial depolarization is somewhat posterior to the AV node.

With rate incremental ventricular pacing or with ventricular extrastimulus testing, the VA interval prolongs smoothly in a manner analogous to that for AV conduction. Dual physiology can be diagnosed in the VA direction in some patients.

To rule out an (nondecremental) accessory pathway, the extrastimulus technique is usually more effective than rate incremental ventricular pacing at demonstrating normal prolongation of the VA interval. If uncertainty continues to exist, adenosine can be extremely helpful. This drug is much more likely to block AV nodal conduction than an accessory pathway.

Retrograde conduction of ventricular extrastimuli can be affected by the baseline sequence of cardiac activation (e.g., sinus rhythm vs. AV pacing with a short AV interval, vs. ventricular pacing) (157).

Multilevel Disease

Many patients with heart disease have prolongation at multiple levels in the conduction system (100,103,104 and 105,161,162 and 163). It is not rare to see prolongations of the PA, AH, and HV intervals. Conversely, some patients with sick sinus syndrome have impaired AV conduction. Before permanent atrial pacing is used for such patients, the physician should be satisfied that there is no significant conduction system disease.

Ventricles

Ventricular stimulation is used to assess retrograde (VA) conduction and refractory periods, to assess retrograde activation patterns including sequences that may indicate an accessory pathway, and in the assessment of vulnerability to inducible ventricular arrhythmias. Details of ventricular stimulation for specific arrhythmias are provided in other chapters. What follows is a more general discussion of ventricular stimulation protocols, supplementing the information presented earlier in this chapter.

Rate Incremental Ventricular Pacing

Straight/stepwise incremental pacing or ramp pacing increasing at 2 to 4 beats/min per second are used in the assessment of retrograde conduction (7). It is unusual to provoke arrhythmias with these tests, even in patients with known ventricular arrhythmia (7,9,164).

Burst Pacing

Again, rate-incremental stimuli are delivered during sinus or other baseline rhythm (9,164,165). The protocol is more aggressive than that used for assessment of retrograde conduction. A typical example would include stimuli resulting in 10 to 15 captures beginning at 150 beats/min (400 ms) with repeated bursts in incremental steps of 25 beats/min until a specified upper rate (commonly 300 beats/min per 200 ms) is achieved, or 1:1 capture is lost

(Steep) Ramp Pacing

In contrast to ramps used for assessment of conduction, this is a steep ramp somewhat analogous to the burst technique just described (9,164,165). Stimuli resulting in 10 to 20 captures are delivered initially at a rate range beginning at 150 beats/min and ramping up quickly to 200 beats/min (400 to 300 ms); repeat ramps are delivered to incremental maximum rates in steps, again with a typical upper limit of 300 beats/min or 200 ms, or failure to maintain 1:1 capture. Because myocardial refractoriness is set by the prior interstimulus interval, it is usually possible to capture at faster rates with the ramp technique than with bursts.

Extrastimulus Technique or Programmed Electrical Stimulation

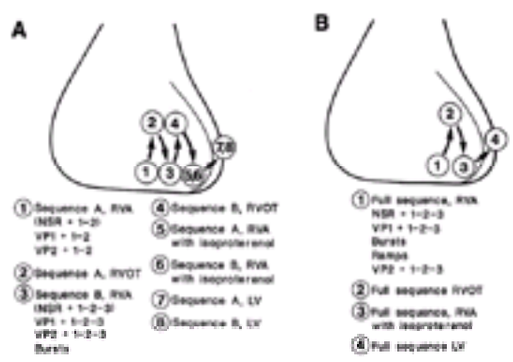
Refractory Periods

The extrastimulus technique or programmed electrical stimulation is used for establishment of refractory periods as described earlier. In the ventricle, the ERP is the longest S_1–S_2 interval that fails to capture. The FRP is dependent on investigator definitions of the site at which the resulting wavefront is measured. The FRP is the shortest coupling interval between depolarizations arriving at the designated site in response to any S_1–S_2 interval.

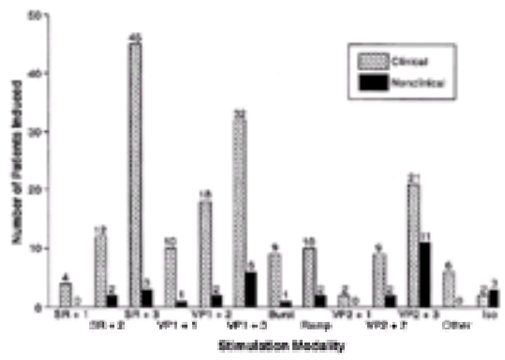
In the study of ventricular arrhythmias (and this applies to atrial stimulation protocols as well), double and triple extrastimuli are often delivered. The refractory periods in response to double and triple extrastimuli must be described in somewhat altered terminology (166). For example, the ERP is usually described as the longest S_1–S_2 interval that *fails* to capture. If extrastimuli are given in 10-ms decrements, the shortest S_1–S_2 interval that does capture is thus only 10 ms longer than the classical ERP. If one is to measure refractory periods of the second and third extrastimulus (S_3 and S_4), then S_1 must continue to capture. Therefore, the terminology is slightly adjusted, with the ERPs being the shortest S_1–S_2, S_2–S_3, and S_3–S_4 intervals that do capture.

Standard Protocols

There is no universally accepted standard protocol, but rather an agreement that an acceptable protocol should meet minimum standards, such as those established by the North American Society of Pacing and Electrophysiology (12) (*e*Fig. 62.0.9 and *e*Fig. 62.0.10). Major variations are the tandem versus simple sequential method (8,9) of delivering sequential extrastimuli and the sequence for delivery of single, double, and triple extrastimuli (*e*Fig. 62.0.9) (8,164,166). Comparative studies of these methods have shown the results to be comparable (8,9).



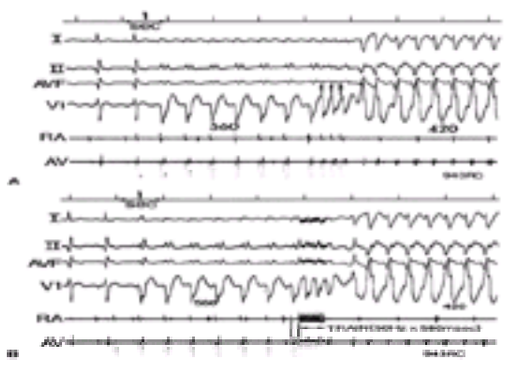
***e*FIGURE 62.0.9** Stimulation sequences. **A:** A complex sequence intended to minimize induction of nonclinical arrhythmias by completing double extrastimuli during sinus rhythm and two ventricular paced rates [normal sinus rhythm (NSR) + 1–2, VP1 and VP2 + 1–2] at the right ventricular apex (RVA) and outflow tract (RVOT) before moving to triple extrastimuli. Some variations complete single extrastimuli at the RVA and RVOT before moving to doubles; very conservative and very time-consuming. **B:** A simpler, but still effective, sequence. LV, left ventricular. (From Fisher JD, Kim SG, Ferrick KJ, et al. Programmed electrical stimulation of the ventricle: an efficient, sensitive, and specific protocol. *PACE* 1992;15:435, with permission.)



***e*FIGURE 62.0.10** Frequency of induced clinical and nonclinical arrhythmia with each stimulating modality (protocol step) in a consecutive series of patients with inducible ventricular tachycardia. All patients received all steps. The sequence actually used is displayed on the abscissa. The ordinate indicates the percent of uses of each modality that resulted in a clinical (*hatched*) or nonclinical (*solid*) arrhythmia. Each of the bar graphs is capped by a number indicating more precisely the percent of arrhythmias induced. SR, sinus rhythm; VP1, the slower paced drive rate; VP2, the faster rate. Numbers 1, 2, and 3 indicate the number of extrastimuli. Note that SR + 3 was more efficacious than either VP1 + 2 or VP2 + 2, and that VP1 + 3 was superior to VP2 + 2. In addition to the *p* values indicated, VP2 + 3 was more likely to induce nonclinical arrhythmias than NSR + 3 or VP1 + 3 (*p* <.05). (From Artoul SG, Fisher JD, Kim SG, et al. Stimulation hierarchy: optimal sequence for double and triple extrastimuli during electrophysiological studies. *PACE* 1992;15:790, with permission.)

Ultrarapid Train Stimulation

Ultrarapid train stimulation of a duration to produce single, double, and triple captures can be used as an efficient alternative to the extrastimulus technique (11) (eFig. 62.0.11).



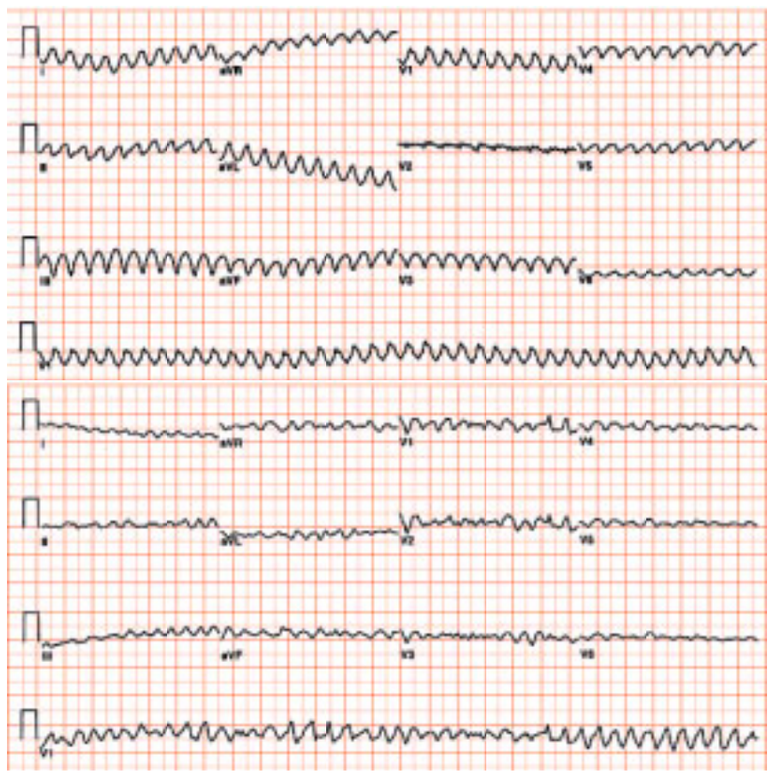
***e*FIGURE 62.0.11** Conventional programmed electrical stimulation and ultrarapid train stimulation. **A:** Surface leads I, II, AVF, and V1 are displayed together with intracardiac recordings from the right atrium (RA) and the atrioventricular junction (AV). Following two sinus beats, eight drive stimuli are delivered at a cycle length of 560 ms, resulting in seven captures. These are followed by triple programmed extrastimuli, which result in induction of ventricular tachycardia with a right bundle branch block morphology and a cycle length of 420 ms. **B:** In the same patient, after ventricular drive pacing at 560 ms, 50 Hz (20 ms) trains produce three captures and ventricular tachycardia of the same morphology and rate produced by conventional programmed electrical stimulation. (From Fisher JD, Platt SB, Cua MC, et al. Ultrarapid train stimulation: an efficient alternative to conventional programmed electrical stimulation for induction of ventricular arrhythmias. *J Intervent Cardiac Electrophysiol* 1997;1:15–21, with permission.)

Other Enhancements

In some patients isoproterenol, prolonged pacing to provoke ischemia, or postural changes may be helpful in producing a desired arrhythmia (see Chapter 58, Chapter 65, Chapter 66, and Chapter 72) (164,166). A variation on the more usual programmed electrical stimulation methods is the sudden change in cycle length protocol, which may enhance dispersion of refractoriness and thereby promote arrhythmia induction (164,167).

Sensitivity and Specificity

Acceptable stimulation protocols should be able to induce sustained monomorphic ventricular tachycardia in 90% of patients with coronary artery disease who present with this arrhythmia (12). Induction of other ventricular arrhythmias (ventricular fibrillation or polymorphic ventricular tachycardia) in patients with a history of such arrhythmias may be as low as 60% (14,164). Induction of sustained monomorphic ventricular tachycardia in patients without a known or suspected history of such arrhythmias is rare (164). Induction of polymorphic ventricular tachycardia or ventricular fibrillation in patients without a history of these arrhythmias may occur in up to 15% of subjects (164).



Ventricular flutter (A). Same patient with degeneration into ventricular fibrillation (B).

An 81-year-old male patient with ventricular tachycardia.

Electrophysiologic Features of Miscellaneous Diseases and Conditions

Mitral Valve Prolapse

Mitral valve prolapse is associated with a variety of sinus node, atrial, and ventricular arrhythmias, the last being sometimes attributable to stressing of the papillary muscles (167,168 and 169). There is a tendency toward cardiac hyperreflexia including neurocardiogenic syncope.

Aortic Valve Disease

AV block may occur, typically at the AV node level in aortic regurgitation and at the His-Purkinje level with aortic stenosis (169,170 and 171).

Congestive Cardiomyopathy

Prolongation of the HV interval is common (172,173 and 174). Conduction disease does not correlate with the degree of ventricular enlargement or end diastolic pressure. Atrial arrhythmias and fatal ventricular arrhythmias are not rare. The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) is a multicenter randomized clinical trial designed to determine whether antiarrhythmic treatment (ICD or amiodarone) is better than placebo.

Hypertrophic Cardiomyopathy

Prolongation of the HV interval is common, and block at that level is not rare. Atrial arrhythmias and fatal ventricular arrhythmias are not rare (175,176,177 and 178).

Infiltrative Cardiomyopathy

In sarcoidosis, amyloidosis, hemochromatosis, and microfibrillar cardiomyopathy, atrial and ventricular tachycardias, sinus node disease, and AV block occur all too commonly (179,180 and 181). Recently described microfibrillar cardiomyopathy (181) is associated with atrial or ventricular arrhythmias, but preservation of ventricular function occurs and it has a prognosis that appears to be more benign than the other conditions.

Collagen Vascular Diseases

Arrhythmias and block may occur and are an adverse prognostic sign (182,183 and 184). Congenital complete heart block is common in offspring of mothers with connective tissue diseases.

Infectious Processes

Viral myocarditis may be associated with ventricular arrhythmias, either acutely or as a result of the subsequent development of dilated cardiomyopathy (185,186 and 187). Varicella myocarditis is associated with malignant ventricular arrhythmias and has a poor prognosis. Bacterial infections may result in heart block. In South America, Chagas' disease is a common cause of heart block and tachycardias (188).

Thyroid Disease

Thyrotoxicosis has been associated with sudden death, ventricular arrhythmias, heart block, and myocardial infarction (189,190). Hyperthyroidism has been reported to cause AV block, but facilitation of AV conduction and sinus tachycardias are more common. Hypothyroidism may cause AV block at the AV node and His-Purkinje levels, and there is prolongation of myocardial action potentials.

Other Phenomena

Phase 3 Block

Phase 3 block (tachycardia-dependent block) (79,80,191,192,193 and 194) occurs when an impulse arrives at tissues that are still refractory (*e*Table 62.0.3) due to incomplete repolarization. Manifestations include bundle branch block and fascicular block as well as complete AV block.

Phase 4 Block

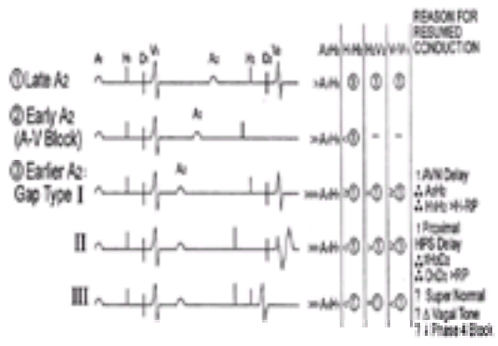
Phase 4 block (bradycardia-dependent block) (79,80,191,192,193,194,195 and 196) occurs when conduction of an impulse is blocked in tissues that are well beyond their normal refractory periods.

Distal Gate and Bundle Branch Reentry

The longest refractory periods in the His-Purkinje system are found most distally, at or near the Purkinje-myocardial junction (197,198). This creates a distal gate that inhibits retroconduction of early ventricular extrasystoles. Thus, when early extrastimuli are delivered to the right ventricular apex, the nearby distal gates of the right bundle branch may still be refractory, preventing retroconduction. However, the impulse may propagate to the left ventricle, and by that time retroconduction up the left bundle branch may be possible (199). In as many as 50% of healthy individuals, the impulse propagated up the left bundle branch may then proceed in an anterograde direction through the right bundle branch to create a bundle branch reentry repetitive response (198). Such bundle branch reentries rarely last more than one or two beats in healthy individuals, but are an occasional cause of sustained tachycardia, particularly in dilated hearts (199,200).

Gap Phenomenon

Using the extrastimulus (A_2) technique in the atrium, AV block or bundle branch block may occur at a certain S_1–S_2 interval, and yet with further prematurity conduction resumes (103,201,202,203,204,205,206,207,208,209,210 and 211) (*e*Fig. 62.0.12). This gap in conduction occurs for many reasons, the most common of which are summarized in *e*Figure 62.0.12.



***e*FIGURE 62.0.12** The gap phenomenon. In line 1, a late atrial extrastimulus (A_2) conducts with prolongation of the A_2–H_2 compared with the A_1–H_1. In line 2, an earlier A_2 fails to conduct because the H_1–H_2 interval is within the effective refractory period of the bundle of His. In line 3, an earlier A_2 results in resumption of conduction due to prolongation of the A_2–H_2 interval such that the H_1–H_2 now exceeds the refractory period of the bundle of His. This is type I gap. The next line shows type II gap in which conduction resumes after delayed conduction through the His-Purkinje system (HPS). In type III gap, conduction is resumed for any of several speculative reasons. A-V, atrioventricular; AVN, atrioventricular node. (Modified from Fisher JD. Role of electrophysiologic testing in the diagnosis and treatment of patients with known and suspected bradycardias and tachycardias. *Prog Cardiovasc Dis* 1981;24:25, with permission.)

Type I gap is most common. An atrial extrastimulus conducted with modest delay through the AV node finds the bundle of His still refractory, causing block. With increasing prematurity of the atrial extrastimulus A_2, the A_2–H_2 interval prolongs further so that the H_1–H_2 interval now exceeds the refractory period of the bundle of His, and conduction resumes. The same principle applies to all levels of the atrium, the AV conduction system, and the ventricle, so that there are virtually endless possibilities for gaps in both the anterograde and retrograde directions.

The gap phenomenon is not an abnormality, but reflects the interplay between conduction velocity and refractory periods in different parts of the heart. Demonstration of the gap phenomenon can be enhanced by creating changes in neurohumoral tone or heart rate.

Supernormality

A stimulus that is precisely timed to occur immediately following repolarization may produce capture at a stimulus amplitude that fails to capture if delivered slightly earlier or later (212,213). This supernormal excitability can be seen clinically (e.g., when a failing pacemaker captures just at the end of the T wave, but not elsewhere in the cardiac cycle). Supernormality has been demonstrated in the His-Purkinje system, Bachmann's bundle in the dog, and in working myocardium of the atrium and ventricle, but not in the AV node. In a somewhat comparable fashion, supernormal *conduction* exists when a precisely timed beat results in restoration or improvement of conduction in a previously depressed or blocked area.

COMPLETE, SCREENING, AND TARGETED ELECTROPHYSIOLOGIC STUDIES

Philosophical, practical, and ethical considerations materially affect not only the decision to perform an EPS, but the thoroughness of the study itself.

Complete Diagnostic Electrophysiologic Study

The complexity and number of possible maneuvers that can be performed during an EPS make it virtually impossible to do a truly complete study. For example, one pharmacologic stress could interfere with other portions of the EPS, so that a second session would be needed to complete a thorough evaluation. In addition to the many tests and maneuvers outlined in this chapter, there are many other variations that can be applied for specific indications related to patients with known or suspected bradycardias or tachycardias (see Chapter 63, Chapter 64, Chapter 65, Chapter 66, Chapter 67, Chapter 68, Chapter 70, Chapter 71, Chapter 72, and Chapter 73). A more complete evaluation is needed when an EPS is performed for evaluation of a patient with syncope of undetermined origin, compared with an EPS performed to assess the efficacy of a drug given to prevent induction of an arrhythmia that has previously been characterized.

Ethical considerations arise on many levels: Is there a true indication for the EPS? How thorough an examination must be done before billing for a "complete diagnostic EPS"?

CONCLUSION

EPSs are appropriate and necessary for a broad range of indications (3). EPS has become indispensable not only for diagnosis and risk stratification, but for selection and assessment of therapies such as pacemakers and drugs and for interventional procedures such as radiofrequency catheter ablation. EPS is associated with low levels of risk compared with diagnostic interventional cardiac angiographic procedures.

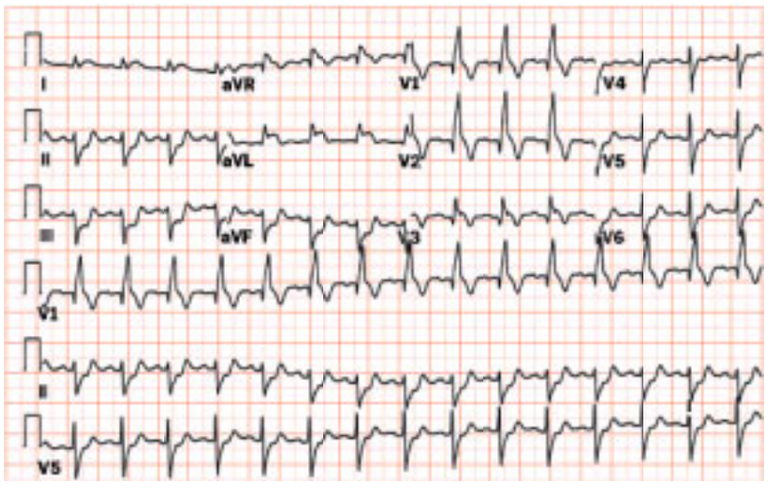
OVERVIEW

Sinus nodal dysfunction and atrioventricular (AV) block account for the majority of significant bradyarrhythmias. In addition to structural abnormalities, drug effects and autonomic influences can cause sinus nodal dysfunction. Acquired AV block is most commonly caused by idiopathic fibrosis, acute myocardial infarction, or drug effects. Patients with asymptomatic sinus bradycardia or sinus pauses have a good prognosis and do not require treatment. On the other hand, those with tachycardia-bradycardia syndrome have a much worse prognosis, because of their risk of thromboembolic complications. Therefore, the aim of therapy is prevention of atrial fibrillation. Atrial pacing and anticoagulation can greatly reduce the incidence of stroke in this high-risk group. Once appropriate pacing has been established for AV block, the prognosis is primarily dependent on the extent of the associated heart disease. The availability of dual-chamber and rate-responsive pacing has greatly improved the lifestyle and prognosis of symptomatic patients. In many instances, the challenge for physicians is documenting sinus nodal dysfunction or AV block in association with symptoms.

GLOSSARY

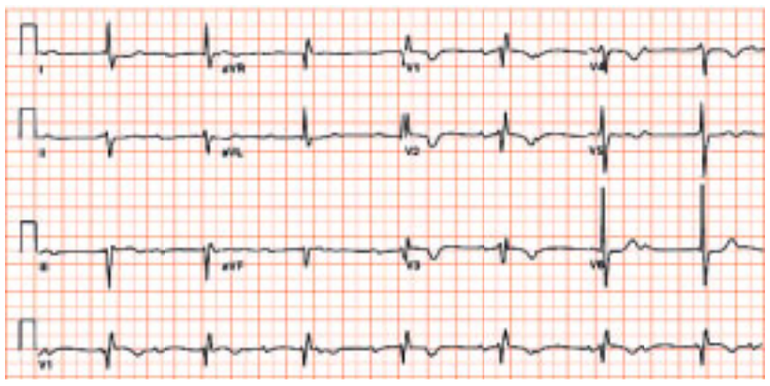
Acquired complete heart block: Third-degree AV block present as a result of some insult to the specialized conduction system, but not present at birth. Usually it is associated with block below the AV node.

Bifascicular block: Conduction delay in two fascicles; right bundle branch block with left anterior fascicular block, right bundle branch block with left posterior fascicular block, or left bundle branch block.



Acute anterolateral myocardial infarction complicated by conduction disturbance. ST-segment elevation in the anterior precordial leads as well as leads I and aV_L is associated with right bundle branch block and left anterior hemiblock.

Congenital complete heart block: Third-degree AV block present from birth and seen as completely dissociated P waves and QRS complexes, each firing at their own pacemaker rate. The level of block is usually within the AV node.



An 83-year-old patient with complete heart block, junctional escape rhythm, left anterior hemiblock, and complete right bundle branch block.

Inappropriate sinus bradycardia: A sinus rate less than 60 beats/min, which is persistent and does not increase appropriately with exercise.

Sick sinus syndrome: See *tachycardia-bradycardia syndrome*.

Sinoatrial conduction time: An indirect measurement obtained during an electrophysiology study. Premature atrial extrastimuli are introduced at the high right atrium at progressively shorter intervals during sinus rhythm until atrial refractoriness is found. Calculations can then be made to estimate the conduction time.

Sinoatrial exit block: A period of asystole resulting from the generated sinus impulse not leaving the sinus nodal region, caused by delay in conduction or block.

Sinus arrest: Used interchangeably with the term *sinus pause*. A result of transient failure of impulse formation at the sinoatrial node during which time no P wave is seen.

Sinus nodal dysfunction: Any abnormality in sinus nodal function, including inappropriate sinus bradycardia, sinoatrial exit block, sinoatrial arrest, or alternating sinus bradycardia and atrial tachyarrhythmias. The term does not indicate a specific etiology or the presence of symptoms.

Sinus nodal recovery time: An indirect measurement obtained invasively by overdrive pacing of the sinus node. The interval between the last paced P wave and the first spontaneous atrial deflection is the sinus nodal recovery time.

Tachycardia-bradycardia syndrome: Frequently referred to as *sick sinus syndrome*. This common manifestation of sinus nodal dysfunction refers to intermittent sinus or junctional bradycardia alternating with atrial tachycardia (usually paroxysmal atrial fibrillation). Symptoms may result from either the bradycardia or the tachycardic phase.

Trifascicular block: Slowed conduction in all three fascicles; PR prolongation in addition to a bifascicular block.

Trifascicular block. Note right bundle branch block, left anterior hemiblock, and associated first-degree atrioventricular block.

Wenckebach periodicity: Type I second-degree AV block, demonstrating the following features: (a) progressive lengthening of the PR interval, (b) lengthening of the RR intervals at progressively decreasing increments, (c) a pause including the nonconducted P wave that is less than the sum of any two consecutively conducted beats, and (d) shortening of the PR interval postblock, compared with the PR interval just preceding the blocked cycle.

Acute inferior myocardial infarction complicated by Wenckebach block. Note inferior ST-segment elevation and Q waves as well as progressive prolongation of the PR interval with grouped beating.

INTRODUCTION

Bradycardia is most commonly secondary to sinus nodal dysfunction. Bradyarrhythmias secondary to AV block at the level of the AV node or distal to the bundle of His also account for a large number of patients who have bradyarrhythmias. In this chapter, we review basic and anatomic concepts, clinical profiles, and therapeutic strategies relevant to the recognition and treatment of patients with bradyarrhythmias.

SINUS NODAL DYSFUNCTION

Historical Perspective

Rhythm disturbances resulting from sinus nodal dysfunction include sinus bradycardia and pauses, as well as atrial tachyarrhythmias alternating with bradyarrhythmias. As early as 1909, episodes of atrial standstill of 4 to 8 seconds in duration were documented by Laslett in a patient with syncope, using combined jugular venous pulse and radial artery tracings (1). This report was followed by Mackenzie's recordings of digitalis-induced atrial standstill (2). These early reports identified the association of atrial standstill with syncope and the possible adverse effects of drugs on the patient with sinus nodal dysfunction. However, the concept of sinus nodal dysfunction as a clinical syndrome did not appear until Short described alternating bradycardia and tachycardia in patients with syncope (3). Some clarification of this association between bradycardia and tachycardia was provided by Katz and Pick in 1956 in their description of overdrive suppression of the sinus node, resulting sinus standstill, and the danger of asystole when subsidiary pacemakers fail (4). In 1967, Lown coined the phrase *sick sinus syndrome* for describing chaotic atrial activity combined with bradycardia postcardioversion (5). This term was further popularized by Ferrer, who defined the spectrum of arrhythmias involved (6,7). The clinical entity of sick sinus syndrome became widely accepted as a frequent and important management problem. Although *sick sinus syndrome* is still used, the terms *sinus nodal dysfunction*, *sinoatrial disease*, and *sinoatrial dysfunction* are more commonly used to describe this syndrome.

Oral medications have not been found useful in treating the symptoms associated with bradyarrhythmias secondary to sinus nodal dysfunction (3,8). Before the availability of permanent pacemakers, replacement of paroxysmal atrial flutter with chronic atrial fibrillation provided the best hope for resolution of symptoms (3). The current management for many patients with sinus nodal dysfunction includes a pacemaker for treatment of their bradycardias, along with antiarrhythmic drug therapy for control of their tachycardias.

Anatomic Considerations

The origin of the normal heartbeat arises from the sinus node, which is located laterally in the epicardial groove of the sulcus terminalis, near the junction of the superior vena cava and right atrium. An early anatomic description by Katz and Pick defined the sinus node as having a head (diameter of 5 mm) and a body and tail

(diameter of 2 mm). Starting epicardially at the junction of the superior vena cava and atrium, it courses downward and to the left, to end subendocardially (4). The sinus node is composed of “nests” of principal pacemaker cells, which spontaneously depolarize and are situated within a fibrous tissue matrix. However, what at first appeared to be a simple concept is now known to be vastly more complex. Instead of a discrete point of impulse initiation, the sinus node is in reality a region, which is functionally larger and less well-defined than initially realized (9). The blood supply to the region is variable, making it more vulnerable to damage during operative procedures (10). The blood supply predominantly comes from the sinus nodal artery, which is a branch of the right coronary artery in 65% of patients. Based on findings in the rabbit sinus node, the zone containing the principal pacemaker cells may be small and contains only a few thousand cells (11). These cells have been referred to as *P cells* because of their relatively pale appearance on electron micrography. In addition to this principal nest of cells, other nests contain cells with slower intrinsic depolarization rates and serve as backup pacemakers in response to changing physiologic and pathologic conditions. The principal pacemaker site shifts within the sinus nodal region, resulting in subtle changes in P-wave morphology (9,12,13).

Normal conduction velocities within the sinus node are slow, on the order of 2 to 5 cm per second, increasing the likelihood of intranodal conduction block (14). Fibrosis no longer appears to be the predominate cause of problems in sinoatrial conduction. Furthermore, the innervation of the sinus node is complex. Both parasympathetic and sympathetic mediators influence the rate of spontaneous depolarization in pacemaker cells and may cause a shift in the principal pacemaker site within the sinus nodal region (14,15). Acetylcholine, from parasympathetic nerve endings, reduces the rate of cell depolarization and prolongs cell refractoriness (16). Therefore, increased parasympathetic activity can produce sinus bradycardia, sinus arrest, and sinoatrial exit block. On the other hand, sympathetic mediators, such as norepinephrine and epinephrine, can increase the sinus rate and reverse sinus arrest and sinoatrial exit block (17). The anatomy and physiology of the sinus node are currently active areas of research.

Electrocardiographic Features of Sinus Nodal Dysfunction

Inappropriate Sinus Bradycardia

Sinus bradycardia (sinus rate less than 60 beats/min) (Fig. 63.1) is considered inappropriate when it is persistent and does not increase appropriately with exercise. This arrhythmia should be distinguished from asymptomatic resting sinus bradycardia in young athletes and in normal adults during sleep (18,19). Chronotropic incompetence is not present in these individuals, as it is in patients with sinus nodal dysfunction.

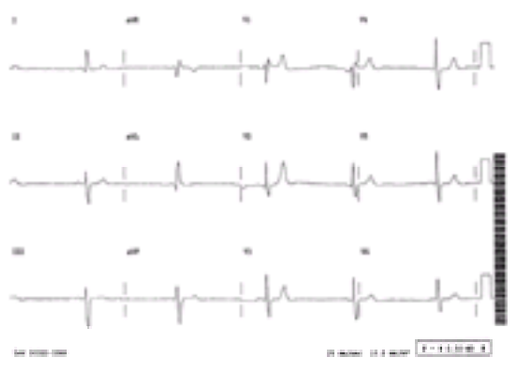


FIGURE 63.1 This electrocardiogram shows sinus bradycardia at a rate of 30 beats/min. Right bundle branch block and left anterior fascicular block are also present. aVF, augmented voltage unipolar left foot lead; aVL, augmented voltage unipolar left arm lead; aVR, augmented voltage unipolar right arm lead.

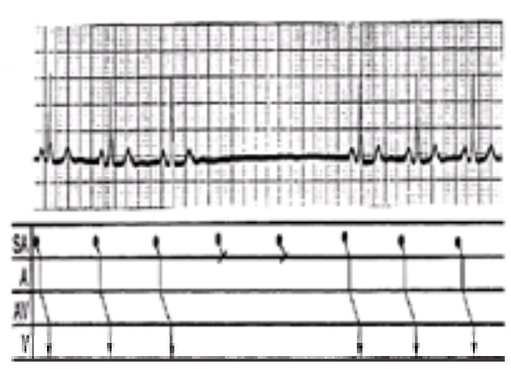
Sinus Arrest

The terms *sinus arrest* (Fig. 63.2) and *sinus pause* are used interchangeably and are a result of the sinus node’s principal pacemaker cells failing to fire. The pause is not an exact multiple of the preceding PP interval. Pauses greater than 3 seconds are rare in normal individuals and may or may not be associated with symptoms, but are usually caused by sinus nodal dysfunction (20,21). In contrast, asymptomatic pauses greater than 2 seconds (but less than 3 seconds) are seen in 11% of normal patients during 24-hour Holter monitoring and are especially common in trained athletes (22).

FIGURE 63.2 These rhythm strips of leads V_1 and V_5 were recorded simultaneously and depict sinus pauses of 3.0 and 2.8 seconds posttermination of atrial tachycardia.

Sinoatrial Exit Block

Like sinus arrest, sinoatrial exit block is characterized by a period of asystole without the expected P wave seen. In patients with sinus nodal dysfunction, an escape beat does not appear, but instead the sinus block is terminated by a sinus beat. In theory, sinoatrial exit block can be distinguished from sinus arrest because the exit block pause is an exact multiple of the baseline PP interval (eFig. 63.2.1). In actuality, the distinction is often not possible because of sinus arrhythmia, causing normal beat-to-beat variations in the sinus rate. Sinoatrial exit block results when a normally generated sinus impulse does not leave the sinus nodal region because of delay in conduction or block. The most common site of block is probably within the sinus node itself, caused by the slow conduction in this region.

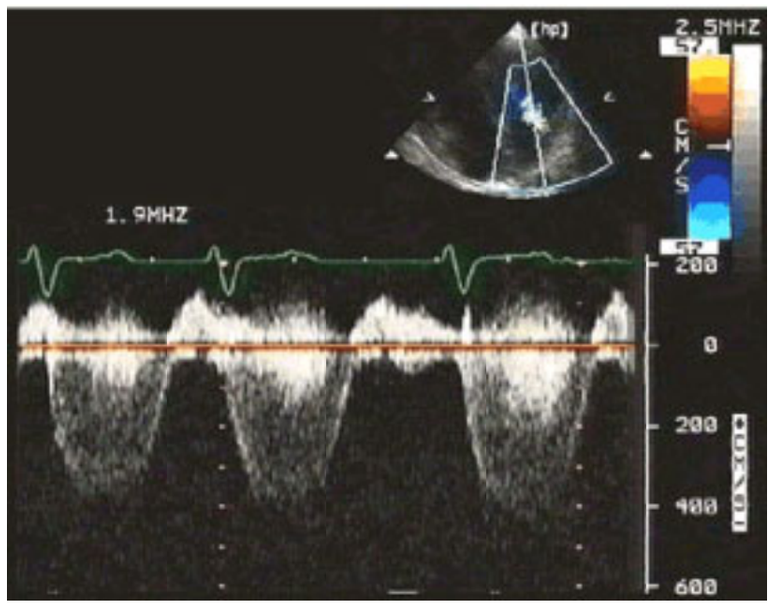


***e*FIGURE 63.2.1** This rhythm strip is an example of sinoatrial exit block. Note that the exit block pause is an exact multiple of the baseline PP interval. The bottom half of the figure is a ladder diagram illustrating conduction from the sinoatrial (SA) region through the atrium (A), atrioventricular (AV) node to the ventricle (V) in the case of the sinus beats. However, the impulse does not exit the SA region during the pause, and no P waves are seen on the surface electrogram.

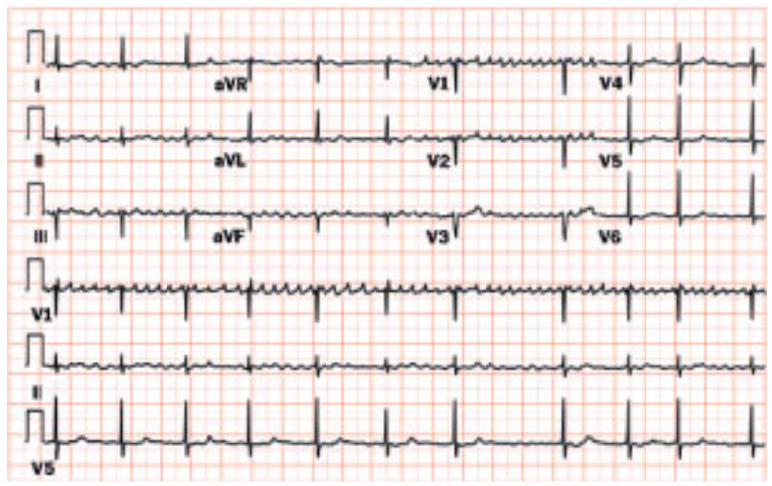
Exit block is classified into three types, analogous to that of AV block. First-degree sinoatrial block is caused by abnormal prolongation of the sinoatrial conduction time. The impulse reaches the atrium, but is delayed. This conduction abnormality cannot be identified from surface electrography, but needs to be verified either by direct recording or indirect measurement of sinoatrial conduction time during an electrophysiologic study. Second-degree sinoatrial exit block is marked by intermittent failure of the sinus impulse to exit the node. This is viewed as Wenckebach periodicity of the P wave on surface electrography. Progressive shortening of the PP interval preceding the dropped P wave is seen. In higher grade, second-degree sinoatrial exit block, abrupt absence of one or more P waves results from failure of the atrial impulse to exit the sinus node. As noted previously, the atrial pause should be an exact multiple of the immediately preceding PP interval. However, normal variations in the sinus rate caused by sinus arrhythmia may obscure this measurement. Third-degree or complete sinoatrial exit block is seen as a pause in the sinus rhythm and cannot be distinguished from prolonged sinus arrest. However, determining the difference is not necessary from a clinical standpoint, as both entities will likely be symptomatic.

Chronic Atrial Fibrillation

The presence of chronic atrial fibrillation in a patient with a slow ventricular response not secondary to drug therapy is a sign of sinus nodal dysfunction. In some cases, cardioversion results in a long sinus pause before the appearance of sinus rhythm, or junctional escape rhythm. Although a combination of sinus nodal and AV conduction disease may be present in many instances, examples of rapid ventricular responses during atrial tachyarrhythmias can frequently be found.



Apical continuous wave spectral Doppler recording of mitral regurgitation (systolic parabolic downward velocities). Note beat-to-beat variation due to atrial fibrillation.



Atrial fibrillation. Narrow complex QRS with irregular RR intervals. Ventricular rate is controlled.

Tachycardia-Bradycardia Syndrome

Tachycardia-bradycardia syndrome refers to the presence of intermittent sinus or junctional bradycardia alternating with atrial tachycardia (usually paroxysmal atrial fibrillation) in the same patient (Fig. 63.3). This condition, frequently referred to as *sick sinus syndrome*, is a common manifestation of sinus nodal dysfunction. The highest incidence of syncope associated with sinus nodal dysfunction probably occurs in this group (3). Syncope typically occurs secondary to a long sinus pause after the spontaneous termination of atrial fibrillation.

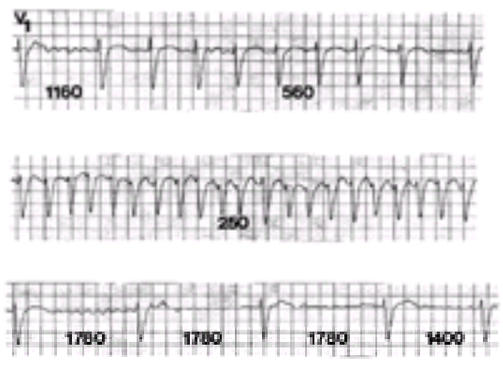


FIGURE 63.3 These three rhythm strips were obtained from the same patient at different times and illustrate the marked variability of heart rates in patients with tachycardia-bradycardia syndrome. The labeled cycle lengths are in milliseconds.

Pathophysiology

Intrinsic Sinus Nodal Dysfunction

Idiopathic degenerative disease is probably the most common cause of intrinsic sinus nodal dysfunction (Table 63.1). Pathologic studies have shown an increase in fibrous tissue in the area of the sinus node with age. Why some individuals develop sinus nodal dysfunction whereas others do not, is not easily explained by fibrous tissue replacement only (23,24). Coronary artery disease may be responsible for one-third of cases of sinus nodal dysfunction. This estimation is based on a study by Shaw et al. (25), in which angiography was used to demonstrate the extent of coronary artery disease in the sinus nodal artery in patients with sinus nodal dysfunction. Transient slowing of the sinus rate, or sinus arrest, can complicate an acute myocardial infarction. This is usually seen with an acute inferior wall myocardial infarction, is caused by neural influences, and rarely persists (26). Cardiomyopathy, long-standing hypertension, infiltrative disorders, collagen vascular diseases, inflammatory processes, and surgical trauma can also result in sinus nodal dysfunction. Orthotopic cardiac transplantation is associated with a high incidence of sinus nodal dysfunction in the donor heart. In an Austrian study with a series of 90 transplant patients, 45% were found to have sinus nodal dysfunction postoperatively, and 21%

required permanent pacing. However, sudden death caused by donor sinus nodal dysfunction appears to be a rare occurrence in post–cardiac transplantation (27). The musculoskeletal disorders of myotonic dystrophy or Friedreich's ataxia are rare causes of sinus nodal dysfunction. A familial form of sinus nodal dysfunction accounts for a small number of cases (28).

Intrinsic causes
Idiopathic degenerative disease
Coronary artery disease
Cardiomyopathy
Hypertension
Infiltrative disorders (amyloidosis, hemochromatosis, tumors)
Collagen vascular disease (scleroderma, lupus erythematosus)
Inflammatory processes (myocarditis, pericarditis)
Surgical trauma (orthotopic cardiac transplantation)
Musculoskeletal disorders (myotonic dystrophy, Friedreich's ataxia)
Congenital heart disease (postoperative or in absence of surgical correction)
Extrinsic causes
Drug effects
Beta blocking agents
Calcium channel blocking agents
Digoxin
Sympatholytic antihypertensives (clonidine, methyldopa, and reserpine)
Antiarrhythmic drugs
Type IA (quinidine, procainamide, disopyramide)
Type IC (flecainide, propafenone)
Type III (sotalol, amiodarone)
Others (lithium, cimetidine, amitriptyline, phenytoin)
Autonomic influences
Excessive vagal tone
Carotid sinus syndrome
Vasovagal syncope
Well-trained athletes
Electrolyte abnormalities
Hyperkalemia
Hypercalcemia
Endocrine disorders: hypothyroidism
Increased intracranial pressure
Hypothermia
Sepsis

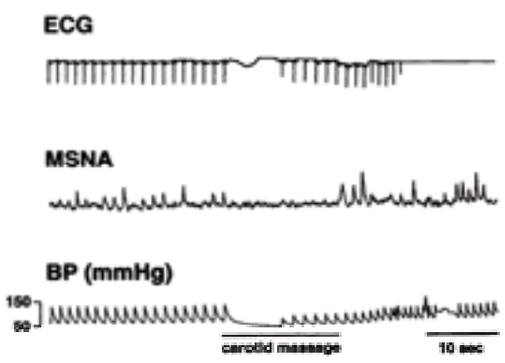
TABLE 63.1 CAUSES OF SINUS NODAL DYSFUNCTION

In the pediatric population, most cases of sinus nodal dysfunction can be attributed to surgical trauma (see Chapter 70 for a further discussion of this subject). Most commonly associated with this complication is Mustard's procedure for transposition of the great arteries (29) and repair of atrial septal defects, especially of the sinus venosus type (30). Sinus nodal dysfunction can occur in children with congenital heart disease, such as secundum atrial defects, even though no surgery has been performed (31). In some children with sinus nodal dysfunction, no structural heart disease is known (32).

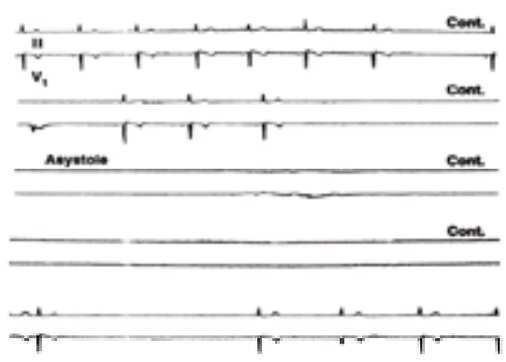
Extrinsic Sinus Nodal Dysfunction

In the absence of structural abnormalities, the predominant causes of sinus nodal dysfunction are drug effects and autonomic influences (Table 63.1). Drugs known to depress sinus nodal function include beta-blockers, calcium channel blockers, digoxin (33), and sympatholytic antihypertensives (e.g., clonidine, methyldopa, and reserpine) (34). Types IA, IC, and III antiarrhythmic drugs can depress sinus nodal function (33) and, occasionally, may produce proarrhythmias in patients with sick sinus syndrome. Paroxysmal primary atrial tachycardias and pause-dependent ventricular tachycardia have been described (35,36). Other drugs reported to affect sinus nodal function include lithium, cimetidine, amitriptyline, and phenytoin (33).

Sinus nodal dysfunction may sometimes result from excessive vagal tone in individuals without intrinsic sinus nodal disease. The transient bradyarrhythmias produced can include marked sinus bradycardia, sinus pauses, or sinoatrial exit block (37,38). Autonomically induced asystole has been reported to occur rarely and may result in sudden death (39). Hypervagatonia can be seen in carotid sinus syndrome (eFig. 63.3.1) and vasovagal syncope (eFig. 63.3.2). Well-trained athletes with increased vagal tone may require some deconditioning to help prevent symptomatic bradyarrhythmias (40). Less common extrinsic causes of sinus nodal dysfunction include hyperkalemia, hypothyroidism, increased intracranial pressure, hypothermia, hypercarbia, and sepsis.



***e*FIGURE 63.3.1** Sinus pause during carotid sinus massage. Note the decrease in muscle sympathetic neural activity (MSNA) during duration of carotid sinus massage and loss of blood pressure (BP) during sinus pause. ECG, electrocardiogram. (Unpublished data from J. Luck and U. Leuenberger.)



***e*FIGURE 63.3.2** Example of prolonged asystole during vasovagal syncope. (Unpublished data from J. Luck.)

Clinical Profile

Incidence

Few data are available regarding the incidence of sinus nodal dysfunction in the general population. However, a Belgian study involving cardiac patients estimated the incidence in patients over 50 years of age to be 3 in 5,000 (41). Sinus nodal dysfunction affects men and women equally (42).

Symptoms

The symptoms reported by patients with sinus nodal dysfunction are varied, and many times nonspecific. Syncope and presyncope are the most frequent symptoms associated with significant bradycardia. Fatigue, angina, and shortness of breath can also be seen. Elderly patients may have the more subtle symptoms of gastrointestinal distress or change in mental status. Patients with tachycardia-bradycardia syndrome may only experience palpitations associated with the tachycardia or embolic events. Syncope in an individual with paroxysmal atrial fibrillation is classically associated with the long sinus pause at the spontaneous termination of the tachycardia. The intermittent nature of these symptoms makes documentation of the associated rhythm disturbance difficult at times. In other cases, marked sinus bradycardia and sinus pauses may be asymptomatic (6,42,43).

Diagnostic Techniques

Both noninvasive and invasive means of diagnosing sinus nodal dysfunction are available. Generally, the noninvasive methods of electrocardiographic (ECG)

monitoring, exercise testing, and autonomic testing are used first. However, if symptoms are infrequent, invasive electrophysiologic testing may be pursued.

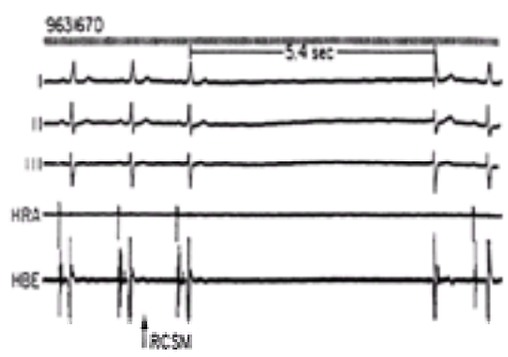
Noninvasive Testing

A 12-lead ECG needs to be obtained in the patient with syncope or near syncopal episodes. However, the diagnosis of sinus nodal dysfunction as the etiology of these symptoms is rarely made from the simple ECG. If symptoms are frequent, 24- or 48-hour ambulatory Holter monitoring can be useful. Documentation of symptoms in a diary by the patient while wearing the Holter monitor is essential for correlation of symptoms with the heart rhythm at the time. In some cases, the Holter monitor can exclude sinus nodal dysfunction as the cause of symptoms, if normal sinus rhythm is documented. In contrast, sinus pauses recorded may not be associated with symptoms. Several Holter monitor studies (21,44) have demonstrated the futility of treating asymptomatic pauses, even if 3 seconds or longer. Most pauses, ranging from 2 to 15 seconds, were asymptomatic, and pacing did not benefit those without associated symptoms. The length of the pause correlated poorly with symptoms and prognosis.

A relatively newer diagnostic tool is the event recorder, or loop recorder, which is useful in patients whose symptoms occur infrequently. This device is used to record the heart rhythm only during symptoms. Later, the recorded ECG is sent transtelephonically by the patient to a central monitoring station.

Exercise testing is of limited value in diagnosing sinus nodal dysfunction. However, in some cases, it is useful in differentiating those patients with hronotropic incompetence from patients with resting bradycardia who demonstrate a normal heart rate increase with exercise. Certain patients with sinus nodal dysfunction and chronotropic incompetence exhibit abnormal heart rate responses to exercise. The increase in heart rate at each stage of exercise may be less than normal, with a plateau seen below the maximum predicted heart rate (adjusted for age). Other patients with sinus nodal dysfunction may achieve an appropriate peak heart rate during exercise but may have a slow heart rate acceleration in the initial stage or rapid deceleration of heart rate in the recovery stage. These abnormal chronotropic responses can help to identify the cause of exercise intolerance in some patients with sinus nodal dysfunction and can help to determine their pacemaker prescription (45,46).

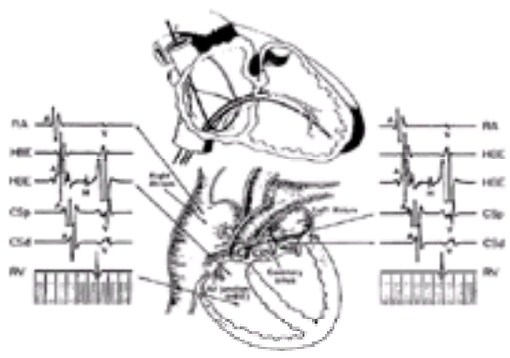
Autonomic testing of the sinus node includes various pharmacologic interventions and maneuvers to test reflex responses. An abnormal response to carotid sinus massage (pause greater than 3 seconds) may indicate sinus nodal dysfunction (*e*Fig. 63.3.3), but this response may also occur in asymptomatic elderly individuals (47). Heart rate response to Valsalva's maneuver (normally decreased) or upright tilt (normally increased) can also be used to verify that the autonomic nervous system is itself intact. The most commonly used pharmacologic intervention is used to determine the intrinsic heart rate. Complete autonomic blockade is accomplished by administering atropine, 0.04 mg per kg, and propranolol, 0.20 mg per kg. The resulting intrinsic heart rate represents the sinus nodal rate without autonomic influences. The normal intrinsic heart rate is age dependent and can be calculated using the following equation: intrinsic heart rate = 118.1 – (0.57 × age) beats/min (48). A low intrinsic heart rate is consistent with abnormal intrinsic sinus nodal function. A normal intrinsic heart rate in a patient with known sinus nodal dysfunction suggests abnormal autonomic regulation.



***e*FIGURE 63.3.3** Abnormal sinus node slowing with carotid sinus massage. During sinus rhythm, right carotid sinus massage (RCSM, *arrow*) was applied, and the patient had a prolonged asystolic pause (5.4 seconds) closed by a junctional escape before resumption of sinus rhythm. This exaggeration of the normal response of the sinus node to carotid sinus massage represents a hypersensitive carotid sinus reflex but may not always be responsible for symptoms. HBE, bundle of His recording; HRA, high right atrial recording. (From Miles MM, Klein LS. Sinus nodal dysfunction and atrioventricular conduction disturbances. In: Naccarelli GV, ed. *Cardiac arrhythmias: a practical approach*. Mount Kisco, NY: Futura, 1991:250, with permission.)

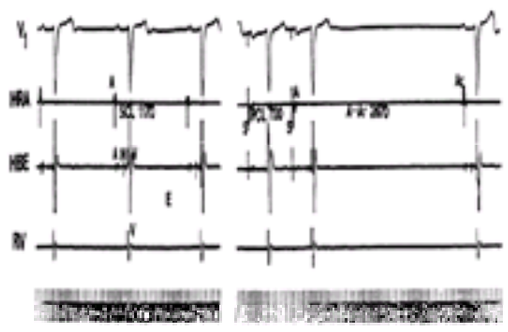
Invasive Testing

Sinus nodal function can also be evaluated invasively with an electrophysiologic study (*e*Fig. 63.3.4). This is usually reserved for symptomatic patients in whom sinus nodal dysfunction is suspected but cannot be documented in association with symptoms by noninvasive means. The pacing tests most commonly used are sinus nodal recovery time and sinoatrial conduction time. However, even when performed appropriately, the ability of these tests to provide a definitive diagnosis is limited. Since the early 1970s, overdrive suppression of the sinus node has been viewed as a marker of sinus nodal dysfunction (49). A delay in the return of spontaneous pacemaker activity is a normal finding immediately after rapid atrial pacing. In those with sinus nodal dysfunction, however, the sinus node generally takes longer to recover. The mechanism of overdrive suppression of the sinus node is unclear. Depression of sinus nodal automaticity is only partially involved. Other factors include the proximity of the pacing site to the sinus node, the local concentrations of acetylcholine and norepinephrine, and the conduction time in and out of the sinus node (up to 250 ms).



***e*FIGURE 63.3.4** Sites of catheter placement and example of intracardiac recordings obtained during electrophysiologic studies. Multipolar catheters can be placed for purposes of simultaneous electrogram recording and pacing in the high right atrium, bundle of His area, right ventricular apex, and coronary sinus. A, atrial activation; AV, atrioventricular; CSd, distal coronary sinus; CSp, proximal coronary sinus; H, bundle of His potential; HBE, bundle of His electrogram; RA, right atrium; RV, right ventricle; V, ventricular activation.

The pacing protocol used to measure the sinus nodal recovery time generally involves pacing at the high right atrium for 30 seconds at several different cycle lengths in the range of 300 to 700 ms (*e*Fig. 63.3.5). The sinus nodal recovery time is the interval between the last paced P wave and the first spontaneous atrial deflection. A better measurement, however, is the corrected sinus nodal recovery time, which is obtained by subtracting the sinus cycle length before pacing from the sinus nodal recovery time. Thus, a patient with an abnormally long sinus nodal recovery time (greater than 1,400 ms) could have a normal corrected sinus nodal recovery time (less than 550 ms) (50).



***e*FIGURE 63.3.5** Intracardiac electrograms demonstrate a prolonged sinus node recovery time. Surface electrogram lead V_1, in addition to a high right atrial recording (HRA), bundle of His electrogram (HBE), and right ventricular electrogram (RV), is demonstrated. In the left panel are the patient's recordings during spontaneous sinus rhythm (notice A_1-A_1 is 1,070 ms or a rate of 57 per minute). In the right panel are recordings during atrial pacing at a cycle length of 400 ms (rate of 150 per minute). On termination of atrial pacing, note the long period of asystole measured from the last paced atrial electrogram to the first recovery atrial electrogram (Ar). By subtracting the resting heart rate (1,170 ms) from the total recovery time (2,670 ms), a prolonged corrected sinus node recovery time of 1,500 ms can be calculated. A, atrial activation; H, bundle of His potential; PCL, pacing cycle length; SCL, spontaneous cycle length; V, ventricular activation. (From Weeks LC, ed. *Advanced cardiovascular nursing*. New York: Blackwell Science, 1986:518, with permission.)

The conventionally obtained sinus nodal recovery time measurement is an indirect one and is therefore associated with several limitations. The corrected sinus nodal recovery time reflects both sinoatrial conduction time and sinus automaticity. Only a direct sinus node electrogram can accurately identify which abnormality is present in sinus nodal dysfunction. Also, indirect sinus nodal recovery time measurements can be confounded by sinus nodal entrance block during rapid atrial pacing, with resultant shortening of the sinus nodal recovery time, and by sinus nodal exit block postpacing, thereby prolonging the apparent sinus nodal recovery time. An abnormal sinus nodal recovery time is not found in all patients with sinus nodal dysfunction. This is due partly to sinus nodal dysfunction not being a homogenous entity from a pathologic standpoint. Despite these limitations, the indirect corrected sinus nodal recovery time is frequently used in the evaluation of sinus nodal function.

Although direct sinus node electrograms are possible to accomplish, they are difficult to obtain, and the technique is rarely used in the electrophysiology laboratory. Comparison of measurements by direct and indirect methods has shown direct sinus nodal recovery time values to be generally shorter. Additionally, direct recordings reveal nonconducted sinus node electrograms during postpacing atrial pauses that go undetected during conventional indirect sinus nodal recovery time measurements.

Additional tools can be used to improve the sensitivity and specificity of the traditional sinus nodal recovery time measurement. Complete autonomic blockade with determination of the intrinsic heart rate during atrial pacing can help identify the mechanism of the sinus nodal dysfunction (abnormal autonomic regulation vs. intrinsic sinus nodal function). The pacing cycle length with the longest sinus nodal recovery time has been found to be less than or equal to 600 ms in normal individuals. However, in patients with sinus nodal dysfunction, the maximum sinus nodal recovery time often occurs at slower pacing cycle lengths (greater than 600 ms), even though a normal sinus nodal recovery time was found. An abnormal perinodal refractory period may explain this observation (51). In some patients with sinus nodal dysfunction, the sinus nodal recovery time is normal, but the following PP intervals are longer. These secondary pauses are uncommonly found in normal subjects. After autonomic blockade, patients with abnormal intrinsic heart rates continue to have secondary pauses, whereas those patients with normal intrinsic heart rates no longer have secondary pauses (52). When the previously mentioned measures are employed, and corrected sinus nodal recovery time is used along with the sinoatrial conduction time in a symptomatic patient, the sensitivity and specificity for sinus nodal dysfunction approach 70% and 90%, respectively (53).

The other commonly used invasive pacing test, the sinoatrial conduction time, is traditionally measured indirectly from the high right atrium (54). The most popular method of pacing involves introducing premature atrial extrastimuli (A_2) at progressively shorter intervals during sinus rhythm (A_1). The A_2 is first introduced in late diastole and brought in until atrial refractoriness is found, thus scanning diastole. The A_2 reverses sinoatrial activation for that cycle. The return cycle (A_2-A_3) is then assumed to be equal to the previous sinus cycle (A_1-A_1), plus the time required for A_2 to enter the node and the time needed for the next sinus beat to exit the node and result in A_3. Estimation of the sinoatrial conduction time by this method is obtained by calculation of the following: (A_2-A_3 interval) – (A_1-A_1 interval). Next, an average of multiple A_2 responses is determined for the sinoatrial conduction time. Several assumptions are used to obtain the calculation; the sinus nodal automaticity is assumed not to be affected by the premature beat, conduction in and out of the sinus node is assumed equal, and the premature atrial beat is assumed not to cause a shift in the principal pacemaker site. An additional limitation of the sinoatrial conduction time test is the need for a regular cycle length in sinus rhythm. Sinus arrhythmia may make calculation of the sinoatrial conduction time by this method impossible. In an effort to circumvent the sinus arrhythmia problem, brief atrial pacing at a rate just above the sinus rate is used. The sinoatrial conduction time becomes the difference between the postpacing interval and sinus cycle length (55).

Estimation of the sinoatrial conduction time by direct sinus node electrograms is less practical than the indirect method and rarely used. As the indirect estimation, the direct measurement is subject to inaccuracy in the presence of sinus arrhythmia. The sinus node electrogram has been used to validate the indirect pacing methods that are used to assess sinus nodal dysfunction. Indirect sinoatrial conduction time measurements are generally shorter but tend to correlate well with direct values obtained using sinus node electrograms (56,57).

Estimation of the sinus node effective refractory period has been proposed as another method of identifying patients with sinus nodal dysfunction. The sinus node effective refractory period is represented by the interpolation zone, or the zone where an atrial extrastimulus fails to enter the node and is interpolated between two sinus impulses. One clinical study found a significant difference between sinus node effective refractory period values in normal individuals and those with sinus nodal dysfunction (58).

Most patients with sinus nodal dysfunction do not require invasive electrophysiologic testing. Invasive sinus nodal evaluation should be reserved for symptomatic patients with suspected sinus nodal dysfunction, but attempts to document dysfunction in association with symptoms by noninvasive means have been unsuccessful. Patients with asymptomatic sinus bradycardia or sinus pauses should not undergo invasive testing. Patients with previously documented sinus nodal dysfunction in association with symptoms do not require further testing, unless the assessment of AV anterograde and retrograde nodal conduction would aid in the pacemaker prescription.

Natural History

The natural history of sinus nodal dysfunction depends largely on the type of dysfunction and the presence of concomitant cardiovascular disease. The worst prognosis is associated with the tachycardia-bradycardia syndrome, whereas sinus bradycardia is much more benign. Those with sinus pauses have a prognosis intermediate to the other two types of sinus nodal dysfunction. These differing outlooks are most likely related to their relative risk for thromboembolic complications, probably the most important cause of death in this group. Because stroke is associated with atrial fibrillation, patients with sinus nodal dysfunction complicated by chronic or intermittent atrial fibrillation have an increased risk of embolization.

In a literature review by Sutton and Kenny (59), the incidence of new onset atrial fibrillation in patients with sinus nodal dysfunction was 5.2% per year. New atrial tachyarrhythmias occurred with less frequency in patients who were atrially paced (3.9%), compared with a greatly increased incidence of similar arrhythmias in those only ventricularly paced (22.3%). A more recent review (60) reported a weighted mean atrial fibrillation per year incidence of 6.8% for VVI pacing, compared with 2.6% (a 62.0% risk reduction) for dual-chamber pacing.

As noted previously, thromboembolic complications are a major cause of morbidity and mortality in patients with sinus nodal dysfunction. Sutton and Kenny's review found a 15.2% incidence of thromboembolism among unpaced patients with sinus nodal dysfunction. Those patients only ventricularly paced did not fare much better (13%). In contrast, atrially paced patients enjoyed a greatly decreased thromboembolic event incidence (1.6%) (59). In the future, increased use of atrial pacing and anticoagulation therapy should significantly reduce the incidence of stroke in high-risk patients with tachycardia-bradycardia syndrome. Several ongoing prospective trials are testing the hypothesis that physiologic pacing reduces the risk of cardiovascular death and stroke.

Of clinical interest is the incidence of concomitant AV nodal disease in patients with sinus nodal dysfunction. In the previously mentioned review (59), 17% of the patients had some degree of AV conduction system disease at the time of diagnosis of sinus nodal dysfunction. New AV conduction abnormalities developed at a rate of approximately 2.7% per year. These data indicate a low frequency and slow progression rate of AV conduction system disease in patients with sinus nodal dysfunction.

Principles of Management

Because of the broad range of symptoms associated with a variety of arrhythmia presentations in patients with sinus nodal dysfunction, treatment modalities must be individualized. For the patient with asymptomatic bradycardia or pauses and no atrial fibrillation, no treatment is necessary. In the case of symptomatic patients with sinus nodal dysfunction and atrial fibrillation, therapy depends on whether the symptoms are related to the tachycardia or bradycardia episodes. Depending on the etiology of the symptoms, drug therapy may be needed to control rapid ventricular response, pacing may be advised to prevent bradycardia, or both treatment modalities may be required. Ideally, if a patient with symptomatic bradycardia is on a drug known to depress sinus nodal function, the drug should be stopped. However, many times this is not possible, as the drug is needed for control of symptomatic tachycardia, ischemia, or hypertension. In these cases, permanent pacing may be required to allow continued use of the needed drug.

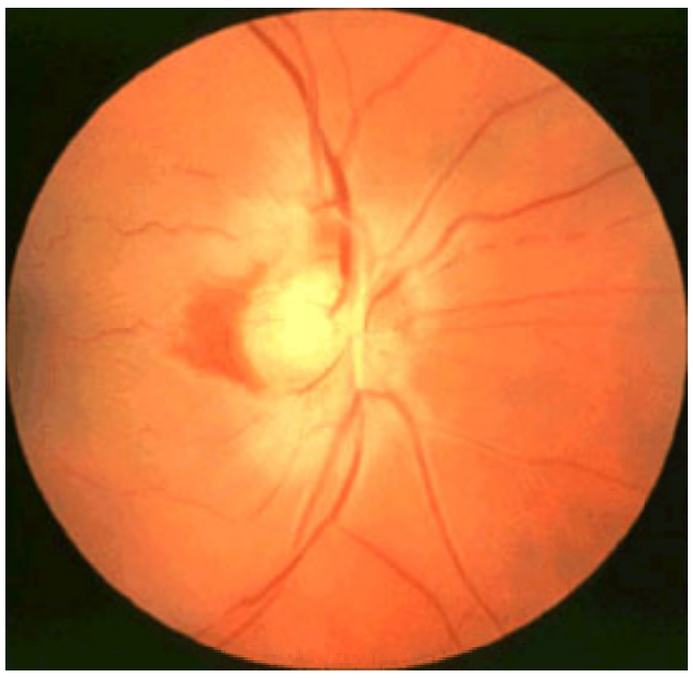
Sinus nodal dysfunction is currently the most common reported diagnosis for pacemaker implantation. However, once the decision to pace is made, choosing the optimal pacemaker prescription is essential to decrease stroke risk and improve quality of life. As discussed previously, a significant number of patients with sinus nodal dysfunction have concomitant atrial fibrillation or develop new atrial tachyarrhythmias after being diagnosed with sinus nodal dysfunction. Atrial pacing has been shown to greatly decrease the incidence of atrial fibrillation and thromboembolism in this population, whereas those who are only ventricularly paced have not seen a similar benefit (59). For those patients with sinus nodal dysfunction who have normal AV conduction, a single-chamber atrial pacemaker is a reasonable consideration. Of course, single-chamber ventricular pacing is still appropriate for individuals with sinus nodal dysfunction and chronic atrial fibrillation. The use of rate-adaptive pacing is important for improving exercise tolerance in single-chamber and dual-chamber pacing devices. Additionally, the development of the mode-switching feature in some dual-chamber devices allows for automatic mode change between DDDR and DDIR (or VVIR) in a patient with intermittent atrial tachyarrhythmias. The DDIR mode permits continued AV synchrony. However, because there is no atrial tracking, unwanted rapid ventricular pacing will not occur during atrial tachycardia. Guidelines for implantation of pacemakers in patients with sinus nodal dysfunction have been established by a task force from the American College of Cardiology and American Heart Association (*e*Table 63.1.1) (61).

***e*TABLE 63.1.1** INDICATIONS FOR PERMANENT PACING IN SINUS NODAL DYSFUNCTION

Class I	Sinus nodal dysfunction documented in association with symptomatic bradycardia and caused by factors that are irreversible or caused by essential drug therapy
Class II	No clear association between sinus nodal dysfunction (with heart rate <40 beats/min) and symptoms can be documented
Class III	Sinus nodal dysfunction with marked sinus bradycardia or pauses, but no associated symptoms

[a]Class I indications are conditions for which it is generally agreed that pacing is needed. Class II indications are conditions associated with varying opinions as to the necessity of pacing. Class III indications are conditions in which pacing is thought not to be indicated.

As discussed previously, because of the high risk of thromboembolic events in patients with chronic or intermittent atrial fibrillation, anticoagulation with warfarin should be instituted in these patients. Warfarin has been clearly shown to be superior to placebo in the prevention of stroke in patients with atrial fibrillation (62). However, the role of aspirin therapy in this population is controversial (63). Patients with contraindications to warfarin or those with lone atrial fibrillation—defined as atrial fibrillation in the absence of underlying heart disease—may be considered candidates for aspirin therapy alone. For the other patients with atrial fibrillation, warfarin therapy to achieve an international normalized ratio between two and three is optimal to decrease stroke risk. A metaanalysis of the five major controlled trials of anticoagulation in atrial fibrillation has shown that patients at the highest risk for strokes are those with hypertension, recent congestive heart failure, or previous thromboembolism (64). The reader is referred to Chapter 64 for a more in-depth discussion of these anticoagulation issues.



Central retinal artery occlusion. There are indistinct margins to the optic disc and pallor of the central retinal artery territory.

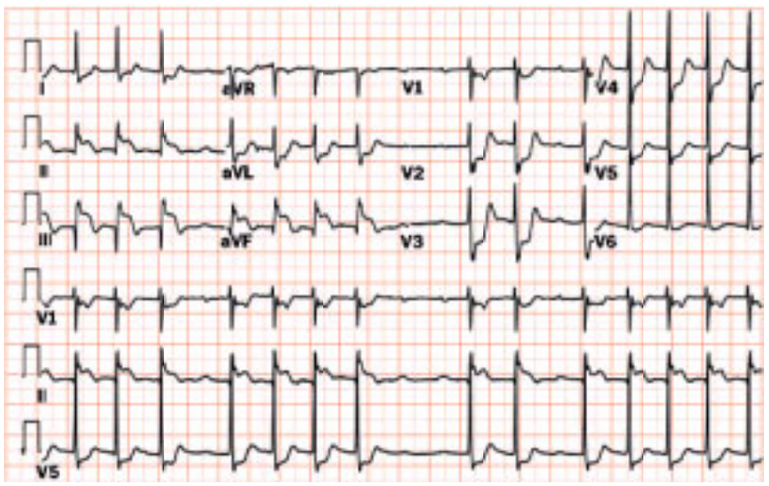
Embolus. Dislodged thrombus that embolized to the toes and caused gangrene (*arrows*).

ATRIOVENTRICULAR NODAL DYSFUNCTION

Historical Perspective

Adams (1827) (65) and Stokes (1846) (66) first described syncope associated with a slow heart rate. In 1906, by analyzing the jugular venous pulse waves, Wenckebach (67) and Hay (68) were able to distinguish two types of second-degree AV block. Once the ECG became available, Mobitz (69) classified them as types I and II. With the development of intracardiac electrocardiology and bundle of His recordings in the late 1960s (70), knowledge of AV conduction was expanded. The ability to localize the site of the block to the AV node, bundle of His, or bundle branch fascicular system was facilitated. After the development of chronic transvenous ventricular pacing in the mid-1960s, the natural history of the patient with symptomatic heart block greatly changed, and mortality significantly decreased. Further

advancements in pacing over the years—namely, dual-chamber and rate-responsive pacing—have improved the quality of life of these patients.



Acute inferior myocardial infarction with Mobitz II atrioventricular block. Note ST-segment elevation in the inferior leads as well as intermittently dropped QRS complexes.

Anatomic Considerations

The AV node lies beneath the right atrial endocardium at the apex of the triangle of Koch, which is formed by the tendon of Todaro and the septal leaflet of the tricuspid valve. This positions the AV node directly above the insertion of the septal leaflet of the tricuspid valve and anterior to the ostium of the coronary sinus. Two different approaches have been commonly used in describing the anatomy of the AV node. One considers the AV node as part of the AV junctional area (71). The area is divided into three regions: the transitional zone, compact portion, and penetrating part of the AV bundle. The transitional cells, or nodal approaches, connect the atrial myocardium to the compact portion of the AV node. At its distal end, the compact portion of the AV node enters the central fibrous body, becoming the penetrating portion, or bundle of His. The other approach more closely correlates nodal anatomy with the physiologic activity of its different cell types (72). Three functional regions of the AV node have been identified based on the differing conduction properties of the cells. The three regions are called atrionodal (AN), nodal (N), and nodal-His (NH) (73). These three regions correspond to the transitional zone and the compact portion and penetrating AV bundle, although there is much overlap of the cell groups. Also, a number of intermediate cell types are found within each group (74). The slowest conduction time (0.03 m per second) occurs in the N region. Whereas the AN and NH regions display spontaneous diastolic depolarizing activity, the N region has no automaticity (75).

The blood supply to the AV node is via the AV nodal artery, a branch of the right coronary artery in 90% of hearts, with the remaining 10% arising from the circumflex artery (76).

As the sinus node, the AV node is richly innervated by sympathetic and parasympathetic fibers (77). Although sympathetic neural input to the sinus node and the AV node overlap substantially, different branches of the vagal and sympathetic nerves act predominantly on certain regions. As a result, if innervation to the sinus node is damaged, neural input to the AV node remains intact (78). The sinus node and AV node are both influenced by the right and left vagus nerves and stellate ganglia. However, stimulation of the nerves on the right has less effect on AV nodal conduction than on sinus nodal rate. Conversely, left-sided autonomic stimulation exerts stronger influence on AV nodal conduction than on sinus rate. Evidence suggests acetylcholine release is predominantly around the N region of the AV node (79).

His-Purkinje System

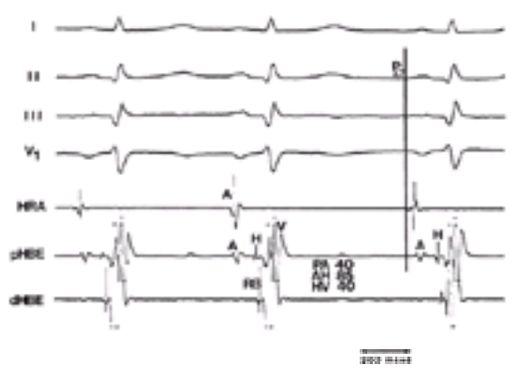
The cells of the proximal bundle of His resemble those of the compact AV node, whereas the distal cells are similar to the cells in the proximal bundle branches. The bundle of His is contained within the connective tissue of the central fibrous body and membranous septum. It courses in the base of the membranous septum or along the left side of the crest of the interventricular septum in most cases. However, right-sided bundles of His do occur, which influence the configuration of the proximal bundle branches. The anatomy of the left bundle branch (LBB) is subject to much variability. The fibers generally travel as a broad band onto the left septum below the noncoronary aortic cusp. In a minority of cases, the origin of the LBB is narrow, even though it arises from a left-sided bundle of His. In the case of a right-sided bundle of His, the LBB originates from the right as a narrow stem. The right bundle branch (RBB) extends unbranched from the bundle of His, traveling down the right side of the interventricular septum to the apex of the right ventricle, and the base of the anterior papillary muscle. Discrete bifascicular subdivisions with anterosuperior and posteroinferior branches of the LBB are not the norm. Where subdivisions are present, they have multiple interconnections. In other cases, a network is seen without clear divisions (80). Despite this anatomic variability, the concept of the left anterior and posterior fascicular blocks remains clinically useful (81). The bundle branches end in Purkinje's fibers, forming a network over the surface of the endocardium of the ventricles. Their interweaving configuration allows the cardiac impulse to reach the entire right and left ventricular endocardium almost simultaneously. Purkinje's fibers have a rapid conduction time of 2.4 m per second.

The bundle of His has a dual blood supply from branches of the anterior and posterior descending coronary arteries. Dual blood supply from the left and right coronary arteries is the usual case for the bundle branches (81).

Electrocardiographic and Electrophysiologic Findings

Normal Atrioventricular Conduction

On the surface ECG, the PR interval is normally between 120 and 200 ms in duration. This interval reflects the conduction time from the high right atrium to the point of ventricular activation. To measure the different components of the conduction system that the PR interval includes, intracardiac tracings from the high right atrium and bundle of His region are needed (*e*Fig. 63.3.6). The PA interval—measured from the high right atrial electrogram to the low right atrial deflection in the bundle of His electrogram—gives an indirect approximation of the right atrial conduction time. The AH interval, measured from the low atrial to the bundle of His deflection, reflects conduction time through the AV node. The HV interval, measured from the bundle of His deflection to the earliest ventricular depolarization on the surface electrogram, represents the conduction time from the proximal bundle of His to the ventricular myocardium (82) (Table 63.2). The AH interval can vary greatly in an individual because of changes in sympathetic and parasympathetic tone. In contrast, the HV interval should remain constant, because this interval is not significantly affected by changes in autonomic tone.



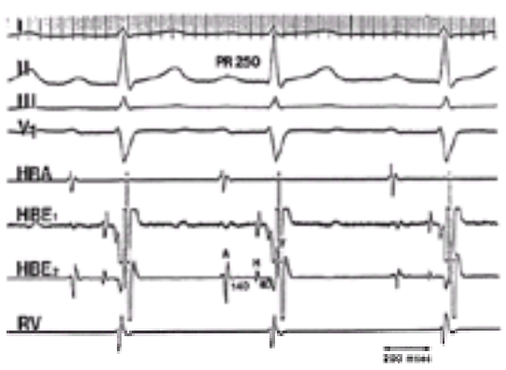
***e*FIGURE 63.3.6** Surface and intracardiac electrograms recorded during sinus rhythm. Surface electrogram leads I, II, III, and V_1 are recorded simultaneously with a high right atrial (HRA) electrogram and proximal (pHBE) and distal bundle of His electrograms (dHBE). Notice that the atrial activation sequence starts in the high right atrium and goes down to the atrial electrogram (A wave) in the bundle of His lead. This lower atrial activity is being recorded from the atrium near the atrioventricular node. See text for details of measuring the PA, AH, and HV intervals. RB, right bundle branch block. (From Weeks LC, ed. *Advanced cardiovascular nursing*. New York: Blackwell Science, 1986:517, with permission.)

Type	Interval (ms)
PA	20–50
AH	50–140
HV	35–55
H	10–25

TABLE 63.2 NORMAL CONDUCTION INTERVALS IN ADULTS

First-Degree Atrioventricular Block

First-degree AV block on the surface ECG is seen as a PR interval >0.20 seconds in adults or >0.18 seconds in children. Each P wave is followed by a QRS complex with a constant, prolonged interval. Although the conduction delay can be anywhere along the system, the PR prolongation is usually caused by delay within the AV node (87% when the QRS complex is narrow). On the bundle of His electrogram, this would be seen as an AH interval >130 ms with a normal HV interval (*e*Fig. 63.3.7). In cases in which first-degree AV block is seen in the presence of a bundle branch block, a bundle of His electrogram is necessary to localize the site of block (83,84 and 85) (*e*Fig. 63.3.8). Infranodal conduction delay is present in 45% of these cases. A combination of delay within the AV node and in the His-Purkinje system must also be considered (86). In certain cases of congenital structural heart disease, such as Ebstein's anomaly of the tricuspid valve or endocardial cushion defects, intraatrial conduction delay can cause first-degree AV block. In addition, intra-Hisian conduction delay can cause first-degree AV block. On the bundle of His electrogram, a split His potential can be seen, resulting in a prolonged His potential, HV, and PR intervals (86). Dual AV nodal physiology can produce transient, abrupt, or alternating first-degree block caused by block in the fast AV nodal pathway (which is normally used), with conduction down the slow pathway instead. The change in the PR interval seen on the surface electrogram corresponds with a jump in the AH interval viewed on the bundle of His electrogram (87).



***e*FIGURE 63.3.7** Bundle of His electrocardiogram in a patient with first-degree atrioventricular (AV) block (PR 250 m per second). Note in the proximal bundle of His lead (HBE_2) that the AH interval is prolonged (140 m per second) and the HV interval is normal (40 m per second). Therefore, the conduction delay causing the first-degree AV block is in the AV node. HRA, high right atrial recording; RV, right ventricular recording. (From Weeks LC, ed. *Advanced cardiovascular nursing*. New York: Blackwell Science, 1986:523, with permission.)

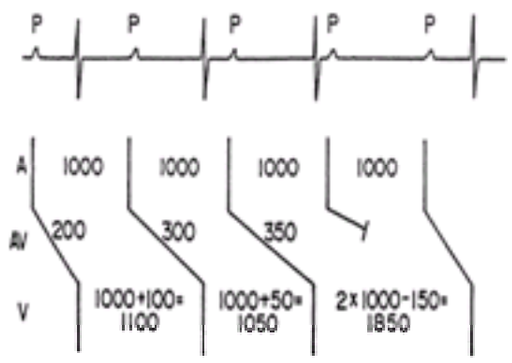
***e*FIGURE 63.3.8** Bundle of His electrogram in a patient with first-degree atrioventricular block (PR 250 ms) secondary to a prolonged HV interval of 165 ms. Because the AH interval is normal (80 ms), the conduction delay causing the block is occurring distal to the bundle of His in the His-Purkinje system. Note the bundle branch block pattern on the surface electrogram. HBE, bundle of His recording; HRA, high right atrial recording. (From Weeks LC, ed. *Advanced cardiovascular nursing*. New York: Blackwell Science, 1986:523, with permission.)

A 47-year-old male patient with Ebstein's anomaly.

Second-Degree Atrioventricular Block

Type I

Type I second-degree AV block, or Wenckebach block, features on the surface electrogram progressive prolongation of the PR interval before failure of an atrial impulse to be conducted to the ventricles. The PR interval immediately postblock returns to its baseline interval, and the sequence begins again. Features of typical Wenckebach periodicity include the following (*e*Fig. 63.3.9):



***e*FIGURE 63.3.9** Schematic of typical Wenckebach periodicity. The top panel shows a schematic electrocardiogram of a 4:3 Wenckebach cycle with prolonging PR intervals until the fourth P wave fails to conduct to the ventricle. On the bottom is a diagram illustrating the atrial (A), atrioventricular (AV) junctional, and ventricular (V) levels. Note that there is increasing conduction delay with each PR interval, but the amount of increase in conduction delay with each subsequent PR interval decreases. Therefore, the longest RR interval at the right of the figure is less than twice as long as the shortest RR interval immediately preceding it (see text for discussion). (From Miles MM, Klein LS. Sinus nodal dysfunction and atrioventricular conduction disturbances. In: Naccarelli GV, ed. *Cardiac arrhythmias: a practical approach*. Mount Kisco, NY: Futura, 1991:261, with permission.)

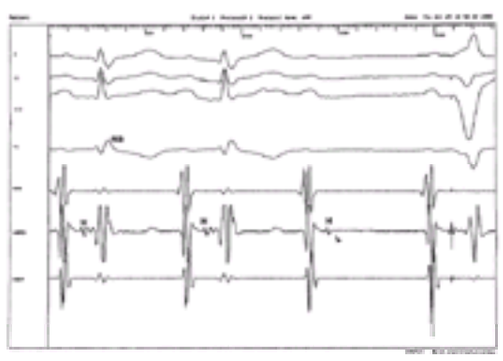
- Progressive lengthening of the PR interval throughout the Wenckebach cycle
- Lengthening of the RR interval occurring at progressively decreasing increments, resulting in progressive shortening of the RR intervals
- A pause including the nonconducted P wave that is less than the sum of any two consecutively conducted beats
- Shortening of the PR interval postblock, compared with the PR interval just preceding the blocked cycle

Less than 50% of type I AV block cases follow this typical pattern (88). Atypical patterns are more likely found with longer Wenckebach periods, >6:5. Differentiating atypical from typical patterns, however, is of little clinical significance.

Wenckebach block is almost always within the AV node when a narrow QRS complex is present (88). Intra-Hisian block is the rare exception (89). When type I block is seen with a bundle branch block, the block is still more likely to be in the AV node, but it could also be localized below the bundle of His. A bundle of His electrogram would be needed to accurately identify the level of block. Wenckebach block in the AV node is characterized by progressive prolongation of the AH interval, until an atrial deflection is not followed by a bundle of His or ventricular deflection. In type I block secondary to block below the bundle of His, progressive prolongation of the HV interval is followed by an H deflection without an associated ventricular depolarization.

Type II

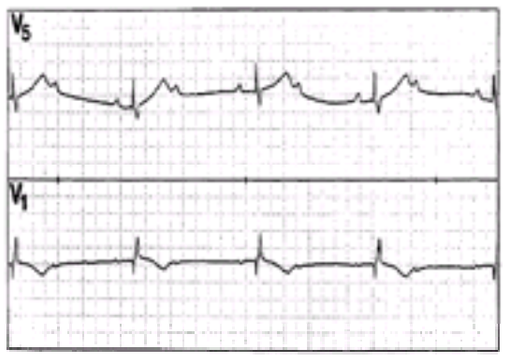
Type II, or Mobitz II, second-degree AV block is characterized on the surface electrogram by a constant PR interval, followed by sudden failure of a P wave to be conducted to the ventricles. The PP intervals remain constant, and the pause including the blocked P wave equals two PP intervals. Therefore, Mobitz II block should not be confused with a nonconducted premature atrial complex. Mobitz II block is usually associated with bundle branch block or bifascicular block. In a majority of these cases, the site of block is within or below the bundle of His (*e*Fig. 63.3.10) (84,86). When presumed Mobitz II block is seen in conjunction with a narrow QRS complex, Mobitz I with only minimal PR variation should be suspected. Only rarely is Mobitz II found with a narrow QRS complex and is caused by intra-Hisian block (90). The bundle of His electrogram is useful in verifying the site of the Mobitz II block. The blocked cycle features atrial and bundle of His deflections without a ventricular depolarization. The conducted beats usually show evidence of infranodal conduction system disease, with a prolonged HV interval, or even a split bundle of His potential (86).



***e*FIGURE 63.3.10** The surface leads I, II, III, and V_1 show first-degree atrioventricular block and right bundle branch block (RB). The third P wave is not followed by a QRS complex. The intracardiac tracings [HRA, high right atrial recording; proximal (HBEP) and distal bundle of His electrograms (HBED)] reveal the diagnosis of block within the bundle of His. The His deflection (H) is fractionated. The third beat shows only the first half of the His, and no ventricular electrogram follows.

2:1 Atrioventricular Block

Fixed 2:1 AV block poses a diagnostic dilemma because it is usually impossible to classify as type I or II block by a surface electrogram alone (*e*Fig. 63.3.11). A narrow QRS complex and recently seen Wenckebach block is highly suggestive of block at the AV nodal level. A 2:1 block associated with a wide QRS complex is likely infranodal, but it could still be at the level of the AV node. A definitive diagnosis can only be made with an intracardiac recording at the bundle of His region.



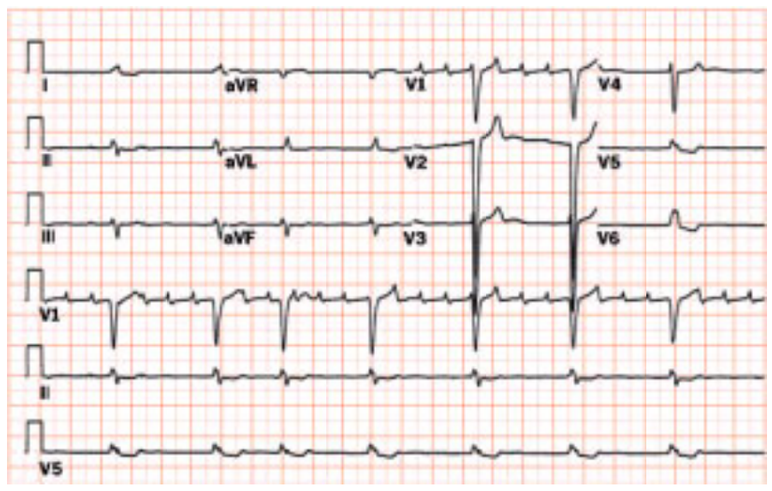
***e*FIGURE 63.3.11** Simultaneous surface tracings of leads V_1 and V_5 showing fixed 2:1 atrioventricular block and narrow QRS complexes. A definite diagnosis of either type I or II atrioventricular block cannot be made using this tracing alone.

Nonconduction of two or more consecutive P waves when AV synchrony is otherwise maintained is sometimes termed *high-degree AV block*. The level of block can be at the AV node or the His-Purkinje system. When high-degree AV block is caused by block in the AV node, QRS complexes of the conducted beats are usually narrow. Wenckebach periodicity is also seen, and atropine administration produces 1:1 conduction. Features pointing toward block in the His-Purkinje system are conducted beats with bundle branch block and no improvement in block with atropine. Bundle of His recordings are sometimes needed to confirm the site of block.

Third-Degree Atrioventricular Block

Third-degree, or complete, AV block is seen on the surface electrogram as completely dissociated P waves and QRS complexes, each firing at their own pacemaker rate. The atrial impulse is never conducted to the ventricles, but different levels of block are possible. The level of block determines the QRS morphology along with the site and rate of the escape rhythm. Congenital complete heart block is characterized by a narrow QRS complex with an escape rate between 40 and 60 beats/min, which tends to increase with exercise or atropine. This is consistent with block within the AV node. Acquired complete heart block is usually associated with block in the His-Purkinje system, resulting in a wide QRS complex with an escape rate between 20 and 40 beats/min. The intracardiac electrogram shows bundle of His deflections consistently following the atrial electrograms, but the ventricular depolarization is completely dissociated from these. Block below the bundle of His is thus demonstrated. In contrast, complete heart block at the AV nodal level is seen on the intracardiac tracings as bundle of His potentials consistently preceding each ventricular depolarization. The atrial electrograms are dissociated from the HV complexes (*e*Fig. 63.3.12). The sinus rate is faster than the ventricular rate in patients with complete heart block. Data collected from patients with congenital complete heart block have showed the atrial rate to usually be age appropriate (92). It is important to note that complete antegrade AV block does not always predict retrograde (VA) conduction. Retrograde conduction may be intact in an individual with complete antegrade AV block (Fig. 63.1).

***e*FIGURE 63.3.12** Congenital complete heart block located within the atrioventricular (AV) node. Sinus arrhythmia with a cycle length of approximately 860 ms is completely dissociated from a regular junctional escape rhythm with a cycle length of 1,360 ms. There is no relationship between atrial and ventricular depolarizations. There is no bundle of His deflection after any atrial depolarization. A bundle of His electrogram with a normal HV interval precedes each junctional escape complex in the bundle of His lead. Therefore, the site of AV block is within the AV node. Note the normal (narrow) morphology of the junctional escape QRS complexes. HBE, bundle of His electrogram; HRA, high right atrial recording. (From Miles MM, Klein LS. Sinus nodal dysfunction and atrioventricular conduction disturbances. In: Naccarelli GV, ed. *Cardiac arrhythmias: a practical approach*. Mount Kisco, NY: Futura, 1991:269, with permission.)



High-grade atrioventricular block. Note marked discrepancy between atrial and ventricular heart rates.

Atrioventricular Dissociation

AV dissociation is a secondary phenomenon that results from a primary conduction disorder. It is characterized by the atria and ventricles depolarizing independent of each other. By definition, there is no retrograde conduction from the ventricles to the atria. AV dissociation may occur because of slowing or a failure of impulse formation or conduction from the sinus node. In this situation, the atrial rate may become slower than a subsidiary escape focus from the AV junction or ventricle. Thus, a competing AV junctional or idioventricular rhythm may develop. AV dissociation may occur if there is an increase in the automaticity of a subsidiary pacemaker, such as accelerated junctional rhythm or ventricular tachycardia.

AV dissociation may be complete or incomplete (91). In complete AV dissociation, both the atrial and ventricular rates remain constant, and, therefore, the PR interval varies, with none of the atrial complexes conducted to the ventricles. In incomplete AV dissociation (interference dissociation), ventricular capture beats occur because some of the atrial impulses arrive at the AV junction when the AV junction is no longer refractory. This phenomenon is common in advanced AV block with periodic capture beats.

Pathophysiology

The term *AV block* denotes a delay or nonconduction of an atrial impulse to the ventricles when the AV junction is not physiologically refractory. Table 63.3 lists the majority of causes of AV block that have been identified. In each case, the abnormality may vary from a delay in conduction to intermittent or complete conduction failure.

TABLE 63.3 CAUSES OF ATRIOVENTRICULAR BLOCK

Drug effects are a common cause of acquired AV block in adults. Digoxin and beta-blocking agents act indirectly on the AV node through their effect on the autonomic nervous system. Calcium channel blockers and other antiarrhythmic drugs, such as amiodarone, act directly to slow conduction in the AV node. Type I and III antiarrhythmic drugs can also affect conduction in the His-Purkinje system, resulting in infranodal block. Drugs that have a significant effect on blocking the sodium channels, such as flecainide, have the most effect on slowing conduction in the His-Purkinje system. When AV block occurs secondary to antiarrhythmic therapy, it is usually in cardiac patients with preexisting conduction abnormalities. Patients with normal conduction system function rarely develop complete heart block as a result of

using antiarrhythmic agents.

Acute myocardial infarction is associated with varying degrees of AV block and is the most common cause of acquired complete AV block. Second- and third-degree AV blocks occur in up to 30% of patients presenting with acute myocardial infarction (93,94).

Abnormalities in AV nodal conduction are seen in 20% of patients hospitalized for acute inferior myocardial infarction (95), with the onset of block falling in a bimodal distribution (96,97). Eleven percent of those presenting in the first hour of symptoms are found to have second- or third-degree AV block (96). In contrast, the incidence of heart block is low in the second hour of symptoms. The majority of conduction abnormalities occur between 2 and 72 hours (95,98). Because of the short duration of the early conduction abnormalities and their favorable response to atropine, an increase in vagal tone associated with acute inferior myocardial infarction is the probably etiology of this early phenomenon (99). Type I AV block occurring later in the course of an acute inferior myocardial infarction is less responsive to atropine and probably is associated with reversible ischemia of the AV node or the release of adenosine during acute infarction (100). In this setting, type I AV block rarely progresses to more advanced block and commonly resolves within 2 to 3 days of onset.

Type II AV block occurs in only 1% of patients with acute myocardial infarction, but it has a worse prognosis than type I block. It is associated with bundle branch infarction during an acute anterior myocardial infarction and frequently progresses to complete heart block.

Complete heart block can occur with either anterior or inferior acute myocardial infarction. The site of the block in inferior myocardial infarction is usually at the level of the AV node, resulting in a junctional escape rhythm with a rate of 50 to 60 beats/min and narrow QRS complex. The abnormality tends to be reversed with vagolytic drugs or exercise and usually resolves in several days. Complete heart block in the setting of acute anterior myocardial infarction is usually associated with infarction of the bundle branches (101,102). The escape rhythm is approximately 40 beats/min, with a wide QRS complex originating from the bundle branch and Purkinje's system. It is less likely to be reversible. In general, patients who develop either transient or irreversible AV block are older and have a larger area of damage associated with their acute myocardial infarction. Other markers seen in this group include high levels of cardiac enzymes, bundle branch block, right ventricular infarction, or left ventricular failure (93,103,104,105 and 106).

In addition to acute myocardial infarctions, chronic ischemic heart disease can result in persistent AV block (107). Transient AV block can occur not only during angina pectoris (108), but during episodes of Prinzmetal's variant angina (109).

The most common cause of acquired conduction system disease is progressive idiopathic fibrosis. Lev's disease (110) is a result of proximal bundle branch fibrosis. It is postulated as a hastening of the aging process by hypertension and arteriosclerosis of the blood vessels supplying the conduction system. Lenègre's disease (111) is a degenerative process occurring in a younger population and involving the more distal portions of the bundle branches.

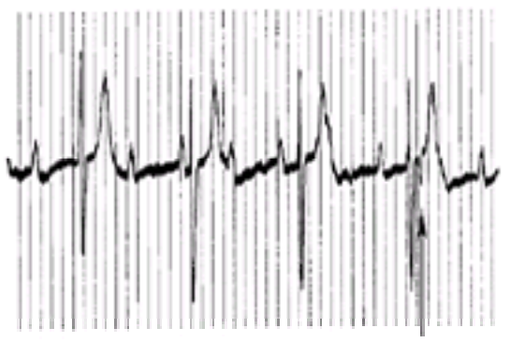
Calcification of the aortic or mitral valve annulus can extend to the nearby conduction system and produce AV block (112,113). The incidence is more frequent with aortic than mitral stenosis. AV block can also result from a stenotic bicuspid aortic valve (114,115). Other causes of AV block include infiltrative cardiomyopathies such as amyloidosis (116), sarcoidosis (116,117), and hemochromatosis (118,119), as well as the collagen vascular diseases of scleroderma (120), rheumatoid arthritis (121), Reiter's syndrome (122), systemic lupus erythematosus (123), ankylosing spondylitis (124), and polymyositis (125).

Complete heart block occurs in 3% of cases of infective endocarditis, with the aortic valve being involved more frequently than the mitral valve (126,127). A variety of viral, bacterial, and parasitic etiologies of myocarditis result in varying degrees of AV block and include Lyme disease, rheumatic fever, Chagas's disease (128), tuberculosis, measles, and mumps. Transient AV block is the most frequently seen cardiac abnormality associated with Lyme disease. First-degree block is almost always observed in these cases, representing up to 8% of those infected. Complete heart block can develop in 50% of those with first-degree block, especially if the PR interval exceeds 0.30 seconds (129,130). Acute rheumatic fever almost invariably results in PR prolongation when carditis is present (131,132). Second-degree block occurs only occasionally, and progression to complete heart block is rare (133).

Cardiac surgery can be complicated by varying degrees of AV block caused by trauma and ischemic damage to the conduction system. Block is most frequently associated with aortic valve replacement (134). In the absence of myocardial infarction or a long ischemic time, block is rarely seen post–coronary artery bypass grafting. Repair of congenital heart defects in the region of the conduction system—such as endocardial cushion malformations, ventricular septal defects, and tricuspid valve abnormalities—can lead to transient or persistent AV block (see Chapter 70). The block is usually temporary and thought to be secondary to postoperative local inflammation. However, block can appear years later, usually in those who had transient block just after the operation (135).

Intracardiac catheter manipulation can inadvertently produce complete heart block, which is usually temporary. This can occur during a right-sided heart catheterization in a patient with preexisting left bundle branch block, or even during left ventricular angiography in a patient with previous right bundle branch block (136,137 and 138). Radiofrequency catheter ablation techniques are used to modify the AV nodal junction or to produce complete heart block in patients with supraventricular tachyarrhythmias that cannot be controlled by medical therapy alone (139). AV block can also complicate radiofrequency catheter ablation used to treat AV nodal reentrant tachycardia or AV reentrant tachycardia. The incidence of complete heart block complicating this procedure is low when performed by experienced operators and when the bundle of His region is avoided (140,141).

Other causes of acquired AV block include hyperkalemia (142), hypermagnesemia, Addison's disease (143), tumors that infiltrate the heart (144), and neuromyopathic disorders (145,146 and 147). Additionally, transient AV block can be seen with carotid sinus syndrome (eFig. 63.3.13) (148) and vasovagal syncope (149).



***e*FIGURE 63.3.13** Electrogram of acquired complete atrioventricular block. The P-wave cycle length is 840 ms and is independent of the regular wide QRS escape mechanism at 1,800 ms (less than 40 per minute). There is no relationship between the P waves and the QRS complexes at any time during the recording until the next to the last P wave (*arrow*), where there is early retrograde atrial activation representing ventriculoatrial conduction despite complete anterograde atrioventricular block. Therefore, in some patients, retrograde conduction may be intact, even though anterograde conduction is not, or vice versa. (From Miles MM, Klein LS. Sinus nodal dysfunction and atrioventricular conduction disturbances. In: Naccarelli GV, ed. *Cardiac arrhythmias: a practical approach*. Mount Kisco, NY: Futura, 1991:269, with permission.)

Congenital complete AV block is thought to result from abnormal embryonic development of the AV node (150) and is thought to occur in 1 of every 25,000 live births (151). As the defect usually occurs proximal to the bundle of His, the QRS complex is narrow. This abnormality is found in otherwise structurally normal hearts in 50% of cases, whereas the rest have concurrent congenital heart disease (see Chapter 70) (152). Corrected transposition of the great vessels (153), ventricular septal defects, ostium primum atrial septal defects, and Ebstein's anomaly of the tricuspid valve (154) are all associated with AV nodal defects. Congenital complete heart block is also associated with collagen vascular disease in the mother, especially lupus erythematosus (155).

Clinical Profile

Incidence

PR prolongation, or first-degree AV block, is rarely found in young healthy adults, but the incidence increases with age and in those with heart disease. An epidemiologic study involving a large population of asymptomatic male pilots revealed PR intervals more than 0.2 seconds in only 0.52% (156). Two percent of adults over 20 years of age in Tecumseh, MI, were found to have a PR greater than or equal to 0.22 seconds (157). Both studies noted the PR interval to vary over time in young, healthy adults. Frequently in this population, the PR shortens with an increase in heart rate, suggesting vagal influence (156,157). Other epidemiologic surveys

have shown a 5% incidence of first-degree AV block in men over 60 years of age and as high as 10% in older patients with cardiac disease (158,159).

In the large study of a population of healthy pilots, type II second-degree block was found to be extremely rare. In contrast, type I (Wenckebach) block can be seen in young athletes at rest and has been documented by ambulatory Holter monitoring in healthy teenagers during rest or sleep (160). Wenckebach periodicity in these settings disappears with exercise and should be considered a normal variant. On the other hand, in a population of patients with heart disease, the incidence of second-degree AV block (types I and II) was 2.7% (161).

Congenital complete heart block is estimated to occur in 1 of 15,000 to 25,000 live births, with a 60% female predominance (162,163). Acquired complete heart block is rarely seen in young individuals without heart disease (156). The highest incidence occurs in the seventh decade, and there is a 60% male predominance (164,165).

Symptoms

Individuals with first-degree AV block are asymptomatic. Symptoms of dizziness or syncope usually occur with acquired high-grade or complete AV block. With time, the majority of these patients experience a Stokes-Adams attack (166). Other symptoms can occur as a result of low cardiac output, including fatigue, congestive heart failure (166), dyspnea on exertion, angina, or even mental status changes.

Most children and adolescents with congenital complete heart block are asymptomatic, but some go on to develop symptoms later as adults. Those with concomitant structural heart disease, a wide QRS complex, long QT, or complete heart block discovered at an early age have an increased risk of developing symptoms, and some may die suddenly (167,168 and 169).

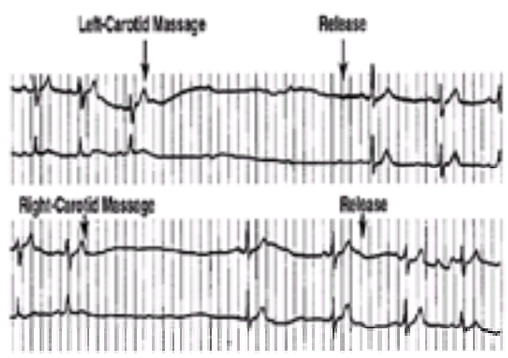
Diagnostic Techniques

Because the prognosis and the treatment differ in AV block depending on whether block is within the AV node or infranodal, determining the site of block is important. In many cases, this can be done noninvasively. As described previously, the QRS duration, PR intervals, and ventricular rate on the surface electrogram can provide important clues in localizing the level of block. Several noninvasive interventions may also prove helpful, such as vagal maneuvers, exercise, or administration of atropine. These methods take advantage of the differences in autonomic innervation of the AV node and His-Purkinje system. Whereas the AV node is richly innervated and highly responsive to both sympathetic and vagal stimuli, the His-Purkinje system is influenced minimally by the autonomic nervous system. Carotid sinus massage increases vagal tone and worsens AV nodal block. Exercise or atropine improves AV nodal conduction because of sympathetic stimulation. In contrast, carotid sinus massage improves infranodal block, whereas exercise and atropine worsen infranodal block because of the change in the rate of the impulses being conducted through the AV node.

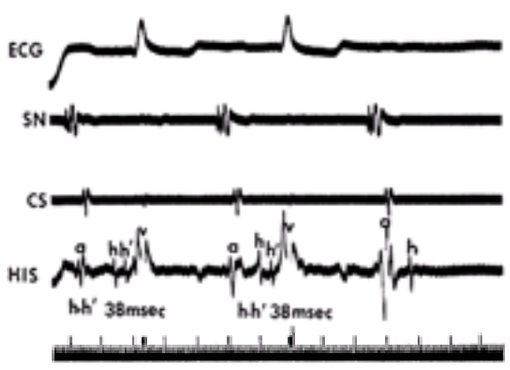
Exercise testing is a useful tool to help confirm the level of block already suspected in second- or third-degree block caused by a narrow or wide QRS complex. Patients with presumed type I block or congenital complete heart block and a normal QRS complex usually enjoy an increased ventricular rate with exercise. On the other hand, patients with acquired complete heart block and a wide QRS complex usually show minimal or no increase in ventricular rate.

An electrophysiologic study is indicated in a patient with suspected high-grade AV block as the cause of syncope or presyncope, when documentation cannot be obtained noninvasively. In patients with coronary artery disease, it may be unclear whether symptoms are secondary to AV block or ventricular tachycardia; therefore, an electrophysiologic study can be useful in establishing the diagnosis. Some patients with known second- or third-degree block may benefit from an invasive study to localize the site of AV block to help determine therapy or assess prognosis. Once symptoms and AV block are correlated by ECG, further documentation by invasive studies is not required, unless additional information, as discussed previously, is needed. Others who should not undergo electrophysiologic studies are asymptomatic patients with transient Wenckebach block associated with increased vagal tone.

The electrophysiology study allows analysis of the bundle of His electrogram, as well as atrial and ventricular pacing to look for conduction abnormalities and inducible ventricular tachycardia. The AH and HV intervals are measured from the bundle of His electrogram. A markedly prolonged HV interval greater than or equal to 100 ms is associated with a high incidence of progression to complete heart block (170). A His potential greater than or equal to 30 ms in duration or frankly split into two deflections is indicative of intra-Hisian conduction delay (eFig. 63.3.14). When the bundle of His electrogram is observed during atrial pacing, the AH interval normally gradually lengthens until Wenckebach block is seen. The HV interval normally remains consistent, despite different pacing rates. Abnormal AV nodal conduction produces Wenckebach block at slower atrial-paced rates than what is normally seen (i.e., greater than 500 ms). To determine whether AV nodal disease is truly present or just under the influence of excessive vagal tone, atropine or isoproterenol is given to see if conduction improves. As discussed in the section Third-Degree Atrioventricular Block, infranodal block is present when the atrial deflection is followed by the bundle of His electrogram, but no ventricular depolarization is seen. Block below the bundle of His is abnormal, unless associated with short paced cycle lengths (350 m per second or less) (eFig. 63.3.15) (171).



***e*FIGURE 63.3.14** The top tracing demonstrates advanced atrioventricular block during left carotid massage. Two consecutive P waves are seen without following QRS complexes. The bottom tracing shows a sinus pause during right carotid massage. (Unpublished data from J. Luck.)



***e*FIGURE 63.3.15** A prolonged His potential of 38 m per second is seen, along with a split His (h-h') on the intracardiac electrogram. CS, carotid sinus; ECG, electrocardiogram; SN, sinus node. (Unpublished data from R. DeJoseph.)

Natural History of Atrioventricular Blocks

The prognosis of any AV block is primarily dependent on the extent of the associated heart disease. First-degree AV block is usually benign and carries no increased mortality risk when seen as an isolated finding (157). However, first-degree AV block can be found in conjunction with bifascicular block or infranodal disease, therefore increasing the risk of progression to complete heart block.

Type I second-degree, or Wenckebach, AV block is generally benign, usually being transiently observed in the setting of acute inferior myocardial infarction or

associated with increased vagal tone in healthy, athletic individuals. However, as with first-degree AV block, when type I AV block occurs in association with bifascicular or trifascicular block the risk of progression to complete heart block is significantly increased because of probable infranodal disease. Type II second-degree AV block, usually seen with bundle branch block, and associated with acute anterior myocardial infarction, carries a high risk of progression to advanced or complete AV block. The prognosis of 2:1 AV block depends on whether the site of block is within or below the AV node.

Before the availability of pacemakers, the prognosis for patients with symptomatic complete heart block was dismal, regardless of the extent of underlying heart disease. The 1-year survival rate after the first Adams-Stokes attack was less than 50% (172). Presently, once appropriate pacing therapy has been established, the prognosis depends on the underlying disease process (173). Patients who develop complete heart block as a result of an anterior myocardial infarction have a poor prognosis because of extensive cardiac damage. In contrast, those who develop complete heart block from idiopathic bundle branch fibrosis and who have no additional cardiac disease have a prognosis similar to those of similar age without heart block.

Congenital complete heart block generally carries a more favorable diagnosis than the acquired form when not associated with underlying heart disease. However, data have shown a significant risk of syncope, sudden death, and acquired mitral insufficiency in this group (174).

Principles of Management

Pacing is now the mainstay of treatment for symptomatic heart block. Medical therapy is only effective as a short-term emergency measure, until pacing can be accomplished. Before the availability of permanent pacing, drugs were used, but only because they were the only known therapies; no effective long-term medical therapy existed.

Complicated acute inferior myocardial infarction. Note inferior ST-segment elevation as well as atrioventricular dissociation secondary to complete heart block.

Before instituting permanent pacing, the possibility of a reversible cause of the heart block should be investigated (Table 63.3). Any offending drugs, such as digoxin, calcium channel blockers, or membrane-active antiarrhythmic drugs, should be withdrawn, if possible, to see if the block improves. Electrolyte abnormalities should also be looked for and then corrected. The possibility of infectious processes should be considered and then treated.

The key point in the decision to provide permanent pacing in AV block is the presence of symptoms. Intermittent block may make correlating bradycardia with symptoms difficult. However, once this is done, pacing should be instituted. Patients with complete heart block and syncope have clearly been shown to have improved survival with permanent pacing (175). Most patients with acquired complete heart block are symptomatic and require pacing. Patients with congenital complete heart block are more likely to be asymptomatic, but prophylactic pacemaker implantation is an appropriate consideration (174). Block in the AV node is less likely to be associated with slow ventricular rates, progression to complete heart block, and symptoms than is infranodal block.

The decision to pace is not always clear when dealing with the asymptomatic patient. However, investigation data and the American College of Cardiology/American Heart Association task force report (61) are helpful in providing some general guidelines (eTable 63.3.1). Permanent pacing is recommended in asymptomatic awake patients with documented pauses of greater than 3.0 seconds or a ventricular escape rhythm of less than 40 beats/min. When type II second-degree heart block is found in an asymptomatic individual, an electrophysiologic study is warranted to determine if the block is infranodal. If this is the case, prophylactic pacing may be considered because of the high risk of progression to complete heart block (176). Permanent pacing is recommended in asymptomatic children with congenital heart block when found in association with a wide complex escape rhythm, complex congenital heart disease, ventricular dysfunction, or a long QT interval. Additionally, exercise intolerance, abrupt pauses in the intrinsic rate, and average ventricular rate inappropriate for the child's age are criteria for pacing in this population (eTable 63.3.2) (177,178 and 179). It is now recognized that dual-chamber pacing can be beneficial in some patients with marked first-degree AV block (>3.0 seconds) to reduce symptoms similar to pacemaker syndrome (180). Additionally, patients with left ventricular dysfunction and a long PR interval may see hemodynamic improvement once paced with a shorter AV delay. In both scenarios, improvement in symptoms, hemodynamics, or both should be documented with temporary AV pacing before the implantation of a permanent device (181).

***e*TABLE 63.3.1** INDICATIONS FOR PERMANENT PACING IN ACQUIRED ATRIOVENTRICULAR (AV) BLOCK[a]

Class I
Symptomatic complete heart block (including associated congestive heart failure, angina, or confusional states)
Asystole ³3 seconds or escape rhythm <40 beats/min in asymptomatic, awake patients with complete heart block
Symptomatic second-degree AV block (regardless of site of block)
Symptomatic bradycardia resulting from required cardiac drugs
After catheter ablation of the AV junction
Class IIa
Asymptomatic complete heart block with ventricular rate >40 beats/min
Asymptomatic type II second-degree AV block
Asymptomatic type I second-degree AV block at intra-His or infra-His levels
Symptomatic first-degree AV block (similar to pacemaker syndrome)
Class IIb
Marked first-degree AV block (>0.3 seconds) shown to cause hemodynamic compromise in patients with left ventricular dysfunction
Class III
First-degree AV block
Asymptomatic type I second-degree AV block at the level of the AV node

[a]Class I indications are conditions for which it is generally agreed that pacing is needed. Class II indications are conditions associated with varying opinions as to the necessity of pacing. The efficacy of pacing is less well established for class IIb than for class IIa. Class III indications are conditions in which pacing is thought not to be indicated.

***e*TABLE 63.3.2** INDICATIONS FOR PERMANENT PACING IN CHILDREN[a]

Class I
Symptomatic second- or third-degree AV block
Symptomatic sinus nodal dysfunction
Advanced second- or third-degree AV block persisting 7 days post–cardiac surgery
Congenital AV block with wide QRS or ventricular dysfunction
Congenital AV block in an infant with a ventricular rate <50 beats/min (or <70 beats/min with congenital heart disease)
Sustained, pause-dependent ventricular tachycardia, with or without prolonged QT, when efficacy of pacing is documented
Class IIa
Tachycardia-bradycardia syndrome with antiarrhythmic drug therapy needed
Long QT syndrome with 2:1 AV block or third-degree AV block
Average heart rate <50 beats/min or abrupt ventricular pauses two or three times the basic cycle length in a child (over 1 year old) with congenital third-degree AV block
Resting heart rate <35 beats/min or ventricular pauses >3 seconds in an asymptomatic child with complex congenital heart disease and sinus bradycardia
Class IIb
Transient third-degree AV block post–cardiac surgery that reverts to bifascicular block

Asymptomatic child of any age with congenital third-degree AV block and an appropriate heart rate, normal ventricular function and narrow QRS complex
Adolescent with congenital heart disease and asymptomatic sinus bradycardia with a resting heart rate <35 beats/min or ventricular pauses >3 seconds
Class III
Asymptomatic postoperative bifascicular or trifascicular block
Transient postoperative AV block that reverts to normal conduction within 7 days
Asymptomatic sinus bradycardia in an adolescent with a heart rate >40 beats/min and the longest RR interval <3 seconds
Asymptomatic type I second-degree AV block

AV, atrioventricular.
[a]Class I indications are conditions for which it is generally agreed that pacing is needed. Class II indications are conditions associated with varying opinions as to the necessity of pacing. The efficacy of pacing is less well established for class IIb than for class IIa. Class III indications are conditions in which pacing is thought not to be indicated.

Temporary pacing is sometimes required in patients with acute myocardial infarction (anterior more often than inferior wall). Patients with asymptomatic first-degree or type I second-degree block do not require pacing. However, patients with type II second-degree or complete heart block should be temporarily paced, even if asymptomatic.

If type II second-degree block or complete AV block persists once out of the periinfarct period, permanent pacing is indicated. Even if the type II or third-degree block was transient but associated with bundle branch block, studies suggest permanent pacing of the postmyocardial infarction patient improves long-term survival (182). In the setting of myocardial infarction, the criteria for permanent pacing depends less on the presence of symptoms (*e*Table 63.3.3).

***e*TABLE 63.3.3** INDICATIONS FOR PERMANENT PACING POST–MYOCARDIAL INFARCTION[a]

Class I
Persistent high-grade or complete AV block with bilateral bundle branch block (infranodal)
Transient high-grade AV block associated with bundle branch block
Persistent, symptomatic second- or third-degree AV block
Class IIa
None
Class IIb
Persistent high-grade block at the AV nodal level
Class III
Transient AV block without intraventricular conduction defect
Transient AV block with isolated left anterior (or posterior) fascicular block
New left anterior (or posterior) fascicular block without AV block
First-degree AV block with new bundle branch block

AV, atrioventricular.
[a]Class I indications are conditions for which it is generally agreed that pacing is needed. Class II indications are conditions associated with varying opinions as to the necessity of pacing. The efficacy of pacing is less well established for class IIb than for class IIa. Class III indications are conditions in which pacing is thought not to be indicated.

The need for permanent pacing because of advanced or complete AV block post–myocardial infarction appears to be significantly reduced by reperfusion therapy. The anticipated result of early reperfusion would be greater myocardial salvage, making damage to the conduction system less likely. Although few data are available to confirm this hypothesis, an analysis of a large series of patients with acute myocardial infarction treated with thrombolytic therapy, who also underwent continuous 12-lead ECG monitoring for 36 to 72 hours, shows the occurrence of persistent bundle branch block to be reduced in this group (5.3%, compared with 8% to 18% reported in the prethrombolytic era) (183). In this study population, patients with persistent bundle branch block had lower ejection fractions, and most had left anterior descending artery infarcts. The higher mortality associated with bundle branch block is caused by the associated increased risk of complete heart block and sudden death in this group. Despite thrombolytic therapy, the occurrence of persistent bundle branch block still identifies a subset of patients with higher mortality than those with either transient or no bundle branch block.

BUNDLE BRANCH BLOCKS

Although the trifascicular concept is not consistent with pathologic findings, it remains clinically useful and provides an accepted framework for the discussion of intraventricular conduction abnormalities. It should be noted that even though we refer to intraventricular conduction disorders as *block*, they are more accurately described as slowed conduction in one or more portions of the fascicles, or partial blocks. ECG criteria have been established for recognition of right and left bundle branch blocks and hemiblocks (*e*Table 63.3.4). Bifascicular block is defined as conduction delay in two of the fascicles: right bundle branch block with left anterior fascicular block, right bundle branch block with left posterior fascicular block, or left bundle branch block. Trifascicular block is recognized with slowed conduction in three fascicles, namely PR prolongation in addition to bifascicular block. In some cases, progressive slowing of multiple areas of conduction can result in complete heart block. Acquired intraventricular conduction delay is most commonly a product of idiopathic degenerative conduction disease. The incidence is 0.6% in the total population and increases with age (up to 2% in those more than 60 years of age). There is a high association with structural heart disease, especially coronary artery disease (184).

A 93-year-old male patient with trifascicular block.

***e*TABLE 63.3.4** ELECTROCARDIOGRAPHIC CRITERIA OF BUNDLE BRANCH BLOCKS AND HEMIBLOCKS

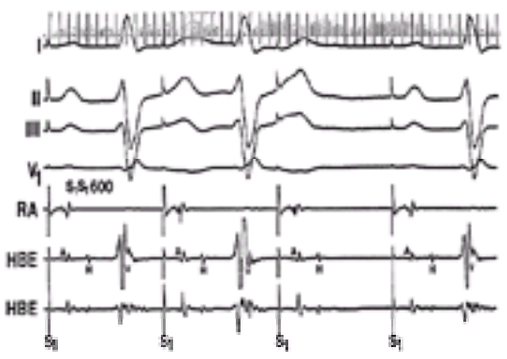
Electrocardiographic criteria for right bundle branch block
QRS duration ³120 ms
Lead V, with rsR[1] or rSR[1] morphology
Leads I, aVL, and V_6 with qRS, where terminal S deflection is wide
Electrocardiographic criteria for left bundle branch block
QRS duration ³120 ms
Leads V_6, I, and aVL showing broad monophasic R wave
Lead V_1 with rS or QS morphology
ST and T wave directed opposite to the predominate deflection of the QRS complex
Electrocardiographic criteria for left anterior fascicular block
Left axis deviation (³ –45 degrees)
rS pattern in leads II, III, and aVF
QR pattern in aVL with a delayed intrinsicoid deflection
Peak of the terminal R wave in aVL preceding the peak of the terminal R wave in aVR
Peak of the initial R wave in lead III preceding the peak of the initial R wave in lead II
Electrocardiographic criteria for left posterior fascicular block
Right axis deviation (³120 degrees)
S_1 Q_3 pattern, with rS in lead I and qR complexes in leads II, III, and aVF
Delayed intrinsicoid deflection in lead aVF

aVF, augmented voltage unipolar left foot lead; aVL, augmented voltage unipolar left arm lead; aVR, augmented voltage unipolar right arm lead.

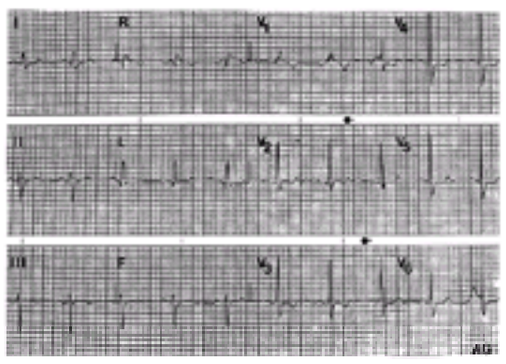
Right bundle branch block is more common than left bundle branch block (185). It rarely progresses to AV block or produces symptoms. There is not an increased association with coronary artery disease (186). Left bundle branch block is less common than right bundle branch block, but it is commonly associated with heart disease (187) and an increased mortality that rises significantly when the abnormality is newly acquired (188). Left anterior fascicular block is more frequently found than right bundle branch block. Left posterior fascicular block is seen less frequently than left bundle branch block (187) and is almost always associated with right bundle branch block.

Left bundle branch block. Wide QRS complex, negative in lead V_1, is associated with secondary T-wave inversions.

Right bundle branch block in association with left anterior fascicular block is the most common type of bifascicular block (*e*Fig. 63.3.16 and *e*Fig. 63.3.17); however, only 6% of these cases go on to complete heart block. Right bundle branch block with left posterior fascicular block is rare, but progression to complete heart block is higher, presumably because of more widespread conduction disease. Patients with left bundle branch block and left axis deviation have a 6% incidence of progressing to complete heart block. Those patients with left bundle branch block alone have a much lower rate of progression (189).



***e*FIGURE 63.3.16** Bundle of His electrograms (HBE) during high right atrial (RA) pacing (S_1-S_1 600 m per second, 100 beats/min) in a patient with right bundle branch block and left anterior hemiblock documenting block distal to the bundle of His. Note that after the third atrial depolarization there is a His deflection but no ventricular depolarization. Therefore, block of the impulse occurred distal to the bundle of His. (From Weeks LC, ed. *Advanced cardiovascular nursing*. New York: Blackwell Science, 1986:525, with permission.)



***e*FIGURE 63.3.17** Twelve-lead electrocardiogram demonstrating right bundle branch block and left anterior fascicular block.

The prognosis of patients with bifascicular block depends on the extent of underlying heart disease. There is no group in which a high incidence of progression to AV block can be predicted by surface ECG alone. However, the bundle of His electrogram is useful to identify a group at higher risk of developing complete AV block. If the HV interval is found to be markedly prolonged (90 to 100 ms), or if block below the bundle of His is seen during atrial pacing, prophylactic pacing is indicated because of a high progression of complete heart block (*e*Table 63.3.5) (170,190).

***e*TABLE 63.3.5** INDICATION OF PERMANENT PACING IN BIFASCICULAR AND TRIFASCICULAR BLOCK[a]

Class I
Bifascicular block with intermittent complete heart block
Bifascicular or trifascicular block with type II second-degree AV block
Class IIa
Bifascicular or trifascicular block in syncope patient in which complete heart block is the presumed (but not proven) etiology
HV interval >100 ms
Pacing-induced block below the bundle of His that is not physiologic
Class IIb
None
Class III
Asymptomatic fascicular block with first-degree AV block

AV, atrioventricular.

[a]Class I indications are conditions for which it is generally agreed that pacing is needed. Class II indications are conditions associated with varying opinions as to the necessity of pacing. The efficacy of pacing is less well established for class IIb than for class IIa. Class III indications are conditions in which pacing is thought not to be indicated.

CONTROVERSIES AND PERSONAL PERSPECTIVES

The proper choice of the most appropriate, cost-effective pacemaker is often straightforward. A patient with chronic atrial fibrillation who needs a pacemaker should be prescribed a VVI or VVIR device. A patient with complete AV block and normal sinus node function should receive a dual-chamber device. In patients with chronotropic incompetence, a rate-responsive device should be prescribed. Because of technologic breakthroughs, industry continues to tempt physicians to use the smallest,

newest, most sophisticated, dual-chamber, rate-responsive pacemakers in almost all patients, even though this approach may not be cost effective. *e*Table 63.3.6 lists current recommendations for optimal pacing modes recommended by the British Pacing and Electrophysiology Group (191).

***e*TABLE 63.3.6** RECOMMENDATIONS OF THE BRITISH PACING AND ELECTROPHYSIOLOGY GROUP

Diagnosis	Optimal mode	Alternative mode	Inappropriate mode
Sinus nodal disease	AAIR	AAI	VVI VDD
Atrioventricular block	DDD	VDD	AAI DDI
Sinus nodal disease and atrioventricular block	DDDR DDIR	DDD DDI	AAI VVI
Chronic atrial fibrillation and atrioventricular block	VVIR	VVI	AAI DDD VDD
Hypersensitive carotid sinus syndrome	DDI	DDD VVI	AAI VDD
Malignant vasovagal syndrome	DDI	DDD	AAI VVI VDD

Many investigators propose that dual-chamber devices should be implanted in all patients who need pacemakers, unless the patient has chronic atrial fibrillation. This approach preserves AV synchrony under all scenarios except for paroxysms of atrial tachyarrhythmias. Retrospective studies have suggested that atrial-based pacing leads to fewer cases of chronic atrial fibrillation and thromboembolism and a possible reduction in mortality when compared with single-chamber ventricular pacing systems (60). In addition, dual-chamber systems minimize the occurrence of pacer syndrome, which can occur in 8% to 10% of patients with VVI pacemakers (192).

Antagonists of the previously mentioned position argue that these data are based on retrospective, uncontrolled trials. A metaanalysis of a large number of trials suggested that the data are not convincing for the superiority of dual-chamber pacing (60).

Several prospective trials are testing the hypothesis of the long-term superiority of dual-chamber or atrial-based pacing compared with single-chamber ventricular-based pacing. The Canadian Trial of Physiologic Pacing completed a 3-year follow-up of patients with sinus nodal dysfunction. Although the rate of atrial fibrillation was significantly lower in the physiologically paced group, more perioperative complications were noted caused by implantation of an atrial lead. The rate of cardiovascular death and stroke was similar in the two groups, as well as overall mortality and hospitalizations for heart failure (192). In a smaller Danish trial (193), a significant reduction in mortality was found with atrial pacing after 5.5 years, but not after only 3.3 years of follow-up. Therefore, the Canadian Trial of Physiologic Pacing investigators have elected to follow their cohort for an additional 3 years to see if a delayed benefit of physiologic over ventricular pacing occurs (194).

The results of the Pacemaker Selection in the Elderly Trial showed that patients with sinus nodal dysfunction—but not AV block—experienced improved quality of life and cardiovascular functional status with dual-chamber pacing as opposed to ventricular pacing (195). The Mode Selection Trial should help further define the benefits of dual-chamber versus single-chamber ventricular pacing in patients with sinus nodal dysfunction (196). The United Kingdom Pacing and Cardiovascular Events Trial is designed to answer the same question in elderly patients with high-degree AV block (197). Both studies have completed enrollment of 2,000 patients each and are now in their follow-up phases. The results of these trials, along with the extended follow-up Canadian Trial of Physiologic Pacing data, will likely provide the information needed for definitive evidence-based recommendations on pacemaker mode prescriptions (195).

THE FUTURE

Decreased pacemaker size along with software enhancements and increased battery longevity will help make the implantation and follow-up of pacemakers safer and more cost effective. Outcome studies will ultimately help us develop the most cost-effective and efficient strategies for prescribing and following pacemaker patients.

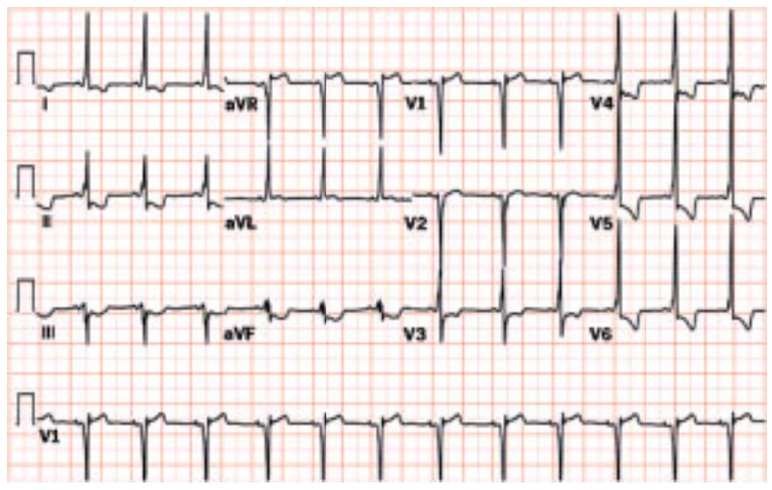
OVERVIEW

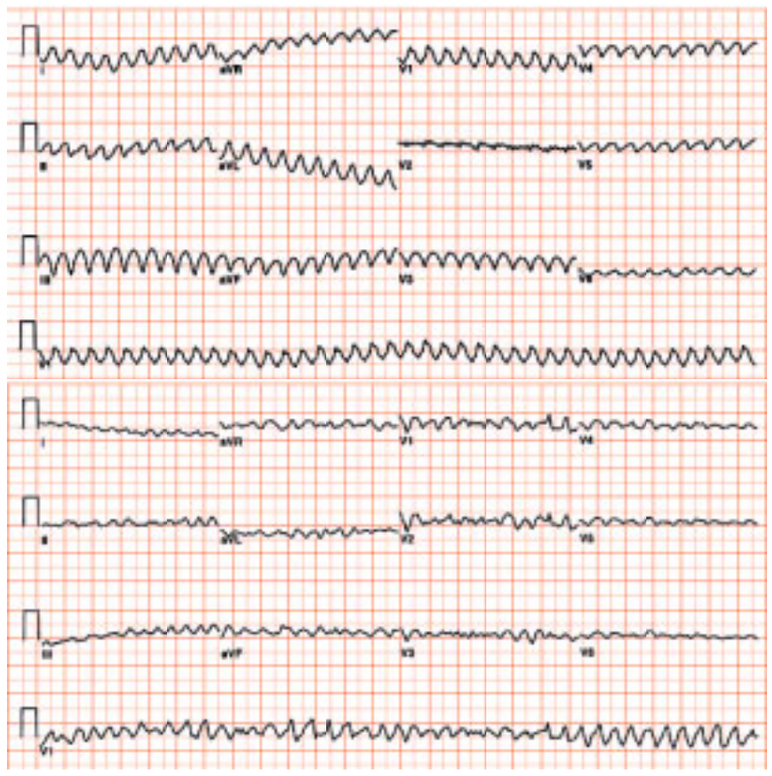
Atrial fibrillation is the most common sustained arrhythmia affecting humans. Pathology studies have found loss of atrial myocardium with fibrosis and fatty infiltration, but many similar changes can occur as a result of aging alone. Maintenance of atrial fibrillation likely depends on reentry, with multiple wavelets occurring simultaneously. The initiation of atrial fibrillation in many patients may be caused by a rapidly firing focus, often in the pulmonary vein(s). Although the atrial rate is rapid, typically greater than 300 beats/min, the ventricular response depends on atrioventricular (AV) node conduction properties and the level of autonomic tone. AV node conduction is facilitated by sympathetic tone and inhibited by parasympathetic tone. A variety of medical conditions are associated with atrial fibrillation, most frequently hypertension, coronary artery disease, and valvular heart disease. Many patients have idiopathic, or lone, atrial fibrillation. There are three major tenets of therapy: (a) restoration and maintenance of sinus rhythm, (b) ventricular rate control, and (c) prevention of thromboembolism. One or more of these may be indicated in a particular patient. Several antiarrhythmic agents are effective for restoring and maintaining sinus rhythm, and selection of a particular drug depends on many factors, including the presence and type of underlying heart disease, concomitant illnesses, and renal or hepatic dysfunction. Beta-adrenergic blockers and calcium channel blockers are more effective than digoxin in controlling ventricular response, although digoxin is the first-line treatment for patients who have congestive heart failure. In patients who have Wolff-Parkinson-White syndrome (WPW), intravenous procainamide or ibutilide is the preferred therapy for blocking conduction over the accessory pathway during atrial fibrillation, and digoxin, adenosine, beta-adrenergic blockers, and calcium channel blockers are contraindicated. In patients at high risk for thromboembolism, anticoagulation therapy using warfarin is recommended, aiming for an international normalized ratio (INR) of 2.0 to 3.0. Anticoagulation is also recommended for patients who are undergoing pharmacologic or electrical cardioversion, if atrial fibrillation has been present for at least 48 hours. Nonpharmacologic approaches to therapy include atrial pacing, radiofrequency catheter ablation, surgery, and implantable atrial defibrillators.

Historical Perspective

Atrial fibrillation is the most common sustained arrhythmia affecting humans. Interest in it has waxed and waned for decades, and recently it has taken a back seat to research into arrhythmias such as AV reentry (WPW), AV node reentry, sustained ventricular tachycardia, and ventricular fibrillation. However, there has been a resurgence in interest in the mechanisms and treatment of patients with atrial fibrillation, especially in the potential for curing this arrhythmia using intracardiac catheter ablation techniques. The following is a brief summary of luminaries who have made important observations concerning atrial fibrillation.



Wolff-Parkinson-White syndrome. Eleven-year-old patient with manifest preexcitation consistent with Wolff-Parkinson-White.



Atrioventricular nodal reentrant tachycardia. Note retrograde P wave buried within the ST segment.

Ventricular flutter (A). Same patient with degeneration into ventricular fibrillation (B).

Evaluation of the peripheral pulse has fascinated physicians for centuries. In approximately 1187, Moses Maimonides (1) wrote aphorisms pertaining to the pulse. He described an irregular pulse that was regularly irregular and one that becomes completely irregular. He was at least partially correct when he mentioned, with regard to the origin of the regularity, “all types of pulses which are irregular in more than one beat are a direct result of an abnormal constitution of the heart which is also irregular or due to an affliction arising in the stomach or in one’s strength” (p. 62). Before the electrocardiographic confirmation of atrial fibrillation, many observant physicians commented on grossly irregular pulses that, in at least some cases, were likely atrial fibrillation. William Stokes (2), in his classic 1853 text on heart disease, stated, “It has happened often to me to find the action of the heart, which, for many months together, had been in the highest degree irregular, suddenly restored to a condition in which the rhythm and sounds were perfectly natural.” In 1904, Wenckebach (3) published a monograph on cardiac arrhythmias. He described cases of excessive irregularity, or “delirium cordis.” One such example is accompanied by a pulse tracing that demonstrates a very irregular rhythm, likely atrial fibrillation.

Cushny (4), Mackenzie (5), Rothberger and Winterberg (6), and especially Lewis (7) made significant early observations concerning atrial fibrillation. The magnum opus of Sir Thomas Lewis is a must-read for any student of atrial fibrillation. The pioneering work of Einthoven (8) enabled clinical investigators to record the electrocardiographic representation of the clinical observations of atrial fibrillation.

EPIDEMIOLOGY

Atrial fibrillation has a profound effect on morbidity and mortality among hundreds of thousands of patients and on health care costs in the United States (9). One report analyzed 3,806,000 patient hospital discharges in 1990 from 678 hospitals to determine the frequency with which arrhythmia was the principal diagnosis (10). Approximately 1.5% of all hospital discharges listed arrhythmia as a principal diagnosis, and atrial fibrillation accounted for nearly 35% of the arrhythmias noted. The epidemiology of atrial fibrillation has changed substantially since the early part of the twentieth century, primarily because of the dramatic decrease in rheumatic fever and the longer life span of the population (Table 64.1) (11,12,13,14,15 and 16). The patient populations evaluated in Table 64.1 differ substantially. For example, two studies included patients admitted through the emergency department (13,14), and one evaluated only outpatients (15). Regardless, it is obvious that rheumatic heart disease plays a relatively minor role in the current etiology of atrial fibrillation in the Western world, whereas hypertension and, to a lesser extent, coronary artery disease currently are major etiologic factors in atrial fibrillation. The incidence of lone atrial fibrillation is quite variable and is influenced by the intensity of the diagnostic workup, the definition of *lone atrial fibrillation* used, and the patient population studied. Kannel and associates (12) reported a 31% incidence of lone atrial fibrillation, but some of their patients had obvious heart disease identified by an enlarged heart on chest radiography. Thus, these data are problematic. In contrast, Prystowsky and colleagues (15) studied only patients who had no known etiologic factors for atrial fibrillation and normal ventricular function identified by echocardiography. However, in their study, only outpatients were evaluated. It is clear that the prevalence and types of etiologic factors for atrial fibrillation depend on the setting in which atrial fibrillation is evaluated, including the country of origin.

Author	Year	Country	Number of patients	Rheumatic heart disease (%)	Hypertensive heart disease (%)	Coronary heart disease (%)	Hyperthyroidism (%)	No heart disease (%)

[b]Atherosclerotic cardiovascular disease included hypertension.
[c]Consecutive series of outpatients only.

TABLE 64.1 ETIOLOGY OF ATRIAL FIBRILLATION

Changes in etiology of atrial fibrillation may affect the course of atrial fibrillation, especially the evolution of paroxysmal atrial fibrillation into established atrial

fibrillation. In a study involving 1,212 patients from Denmark, three time periods, 1940 through 1948, 1949 through 1957, and 1958 through 1967, were evaluated (16). Atherosclerotic heart disease was present in 23%, 37%, and 38% of patients, respectively; hypertensive heart disease was present in 8%, 7%, and 10% of patients, respectively; and rheumatic heart disease occurred in 27%, 17%, and 15% of patients, respectively. During follow-up, the transition rate from paroxysmal to established or permanent atrial fibrillation varied according to the etiology of the disease and was 27% among patients with atherosclerotic heart disease, 40% among patients with hypertensive heart disease, and 66% among patients with rheumatic heart disease. Few data are given on the use of antiarrhythmic drugs to prevent transition to established atrial fibrillation. However, given the dates of the study, only quinidine would have been used with any frequency. These data suggest that the transition from paroxysmal to established atrial fibrillation is not inevitable, especially among patients without rheumatic heart disease. It is quite possible that antiarrhythmic therapy may further decrease the number of patients with established atrial fibrillation. This issue is discussed in more detail in the section Therapy of Atrial Fibrillation.

Effect of Age and Gender

The prevalence of atrial fibrillation increases with age and is 0.5% for patients aged 50 to 59 years and 8.8% for those aged 80 to 89 years (17). Men are affected slightly more often than women. In the Framingham data, excluding individuals with rheumatic heart disease, the 2-year incidence of development of atrial fibrillation was 0.04% and 0.00% for men and women, respectively, aged 30 to 39 years, and 4.6% and 3.6%, respectively, for men and women aged 80 to 89 years (18). Thus, the number of patients who have atrial fibrillation will rise pari passu with the aging of the population. In the first two decades of life, atrial fibrillation is relatively rare (9). When it is found in patients in this age group, it is usually associated with heart disease or the presence of an accessory pathway.

PATHOLOGY

Changes Associated with Aging

The incidence of atrial fibrillation increases with age, and the condition is especially prevalent among individuals aged 60 years or more. Thus, it is important, in attempts to identify the pathologic changes associated with atrial fibrillation, to consider changes that are associated with the aging process in and of itself. Macroscopic and microscopic alterations in atrial tissue begin in the first year of life (19). By the fourth and fifth decades, small fat spots appear in the right atrium in the region of the AV node and septum. There is accentuation of the thickening of the plaques in later decades. In the left atrium, the endocardial thickening is diffuse. With aging, increased thickening occurs, especially at the mitral valve annulus. Calcification and fatty infiltration may be present in the annulus. Histologic examination reveals an endothelial lining, beneath which is a fibroelastic core. With aging, there is focal or diffuse proliferation of smooth muscle cells, elastic fibers, or both and, in some cases, collagen fibers. This process has been termed *endocardial hypertrophy* (19). In the fourth decade, hypertrophic and sclerotic changes occur in previously uninvolved portions of the right atrium, and in the fifth decade, atrophy of smooth muscle layers can be seen. Increased sclerotic changes occur in the sixth decade (*e*Fig. 64.0.1). By the fourth decade, the entire left atrium appears to be affected by hypertrophy and sclerosis, and collagen replacement is frequent. The changes associated with aging result in eventual loss of myocardial fibers and an increase in fatty metamorphosis and connective tissue in the sinus node, the AV node, and the atrial approaches to these structures (19).

Histology of the normal and diseased atrium. In: Falk RH, Podrid PJ, eds. *Atrial fibrillation: mechanisms and management*. New York: Raven Press, 1992, with permission.)

Pathology of the Atrium in Atrial Fibrillation

One study analyzed pathologic changes in the atria in 145 patients with atrial fibrillation (20). Etiologies were diverse and included conditions such as rheumatic fever, hypertension, hyperthyroidism, and coronary artery disease. The hearts of 35 control subjects were compared with those of patients who had atrial fibrillation. No distinctions that would account for the atrial fibrillation were seen in the atria of the control subjects and those of patients with atrial fibrillation. Indeed, the author speculated that no specific histologic syndrome is associated with atrial fibrillation (20).

In another study, lesions of the sinus node were evaluated in the hearts of 65 patients (21). The anatomy of the sinus node was compared with clinical data in a blinded manner. The sinus node was obviously damaged in 15 patients, and an established arrhythmia, usually atrial fibrillation, was seen in 14 patients. The sinus node was not identified with certainty in one patient who had established atrial fibrillation. The sinus node was normal in 49 patients, and atrial fibrillation had been present in 5 patients. These data are interesting and important clinically, because it is well established that atrial fibrillation and sinus node dysfunction often occur in the same patient (this has been termed *tachycardia-bradycardia syndrome*). The common association in this study between sinus nodal damage and a clinical history of atrial fibrillation supports the idea that sick sinus syndrome is a panatrial disorder in many patients.

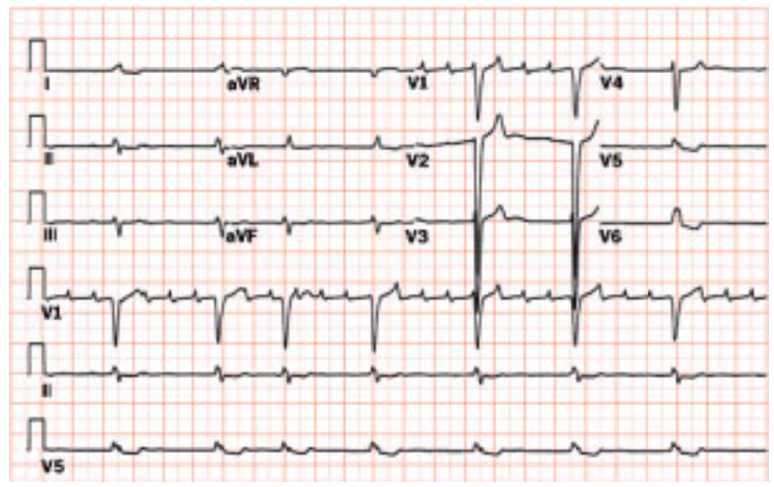
One of the most important pathologic studies of the atria of patients with atrial fibrillation was done by Davies and Pomerance (22). These authors analyzed the hearts of 100 patients with atrial fibrillation and subgrouped them into patients who had atrial fibrillation for less than 2 weeks before death and those who had atrial fibrillation for more than 1 month before death. Among patients who had long-term atrial fibrillation, cor pulmonale, rheumatic heart disease, and ischemic heart disease were the most frequently associated clinical conditions. In nearly 75% of cases of chronic atrial fibrillation, sinus node muscle loss, internodal tract muscle loss, and atrial dilatation of some degree were present. Notably, left atrial appendage thrombosis was identified in 46 patients with long-term atrial fibrillation, and cerebral infarction was identified in 19. However, only 3 of 19 patients with short-term fibrillation had left atrial thrombus, and only 1 patient with cerebral infarction. These authors offered an important hypothesis concerning the origin of pathologic changes in the atria. They stated that “while it is conventional to regard the fibrotic changes in the node and atria as the cause of atrial fibrillation, it is also possible that they result from the arrhythmia and consequent disordered function of the chamber” (22). This prescient observation supports the current belief that atrial fibrillation begets atrial fibrillation, therefore making it possible to retard or even prevent the development of permanent atrial fibrillation in some patients by maintaining sinus rhythm, which may beget sinus rhythm (see the section Therapy of Atrial Fibrillation.).

In recent studies involving patients with lone atrial fibrillation, atrial biopsies have shown histologic changes consistent with myocarditis (23), and high serum levels of antibodies against myosine heavy chains have been found (24). The pathophysiologic significance of these findings is unclear.

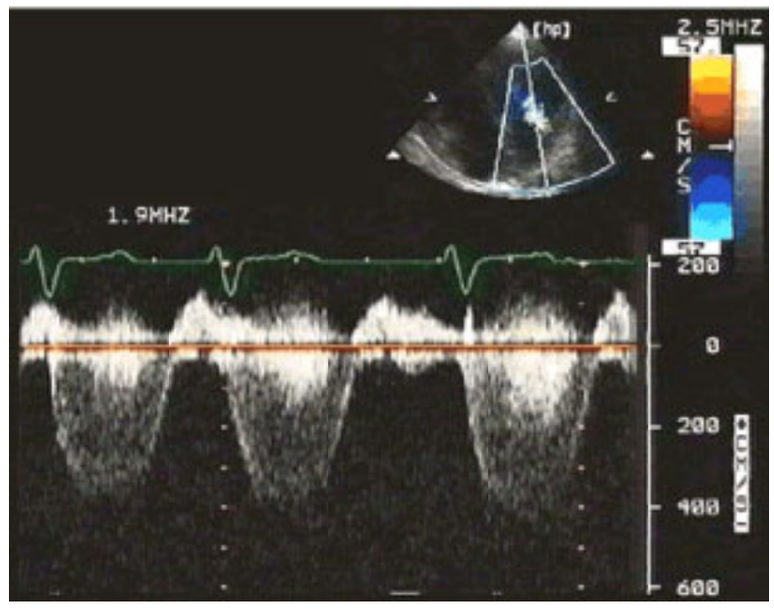
PATHOPHYSIOLOGY

Electrophysiologic Mechanism of Atrial Fibrillation

A wealth of data suggests that reentry is the primary mechanism of atrial fibrillation. An alternative theory, the ectopic focus theory, was championed by Scherf and coworkers (25,26). Using topical application of aconitine to the atria, several observations were made that appeared to indicate that there was a focal mechanism for atrial fibrillation. Aconitine could be applied to the appendix of the right or left atrium and yield arrhythmias that were similar in appearance. Clamping off the area of application from the rest of the atrium allowed the arrhythmia to continue in the area that was clamped off, but not in the rest of the atria. Similarly, cooling of the area on which aconitine had been applied terminated fibrillation. The experiments with aconitine suggested that atrial fibrillation depended on a single focus. However, atrial fibrillation induced by topical application of acetylcholine did not terminate when the area in which drug had been applied was cooled (26). The authors postulated that the AV node was able to maintain atrial fibrillation in this situation. These observations led to the supposition that an additional mechanism of atrial fibrillation existed, one with multiple (tachysystolic) foci.



High-grade atrioventricular block. Note marked discrepancy between atrial and ventricular heart rates.



Apical continuous wave spectral Doppler recording of mitral regurgitation (systolic parabolic downward velocities). Note beat-to-beat variation due to atrial fibrillation.

The ectopic focus theory for atrial fibrillation was essentially smothered by the overwhelming weight of observations indicating that reentry is the mechanism of atrial fibrillation. However, recent observations made during intracardiac radiofrequency catheter ablation of atrial fibrillation have rekindled interest in the ectopic focus theory (27,28 and 29). These authors (27,28) were able to terminate atrial fibrillation with discrete applications of energy, primarily in the area of the pulmonary veins in the left atrium, although right atrial sites have also been identified (29). In such cases, it is likely that atrial fibrillation results from rapid, focal atrial tachycardia, a form of tachycardia-induced tachycardia (see the section Tachycardia-Induced Tachycardia). Thus, elimination of the primary inciting arrhythmia prevents the secondary arrhythmia. The pulmonary veins are most frequently the origin of these rapid atrial foci, and studies have confirmed that cardiac muscle extends onto the pulmonary veins in humans (30) and have found automaticity in an experimental model (31).

In a classic paper, Mines (32) demonstrated reentry in the myocardium. He used various experimental preparations and showed reciprocating rhythm in an AV preparation. In one experiment, using a tortoise heart, stimulation of one portion of the heart was followed by an orderly sequence of activation using the atrium and ventricle repeatedly without any further stimulation. He suggested that this mechanism was the cause of atrial fibrillation. Working independently, Garrey (33) performed innovative experiments that implicated reentry as the mechanism of fibrillation. He further proposed that persistence of fibrillation is directly proportional to the size of the tissue mass involved. Indeed, atrial fibrillation is relatively rare in children with normal-sized hearts (9).

A key development in our understanding of the mechanism of atrial fibrillation was the multiple wavelet hypothesis proposed by Moe and coauthors (34,35). They noted, “the grossly irregular wave front becomes fractionated as it divides about islets or strands of refractory tissue, and each of the daughter wavelets may now be considered as independent offspring. Such a wavelet may accelerate or decelerate as it encounters tissue in a more or less advanced state of recovery” (34). Thus, the larger the number of wavelets that present, the more likely it is that the arrhythmia will sustain. The number of wavelets depends on the atrial mass, the refractory period, and the conduction velocity of various areas of the atria. In essence, a large atrial mass with short refractory periods and conduction delay would yield increased wavelets and would present the most favorable situation for atrial fibrillation to be sustained. In the work of Moe and many other investigators, atrial fibrillation could only be sustained during constant vagal stimulation. This is consistent with Moe’s hypothesis, because vagal stimulation shortens refractoriness in many atrial cells, a condition that should allow more wavelets to be present. A computer model of atrial fibrillation supported the multiple wavelet hypothesis (35).

Experimental validation of the multiple wavelet hypothesis was demonstrated by Allessie and colleagues (36). They analyzed the excitation of canine atria during induced atrial fibrillation with two egg-shaped multiple electrodes inserted into the cavities of the atria. Each electrode contained 480 recording electrodes, with an interelectrode distance of 3 mm. This enabled the first highly detailed activation sequencing of atrial fibrillation. As noted by other investigators, enhanced vagal tone was necessary for maintenance of atrial fibrillation, and infusions of acetylcholine were used for this purpose. Figure 64.1 demonstrates an arbitrary moment during atrial fibrillation and reveals seven wavelets (36). These reentrant wavelets were not stable, and over the course of time, various pathways of reentry could be demonstrated. When only three wavelets existed, there was a high chance that all would cease to exist, but when six wavelets were present, spontaneous termination of atrial fibrillation did not occur.

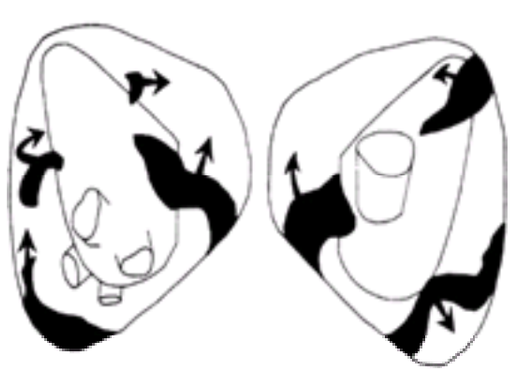


FIGURE 64.1 Canine atria with multiple propagating wavelets during sustained atrial fibrillation. Seven wavelets are present—three in the right atrium and four in the left atrium. The black contours mark the atrium that has been excited during the last 10 ms. (From Allessie MA, Lammers WJEP, Bonke FIM, et al. Experimental evaluation of Moe’s multiple wavelet hypothesis of atrial fibrillation. In: Zipes DP, Jalife J, eds. *Cardiac arrhythmias.* New York: Grune & Stratton, 1985:265–276, with permission.)

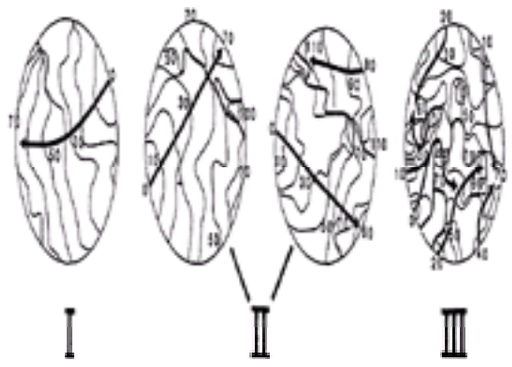
Multiple simultaneous electrode mapping of human atrial fibrillation has been accomplished during surgery (37,38). In one study, wavefronts of activation appear to turn around functional arcs of conduction block and natural anatomic obstacles (37). In another study, high-density electrode mapping was obtained in the free wall of the right atrium during surgery in patients with WPW, using 244 unipolar electrodes (38). Activation patterns during atrial fibrillation were quite variable between patients and ranged from single broad wavefronts to extremely complex multiple wavefronts. The authors define three types of activation, although they stressed that the activation maps were part of a continuous spectrum of increasing complexity (eFig. 64.1.1) (38). Right and left atria were mapped simultaneously in eight patients, five of whom showed the same type of activation during atrial fibrillation, but three different activation patterns were noted. The simultaneous appearance of various

activation patterns during atrial fibrillation is likely more common than was demonstrated by this study, which examined relatively short-duration atrial fibrillation. In fact, multiple-site simultaneous electrogram recordings during sustained atrial fibrillation in canine atria often demonstrate various local atrial rates and electrogram morphologies (eFig. 64.1.2) (39). Indeed, dissimilar atrial rhythms are commonly observed by electrophysiologic study during atrial fibrillation in humans (eFig. 64.1.3).



***e*FIGURE 64.1.1** Classification of activation maps during atrial fibrillation. Type I is a single uniformly propagating wave; type II involves single nonuniformly conducting waves or the presence of two wavelets; type III is characterized by the presence of three or more wavelets with arcs of conduction block and areas of slow conduction. Numbers denote activation sequence. (From Konings KTS, Kirchhof CJ, Smeets JRLM, et al. High-density mapping of electrically induced atrial fibrillation in humans. *Circulation* 1994;89:1665–1680, with permission.)

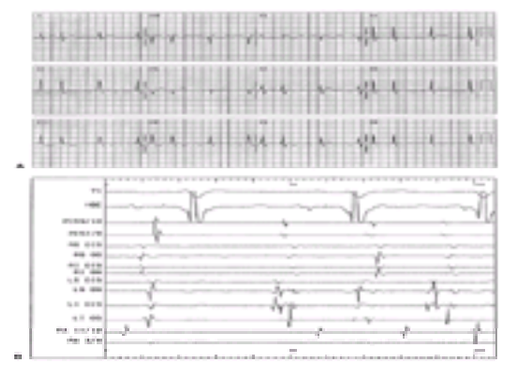
Traditionally, it has been thought that reentry requires a significant mass of tissue. The seminal work of Spach and associates (40,41) on conduction led to the understanding that anisotropic reentry is possible. Typically, propagation in the myocardium is faster in the longitudinal direction than in the perpendicular direction, and this anisotropic propagation can be uniform or nonuniform. Nonuniform conduction is associated with decreased side-to-side electrical coupling between small groups of cells, which typically occurs with aging (40). During investigation of human atrial pectinate muscle bundles obtained at surgery, reentry was demonstrated in 1 to 2 mm areas (eFig. 64.1.4). Even if the maintenance of reentry in atrial fibrillation requires the presence of multiple wavelets throughout the atria, this important observation may explain the initiation of atrial fibrillation in some circumstances, for example, in patients with tachycardia-induced tachycardia who have AV reentry, in which disorganization of the right atrium typically precedes that of the left atrium (Fig. 64.2) (42). An alternative mechanism for tachycardia-induced atrial fibrillation may be induction of a rapidly firing atrial focus, for example, in the superior right pulmonary vein, with initial activation observed at the right atrial recording site.



***e*FIGURE 64.1.4** Microreentry in older, nonuniform anisotropic bundle. The upper left drawing demonstrates locations of recording sites. Transverse propagation (TP) reveals markedly polyphasic extracellular waveforms consistent with loss of side-to-side electrical coupling. Longitudinal propagation (LP) demonstrates uniphasic electrogram waveforms. The pacing cycle length is 350 ms, and premature stimuli are introduced. A premature interval of 233 ms does not produce reentry. A premature interval of 228 ms initiates reentry, schematically demonstrated in the lower right portion of the figure. Note that decremental transverse propagation occurred (sites 1 and 2), but block appears to occur after recording site 4 in the longitudinal direction. (From Spach MS, Dolber PC, Heidlage JF. Influence of the passive anisotropic properties on directional differences in propagation following modification of the sodium conductance in human atrial muscle: a model of reentry based on anisotropic discontinuous propagation. *Circ Res* 1988;62:811–832, with permission.)

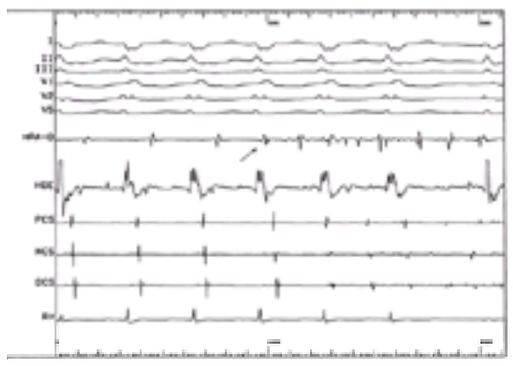


FIGURE 64.2 Patient with atrioventricular reentry using a left-sided accessory pathway in which atrioventricular reentry degenerates to atrial fibrillation. The arrow notes the earliest disorganization in the high right atrial electrogram, positioned near the junction of the right atrium and the superior vena cava. DCS, distal coronary sinus; HBE, bundle of His electrogram; HRA-D, high right atrium–distal; MCS, midcoronary sinus; PCS, proximal coronary sinus; RV, right ventricle.

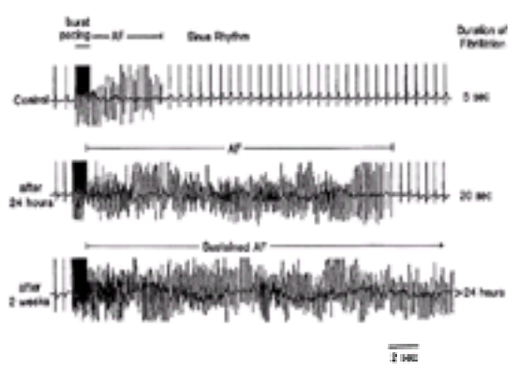
The mechanism of initiation of atrial fibrillation is not certain in most cases and likely is multifactorial. Even the example given in this chapter of tachycardia-induced tachycardia is merely descriptive, and the actual mechanism for induction of atrial fibrillation might be related to the tachycardia cycle length, to intrinsic atrial vulnerability, to contraction-excitation feedback, or to a combination of these factors (42). If reentry is assumed to be the mechanism of atrial fibrillation, initiation would require an area of conduction block and a wavelength of activation that is short enough to allow the reentrant circuit in the myocardium. The normal aging process results in anatomic changes likely to yield inhomogeneity in conduction that may create the milieu necessary for the development of reentry (19,40). These changes are likely magnified by the presence of certain disease processes, for example, those of coronary artery disease. Using high-density mapping of the left atrium of a rabbit, inhomogeneity in conduction was found to be significantly increased by the presence of single close-coupled atrial premature complexes and further increased by the presence of multiple premature complexes (43). Of particular note was the marked inhomogeneity in conduction that occurred with rapid atrial pacing. The clinical counterpoint of this phenomenon is the presence on electrophysiologic study in humans of relatively frequent accidental initiation of atrial fibrillation during rapid atrial pacing, and the necessity that a relatively rapid rate of tachycardia be present for either AV or AV node reentry to initiate atrial fibrillation (42).

In a successful reentrant circuit, the wavefront of excitation must encounter excitable cells or the tachycardia will terminate. The wavelength of the electrical impulse is defined as the conduction velocity multiplied by the refractory period of the tissue involved in the circuit, which defines the anatomic size of the circuit. In a macroreentrant circuit such as WPW reentry, the anatomic circuit is clearly longer than the wavelength of the tachycardia. However, most forms of intramyocardial reentry require a substantial decrease in conduction velocity to enable sustained reentry. The wavelength formula makes it clear that a decrease in conduction velocity or a shortened refractory period results in a decrease in the wavelength or a lessening of the amount of tissue needed to sustain reentry. This situation favors initiation and maintenance of reentry, especially atrial fibrillation. Alternatively, an increase in conduction velocity or prolongation of refractoriness will prolong the wavelength of excitation, and in this situation, a larger anatomic circuit will be necessary to sustain reentry. If a larger circuit is not possible, initiation or maintenance of tachycardia cannot occur. Anisotropic reentry can occur over a very small area. In a canine atrial model, the type of atrial arrhythmia initiated correlated with the wavelength of the premature beats. Atrial flutter was initiated at a wavelength less than 9.7 cm, and atrial fibrillation occurred at wavelengths less than 7.8 cm (44). Administration of acetylcholine substantially shortened the wavelength, primarily because of a decrease in the refractory period (38). This is consistent with the well-reported facilitation of initiation and maintenance of atrial fibrillation by heightened vagal tone.

Tachycardia-Induced Atrial Cardiomyopathy

It has been recognized for several decades that a persistently fast ventricular rate secondary to supraventricular tachycardia can lead to ventricular cardiomyopathy, which is reversible if recognized in time. In fact, this is not an uncommon phenomenon in patients who present with atrial fibrillation and dilated cardiomyopathy. But might such a situation lead to tachycardia-induced atrial cardiomyopathy? It is not only possible, but probable, although this has not been investigated in detail until recently (45). Notably, this concept was put forth in an earlier study on the pathology of atrial fibrillation, in which the authors suggested that the fibrotic changes in the sinus node and atria may be the result of atrial fibrillation rather than its cause (22). More recently, the effect of persistent atrial fibrillation on changes in atrial size was investigated in 15 patients who showed no evidence of significant structural or functional cardiac abnormalities other than atrial fibrillation (46). Normal left atrial size was among the inclusion criteria. During an average follow-up period of 20.6 months, mean left atrial volume increased from 45.2 to 64.1 cm^3. Similarly, right atrial volume significantly increased, from 49.2 to 66.2 cm^3. These changes in atrial size are consistent with the observation that atrial fibrillation begets atrial fibrillation. In another study, atrial size was evaluated at 6 months' follow-up after cardioversion in patients in whom sinus rhythm persisted and in patients in whom atrial fibrillation recurred (47). Importantly, in the 28 patients in whom sinus rhythm was maintained, left atrial volume decreased from 72.6 ± 15.1 to 58.5 ± 13.8 cm^3 and right atrial volume decreased from 68.7 ± 14.6 to 58.6 ± 11.6 cm^3 (p <.05). In contrast, atrial size did not change in patients in whom atrial fibrillation recurred. Thus, a window of opportunity appears to be present for reversal of the atrial dilatation that is often noted in association with atrial fibrillation.

Persistence of atrial fibrillation also produces changes in the electrophysiology of the atrium (39,48). In dogs subjected to sustained rapid atrial pacing, electrophysiologic, anatomic, and pathologic changes were noted to occur over the course of time (39). Biatrial enlargement, disruption of the sarcoplasmic reticulum, increases in mitochondrial size, decreases in atrial refractoriness, and the ability to induce atrial fibrillation were observed. In an elegant study by Wijffels and associates (48), electrophysiologic changes in the atria of chronically instrumented goats were observed. They observed that the initial episode of atrial fibrillation usually terminated within seconds. However, when atrial fibrillation was maintained for longer periods of time, the duration of the induced episodes of atrial fibrillation also increased (*e*Fig. 64.2.1). The atrial effective refractory period and the median fibrillation interval shortened during the first 24 hours of atrial fibrillation (48). These electrophysiologic changes are consistent with a milieu that would promote sustained atrial fibrillation. The electrophysiologic changes were noted to be reversible within 1 week in a small number of goats tested in whom atrial fibrillation had been present for 2 to 4 weeks. Recent data from humans suggest that episodes of atrial fibrillation shorter than 10 minutes can cause a transient decrease in the atrial effective refractory period (49). Changes in action potential shortening may be related to decreased inward current through L-type calcium channels (50).



***e*FIGURE 64.2.1** Duration of atrial fibrillation (AF) is prolonged after AF has been maintained for progressively longer periods of time. The top panel represents the first episode of induced AF, which spontaneously terminates within seconds. The middle panel records AF of 20 seconds' duration after 24 hours of repeated induction of AF. The bottom panel demonstrates a sustained episode of AF that occurred after 2 weeks of electrically maintained AF. (From Wijffels MC, Kirchhof CJ, Dorland R, et al. Atrial fibrillation begets atrial fibrillation: a study in awake chronically instrumented goats. *Circulation* 1995;92:1954–1968, with permission.)

Evidence for a tachycardia-induced atrial cardiomyopathy is supported further by echocardiographic observations before and after cardioversion (51,52). Using transesophageal echocardiography, left atrial appendage blood flow velocity and contractile function were assessed in patients with atrial fibrillation (52). The mean duration of atrial fibrillation was 49 months, and an inverse correlation was seen between the duration of the arrhythmia and left atrial appendage peak outflow velocities. Patients who spontaneously cardioverted to sinus rhythm had significantly greater left atrial appendage outflow velocities. The course of recovery of atrial systolic function after cardioversion was evaluated using transthoracic Doppler echocardiography (51). Within the first week after cardioversion, atrial mechanical function was greater in patients with atrial fibrillation of 2 weeks or less compared with those patients who had atrial fibrillation greater than 6 weeks in duration. Over the course of time, atrial mechanical function improved in all groups of patients. Thus, atrial mechanical function appeared to recover compared that measured before cardioversion, and the time to recovery was a function of the previous duration of atrial fibrillation. However, because atrial mechanical function before atrial fibrillation

was unknown, the degree to which atrial mechanical function approached normal for individual patients remains unclear.

In summary, persistence of atrial fibrillation results in a cascade of electrical and anatomic changes in the atria that promote the persistence of atrial fibrillation. The result is perpetuation of atrial fibrillation and a decrease in atrial mechanical function secondary to tachycardia-induced atrial cardiomyopathy. If sinus rhythm is restored within a reasonable period of time, electrophysiologic changes appear to normalize, atrial size decreases, and restoration of atrial mechanical function occurs. These observations lend support to the idea that the negative downhill spiral in which atrial fibrillation begets atrial fibrillation can be arrested with sinus rhythm that perpetuates sinus rhythm. Two major questions remain unanswered: What duration of atrial fibrillation results in substantial irreversible changes, and can maintenance of sinus rhythm prevent the transition of intermittent atrial fibrillation to permanent atrial fibrillation? These are the subjects of future investigations.

Atrioventricular Conduction

In the absence of an accessory pathway, AV conduction occurs over the AV node during atrial fibrillation. The resultant ventricular rate depends on the intrinsic conduction and refractoriness of the AV node, the rate and organization of atrial inputs to the AV node, and the state of autonomic tone. The compact AV node is located anteriorly in the triangle of Koch (53). The compact AV node is surrounded by transitional cells with various microelectrode action potential characteristics. Maximal conduction slowing occurs predominantly in the zone of N cells in the AV node (53). There are two distinct atrial inputs to the AV node, anteriorly via the interatrial septum and posteriorly via the crista terminalis. Experiments in a rabbit AV nodal preparation demonstrated that propagation of impulses during atrial fibrillation through the AV node to the bundle of His was critically dependent on the relative timing of activation of septal inputs to the AV node at the crista terminalis and interatrial septum (54). Other investigators showed that the ventricular response also depended on atrial input frequency (55,56). Concealed conduction likely plays the predominant role in determining ventricular response during atrial fibrillation (55,57). Concealed conduction into the AV node occurs with atrial impulses that enter the AV node but do not conduct to the ventricle, leaving a wake of refractoriness that is encountered by subsequent impulses. The constant bombardment of atrial impulses into the AV node undoubtedly creates substantial and varying degrees of concealed conduction.

Alterations of autonomic tone can have profound effects on AV nodal conduction (58,59 and 60). Enhanced parasympathetic and sympathetic tone have negative and positive dromotropic effects, respectively, on AV nodal conduction. This can be seen in Figure 64.3, in which recordings of atrial fibrillation during the awake state and during sleep are shown. Note the substantial slowing of ventricular response, even with pauses, during sleep, a state in which there is heightened parasympathetic and decreased sympathetic tone.

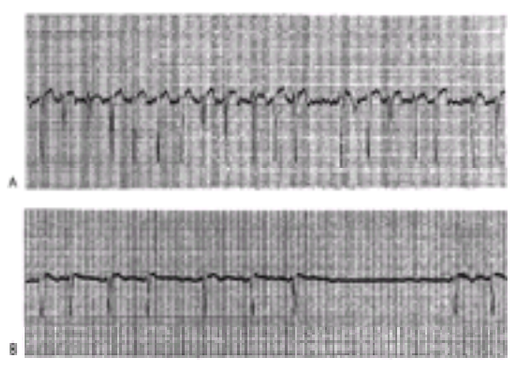


FIGURE 64.3 Effect of autonomic tone on atrioventricular node conduction during atrial fibrillation. **A:** Relatively rapid ventricular response during the awake state. **B:** Slow ventricular response recorded during sleep.

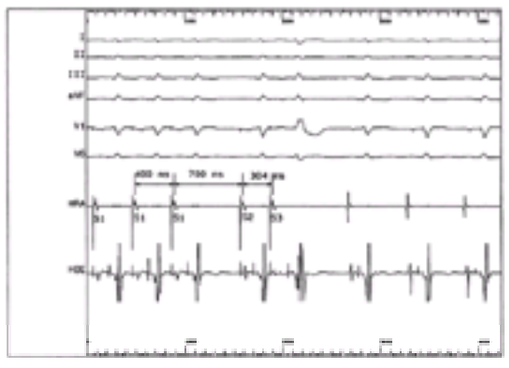
Aberrant conduction commonly occurs during atrial fibrillation. It is important to distinguish aberrant conduction from ventricular ectopy, especially when repetitive wide QRS complexes occur. The refractoriness of the His-Purkinje tissue decreases as the heart rate increases (61). Thus, slower heart rates favor aberrancy. The gross irregularity of ventricular response during atrial fibrillation yields an abundance of RR cycle lengths, which statistically increases the chance for a long-short cycle length combination that will produce aberrant conduction. This phenomenon was described well by Gouaux and Ashman ("Ashman phenomenon") (62) and Lewis (63) and confirmed experimentally by Moe and coworkers (64). Figure 64.4 demonstrates an example of right bundle branch (RBB) block aberrancy during atrial flutter/fibrillation initiated during electrophysiologic study. RBB aberrancy results from the sudden lengthening of the preceding cycle length (long-short sequence), which prolongs RBB refractoriness. RBB block aberrancy is more common than left bundle branch block aberrancy, probably because the RBB has a longer refractory period at slower heart rates (65). To complicate matters further, it has been demonstrated that cycle lengths preceding the pause may also affect the chance for aberrancy after the pause (eFig. 64.4.1) (66).

FIGURE 64.4 Right bundle branch block aberrancy caused by sudden lengthening of the preceding cycle length. See text for details. HBE, bundle of His electrogram; HRA, high right atrium. (From Prystowsky EN, Klein GJ. *Cardiac arrhythmias: an integrated approach for the clinician*. New York: McGraw-Hill, 1994, with permission.)



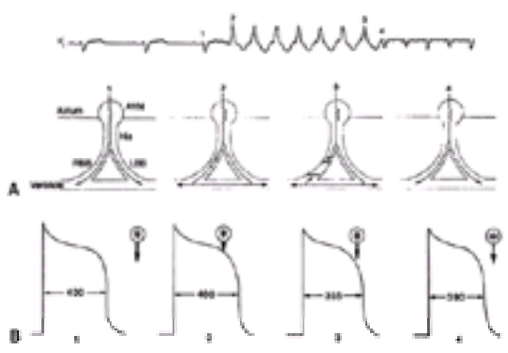
***e*FIGURE 64.4.1** Initiation of right bundle branch block aberrancy at electrophysiologic study. During a pacing cycle 400 ms in length with premature atrial stimulation, no right bundle branch block aberrancy was noted. However, when eight consecutive atrial complexes at 400 ms (150 per minute) were introduced preceding a pause of 700 ms, a premature atrial interval of 304 ms resulted in right bundle branch block aberrancy. HBE, bundle of His electrogram; HRA, high right atrium.

It is important to differentiate between aberrant ventricular conduction and ventricular tachycardia when repetitive wide QRS complexes occur during atrial fibrillation. This can usually be accomplished by careful analysis of the rhythm strip and application of certain guidelines (Table 64.2) (61,67,68). eFigure 64.4.2 is an example of repetitive bundle branch block aberrant complexes induced during electrophysiologic study with sudden onset of rapid atrial pacing. The first three

complexes are sinus rhythm, and pacing started with complex number 2. Note that the long-short sequence produces RBB block, which persists for seven complexes, followed by normalization of the QRS complex. The first RBB block complex (number 2) occurs because the premature atrial interval encounters the RBB refractory period. Two mechanisms have been postulated for the persistence of RBB block aberrancy. The first is schematically represented in part A of the figure. In this situation, retrograde concealed conduction from the left bundle branch into the distal RBB occurs, and when retrograde conduction fails, the RBB can recover, resulting in normalization of the subsequent QRS complex. This is the likely mechanism when bundle branch block aberrancy persists for long periods of time, and it has been confirmed experimentally (64). An alternative mechanism is schematically shown in part B of the figure. In this case, continued bundle branch block aberrancy is caused by persistence of the prolonged action potential duration, which progressively shortens after several complexes, allowing normalization of conduction. This mechanism is most likely the cause of short runs of bundle branch block aberrancy (69). An example of ventricular tachycardia is shown in *e*Figure 64.4.3. Note that the ventricular rate during atrial fibrillation is relatively slow, and there is no reason to expect a sudden acceleration in heart rate unless some profound increase in sympathetic tone occurs, which was not present in this instance. Further, the first wide QRS complex is not short coupled.

Long-short cycle length sequence
Typical right bundle branch block
Relatively rapid ventricular rate
Lack of compensatory pause
Absence of bundle branch block with shorter cycle length without preceding pause
Normalization of QRS complexes with minimal change in cycle length

TABLE 64.2 FACTORS FAVORING ABERRANT VENTRICULAR CONDUCTION



***e*FIGURE 64.4.2** Potential mechanisms for repetitive bundle branch block aberrancy. See text for details. ***e*FIGURE 64.4.3** Nonsustained ventricular tachycardia in a patient with underlying atrial fibrillation. See text for details.

The presence of a grossly irregular, very rapid ventricular response during atrial fibrillation is diagnostic of conduction over an accessory pathway, with rare exceptions (Fig. 64.5). At very fast heart rates, a tendency toward regularization of the RR intervals is present, but careful measurement always discloses definite irregularities. It would be rare for such rapid responses to result from conduction over the AV node, and the only other alternative is ventricular tachycardia. It is axiomatic that rapid, irregular ventricular tachycardia is unstable and quickly degenerates into ventricular fibrillation. Thus, when a rapid, irregular wide QRS complex tachycardia is noted in a patient who has a reasonably stable hemodynamic state, preexcitation is the most likely diagnosis. The ability to conduct rapidly over an accessory pathway is determined primarily by the intrinsic conduction and refractory properties of the accessory pathway. However, as with AV node conduction, factors such as spatial and temporal characteristics of atrial wavefronts during atrial fibrillation, autonomic tone, and concealed conduction influence activation over the accessory pathway (70,71 and 72).

FIGURE 64.5 Twelve-lead electrocardiogram in a patient with ventricular preexcitation during atrial fibrillation who had a rapid preexcited ventricular response.

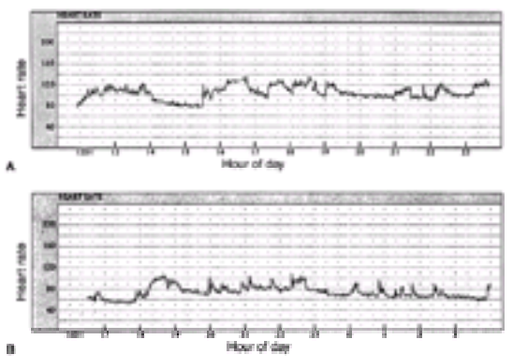
Tachycardia-Induced Ventricular Cardiomyopathy

Patients with idiopathic dilated cardiomyopathy commonly have atrial fibrillation. The usual assumption is that atrial fibrillation is caused by the cardiomyopathy. Importantly, the reverse is often documented—that is, a persistently rapid ventricular response during atrial fibrillation results in a tachycardia-induced ventricular cardiomyopathy (73,74,75,76,77,78 and 79). This phenomenon has been well recognized in patients with long-standing incessant or nearly incessant supraventricular tachycardia other than atrial fibrillation. In fact, the first patient who underwent successful surgical ablation of an accessory pathway at Duke University had congestive

heart failure and dilated myopathy that disappeared over the course of time after surgery, with restoration of sinus rhythm (80). Recognition of the possible presence of tachycardia-induced ventricular cardiomyopathy is critical, because control of ventricular response over the course of time may lead to partial or complete reversal of the myopathic process. In general, unless the cardiomyopathy is known to have preceded the onset of atrial fibrillation, it should always be assumed that the fibrillation is potentially reversible, and every effort should be made to control the ventricular response as part of the therapeutic plan.

Amelioration of tachycardia-induced cardiomyopathy can occur with multiple mechanisms of rate control, including persistence of atrial fibrillation with rate control using drugs or ablation of the AV junction, or after cardioversion to sinus rhythm. In one study of ten patients, sinus rhythm was restored in five, and better rate control was achieved in the other five patients (75). Importantly, patients had minimal awareness of palpitations, even though the mean heart rate during atrial fibrillation was 145 beats/min. After appropriate rate control or restoration of sinus rhythm, the median left ventricular ejection fraction increased from 25% to 52%. In another study evaluating improvement in left ventricular function after ablation of the AV junction with insertion of a permanent pacemaker, changes in left ventricular ejection fraction were evaluated a mean of 14 months after ablation (77). In the 12 patients who had a left ventricular ejection fraction less than or equal to 50% before ablation, the ejection fraction increased significantly, from 43% ± 8% to 54% ± 7%. However, no change was seen in left ventricular ejection fraction in patients in whom the ejection fraction was greater than 50% before ablation. The time course of hemodynamic changes after cardioversion of atrial fibrillation to sinus rhythm was evaluated in another study (78). In the eight patients studied, the resting ventricular response during atrial fibrillation before cardioversion was 123 ± 28 beats/min, and this decreased to 81 ± 16 beats/min after cardioversion. The ejection fraction before cardioversion was 36% ± 13%, and improvement was minimal at 1 week, but a significant increase, to 53% ± 8%, occurred after 1 month; minimal change was seen thereafter. Although this study suggests that maximal hemodynamic improvement occurs within 1 month, other observations suggest that it may take several months for full improvement in ejection fraction and decrease in left ventricular size to occur. Interpatient variability obviously exists, and some of this may relate to the duration of atrial fibrillation or concomitant disease processes.

Rate control has a salutary effect on improvement of left ventricular function in at least some patients who have dilated cardiomyopathy and atrial fibrillation. It matters little what mechanism is used to control rate: cardioversion to sinus rhythm, drugs that control the ventricular response, or ablation of the AV junction with pacemaker insertion. Many patients who undergo such treatment have minimal symptoms and are first diagnosed with cardiomyopathy with atrial fibrillation. It is especially important in this circumstance to assume reversibility of all or part of the myopathic process and to make every effort to control the ventricular response by whatever mechanism is most appropriate for that patient. *e*Figure 64.5.1 is from an 82-year-old man who presented with atrial fibrillation that was detected during a routine physical examination. His ejection fraction was 25%, and global hypokinesis was identified by echocardiography. Note the persistently elevated ventricular response that is present before therapy, with heart rates greater than 100 to 120 beats/min present in many hours. Slow-release verapamil was prescribed, and repeat Holter monitoring was performed, which demonstrated excellent rate control during the 24-hour observation period. Ejection fraction 6 months later was 45%, and the patient remains free of symptoms.



***e*FIGURE 64.5.1** Heart-rate trends in a patient with atrial fibrillation before therapy **(A)** and while receiving verapamil slow release, 240 mg daily **(B)**. Note the marked reduction in overall heart rate during verapamil therapy.

CLINICAL PROFILE

Associated Disease States

Atrial fibrillation has been reported to occur in patients with a wide variety of diseases, many of which are listed in Table 64.3. Why a particular disease results in atrial fibrillation is often unclear. In some cases—for example, hypertension—both occur with increased frequency in the elderly, and it is possible that a cause-and-effect relationship does not always exist. However, echocardiographic studies of left atrial function in patients who have hypertension have demonstrated that patients with paroxysmal atrial fibrillation had left atrial enlargement and depression of atrial contractile function associated with an increased ventricular inflow during early diastole (81). It is unclear whether these changes cause or are the result of paroxysmal atrial fibrillation. In contrast, in patients with mitral valve disease with progressive enlargement of the atria, a pathophysiologic link between the disease state and the onset of atrial fibrillation is easier to understand.

TABLE 64.3 FACTORS ASSOCIATED WITH ATRIAL FIBRILLATION

Thyrotoxicosis

Thyroid hormone affects the circulatory system and myocardium (82). There is a decrease in total systemic vascular resistance, an increase in total blood volume, and a decrease in circulation time. This leads to an increase in preload and a reduction in afterload. There is also an increase in sinus rate and a reduction in the electrical threshold for excitation of the atrium. There appears to be an interaction between excess thyroid hormone and catecholamine action, including potentiation of catecholamine effect and an increased number of cardiac beta-adrenergic receptors (82). Atrial fibrillation is not uncommonly associated with thyrotoxicosis, is more frequent among men than among women, and increases with age. It occurs in more than 25% of patients aged 60 years or older, but it is rare in patients younger than 40 years. Although exclusion of occult thyrotoxicosis as a cause for atrial fibrillation is recommended, situations in which it is the cause are very uncommon. Notably, in one study, a low serum thyrotropin concentration in patients aged 60 years or older who show no evidence of hyperthyroidism was associated with a threefold higher risk of development of atrial fibrillation during a 10-year follow-up period (83). An increased risk of arterial thromboembolism is seen in association with thyrotoxicosis, mandating use of warfarin in patients with atrial fibrillation until a euthyroid state and sinus rhythm are achieved. The dose of warfarin necessary to maintain an INR of 2.0 to 3.0 may be smaller initially because of increased plasma clearance of vitamin K–dependent clotting factors, and a higher dose may be necessary as the thyroid hormone concentration decreases (82).

Congenital Heart Disease

Atrial fibrillation is relatively common in two forms of congenital heart disease in particular: atrial septal defect and Ebstein's anomaly. In patients with atrial septal defect, the incidence of atrial fibrillation is greater as patients age and has been reported to be more than 50% in a study involving patients aged 60 years or older (84). In general, the incidence of atrial fibrillation begins to increase in the fourth decade of life.

Ebstein's anomaly is commonly associated with atrial fibrillation, often at an early age (85). Atrial fibrillation may be caused by the underlying atrial dysfunction or, more commonly, may be a consequence of concomitant WPW. In patients who have WPW and AV reentry, atrial fibrillation is relatively common and most often secondary to degeneration of AV reentry into atrial fibrillation (42). Among patients who underwent surgical ablation of the accessory pathway and were followed up for 6.2 years, atrial fibrillation was documented in 42% of the patients before surgery, and this was reduced to 9% postoperatively (86). Thus, in patients with Ebstein's anomaly, the most significant etiologic factor for atrial fibrillation appears to be concomitant WPW.

Cardiac Surgery

Atrial fibrillation is the most frequent atrial arrhythmia noted after cardiac surgery. New atrial fibrillation develops in 25% to 50% of adult patients who undergo cardiac surgery (87). It is usually benign and self-limiting, but it may be associated with hemodynamic compromise, prolonged hospitalization, and embolic stroke (88). Patients most likely to develop atrial fibrillation are those with a history of atrial fibrillation before surgery who are in sinus rhythm initially after the operation (89).

Patients undergoing coronary artery bypass graft surgery are the group most likely to have a first episode of atrial fibrillation postoperatively. Development of atrial fibrillation is multifactorial, and several risk factors have been identified. Postoperative discontinuation of beta-adrenergic blockers that were taken regularly before surgery increases the risk of atrial fibrillation during the postoperative period; this complication can be expected in approximately 40% of patients in such a situation (90). Increased postoperative sympathetic activity demonstrated by elevated norepinephrine levels is associated with an increased risk of atrial fibrillation (91). Age is a major risk factor, and atrial fibrillation occurs in approximately 4% and 30% of patients aged less than 40 and 70 or more years, respectively, who are undergoing coronary artery bypass graft surgery (87). Other risk factors include chronic obstructive pulmonary disease, chronic renal disease, decreased postoperative serum magnesium level, history of paroxysmal atrial fibrillation, premature atrial complexes in the preoperative period, the presence of severe right coronary artery stenosis, and a history of congestive heart failure (91,92,93 and 94). The type of cardioplegia does not appear to correlate with the development of atrial fibrillation after cardiac operation (87,95). Notably, minimally invasive cardiac valve surgery may not reduce the incidence of postoperative atrial fibrillation (96).

Neurogenic

It has been known for decades that sustained atrial fibrillation is facilitated by increased parasympathetic tone. The atrial refractory period is decreased by acetylcholine, which shortens the wavelength, making it easier for atrial fibrillation to be sustained (44). Earlier investigators were aware of the profound influence of heightened vagal tone on atrial fibrillation (97,98,99,100,101 and 102). It was noted that rapid atrial stimulation in the presence of acetylcholine alone induced atrial fibrillation, and atrial fibrillation would continue in the absence of stimulation until the acetylcholine infusion was discontinued (100). Importantly, a nonuniform distribution of vagal effects on the refractoriness of the atrium has been found (102). In one study, right atrial refractoriness was determined at various sites before and during vagal stimulation (102). In the control state, atrial refractoriness differed by no more than 40 ms between sites. However, during vagal stimulation there was marked shortening of atrial refractoriness at some sites and minimal change at others. Because dispersion of refractoriness often promotes the development of reentry, this may be one mechanism by which heightened vagal tone facilitates the initiation of atrial fibrillation.

In some patients, atrial fibrillation occurs during enhancement of vagal tone. The patient's clinical history usually provides clues for this mechanism. For example, onset of atrial fibrillation during swallowing of a cold substance (e.g., ice cream or an ice cube) indicates that a vagal reflex may initiate atrial fibrillation. A specific syndrome of vagal atrial fibrillation has also been described (103), with occurrence at time of heightened vagal tone such as at night, during rest, or after consumption of food or alcohol. Reportedly, patients with vagal atrial fibrillation have an increased number of attacks during therapy involving beta-blockers and digitalis (103). Although many patients relate a tendency towards increased episodes of atrial fibrillation during periods of presumed increased vagal tone, in our experience, it is rare for patients to have atrial fibrillation only during enhanced parasympathetic tone.

An adrenergic form of atrial fibrillation has also been described (103), with onset exclusively during the daytime hours and often preceded by emotional stress or exercise. In contrast to vagal atrial fibrillation, beta-adrenergic blockers are the treatment of choice.

Tachycardia-Induced Tachycardia

Tachycardia-induced tachycardia is a phenomenon in which one tachycardia degenerates into another tachycardia (42). A relatively common example is rapid ventricular tachycardia that degenerates into ventricular fibrillation. Several different tachycardias can degenerate into atrial fibrillation (42). Atrial flutter and atrial tachycardia are likely the most common causes of tachycardia-induced tachycardia that results in atrial fibrillation, but arrhythmias as diverse as ventricular tachycardia, AV node reentry, and AV reentry may also initiate atrial fibrillation (Fig. 64.2) (42,104,105 and 106). In WPW, transition of AV reentry into atrial fibrillation can produce dire consequences, with a rapid preexcited ventricular response that degenerates into ventricular fibrillation leading to sudden death (Fig. 64.6) (61,107,108,109,110 and 111).

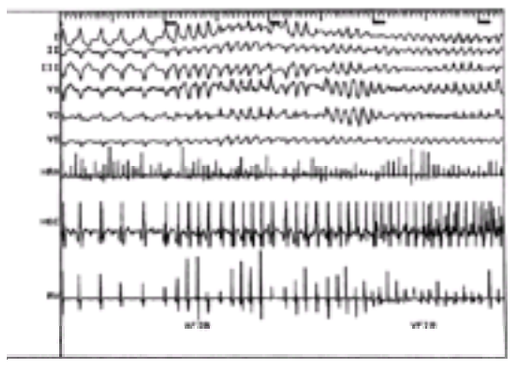

FIGURE 64.6 Atrial fibrillation in a patient with Wolff-Parkinson-White syndrome with degeneration from atrial fibrillation to ventricular fibrillation. AFIB, atrial fibrillation; HBE, bundle of His electrogram; HRA, high right atrium; RV, right ventricle; VFIB, ventricular fibrillation. (From Prystowsky EN, Knilans TK, Evans JJ. Diagnostic evaluation and treatment strategies for patients at risk for serious cardiac arrhythmias. II. Ventricular tachyarrhythmias and Wolff-Parkinson-White syndrome. *Mod Concepts Cardiovasc Dis* 1991;60:55, with permission.)

Several factors may affect the conversion of a variety of sustained tachycardias into atrial fibrillation. These include tachycardia cycle length, intrinsic atrial vulnerability, the electrophysiologic characteristics of accessory pathways, and contraction-excitation feedback (42). Shorter atrial pacing cycle lengths appear to increase atrial vulnerability (112). In one study (113), the cycle length of AV reentry in patients with WPW who had a history of atrial fibrillation was 304 ± 40 ms, compared with 321 ± 54 ms in patients without a history of atrial fibrillation. Further, using electrophysiologic studies, AV reentry cycle length was found to be significantly shorter (289 ± 26 ms vs. 316 ± 51 ms; $p < .005$) in cases in which AV reentry degenerated into atrial fibrillation (113). It has also been postulated that the accessory pathway network itself may play a role in the initiation or maintenance of atrial fibrillation in some patients with WPW. Whatever the exact mechanism(s) of atrial fibrillation in patients with WPW, it is well reported that successful ablation of the accessory pathway prevents episodes of atrial fibrillation in more than 90% of these individuals (113,114).

Intrinsic atrial vulnerability may also play a role in the initiation of atrial fibrillation in tachycardia-induced tachycardia. Observations made using electrophysiologic study of patients with WPW have commonly demonstrated that atrial degeneration is observed first in the high right atrial region (Fig. 64.2). Of course, catheters are not located throughout all portions of the atria during study, and the initiation may occur in another area, for example, in a pulmonary vein. The high right atrium may be particularly susceptible to atrial fibrillation. Human atrial pectinate muscle bundles from the atrial appendage obtained during surgery may be involved in macroreentry caused by anisotropy (41). It is possible that this portion of the atria may be responsible for the initiation of atrial fibrillation in many situations, even if the area is not critical to maintenance of the tachycardia.

One other potential mechanism for degeneration into atrial fibrillation is contraction-excitation of feedback (115). During the era of surgical ablation of accessory pathways, it was typical to observe, during open-chest surgery in humans, a sudden dilatation of the atria shortly after the onset of AV reentry. The effects of sudden stretching of atrial tissue can produce electrophysiologic alterations in atrial refractoriness (116,117 and 118). In one study (116), increases in right atrial pressure were associated with prolongation of the right atrial effective refractory period, but a shortened right atrial refractory period was noted by other investigators (118). Regardless, under appropriate experimental conditions in humans, dilatation and increased pressure in the atria can cause changes in refractoriness, which could, in a

susceptible individual, facilitate initiation of atrial fibrillation.

Identification of the role of tachycardia-induced tachycardia as a mechanism for atrial fibrillation has important therapeutic implications. It presents an opportunity for the clinician to prevent further episodes of atrial fibrillation, not by treating atrial fibrillation itself, but by directing therapy at the initiating arrhythmia. The paradigm for this is ablation of an accessory pathway in a patient with AV reentry. Likewise, in patients who have atrial flutter predominantly with occasional episodes of atrial fibrillation, electrocardiographic confirmation that atrial fibrillation is caused by atrial flutter may allow cure using ablation of the atrial flutter reentrant circuit.

Lone (Idiopathic) Atrial Fibrillation

Certain patients have no clear etiologic factors that explain the presence of atrial fibrillation; in such patients, the condition is called *idiopathic* or *lone atrial fibrillation*. Our definition for lone atrial fibrillation is the absence of any potential etiologic factor and the lack of evidence of ventricular dysfunction on echocardiography (15). We do not use an age cutoff point to designate lone atrial fibrillation. The prevalence of lone atrial fibrillation depends on the population of patients studied, as demonstrated in Table 64.1.

Awareness of lone atrial fibrillation has existed for decades (7,11,119,120,121,122 and 123). Clearly, because normal atria do not spontaneously fibrillate, some anatomic or electrophysiologic milieu must allow emergence of atrial fibrillation in these patients. In some cases, autonomic perturbations may be the etiology and likely are transient in nature. In other patients, left atrial size is increased, even though ventricular function is normal, and these patients may have some unidentified anatomic pathophysiologic basis for atrial fibrillation (15).

Investigators have attempted to identify electrophysiologic differences between patients who have lone atrial fibrillation and control subjects (124,125). Patients with atrial fibrillation have shorter atrial refractory periods, a larger dispersion of refractoriness, and a higher incidence of sinus nodal dysfunction (124,125). Because atrial fibrillation can shorten atrial refractoriness (48,49), it is impossible to know whether alterations in refractoriness preceded or were caused by atrial fibrillation. Further, in a recent investigation of canine subjects, several weeks of atrial fibrillation was shown to prolong sinus nodal recovery time (126), raising the possibility that in some patients with tachycardia-bradycardia syndrome, sinus node dysfunction may result from atrial fibrillation.

Familial atrial fibrillation is extremely uncommon in our experience. However, a genetic locus for familial atrial fibrillation has been described recently, and lone atrial fibrillation was present in almost all patients with this genetic marker (127). Of particular note was the relatively early age of onset of atrial fibrillation, with a mean age of less than 20 years. The gene responsible for atrial fibrillation was located on chromosome 10q in the region of 10q22 to 10q24; the genes for the beta-adrenergic receptor and alpha-adrenergic receptor are located on 10q23 to 10q26. Further work in the genetics of atrial fibrillation may shed light on the pathogenesis of idiopathic atrial fibrillation.

We agree with most investigators regarding the excellent long-term prognosis for patients with lone atrial fibrillation (11,120,121,128,129). In the Framingham study, a significant stroke rate was seen, but the mean age was greater than 65 years in those subjects (130).

Definition of Atrial Fibrillation

Traditionally, atrial fibrillation has been termed *paroxysmal* or *chronic atrial fibrillation*. However, no standardization regarding these terms has ever been achieved, and quite disparate time frames have been proposed for each category. A new classification has been proposed by the American College of Cardiology/American Heart Association/European Society of Cardiology Guidelines for the Management of patients with Atrial Fibrillation (131). Paroxysmal atrial fibrillation is self-terminating; persistent atrial fibrillation requires treatment for termination; in permanent atrial fibrillation, sinus rhythm cannot be restored, or the decision to avoid cardioversion has been made.

Symptoms of Atrial Fibrillation

Atrial fibrillation is associated with a diverse group of symptoms, palpitation being the most common (15,121,132). In one study that compared symptoms in patients with and without heart disease, palpitations occurred in 59% of patients with heart disease and in 77% of those with no heart disease (p <.002) (15). Other frequent symptoms were presyncope, fatigue, and dyspnea, and less common symptoms were chest pain and syncope. In a small group of patients, atrial fibrillation caused no symptoms. Care should be taken in ascribing a specific symptom to the actual occurrence of atrial fibrillation, because it is well documented that patients may have similar symptoms in the presence of sinus rhythm (132,133). Patients who experience dizziness, presyncope, or syncope may have associated carotid sinus hypersensitivity or neurally mediated syncope (134,135).

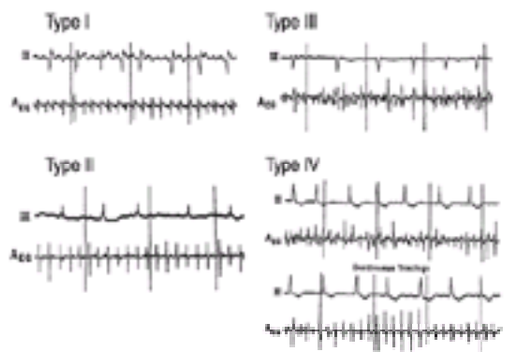
Why atrial fibrillation occurs at a particular point in time is unclear. In some patients, the onset may be related to a relative increase in parasympathetic tone, as demonstrated by an increased prevalence at night (136). Because patients with atrial fibrillation can have asymptomatic recurrences (137), it is possible that atrial fibrillation occurs even more frequently at night. In certain individuals, the reason for onset of atrial fibrillation is more obvious, for example, an alcoholic binge. For the majority of patients, no specific time of day, level of activity, or obvious inciting factor underlies each occurrence of atrial fibrillation, and initiation is likely multifactorial.

Electrocardiography of Atrial Fibrillation

During atrial fibrillation, electrocardiography demonstrates a lack of clearly defined P waves, with an undulating baseline that may alternate between recognizable atrial activity and a nearly flat line (Fig. 64.3). The ventricular response is irregular, and the rate depends on multiple factors, including intrinsic AV nodal conduction properties, level of parasympathetic and sympathetic tone, and the presence of negative dromotropic drugs such as beta-adrenergic blockers, calcium channel blockers, and digitalis. The underlying atrial rate is typically greater than 300 beats/min, but may vary considerably at different sites in the atria. The electrocardiographic appearance at any moment in time depends on the predominant underlying atrial activation, which is often protean (*e*Fig. 64.6.1).

***e*FIGURE 64.6.1** Twelve-lead electrocardiogram recorded at the same time as intracardiac atrial electrogram. **A:** The 12-lead electrocardiogram reveals atrial fibrillation with coarse atrial activity that resembles P waves in certain leads. **B:** The patient had a permanent pacemaker that was interrogated, and the intracardiac right atrial appendage electrogram showed an organized atrial rhythm of approximately 240 ms.

The variable electrocardiographic pattern that is seen during atrial fibrillation is not surprising, considering the multiple potential types of atrial activation that may be present at the same time at different locations throughout the atria. The presence of coarse versus fine atrial fibrillation has been recognized for many years (138). In one study, in an attempt to codify atrial fibrillation, right atrial epicardial electrograms were studied after cardiac surgery (139). Four distinct types of atrial fibrillation were identified (*e*Fig. 64.6.2). Type I atrial fibrillation showed atrial electrograms with discrete complexes of variable morphology separated by an isoelectric baseline. The mean atrial rate ranged from 291 to 405 beats/min. Type II atrial fibrillation demonstrated discrete atrial electrograms in the absence of an isoelectric baseline. The mean atrial rate was 383 beats/min. Type III atrial fibrillation was characterized by the absence of discrete atrial complexes or isoelectric intervals. Type IV atrial fibrillation involved alternation of type III with either type I or type II electrograms. Recent observations analyzing unipolar atrial electrograms during high-density mapping of the right atrium at surgery have clarified the etiology of the various types of atrial electrogram morphologies (140). The fragmented potentials recorded in type III atrial fibrillation likely represent areas of slow conduction or pivot points during atrial fibrillation.



***e*FIGURE 64.6.2** Types of atrial fibrillations recorded using bipolar right atrial electrograms (A_{EG}) in humans after cardiac surgery. See text for further description. (From Wells JL, Karp RB, Kouchoukos NT, et al. Characterization of atrial fibrillation in man: studies following open heart surgery. *Pacing Clin Electrophysiol* 1978;1:426–438, with permission.)

Echocardiography

An echocardiogram is an important test to obtain in patients with atrial fibrillation. It allows evaluation of atrial size, right and left ventricular function, and the presence of valvular lesions. Echocardiography, especially transesophageal echocardiography, has been valuable in investigating atrial function in patients with atrial fibrillation (45,51,52). Transesophageal echocardiography, but not transthoracic echocardiography, can provide valuable information on the presence of atrial thrombi, typically in the left atrial appendage (Fig. 64.7) (141,142,143 and 144). Atrial thrombi have been detected in as many as 15% of patients before cardioversion. Importantly, new thrombi can occur after successful cardioversion and may cause embolic events (142). Thus, at least two mechanisms are possible for thromboembolism after cardioversion: dislodgment of a preexisting thrombus and formation of a new hrombus after cardioversion.

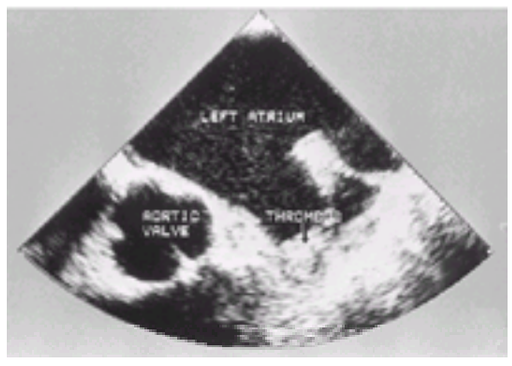


FIGURE 64.7 Transesophageal echocardiogram demonstrating left atrial appendage thrombus (*arrow*). (Courtesy of Drs. J. Bates and J. Steinmetz, the Care Group, St. Vincent Hospital, Indianapolis, IN.)

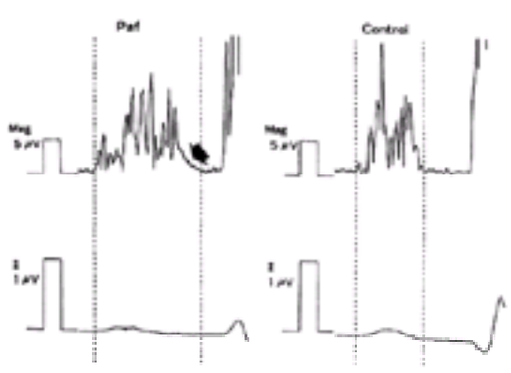
Signal-Averaged P-Wave Electrocardiography

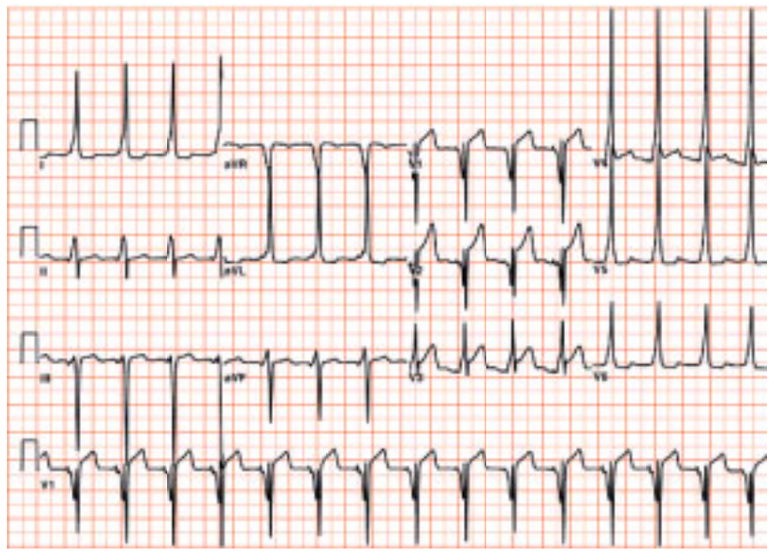
The signal-averaged electrocardiogram has been used for years to detect areas of slow conduction in the QRS complex during depolarization. More recently, P wave–triggered signal-averaged electrocardiograms have been performed to evaluate atrial abnormalities in patients who have atrial fibrillation (145). The authors of this study demonstrated the presence of atrial late potentials in patients with atrial fibrillation (*e*Fig. 64.7.1). Using various methods to analyze the root mean square voltage of the terminal portion of the filtered P wave and the duration of the filtered P wave, they developed criteria that yielded a sensitivity of 91% and a specificity of 76% for defining the atrial late potential. The use of signal-averaged P-wave electrocardiography has been evaluated for prediction of atrial fibrillation after cardiac surgery (146). Atrial fibrillation occurred in 25% of patients at a mean of 6.2 days after surgery. The signal-averaged P-wave duration was significantly longer among patients who developed atrial fibrillation (152 ± 18 ms vs. 139 ± 17 ms; p <.001). However, use of a filtered P-wave duration greater than 140 ms yielded a sensitivity of 77%, a specificity of 55%, a positive predictive accuracy of 37%, and a negative predictive accuracy of 87%. As is true for the use of signal-averaged electrocardiography of the QRS complex, negative predictive accuracy is far better than positive predictive accuracy. More data are needed to define the role of signal-averaged P-wave electrocardiography in clinical practice.



***e*FIGURE 64.7.1** Signal-averaged electrocardiogram of P waves in a patient with paroxysmal atrial fibrillation (Paf) versus those in a control patient. Arrowhead points to low-amplitude signal in the terminal portion of the filtered P wave, referred to as an *atrial late potential*. Mag, magnitude. (From Fukunami M, Yamada T, Ohmori M, et al. Detection of patients at risk for paroxysmal atrial fibrillation during sinus rhythm by P wave–triggered signal-averaged electrocardiogram. *Circulation* 1991;83:162–169, with permission.)

Wolff-Parkinson-White Syndrome

Atrial fibrillation in patients who have preexcitation can result in ventricular fibrillation and sudden cardiac death. This sequence of events occurs most commonly when a rapid preexcited ventricular response is present (Fig. 64.5), and degeneration to ventricular fibrillation may follow (Fig. 64.6). In our opinion, patients with ventricular preexcitation who have symptoms suggestive of tachycardia or documented arrhythmias should undergo electrophysiologic evaluation and, if indicated, endocardial catheter ablation of the accessory pathway (see Chapter 73). A more difficult situation exists for asymptomatic patients who have ventricular preexcitation during sinus rhythm (147). Some of these patients may be at risk for sudden cardiac death, although this is rarely the initial presentation of WPW. Because patients resuscitated from ventricular fibrillation invariably have a preexcited RR interval seen on electrophysiologic study during induced atrial fibrillation that is, at its shortest, less than 250 ms, the possibility for screening asymptomatic patients to detect those at risk for ventricular fibrillation exists (147). In general, we do not favor mass screening of asymptomatic patients who have ventricular preexcitation (147). Instead, we tend to screen patients who have a familial history of sudden death or tachycardia, patients who are considering competitive athletics, or individuals who are in certain occupations (e.g., airline pilots). See Chapter 66 for a more detailed discussion of this problem.



A 16-year-old male patient with Wolff-Parkinson-White syndrome.

Hypertrophic Cardiomyopathy

Approximately 15% of patients with hypertrophic cardiomyopathy develop atrial fibrillation (148). In these individuals, atrial fibrillation can result in profound hemodynamic deterioration, leading to chest pain, presyncope, syncope, and even sudden cardiac death (148,149 and 150). In one retrospective study, the acute onset of atrial fibrillation resulted in deterioration by at least one New York Heart Association functional class in the majority of patients (148). Importantly, the mean values for maximal left ventricular wall thickness may be lower among patients with atrial fibrillation compared with those of patients with sinus rhythm (151). Thus, prediction of which patients are most likely to develop atrial fibrillation using analysis of ventricular wall thickness may not be possible. The weight of clinical data strongly suggests that efforts should be directed at maintaining sinus rhythm in these individuals, to avoid functional deterioration and the possibility of sudden cardiac death.

THERAPY OF ATRIAL FIBRILLATION: GENERAL PRINCIPLES

There are three potential therapeutic goals of treatment for patients with atrial fibrillation (Fig. 64.8) (152). These include restoration and maintenance of sinus rhythm, rate control during atrial fibrillation, and prevention of thromboembolism. The decision to try to maintain sinus rhythm rather than use ventricular rate control should be individual to each patient, based on analysis of the risk-benefit ratio for that individual. No large prospective, randomized clinical trials have demonstrated that either approach has a survival advantage. Advantages of sinus rhythm include amelioration of symptoms, possible retardation or prevention of the transition from intermittent to permanent atrial fibrillation, and a theoretical, though not proven, benefit in reduction of the risk for thromboembolic stroke. The primary risk is proarrhythmia, which can cause sudden death (153). The option of allowing atrial fibrillation to persist but controlling the ventricular response has the advantage of not exposing patients to the potential proarrhythmic effects of antiarrhythmic drugs. Two major disadvantages are continuation of symptoms in many patients, although symptoms may be lessened, and the absolute need for continued anticoagulation in patients at risk for thromboembolism. The longer a patient remains in atrial fibrillation, the greater are the chances that progressive electrophysiologic and anatomic atrial changes will occur, which over the course of time make it more difficult to maintain or even to restore sinus rhythm. Thus, the clinician should decide within a short period of time which approach is best for the patient.

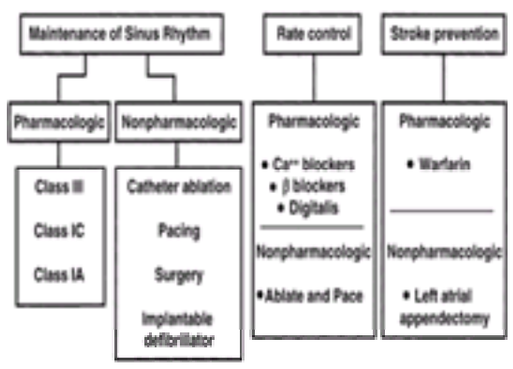

FIGURE 64.8 Therapeutic options in the treatment of patients with atrial fibrillation. See text for details. (From Prystowsky EN. Management of atrial fibrillation:

therapeutic options and clinical decisions. *Am J Cardiol* 2000;85:3D–11D, with permission.)

PHARMACOLOGIC THERAPY

Use of Intravenous Agents to Restore Sinus Rhythm

Use of intravenous verapamil, digitalis, esmolol, or propranolol is not useful to terminate atrial fibrillation (9,154,155 and 156). An exception might be the use of beta-adrenergic blockers in patients after cardiac surgery. In general, drugs that alter atrial electrophysiologic properties are useful to terminate atrial fibrillation (Table 64.4) (9).

Drug	Dosage
To decrease ventricular response[a]	
Verapamil	5–10 mg i.v. over the course of 2 min; additional 5–10 mg i.v. every 4–6 h for rate control
Diltiazem	0.25 mg/kg i.v. over the course of 2 min; if response is inadequate, a second dose of 0.35 mg/kg over the course of 2 min may be given 15 min later; bolus may be followed with constant infusion of ≤10 mg/h for rate control.
Propranolol	1 mg/min i.v. to total dose of 0.15 mg/kg or 12 mg total; additional 1 mg doses as needed for control of heart rate
Esmolol	Initial load of 500 μg/kg/min i.v. for 1 min followed by 50 μg/kg/min for 4 min; if response inadequate, then repeat in 5 min with 500 μg/kg/min for 1 min and 100 μg/kg/min for 4 min; continue to titrate every 5 min until desired heart rate is reached; 50–200 μg/kg/min is usual maintenance dose
Digoxin	0.5–1.0 mg i.v., followed by 0.25 mg every 2–4 h, with total 24 h dose <1.5 mg
For pharmacologic conversion to sinus rhythm	
Procainamide	50 mg/min i.v. to total dose of 10–14 mg/kg
Ibutilide	1 mg i.v. over the course of 10 min; may repeat if atrial fibrillation is present after 20 min

[a]Avoid use of this agent in patients with ventricular preexcitation.

TABLE 64.4 ACUTE DRUG THERAPY (INTRAVENOUS) FOR ATRIAL FIBRILLATION

Procainamide

In one study, 9 of 21 patients converted to sinus rhythm while receiving procainamide at a mean dose of 13.3 ± 3.6 mg per kg (157). Notably, the left atrial diameter seen on echocardiography was less than 4.0 cm in all patients who converted to sinus rhythm, whereas it was greater than 4.0 cm in all but one of the patients who did not convert. Further, the range of duration of atrial fibrillation among patients who converted was 2 hours to 1 day. In another investigation, patients who converted to sinus rhythm had a shorter mean duration of atrial fibrillation than did patients who did not convert (6 ± 7 days vs. 79 ± 88 days; p <.01) (158). Among patients with atrial fibrillation of less than 24 hours' duration, 92% were converted to sinus rhythm when intravenous flecainide was administered, compared with 65% who converted when intravenous procainamide was administered (159). Procainamide also appears to be useful in converting atrial fibrillation after cardiac surgery (160).

Ibutilide

Ibutilide prolongs refractoriness by enhancing an inward sodium current during the plateau, although it also may block outward potassium current (161). It may increase the QT interval, and torsades de pointes can occur with its use. It is effective for converting atrial fibrillation to sinus rhythm (162,163 and 164). The typical recommended dose is 1.0 mg administered over 10 minutes, which can be repeated if atrial fibrillation does not terminate during or within 10 minutes after the end of the initial infusion (163). The dosage can be adjusted downward for patients who weigh less than 60 kg. The conversion rate for atrial fibrillation in one study was 31%, and the success rate was higher among patients with shorter duration of atrial fibrillation (10 ± 13 days vs. 18 ± 15 days) (163). Further, conversion to sinus rhythm occurred in 67% of patients who had a left atrium of normal size compared with only 27% of patients who had an enlarged left atrium. Torsades de pointes may be associated with ibutilide infusion, but in almost all instances, it occurs either during infusion or within a few hours after termination of the final ibutilide infusion. Thus, administration of ibutilide, as well as procainamide, should be performed under circumstances in which resuscitative measures can be readily performed.

Amiodarone

Unlike oral amiodarone, minimal prolongation of the effective refractory period of the right atrium and right ventricle occurs shortly after administration of intravenous amiodarone (5 mg/kg) (165). In some studies, the effectiveness of intravenous amiodarone was similar to that of placebo in restoring sinus rhythm (166,167), whereas other studies suggest that amiodarone has a more beneficial effect (168). Oral quinidine is as effective or more effective in converting atrial fibrillation to sinus rhythm (169,170), but we rarely use it for this purpose because of the significant associated side effects. Intravenous amiodarone has the added effect of significantly slowing ventricular response. This can prove very useful when other agents, such as beta-adrenergic blockers and slow calcium channel blockers, are relatively contraindicated.

Flecainide, Propafenone, Sotalol, and Dofetilide

Intravenous flecainide, propafenone, and sotalol are not available for use in the United States. Intravenous flecainide is very effective in converting atrial fibrillation to sinus rhythm (159,167,171,172 and 173). Intravenous propafenone is useful in converting recent-onset atrial fibrillation to sinus rhythm, but it is ineffective in patients in whom atrial fibrillation has lasted many months (174,175). Intravenous sotalol is minimally effective in converting atrial fibrillation to sinus rhythm (176). Intravenous dofetilide, which prolongs refractoriness, appears to be useful in terminating atrial fibrillation (177,178 and 179).

Use of Oral Antiarrhythmic Agents for Restoration and Maintenance of Sinus Rhythm

A variety of antiarrhythmic drugs with disparate electrophysiologic actions can terminate or prevent atrial fibrillation. These include disopyramide, quinidine, procainamide, propafenone, flecainide, sotalol, dofetilide, amiodarone, and morizicine (180,181,182,183,184,185,186,187,188,189,190,191,192,193,194,195,196,197,198,199,200,201,202,203 and 204). A single oral loading dose of 300 to 600 mg of propafenone or 200 to 300 mg of flecainide is successful in restoring sinus rhythm in more than 50% of selected patients with recent-onset atrial fibrillation (181,182). Few comparative studies exist that assess the efficacy of various agents in maintaining sinus rhythm during long-term follow-up. Overall, approximately 50% of patients maintain sinus rhythm for at least 6 months during antiarrhythmic therapy. Flecainide and propafenone appear to have equal efficacy (187). Quinidine is more useful than sotalol for conversion of atrial fibrillation to sinus rhythm (192), but the two drugs are equally effective in maintaining sinus rhythm (191). In one study, propafenone prevented atrial fibrillation more often than sotalol (193), but there was no difference between them in another investigation (190). Amiodarone is considered by some to be the most effective agent for drug-refractory recurrent atrial fibrillation, although few prospective comparative data are available (205). In small groups of patients, amiodarone prevented atrial fibrillation more often than quinidine or disopyramide (198,199). Amiodarone maintains sinus rhythm in nearly two-thirds of patients for up to 1 year follow-up (194,195,196 and 197). Typically, amiodarone has been associated with frequent side effects, some life-threatening (e.g., pulmonary toxicity). However, lower doses likely will decrease the risk of nuisance and serious side effects. In one study, in which amiodarone was administered at 600 mg daily for 4 weeks, approximately 16% of patients converted to sinus rhythm (197). During long-term therapy, the mean dose was 204 mg, and sinus rhythm was maintained in 53% of patients after 3 years with minimal serious side effects (197). The efficacy of antiarrhythmic drug therapy in maintaining sinus rhythm can be enhanced using a serial drug approach (206,207). Several large prospective trials have demonstrated the efficacy of dofetilide in maintaining sinus rhythm (202,203 and 204). Although procainamide is useful in preventing atrial fibrillation, in our opinion, its substantial side-effect profile precludes long-term use.

The efficacy of antiarrhythmic drug therapy should not be judged solely on the basis of whether atrial fibrillation recurs during follow-up (152). Preventing all episodes of atrial fibrillation over the course of years of treatment is exceedingly difficult. Therapeutic success should be based on the reduction in frequency and duration of symptomatic episodes of atrial fibrillation. For example, in a patient who has several episodes of atrial fibrillation weekly before treatment, recurrence of one or two short-lived episodes per year during drug therapy is an outstanding success. Recurrence of atrial fibrillation should not be equated with arrhythmias such as sustained ventricular tachycardia or ventricular fibrillation. An analogy can be made with treatment for angina or congestive heart failure. In both conditions, the need for occasional nitroglycerin use or an increase in diuretics, respectively, in patients who otherwise are well compensated is readily accepted.

Proarrhythmia

Proarrhythmia is the most serious side effect of antiarrhythmic drug therapy (9,153). Proarrhythmic events can be caused by tachyarrhythmias or bradyarrhythmias.

Proarrhythmia caused by tachyarrhythmia is the most dangerous and life threatening, and torsades de pointes is the most frequently observed proarrhythmic event in this category (Fig. 64.9) (153). Torsades de pointes can occur during use of any drug that prolongs QT interval; amiodarone appears to have the lowest incidence among such agents. It has been postulated that early after-depolarizations initiate torsades de pointes (153). Conditions that favor early after-depolarizations are ventricular hypertrophy, slow heart rate, hypokalemia, and the presence of potassium channel blocking drugs (153), which commonly occur in patients with atrial fibrillation. Torsades de pointes is uncommon during atrial fibrillation in patients who have a relatively rapid ventricular response. It is more likely to emerge after restoration of sinus rhythm, with a resultant slower heart rate (153), which has been referred to as the "paradoxical risk of sinus rhythm for sudden cardiac death" (144). Other types of malignant ventricular arrhythmias can occur. Use of flecainide should be avoided in patients who have experienced myocardial infarction (208), and an enhanced mortality was reported among patients with atrial fibrillation and heart failure who were treated with drugs such as quinidine and procainamide (209). However, amiodarone and dofetilide do not appear to increase mortality in patients with congestive heart failure (202,210,211).

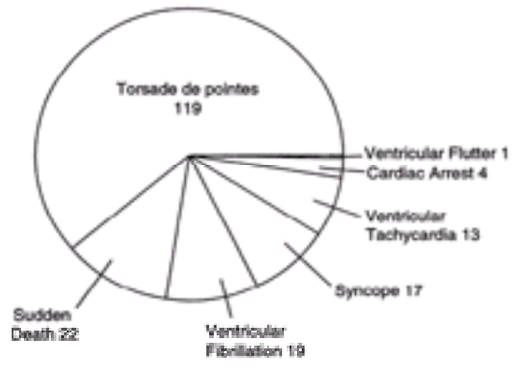

FIGURE 64.9 Types of proarrhythmic events (n = 195) occurring during drug therapy for supraventricular tachycardia. [Modified from Prystowsky EN. Proarrhythmia during drug treatment of supraventricular tachycardia: paradoxical risk of sinus rhythm for sudden death. *Am J Cardiol* 1996;78(8A):35–41.]

Bradyarrhythmias, including sinus nodal dysfunction and AV conduction disturbances, may also complicate antiarrhythmic drug therapy. One type of proarrhythmia, 1:1 AV conduction with conversion of atrial fibrillation to atrial flutter or tachycardia, is clearly preventable. This more frequently occurs with drugs such as propafenone and flecainide, which can markedly slow atrial tachycardia rates (9). It is important to prescribe concomitant AV nodal blocking agents to avoid this complication, especially for patients who are receiving propafenone or flecainide (152). Administration of concomitant AV nodal blocking agents is not necessary when sotalol or amiodarone is used, because both agents substantially decrease conduction through the AV node.

Antiarrhythmic Drug Selection

Reversible causes of atrial fibrillation (e.g., excess alcohol intake) should be considered and treated if possible. Correction of electrolyte abnormalities and cardiovascular problems such as heart failure need to be addressed before an antiarrhythmic agent is administered. Prophylactic drug therapy typically is not necessary for patients who have experienced a single detected episode of atrial fibrillation, or for patients who have infrequent, transient, and well-tolerated paroxysmal atrial fibrillation.

Every effort should be made to minimize the chance for proarrhythmia and other drug side effects. Antiarrhythmic drug therapy should be initiated in the hospital for patients who have heart disease, especially for patients with a history of congestive heart failure (9,152). Outpatient initiation of therapy appears to be reasonable for individuals who have normal QT intervals and no or minimal heart disease (9,131,152). Because no antiarrhythmic drug has been shown conclusively to be superior to other agents, selection of initial drug therapy is based more on avoidance of serious side effects than on predicted efficacy. Figure 64.10 shows our current scheme for choosing initial and subsequent antiarrhythmic agents to prevent atrial fibrillation. For patients who have lone atrial fibrillation, we prefer to use drugs that have minimal organ toxicity; initial choices are flecainide, propafenone, and sotalol. For patients who have congestive heart failure, amiodarone and dofetilide are our treatments of choice (202,210,211). Sotalol is our initial selection for patients who have coronary artery disease, because we prefer to use beta-adrenergic blockers for such individuals. Sotalol has both beta-adrenergic blocker and class III antiarrhythmic activity, and safety data are available for its use in such patients (212). Amiodarone and dofetilide also have safety data in patients after myocardial infarction (213,214 and 215). Patients with hypertension and left ventricular hypertrophy may be at increased risk for torsades de pointes, because hypertrophied ventricles appear more prone to develop early after-depolarizations (153). Thus, we prefer to start with flecainide or propafenone. If a patient has substantial left ventricular hypertrophy, use of flecainide and propafenone carries concerns about an increased proarrhythmic risk, and we prefer to use amiodarone.

Use of Drug Therapy to Control Ventricular Rate

In the absence of ventricular preexcitation, drugs that decrease conduction in the AV node are useful in controlling ventricular rate in patients who have atrial fibrillation (Table 64.4). It is very important to control ventricular rate, not only to decrease symptoms, but to prevent tachycardia-mediated cardiomyopathy (see the section Tachycardia-Induced Ventricular Cardiomyopathy). Drugs that depress conduction and prolong refractoriness in the AV node include digoxin, beta-adrenergic antagonists, and calcium channel blockers (9,155,156,216,217,218,219,220,221,222 and 223). Notably, the electrophysiologic effects of digoxin on the AV node are indirect and depend on an intact autonomic nervous system (224). Thus, whereas digoxin may slow ventricular response at rest, it is relatively ineffective in controlling the ventricular rate during exercise (220). Beta-adrenergic blockers and calcium channel blockers are preferred over digoxin for rate control in patients who have not experienced heart failure (9). Beta-adrenergic blockers are also recommended in situations in which sympathetic tone is increased, such as thyrotoxicosis (9). In patients who have congestive heart failure, digitalis is the first-line treatment (9). As noted previously, both sotalol and amiodarone may be used as monotherapy because they depress conduction through the AV node. In some patients, control of ventricular response can be facilitated with the use of combination drug therapy, for example, digoxin and a calcium channel blocker or a beta-adrenergic blocker. In this situation, rate control may be achieved without undue side effects. Preliminary data on the use of clonidine suggest that such agents may have a role in controlling ventricular response in patients who have atrial fibrillation (225).

In patients who have WPW, control of the rapid preexcited ventricular response requires the use of agents that depress conduction over the accessory pathway. In the acute setting, intravenous procainamide or ibutilide are the treatments of choice, unless the patient is unstable and requires urgent electrical cardioversion. The use of drugs such as digoxin, calcium channel blockers, beta-adrenergic blockers, and adenosine are contraindicated in this situation. They do not block conduction over the accessory pathway and may accelerate the ventricular response, resulting in a potentially very unstable clinical situation.

Treatment of Atrial Fibrillation after Cardiac Surgery

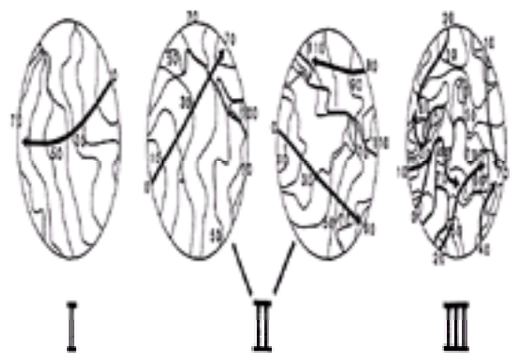
Beta-adrenergic blockers are the best treatment currently available for prevention of atrial fibrillation after cardiac surgery (90,226,227,228 and 229). In a randomized, controlled study, sotalol demonstrated superiority to placebo in prevention of atrial fibrillation (230). Administration of intravenous amiodarone, 1 g per day for 2 days

starting immediately after cardiac surgery, reduced the incidence of postoperative atrial fibrillation compared with placebo (231). Administration of oral amiodarone, starting at least 1 week before surgery, may also decrease postoperative atrial fibrillation (232).

The optimum approach to treating atrial fibrillation in the postoperative period is unclear. In most patients who experienced no preoperative atrial fibrillation, atrial fibrillation is a transient arrhythmia and typically is not a long-term problem (233). If simple measures such as administration of beta-adrenergic blockers do not prevent atrial fibrillation, additional therapy can be pursued to restore and maintain sinus rhythm or merely to control the ventricular response. In the latter situation, anticoagulation therapy should be started as soon as it is considered safe. The patient should be reevaluated 4 to 6 weeks after surgery.

PREVENTION OF THROMBOEMBOLISM

Prevention of stroke is key to the management of the condition of patients with atrial fibrillation (Fig. 64.8). A hypercoagulable state appears to exist in patients with atrial fibrillation (234,235). A high stroke risk has been well described for years in patients with atrial fibrillation and mitral stenosis or prosthetic mitral valves. Recently, several prospective multicenter, randomized clinical trials have conclusively demonstrated that warfarin is highly effective in reducing the incidence of ischemic stroke among patients with atrial fibrillation (*e*Fig. 64.10.1) (9). Overall, a combined risk reduction of 68% is seen.



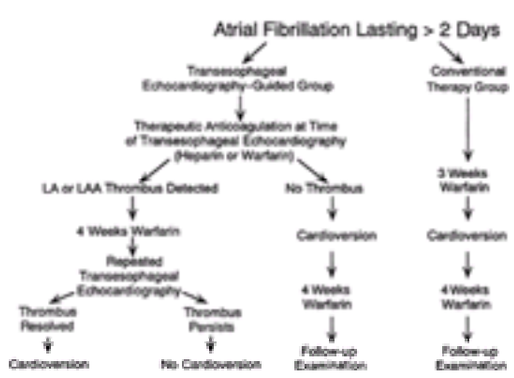
***e*FIGURE 64.10.1** Plot of risk-reduction strategy for five randomized clinical trials that compared atrial fibrillation patients receiving warfarin for prevention of ischemic stroke with control patients. Management of patients with atrial fibrillation: a statement for healthcare professionals from the subcommittee on electrocardiography and electrophysiology, American Heart Association. *Circulation* 1996;93:1262–1277, with permission.)

Embolus. Dislodged thrombus that embolized to the toes and caused gangrene (*arrows*).

Independent predictors of thromboembolic risk have been identified (9,131). High-risk patients have a 5% to 7% or greater yearly risk of thromboembolism. High-risk variables from prospective trials include a history of hypertension, prior stroke or transient ischemic attack, diabetes, recent heart failure, and age greater than 65 years (9). Notably, paroxysmal atrial fibrillation has not been found to be an independent predictor of thromboembolic risk. Other studies have considered coronary artery disease to place a patient at high risk for stroke (131). At present, high-risk patients who can receive anticoagulation therapy should be treated with warfarin, with the INR adjusted to between 2.0 and 3.0. Patients greater than 75 years old should be observed carefully, because bleeding complications increase in elderly patients. Patients with atrial fibrillation who have low risk for stroke may be treated with 325 mg of aspirin daily (9). Patients with lone atrial fibrillation who are less than 60 years old do not require specific therapy for prevention of thromboembolism. Some physicians prescribe aspirin to this group of patients, but few data are available to support this approach. Recent guidelines offer more detailed information (131).

Anticoagulation for Cardioversion

Electrical and pharmacologic cardioversion can result in thromboembolism (9). Prior anticoagulation appears to decrease the risk of emboli (9,45,236,237,238 and 239). In patients who have atrial fibrillation of unknown duration or duration greater than 48 hours, current recommendations are to administer warfarin for 3 weeks before and 4 weeks after cardioversion, maintaining an INR of 2.0 to 3.0 (9). In high-risk patients, warfarin therapy should be continued on a long-term basis after cardioversion. In an alternative approach, transesophageal echocardiography is used (9,131,141,144) (eFig. 64.10.2). The use of transesophageal echocardiography appears to offer an advantage to patients who are already hospitalized or in whom restoration of sinus rhythm is more urgent. However, the widespread use of this method for outpatient cardioversion cannot be supported at this time (45).



***e*FIGURE 64.10.2** Protocol for the ACUTE (Assessment of Cardioversion Using Transesophageal Echocardiography) study. NONPHARMACOLOGIC THERAPY

Pharmacologic treatment has been used for decades for cardioversion and prevention of recurrent atrial fibrillation. Use of antiarrhythmic drugs is associated with substantial side effects and mortality in some groups of patients. Accordingly, it is not surprising that nonpharmacologic techniques for managing atrial fibrillation have been developed, including external and internal electrical cardioversion, atrial pacing methods to prevent atrial fibrillation, surgery, radiofrequency catheter ablation procedures, and use of implantable atrial defibrillators.

Electrical Cardioversion

Transthoracic Electrical Cardioversion

The technique of transthoracic direct current (DC) electrical cardioversion of atrial fibrillation was developed by Lown and associates (240). Lown (241) reported that "sinus rhythm was reinstated in 94% of the 456 episodes of atrial fibrillation." Although any patient who has atrial fibrillation may be a candidate for transthoracic DC cardioversion, certain characteristics predict immediate success and long-term maintenance of sinus rhythm. The best candidates are patients without mitral valve disease or a very large left atrium and patients who have atrial fibrillation of relatively short duration. Early echocardiographic studies suggested that there was minimal possibility of achieving or maintaining sinus rhythm when the anterior-posterior diameter of the left atrium was greater than 4.5 cm (242). In contrast, a recent randomized study showed that the size of the left atrium was not related to the success of cardioversion or to recurrence of atrial fibrillation (243). At present, no universally accepted threshold value for left atrial size or severity of mitral stenosis that would preclude attempts at cardioversion exists. It is our policy to attempt cardioversion at least once in most patients with atrial fibrillation in whom we think sinus rhythm would be preferable. Exceptions might be individuals known to have had atrial fibrillation for many years.

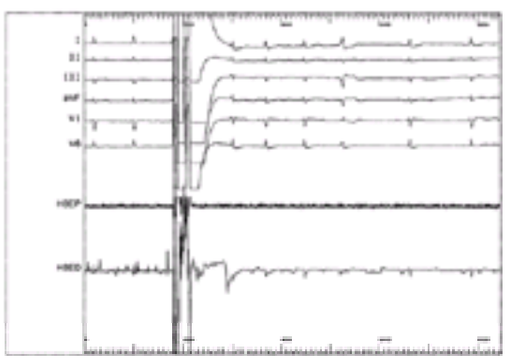
In patients undergoing transthoracic DC cardioversion, antiarrhythmic drugs are frequently used to maintain sinus rhythm (207). Drug therapy should be considered before use of cardioversion in patients with long-standing atrial fibrillation (e.g., more than 3 months), to lessen the chance of relapse into atrial fibrillation in the first few days after cardioversion. Digitalis therapy is not a contraindication to elective cardioversion, although it is customary to withhold digoxin on the day of cardioversion, a custom that is based on few scientific data. On the other hand, attempts to cardiovert arrhythmias associated with digitalis toxicity are hazardous and should be avoided (244). Concomitant antiarrhythmic drug therapy may increase energy requirements for successful cardioversion. In a nonrandomized series of 57 patients, flecainide was associated with a higher energy requirement than class Ia or III drugs, although overall success was similar in all groups (245).

Success of transthoracic DC cardioversion to restore sinus rhythm depends on several technical factors (246). The optimal electrode size is 12 to 13 cm in diameter. Initial electrode placement is right anterior–left posterior or left anterior–left posterior. If cardioversion with these electrode orientations is unsuccessful, a right anterior–apical electrode position can be tried. The clinician must be flexible and willing to try several electrode orientations. Application of firm pressure to the anterior electrode during full expiration may facilitate delivery of current to the heart. For most patients, we use an energy delivery of 360 J synchronized to the QRS complex for the first shock (246,247). Appropriate anesthesia is mandatory before shock delivery. If reversion to sinus rhythm is not achieved after multiple shocks have been given using various electrode positions, adjunctive measures can be used, such as higher energy levels (248), pretreatment with ibutilide (249), and internal cardioversion (250). More experience with transthoracic cardioversion using biphasic shocks will likely improve success of treatment at lower energies (251).

Intracardiac Defibrillation

Intracardiac defibrillation is used to decrease the amount of extracardiac tissue involved in the current path, which maximizes the potential gradient within the atrial tissue and increases the success rate of atrial defibrillation. In 1974, Mirowski and colleagues (252) demonstrated the efficacy of low-energy defibrillation of atrial fibrillation using an intracavitary lead system in a canine model of atrial fibrillation. In recent years, there has been substantial interest in development of a catheter-based lead system for internal atrial defibrillation. High- and low-energy systems have been studied.

The high-energy method defibrillates the atrium between a back patch electrode and a standard quadripolar electrode catheter positioned in the posterior right atrium. Shocks of 200 to 300 J successfully defibrillated 9 of 10 patients with atrial fibrillation that was resistant to external DC cardioversion in one study (*e*Fig. 64.10.3) (253). A comparison of external and internal cardioversion demonstrated superiority of internal defibrillation (250). Low-energy internal atrial defibrillation has been performed in animals and humans (254,255). Defibrillation between the coronary sinus and the right atrium offered the lowest defibrillation threshold of the available transcatheter techniques, with use of an energy level of 1.1 to 8.9 J. Low-energy transcatheter atrial defibrillation is safe and is associated with low complication and high success rates (256). However, even though low energy levels are used, the shocks are often painful and intolerable to the patient (257). This has impeded the clinical usefulness of "stand alone" implantable atrial defibrillators.



***e*FIGURE 64.10.3** Example of internal cardioversion through a catheter in the right atrium connected to a defibrillator pad on the back. Note that no deflection from the bundle of His occurs on the distal electrode (HBED), because the catheter has been positioned in the posterior portion of the atrium. A 200-J shock restored sinus rhythm, as can be noted on the right-hand portion of this figure. HBEP, proximal electrode pair from the His electrogram.

Atrial Pacing

Patients with sick sinus syndrome commonly develop supraventricular tachycardias, predominantly atrial fibrillation (tachycardia-bradycardia syndrome). Much debate has occurred about whether use of atrial-based or of ventricular-based pacing is preferred for patients with sick sinus syndrome. Retrospective data indicate that the incidence of atrial fibrillation is reduced among patients who receive atrial-based pacing (258). A randomized, prospective study compared AAI to VVI pacing (259,260). The results show a trend toward an increased incidence of atrial fibrillation and stroke in patients receiving VVI pacing. Thromboembolic events occurred in 17.4% of the VVI group and in only 5.5% of the AAI group (p = .0083). No difference in mortality or development of congestive heart failure was seen. In summary, the data support use of atrial-based pacing for patients with sick sinus syndrome. For patients who have no indication for pacing, data from multiple studies on various pacing techniques to prevent atrial fibrillation have yielded mixed results, and no clear consensus has yet emerged (261,262 and 263). See Chapter 74 for more details on this subject.

A 72-year-old patient with atrial pacing with transition to ventricular pacing.

Intraatrial conduction block results in a very delayed activation of the left atrium and may be associated with an increased incidence of atrial tachyarrhythmias. In a preliminary study involving 28 patients, permanent atrial resynchronization resulting from simultaneous right atrial and coronary sinus pacing corrected the intraatrial dyssynchrony expressed by reduction of P-wave duration (261). In 21 patients, this biatrial synchronous pacing prevented arrhythmia recurrences during a follow-up period of 34 ± 15 months (261). Use of dual-site atrial pacing in the high right atrium and coronary sinus os was evaluated in a prospective study involving patients with paroxysmal atrial fibrillation who had bradyarrhythmias warranting permanent pacemaker implantation (264). Dual-site atrial pacing with use of an optimal drug regimen resulted in a marked decline in atrial fibrillation recurrences. Multisite atrial pacing is feasible and safe and appears to be effective. Further research may demonstrate that this pacing modality should be considered as a primary mode of treatment for prevention of atrial fibrillation.

Catheter Ablation

Atrioventricular Block

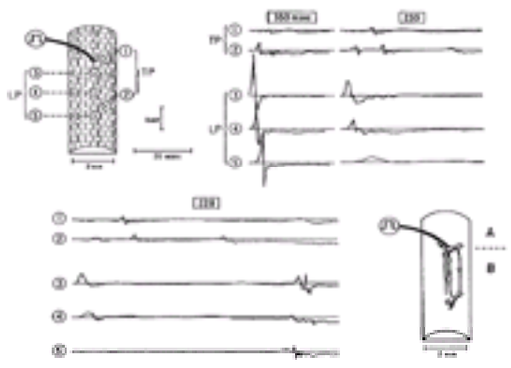
For some patients who have permanent atrial fibrillation, drug therapy used to control ventricular response is either ineffective or not tolerated. An alternative approach is endocardial catheter ablation of the AV junction that results in complete heart block (265,266). Such patients require a permanent rate-responsive pacemaker. This technique can also be used for treatment of patients who have transient or persistent atrial fibrillation, in lieu of drugs that suppress AV node conduction. Improvement in exercise tolerance and quality of life has been demonstrated with this procedure (267). Radiofrequency catheter ablation is currently the method of choice for accomplishing these goals (see Chapter 73 for further details).

Atrioventricular Node Modification

Complete AV junction ablation requires pacemaker implantation. Another technique to slow the ventricular rate during atrial fibrillation without creating irreversible heart block has been developed: modification of AV node conduction to prevent rapid ventricular rates. Several studies have demonstrated the feasibility of modifying AV node function without creating AV block (268,269). AV node modification is effective in approximately 70% of patients. Inadvertent AV block may occur in 16% to 21% of patients, and one episode of sudden death has been reported (269). We prefer complete AV block to AV node modification. In complete block, regularization of the ventricular rate occurs, which reduces or eliminates palpitations while improving cardiac output.

Primary Prevention

Advances in ablation therapy have led to its routine use in nearly all arrhythmias, with the exception of atrial and ventricular fibrillation. The maze procedure has been the primary surgical treatment of atrial fibrillation (37). Endocardial compartmentalization of the atria by linear lesions and creation of a maze-like result have been tried, using radiofrequency catheter ablation energy (270). Right atrial approaches have not been very successful (271). Left atrial approaches, especially focal ablation typically in the pulmonary veins, are promising and much more successful in curing atrial fibrillation (27,28 and 29,272) (*e*Fig. 64.10.4 and *e*Fig. 64.10.5). Improvements in catheter design and energy sources (273,274), as well as in our understanding of the electrophysiology of atrial fibrillation in humans, will undoubtedly elevate catheter ablation to a primary treatment for atrial fibrillation.



***e*FIGURE 64.10.4 A:** Twelve-lead electrocardiogram from a patient with atrial fibrillation originating from a focus in the left inferior pulmonary vein (LI). **B:** Intracardiac recordings made during the onset of atrial fibrillation. The earliest atrial depolarizations originate in the LI. ***e*FIGURE 64.10.5** Successful ablation of the ostium of the left inferior pulmonary vein. Using an electroanatomic mapping system, a series of ablations (*red hexagons*) were placed around the ostium of the vein, curing this patient of atrial fibrillation. Os, ostium; PA, postero-anterior; RF, radiofrequency.

Surgery

The maze surgical procedure for treatment of atrial fibrillation was developed by Cox and associates (37). Multiple atrial incisions are made to direct sinus impulses through a path, or a “maze,” to reach the AV node. The idea is to prevent formation of a critical mass of contiguous atrial tissue that would sustain atrial fibrillation. Further, at least some atrial contractility is maintained. The results of the maze operation have been promising. Alternative operations are the left atrial isolation technique, the “corridor” operation, and simple encircling of the pulmonary veins (275,276 and 277). However, surgery for atrial fibrillation as a primary indication has not gained much momentum and is infrequently used for this problem. We have found it useful for patients with atrial fibrillation who are undergoing other cardiac surgery. Because the left atrial appendage is the usual site of thrombus, we recommend removal of this structure in patients undergoing other cardiac surgery, especially if the patient has a history of atrial fibrillation.

Implantable Atrial Defibrillators

As noted earlier, atrial defibrillation can be accomplished with low-energy shocks (256,257). Clinical trials of implantable atrial defibrillators in humans demonstrated safety and efficacy, but patient intolerance was a major problem. Advances in technology are required to enable defibrillation to occur at energies below the pain threshold to make this a more attractive form of treatment.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Sinus Rhythm versus Rate Control

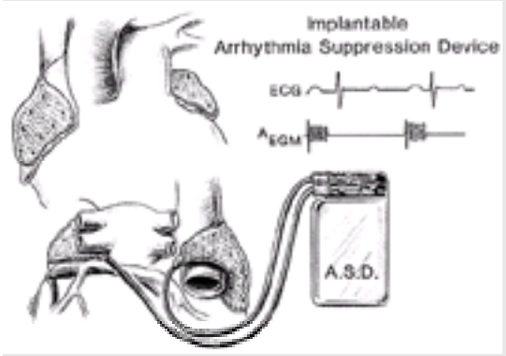
A controversy currently exists regarding the relative merits of administering antiarrhythmic drugs to maintain sinus rhythm versus allowing atrial fibrillation to persist and using drugs to control ventricular rate. No large, randomized, prospective trials have demonstrated the superiority of either approach. Clearly, some patients do well with rate control only. For other patients, sinus rhythm must be achieved to ameliorate symptoms. Sinus rhythm perpetuates sinus rhythm, which is the antithesis of atrial fibrillation begetting atrial fibrillation. Thus, if sinus rhythm can be maintained most of the time, it may be possible to prevent the anatomic and electrophysiologic abnormalities that result from atrial fibrillation. In our experience, if aggressive attempts are made to preserve sinus rhythm shortly after atrial fibrillation occurs, it is possible to prevent or markedly reduce atrial fibrillation recurrences in more than 60% of patients. With regard to the safety of antiarrhythmic drugs, we do not live in a risk-free environment, and it is impossible to guarantee a complete absence of proarrhythmic risk. However, with appropriate selection of antiarrhythmic agents, initiation of drug therapy in-hospital for patients at substantial risk for proarrhythmia, and careful follow-up, morbidity and mortality from proarrhythmia is 1% or less in our experience. For many patients, the risk is worth the gain.

Inpatient versus Outpatient Initiation of Therapy

Initiation of antiarrhythmic drugs to restore or maintain sinus rhythm can be performed on an inpatient or an outpatient basis. The risk of proarrhythmia is low, even among patients who have significant heart disease, and starting treatment in the hospital likely will not be cost-effective. Regardless, we feel that patients who have significant heart disease should be monitored during initiation of antiarrhythmic drug treatment, to identify any potential serious problems, especially proarrhythmia. However, patients who have paroxysmal atrial fibrillation with no or minimal heart disease may start antiarrhythmic drugs as outpatients. Before therapy is begun, normal electrolyte status should be confirmed. When an agent that prolongs the QT interval, such as sotalol, is prescribed, we begin with the lowest dose and obtain an electrocardiogram after 2 to 3 days before increasing the dose. This process is repeated until the desired dose is obtained. Event recorders might be used for this purpose. We have not had any significant problems with proarrhythmia using this approach. It is very important to advise patients about over-the-counter and prescription drugs that may interact with the antiarrhythmic agent. For example, antihistamines that may increase the QT interval should not be given to patients taking drugs that prolong the QT interval. We generally ask patients to call us before starting any new drug. When flecainide or propafenone is prescribed, beta-blockers or calcium channel blockers should be given initially to prevent atrial flutter with a 1:1 ventricular response.

THE FUTURE

New and innovative approaches for the treatment of patients with atrial fibrillation are likely to emerge (278). Technological advances in catheter design and energy sources should facilitate a catheter-based approach to curing atrial fibrillation. This may be intracardiac or extracardiac (e.g., use of a thoracoscope). Antiarrhythmic drug development likely will target specific ionic channels in the atrium that do not involve the ventricles, improving efficacy and decreasing ventricular proarrhythmia. Novel cardiac pacing techniques may provide a nonpharmacologic alternative to prevention of atrial fibrillation. An implantable arrhythmia suppression device may be developed that will use subthreshold atrial stimulation to prevent emergence of atrial fibrillation (eFig. 64.10.6) (279). An alternative new device, Tranquillity, will contain an implantable cardioverter-defibrillator/pacemaker/drug-delivery system (eFig. 64.10.7) (280). This unit will have the capability of atrial and ventricular defibrillation and dual chamber pacing, and it can deliver one or more drugs through the atrial lead. It should manage any potential arrhythmic problem.



***e*FIGURE 64.10.6** Schematic diagram of an implantable arrhythmia suppression device (ASD) used for the prevention of atrial fibrillation. ECG, electrocardiogram; EGM, electrogram. [From Prystowsky EN. Future expectations of implantable cardioverter defibrillator therapy. *Pacing Clin Electrophysiol* 1995;18(Pt II):609–615, with permission.]

OVERVIEW

The clinical presentation of patients with atrioventricular (AV) nodal–independent arrhythmias is quite variable and may include nonspecific symptoms. The 12-lead electrocardiogram (ECG), 24-hour ambulatory ECG (Holter) monitor, and ECG event recorder usually establish the diagnosis. In addition, electrophysiologic studies have now become an important diagnostic tool, particularly with the emergence of effective nonpharmacologic therapies. In patients with frequent or incessant atrial arrhythmias, sustained rapid ventricular rates can lead to a tachycardia-mediated cardiomyopathy (CM) and congestive heart failure (CHF). Therefore, considerable caution should be exercised before attributing cardiac decompensation to worsening intrinsic myocardial disease in the presence of such an arrhythmia.

The management of atrial arrhythmias has improved due to a better understanding of the causative mechanisms. Most AV nodal–independent arrhythmias are due to reentry: atrial flutter, sinus-node reentry, and intraatrial reentrant tachycardia. However, AV nodal–independent arrhythmias may also occur due to automaticity or triggered activity. Regardless, acute treatment consists of obtaining prompt control of the ventricular rate and, if possible, restoring sinus rhythm.

A thorough characterization of the underlying cardiac substrate is usually indicated before embarking on long-term therapy. Catheter-ablation techniques provide the best hope of obtaining a permanent cure in most patients with these arrhythmias. Large clinical experiences now support the use of catheter ablation as primary therapy in symptomatic patients with atrial flutter, atrial tachycardia, and sinus-node reentry tachycardia. Alternative treatments consist of antiarrhythmic drugs to suppress recurrent symptomatic episodes, recognizing that occasional recurrences are common and do not represent drug failure.

INTRODUCTION

This chapter examines the AV nodal–independent tachycardias, with the exception of atrial fibrillation. This chapter deals principally with atrial flutter, the most common of these arrhythmias. The other arrhythmias discussed include atrial tachycardia, inappropriate sinus tachycardia, sinus node reentrant tachycardia, and multifocal atrial tachycardia (MAT).

Atrial tachyarrhythmias are associated with a wide spectrum of potential presentations, including palpitation, syncope, near-syncope, dyspnea, fatigue, malaise, and new or worsening CHF. Many, if not most, of these symptoms are primarily related to the associated rapid ventricular rate and the physiologic adaptation to that rapid rate. This is most fully discussed in the section on atrial flutter (see Atrial Flutter: Epidemiology and Clinical Significance), which serves as a reference for the other atrial tachyarrhythmias. Similarly, many, if not most, of the principles of treatment of atrial flutter apply to the other atrial tachyarrhythmias, particularly those due to a reentrant mechanism.

In the management of patients with an atrial tachyarrhythmia, identification of the mechanism of the atrial arrhythmia remains one of the cornerstones of successful therapy. Such an understanding now provides the opportunity for a definitive cure in many instances. However, providing successful therapy also mandates a careful evaluation of the patient, especially of the overall cardiac milieu. In many instances, non–AV nodal–dependent arrhythmias are associated with a cardiac substrate abnormality of consequence, such as ventricular hypertrophy, valvular heart disease, coronary artery disease, or left ventricular (LV) dysfunction. An assumption of this chapter is that the cardiac milieu must be adequately addressed as a necessary part of the treatment of atrial tachyarrhythmias.

Finally, regardless of the atrial tachyarrhythmia, if it is incessant or frequent and the ventricular response rate is rapid, a tachycardia-induced CM may result. Recognition of this possibility is particularly important, as primary therapy of this CM should be directed at the atrial tachyarrhythmia. An incessant, atrial tachyarrhythmia–induced dilated CM may be entirely reversible with correction of the tachyarrhythmia or control of the ventricular rate. In patients with preexisting heart

disease, frequent or incessant atrial tachyarrhythmias may cause additional cardiac decompensation that may go unrecognized or may be incorrectly attributed to worsening of the underlying structural heart disease. This, too, should be improved or reversed with correction of the tachyarrhythmia or control of the ventricular rate.

ATRIAL FLUTTER

Historical Perspective

After atrial fibrillation, atrial flutter is the most common atrial tachyarrhythmia. Although it was first described eight decades ago (1), until recently, knowledge regarding the mechanism was primitive. Lewis (2) originally thought atrial flutter was due to a single focus firing rapidly. He and colleagues later ascribed it to reentry around the great veins (3). Over the ensuing years, a controversy developed regarding which of these mechanisms, either a single focus firing rapidly or some form of reentry, was responsible (4). Techniques for the diagnosis and management of atrial flutter changed little for decades. Diagnosis rested almost entirely on the 12-lead ECG. Treatment options included the use of a digitalis compound to slow and control the ventricular rate, and/or the use of either quinidine or procainamide in an attempt to convert the rhythm to sinus or to prevent recurrence of atrial flutter once sinus rhythm was established.

A 59-year-old female patient with atrial flutter with 4:1 atrioventricular conduction.

The past 25 years have produced major changes. A series of studies advanced our understanding of the mechanism(s) of atrial flutter (4). Old techniques to diagnose atrial flutter have been refined, and new diagnostic and therapeutic techniques have been developed (5,6 and 7).

Beginning with the advent of direct current (DC) cardioversion in the 1960s (8,9), major advances in the therapy of atrial flutter have been made. Beta-blockers and calcium channel blockers now are available for use in lieu of digitalis therapy to control the ventricular rate (10,11,12 and 13). New antiarrhythmic agents are available to suppress atrial flutter or to convert it to sinus rhythm (14,15,16,17 and 18). Atrial pacing techniques to interrupt or suppress atrial flutter have evolved (5). Catheter-ablation techniques either to cure atrial flutter (19,20 and 21) or to control the ventricular rate (22) have been developed. Related surgical therapies (23,24) have been used.

Potential Mechanisms

Many studies, most of which have been performed in experimental models but many also in humans, indicate that atrial flutter is due to reentry in the right atrium. Lewis et al. (3) concluded that atrial flutter was the result of circus movement in the atria, principally around the great veins.

Many years later, Rosenblueth and Garcia-Ramos (25) created a crush lesion between the vena cavae in the canine heart, demonstrating that atrial flutter resulted from intraatrial reentry around the vena cavae using the lesion. More recently it has been shown that in the presence of a similar lesion extending toward the right atrial appendage to make a Y lesion, atrial flutter may be explained by circus movement around the tricuspid valve annulus (26,27). The latter explanation may have a clinical counterpart in atrial flutter seen in patients after repair of complex congenital heart disease that includes large incisions in the right atrium (28,29). Several subsequent canine right atrial free wall lesion models (30,31) have also shown that a stable reentrant wavefront can travel around such a lesion if it is long enough, thereby producing stable atrial flutter.

Relatively early after the recognition of atrial flutter as a clinical entity, a single focus firing rapidly has been believed to be a possible mechanism of atrial flutter (2). Experimental evidence supporting this belief came subsequently from the studies of Scherf and colleagues (32,33), later confirmed by Kimura et al. (34), in which atrial flutter was shown to occur in the canine atria after applying aconitine to a single site. Whether there is a clinical counterpart to this model remains uncertain. Recent findings suggest that a single focus firing rapidly, particularly in the pulmonary veins, may be responsible for some forms of atrial flutter (35,36).

Models that have not required applying substances or creating primary atrial lesions are more likely to be experimental counterparts of spontaneous atrial flutter in patients. The acetylcholine model studies of Allessie et al. (37,38) in the canine heart have shown that atrial flutter due to intraatrial reentry can occur superiorly or inferiorly in either atrium as well as in the absence of an anatomic obstacle. In this model, the atrial rates were extremely fast (more than 600 beats/min), unstable, and may be models for atrial fibrillation in which a reentrant circuit of very short cycle length drives the atria and causes fibrillatory conduction. Other models of atrial flutter in the canine heart that do not demonstrate reentry around an anatomic obstacle include a spontaneous example of atrial flutter in a single dog (39) and one of right atrial enlargement secondary to creation of tricuspid regurgitation and pulmonary artery banding (40,41).

The sterile pericarditis model of atrial flutter described by our laboratory (42) and studied by us (43,44,45,46,47 and 48) and others (49,50 and 51) was believed to be due to functional reentry in the right atrial free wall. However, simultaneous multisite mapping studies have recently demonstrated a critical septal component to the reentrant circuit (52). In this model, either a single reentry loop very similar to that in patients or a figure-of-eight reentry loop where two reentrant circuits use a common pathway in the right atrial free wall may be present. Interestingly enough, figure-of-eight reentry atrial flutter has recently been described in a patient after repair of a congenital lesion (53). Also, atrial flutter due to reentry around a line of block in the right atrial free wall has also been described in a patient (54). Mapping of a canine model of atrial reentry in mitral regurgitation showed that several reentrant circuits, including one resulting from reentry confined to the right atrium, had no anatomic obstacle (55).

Mapping of atrial flutter in humans began in the 1950s with the studies of Prinzmetal et al. (56). Photographic techniques with the heart exposed were used during thoracic surgery. Later, Wellens et al. (57) used sequential-site atrial epicardial mapping to study atrial flutter during human cardiac surgery. On the basis of these studies, both groups suggested that atrial flutter was due to a single focus firing rapidly. Pacing studies by Rosen et al. (58) of the human coronary sinus showed that a single focus firing rapidly could generate the classic clinical ECG of atrial flutter. Nevertheless, this mechanism has not been supported by numerous other mapping studies in humans that primarily have used electrode catheter techniques during electrophysiologic studies. As summarized by Rytand (59), initial and limited catheter mapping studies in the 1950s and 1960s suggested that atrial flutter was an intraatrial reentrant rhythm. The mapping studies of Puech and colleagues (60,61) demonstrated that the entire duration of the atrial flutter cycle length may be explained by circus movement activation of the right atrium alone, with the impulse traveling up the septum and down the right atrial free wall.

Demonstration of transient entrainment and interruption of atrial flutter in humans (62,63 and 64) provided additional strong evidence that atrial flutter was an intraatrial reentrant rhythm with an excitable gap (Fig. 65.1). Subsequent mapping studies, usually in concert with atrial pacing, have confirmed that the atrial flutter reentrant circuit is virtually always confined to the right atrium. Thus, the studies of Cosio et al. (65,66 and 67), Olshansky et al. (68,69), nd Klein et al. (23) indicated that the reentrant circuit in typical atrial flutter in humans involved counterclockwise reentrant excitation in the right atrium in which the impulse traveled in a caudocranial direction in the interatrial septum and in a craniocaudal direction in the right atrial free wall. Atypical, or rare (uncommon), atrial flutter was shown to use the same reentrant circuit but in the opposite direction (70).

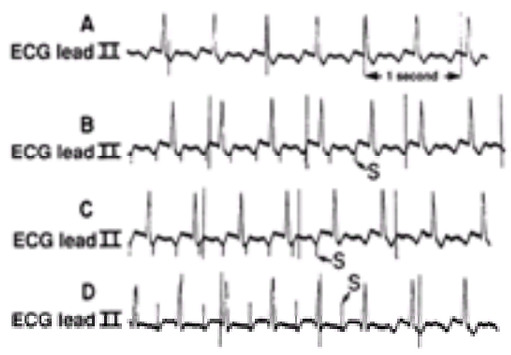

FIGURE 65.1 Electrocardiogram (ECG) lead II recorded during atrial flutter of an atrial cycle length of 264 ms **(A)** and at the end of 30 seconds of rapid atrial pacing from a high right atrial site at a cycle length of 254 ms **(B)**, at a cycle length of 242 ms **(C)**, and at a cycle length of 232 ms **(D)**. The atrial flutter was transiently entrained at each pacing rate. Note that when comparing the morphology of the atrial complexes during atrial pacing at each cycle length, especially that of the atrial complexes during atrial pacing in **D** with that in **A** and **B**, progressive fusion has occurred. Timelines are at 1-second intervals. S, stimulus artifact. (From Waldo AL, MacLean WAH, Karp RB, et al. Entrainment and interruption of atrial flutter with atrial pacing: studies in man following open-heart surgery. *Circulation* 1977;56:737–745, with permission.)

The studies of Cosio et al. (65,66 and 67) and Olshansky et al. (68,69) have also provided evidence that an area of slow conduction is present in the postero-inferior aspect of the right atrium. The central area of block around which the reentrant wavefront circulates likely includes an anatomic component and a functional component in the interatrial septum (65,66,70).

Catheter mapping techniques, including entrainment mapping, have localized the area of slow conduction in the reentrant circuit principally to an isthmus bounded by the coronary sinus ostium, the tricuspid annulus, inferior vena cava, and eustachian ridge (21,71,72 and 73). However, others have suggested that this atrial flutter isthmus is not an area of slow conduction during atrial flutter (74).

Exquisite anatomic and angiographic studies have examined the underlying milieu of the atrial flutter circuit. Marked anatomic variations in the subeustachian isthmus are present in normal hearts. The arrangement of the subendothelial fibers in the isthmus recesses was unique among autopsy specimens (75,76). Furthermore, an angiographic study demonstrated that the inferior subeustachian isthmus is wider in patients with atrial flutter when compared with a control population (77). These studies demonstrate a strong anatomic contribution to the requisite atrial flutter reentrant circuit.

Mapping techniques have demonstrated the critical role of the region of the crista terminalis as one boundary for the reentrant circuit and the role of the tricuspid ring as another boundary of the reentrant circuit (71,72 and 73). Differences in the electrophysiologic properties of the crista terminalis have been identified in patients with atrial flutter (78,79). Specifically, transverse conduction block across the crista terminalis occurs at longer cycle lengths in patients with atrial flutter. This difference may in part explain the absence of atrial flutter in all individuals. But it remains clear that block, probably functional, in a region between the vena cavae is critical to establish stable atrial flutter. Nevertheless, a recent study (80) dismissed the role of the crista terminalis as a critical boundary for atrial flutter. A functional line of block was described in the postero-medial right atrium in the sinus venosa region. This was observed in 28 consecutive patients with atrial flutter. Additional mapping studies are needed to resolve this controversy.

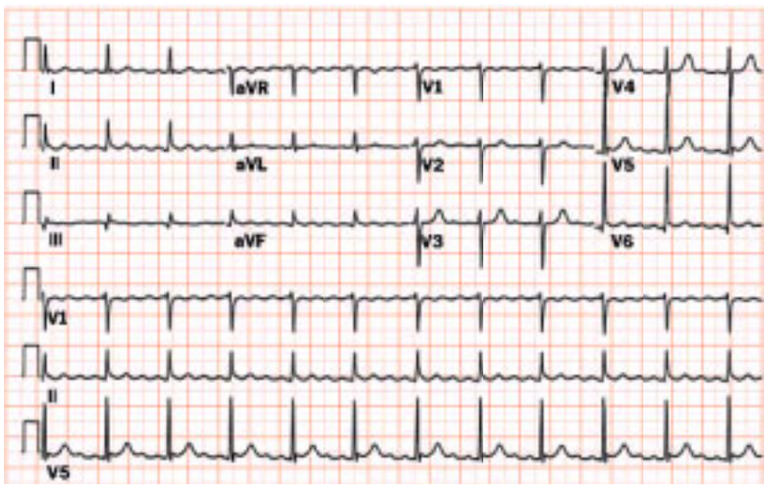
Other locations can support an atrial flutter reentrant circuit and have been identified in humans. These atrial flutter circuits may or may not use the subeustachian isthmus. Locations include (a) the right atrial free wall, (b) the pulmonary veins in the left atrium, (c) nonpulmonary vein sites in the left atrium, (d) lower-loop reentry breaking through the crista terminalis and using the subeustachian isthmus, and (e) double-wave reentry using the usual right atrial flutter reentrant circuit. Better mapping data from studies in humans may well improve our understanding of the various reentrant circuits observed in humans and animals (81,82).

Furthermore, most instances of atrial flutter are preceded by a period of atrial fibrillation, usually brief, during which time the functional components of the atrial flutter reentrant circuit form (83). Anchoring of the multiple reentrant circuits seen in atrial fibrillation to components of the atrial flutter circuit likely explains the transition from atrial fibrillation to flutter. Conversely, breakdown of one or more functional components of the previously stable flutter circuit via crista terminalis breakthrough as seen in lower-loop reentry or via another boundary in the circuit likely explains the transition from atrial flutter to fibrillation.

Classification

With the availability of new mechanistic information, many terms have been used to describe atrial flutter, and considerable confusion has grown regarding terminology. Classification of atrial flutter has always included an atrial rate range, generally 240 to 340 beats/min (84), and a remarkably regular rate with the most constant beat-to-beat cycle length of any tachycardia (85).

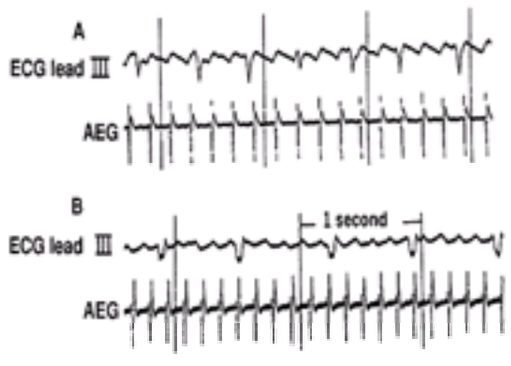
Atrial flutter was first classified by Jolly and Ritchie (1) in 1911. Little change occurred in the classification until the description of the subclasses so-called typical and atypical atrial flutter (86). Typical atrial flutter had the negative, sawtooth flutter waves in ECG leads II, III, and aVF. Atypical atrial flutter was described as having positive atrial complexes in ECG leads II, III, and aVF, although the atrial rate was sometimes slower than that of typical atrial flutter. These two subclasses were subsequently also called *common* and *rare* (uncommon) *atrial flutter*, respectively. We now know that atypical (rare or uncommon) atrial flutter uses the same reentrant circuit as typical (common) atrial flutter, but that the reentrant wavefront travels in the opposite direction. Based on the atrial activation sequence as seen in the left anterior oblique view, the terms *clockwise* and *counterclockwise* atrial flutter were also used. Thus, several names have evolved when describing subclasses of atrial flutter: typical, or counterclockwise, or common atrial flutter and atypical, or clockwise, or rare, or uncommon atrial flutter.



Atrial flutter. Atrial rate of 300 beats/min with upright P waves inferiorly. This is consistent with atypical atrial flutter.

Atrial flutter. Inverted "saw-tooth" waves in the inferior leads suggest typical atrial flutter.

Following the studies of Wells et al. (85), two overall types of atrial flutter were characterized: type I and type II (eFig. 65.1.1). They are distinguished by the fact that type I atrial flutter can always be interrupted by rapid atrial pacing, whereas type II atrial flutter cannot (5,85). Typical (common, counterclockwise) and atypical (rare, uncommon, clockwise) atrial flutter can always be interrupted by rapid atrial pacing techniques and are all categorized as type I atrial flutter. Differentiation of type I from type II atrial flutter has also been made in terms of the range of atrial rates and the ability or inability to interrupt atrial flutter with rapid atrial pacing (26). In the absence of drug therapy, type I atrial flutter is characterized by atrial rates ranging from 240 to 340 beats/min, and type II atrial flutter by atrial rates ranging from 340 to 433 beats/min. Overlap likely exists between the upper range of rates of type I and the lower range of rates of type II atrial flutter.



***e*FIGURE 65.1.1** These tracings demonstrate simultaneous recording of electrocardiogram (ECG) lead III and a bipolar atrial electrogram (AEG) during **(A)** type I atrial flutter with an atrial rate of 296 beats/min and during **(B)** type II atrial flutter with an atrial rate of 420 beats/min. In each example, note the constant beat-to-beat cycle length, polarity, morphology, and amplitude of the recorded atrial electrogram signal. (From Wells JL Jr, MacLean WAH, James TN, Waldo AL. Characterization of atrial flutter: studies in man after open-heart surgery using fixed atrial electrogram. *Circulation* 1979;60:665–673, with permission.)

Little is actually known about the natural history and treatment of type II atrial flutter. It may be due to reentry of very short cycle length or a single focus firing rapidly, either of which can produce fibrillatory conduction (the rest of the atrial tissue cannot follow 1:1) and thereby atrial fibrillation. The reentry may be around the pulmonary vein(s), or the single focus may be from a pulmonary vein (35,36). We continue to learn more about type II atrial flutter.

In view of the new information about atrial flutter as well as the explosion of terms to describe it, the European Society of Cardiology/North American Society of Pacing and Electrophysiology Working Group has offered a new classification based on mechanism (Table 65.1). Any reentrant circuit which requires use of the atrial flutter (subeustachian) isthmus is called *typical atrial flutter*. Usually in typical atrial flutter, the reentrant circuit travels up the septum and down the right atrial free wall (Fig. 65.2A). Atrial flutter that uses the same circuit but in the opposite direction is called *reverse typical atrial flutter*. Lower-loop reentry atrial flutter (Fig. 65.2B) and double-wave reentry atrial flutter (Fig. 65.2C) also use the subeustachian isthmus and thus are classified as types of typical atrial flutter (87,88).

Typical forms of atrial flutter (atrial flutter isthmus dependent)

TABLE 65.1 ATRIAL FLUTTER CLASSIFICATION

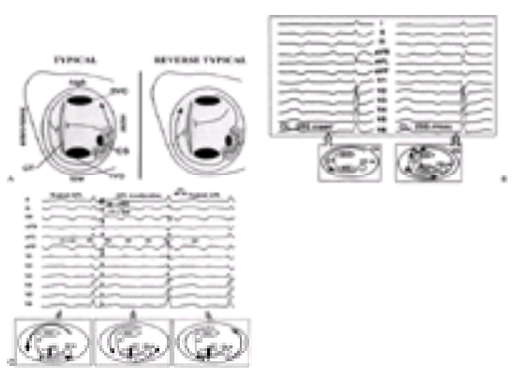

FIGURE 65.2 A: Schematic representation of typical and reverse typical atrial flutter circuits. The left anterior oblique view of the right atrium shows the endocardium through the tricuspid ring in a wide-angle perspective. The endocardium is shaded. The orifices of the superior and inferior caval veins (SVC and IVC) and coronary sinus (CS) are shown in black. The terminal crest (CT) is shown as a bundle of parallel lines linking the lateral aspects of the caval veins. The shaded area around the coronary sinus suggests the probable location of a slow conduction zone. Curved arrows indicate directions of activation. (Adapted from Cosio FG, Lopez-Gil M, Arribas F, Gonzalez HD. Mechanisms of induction of typical and reversed atrial flutter. *J Cardiovasc Electrophysiol* 1998;9:281–291.) **B:** Sustained spontaneous atrial flutter with two cycle lengths was observed in the same patient. Tracings on left show typical atrial flutter with a cycle length (CL) of 285 ms. Tracings on right show lower-loop reentry with a cycle length of 255 ms. Note the similar flutter wave morphologies despite different cycle lengths and different activation sequences, although there is a subtle difference in the terminal portion of the flutter waves in the inferior leads. Drawings depict the circuit anatomy. The hollow star delineates the breakthrough site, and the double line is the site of collision. His, His bundle. (Adapted from Cheng J, Cabeen WR, Scheinman MM. Right atrial flutter due to lower loop reentry, mechanism and anatomic substrates. *Circulation* 1999;99:1700–1705.) **C:** Critically timed atrial extrastimulus (AES) induced atrial flutter (AFL) acceleration. Surface 12-lead electrocardiogram showed P-wave morphology during AES-induced acceleration identical to that of flutter wave during spontaneous AFL. The accelerated flutter cycle length showed beat-to-beat variation (numbers are cycle length in milliseconds). The three diagrams schematically depict the positions of the

activation wavefronts at induction, during, and at termination of double-wave reentry. Two wavefronts transiently are circulating in the typical AFL circuit and at the same time. Decremental conduction results in a cycle length greater than half the cycle length of the typical AFL circuit. (Adapted from Cheng J, Scheinmann MM. Acceleration of typical atrial flutter due to double-wave reentry induced by programmed electrical stimulation. *Circulation* 1998;97:1589–1596.)

At least 90% of atrial flutters fall into the typical category. Atrial flutter in which the reentrant circuit is confined to the left atrium is called *left atrial flutter*. Reentry around an incisional line of block in the rate range of atrial flutter is called *lesion atrial reentry*. All other forms of reentrant atrial tachycardia in the rate range of atrial flutter that are not described by the above are called *atypical atrial flutter*.

Epidemiology and Clinical Significance

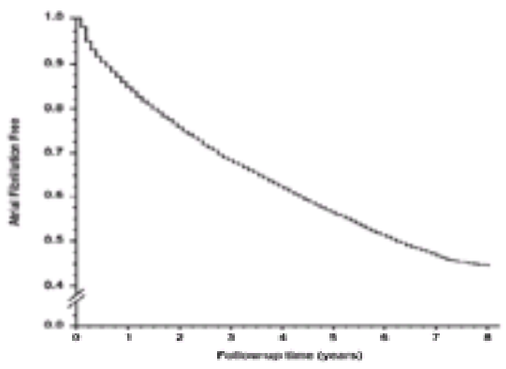
Atrial flutter can be a persistent rhythm, but more typically it is paroxysmal, often lasting for seconds to hours. A stable, chronic rhythm is unusual in atrial flutter because it usually reverts either to sinus rhythm or to atrial fibrillation, spontaneously or as a result of therapy. However, atrial flutter has been reported to be present for up to 20 years or more (89).

The incidence of atrial flutter is uncertain. Based on a review of hospital ECGs (89), atrial flutter has been reported to occur in one in every 81 patients, in every 133 patients, in every 217 patients, and in every 238 patients. A recent review (90) estimated an overall incidence of atrial flutter at 88 per 100,000 person-years in the general population. Atrial flutter was more common in men, in patients with chronic obstructive pulmonary disease, and in patients with heart failure.

Atrial flutter is usually spontaneously induced by premature atrial beats or a transitional rhythm that appears to be atrial fibrillation (91). It can occur in patients with ostensibly normal atria but more commonly in patients with abnormal atria. It is associated with enlargement of the atria, especially the right atrium, from valvular disease or any cause (29). Patients with atrial flutter not uncommonly demonstrate sinus bradycardia or other manifestations of sinus node dysfunction.

Atrial flutter frequently develops in patients in the first week after open-heart surgery, with an overall incidence of 10% to 20% (5). It may also occur after surgical repair of certain congenital cardiac lesions especially in which the Mustard, Senning, or Fontan procedure is used (28,29,92). After congenital heart surgery, the typical atrial flutter isthmus is usually requisite for the atrial arrhythmia, although in a minority of cases the suture line is critical, and the atrial arrhythmia does not involve the typical flutter isthmus (93).

Atrial flutter frequently occurs in association with atrial fibrillation (94,95). In fact, the two rhythms can occur in the same patient, going back and forth between one another. Analysis of a Medicare cohort of patients (96) demonstrated that after an initial hospitalization with atrial flutter, more than 50% of patients were rehospitalized with atrial fibrillation (*e*Fig. 65.2.1). The presence of lung disease, heart failure, hypertension, or coronary disease did not predict which patients would represent with atrial fibrillation.



***e*FIGURE 65.2.1** The incidence of rehospitalization for atrial fibrillation after an index hospitalization for atrial flutter. Atrial fibrillation is common after an episode of atrial flutter. (From Biblo LA, Yuan Z, Quan KJ, et al. Risk of stroke in patients with atrial flutter. *Am J Cardiol* 2001;87:346–349, with permission.)

Atrial flutter is often perceived as a nuisance arrhythmia. However, an episode of atrial flutter can have devastating consequences. The clinical significance lies largely in its association with systemic embolization and stroke, with atrial fibrillation, and with a rapid ventricular response rate. The rapid ventricular rate is primarily responsible for the associated symptoms, including ischemia, hypotension, or heart failure. In the presence of the Wolff-Parkinson-White syndrome or a very short PR interval in the absence of a delta wave, 1:1 AV conduction may occur with even more dire consequences. Furthermore, if the duration of the rapid ventricular rate is prolonged, ventricular dilatation and CHF may result. In fact, atrial flutter can solely cause or exacerbate an existing dilated CM.

Physical Examination and Associated Hemodynamic Effects

Atrial flutter frequently results in a regular ventricular response with either 2:1 or 4:1 AV conduction. However, atrial flutter also can be associated with an irregular ventricular response rate. As a result, the physical examination may mimic that of atrial fibrillation, with an irregular ventricular rate auscultated at the precordium associated with an irregular peripheral pulse rate with dropped beats (i.e., the apical ventricular rate is higher than the peripheral ventricular rate). If neck veins are clinically apparent, examination of the neck may reveal regular jugular venous pulsations at a rapid rate (i.e., the atrial rate). The jugular venous pulsations will be more rapid than the peripheral or apical pulsations, reflecting the degree of AV nodal blockade (e.g., 2:1, 4:1).

Hemodynamic effects depend on the underlying disease, the ventricular rate, the duration of the rhythm, the presence of concurrent medications, and whether the patient is at rest or at exertion (97). At rapid ventricular rates, a decline in cardiac output is usually seen. The abrupt onset of an increased rate typically affects blood pressure with an initial decline and subsequent rise. The blood pressure response, in fact, depends largely on peripheral adaptation (98). The initial decline in blood pressure may be associated with presyncope or even syncope in some cases. There may also be a significant decrease in coronary blood flow and a rate-related increase in myocardial oxygen consumption despite maintenance of baseline cardiac output. The decrease in coronary artery flow is inversely proportional to the ventricular rate and decreases progressively to a maximum of 60% of baseline. During atrial flutter, if the ventricular rate is rapid, this reduction in coronary blood flow is induced by changes in both systolic and diastolic function. First, the diastolic interval is significantly shortened, thereby reducing the time for coronary flow. Second, the mean aortic pressure declines, thereby reducing the coronary artery perfusion pressure. Third, with the associated ischemia or diastolic dysfunction, LV end diastolic pressure rises as the rapid ventricular rate continues. This combination of factors explains the association of symptomatic ischemia with supraventricular tachycardias, including atrial flutter (97).

Diagnosis

Electrocardiogram

Atrial flutter usually can be diagnosed from the ECG. Whenever atrial flutter is suspected, the diagnosis should be clearly established before initiating therapy unless the patient is clinically very unstable. Atrial flutter waves in the ECG, particularly sawtooth atrial complexes in leads II, III, and aVF, remain the standard for diagnosis of atrial flutter (Fig. 65.3). Flutter waves appear as atrial complexes of constant morphology, polarity, and cycle length, with a rate ranging from 240 to 340 beats/min (85).

FIGURE 65.3 A 12-lead electrocardiogram of typical atrial flutter is shown. The atrial rate is 290 beats/min, and the ventricular rate is 145 beats/min; 2:1 atrioventricular conduction is present. Notice that the atrial activity is best seen in leads II, III, and aVF, but is barely perceptible in lead I.

Typical and reverse typical atrial flutter can occur in the same patient at different times. Usually the reverse typical atrial flutter has a slower rate than the typical atrial flutter (eFig. 65.3.1). Atrial fibrillation with prominent (more than 0.2 mV) fibrillatory waves is often confused with atrial flutter (99). Care must be taken to ensure absolute regularity of atrial complexes before making a diagnosis of atrial flutter.

***e*FIGURE 65.3.1** These 12-lead electrocardiogram tracings were obtained from the same patient at different presentations to the same emergency department. Both tracings document typical forms of atrial flutter. **A:** Typical atrial flutter. **B:** Reverse typical atrial flutter. Note the slower atrial rate observed in the reverse typical atrial flutter.

The atrial rate may be slower if the rhythm is present after therapy with antiarrhythmic drugs (i.e., class IA drugs, especially class IC drugs, moricizine, and amiodarone). If the ventricular response is half that of the atrial flutter rate, identifying the flutter waves on the ECG leads may be difficult due to temporal superimposition on other ECG deflections such as the QRS complex or the T wave.

As described in this section, the ventricular rate in atrial flutter is frequently 2:1 or 4:1 and is therefore regular. However, it may be irregular when there is variable AV conduction. Rarely, AV conduction may even be 1:1. The latter may be seen when an accessory AV connection is operative and may also be present in patients who have a very short PR interval during sinus rhythm. AV conduction may be enhanced during exertion, during therapy with catecholamines, or during administration of sympathomimetics for other underlying clinical problems. The ventricular response may paradoxically increase with slowing of the atrial flutter rate secondary to antiarrhythmic therapy (Fig. 65.4).

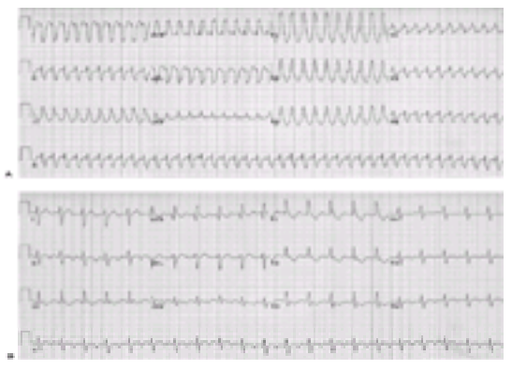


FIGURE 65.4 This patient presented 1 week after initiation of flecainide therapy for atrial flutter. **A** depicts 1:1 atrioventricular (AV) conduction. This was made possible by the slowing of the atrial rate (the pretherapy atrial rate was 300 beats/min with 2:1 AV conduction), now permitting 1:1 AV conduction, which “paradoxically” increased the ventricular rate. **B** was obtained 5 minutes later after therapy with esmolol, which decreased the ventricular response due to 2:1 AV conduction.

The QRS complex during atrial flutter is often identical to that during sinus rhythm. However, atrial flutter beats may be aberrantly conducted due to functional bundle branch block, most frequently a right bundle branch. However, even with normal ventricular conduction, the QRS complex may be distorted by temporal superimposition of flutter waves in the QRS complex. Thus, the QRS complex may acquire a new or larger R, S, or Q wave. A terminal addition to the QRS complex by the flutter wave may result in a false-positive signal-averaged ECG, as pseudo–late potentials may appear (*e*Fig. 65.4.1) (100).

***e*FIGURE 65.4.1** This patient’s signal-averaged electrocardiogram was positive due to the flutter waves abutting the terminal portion of the QRS complex generating a “pseudo–late potential.”

If a diagnosis of atrial flutter is not clear from the ECG, other atrial tachycardias should be considered. In patients with a narrow QRS complex with 2:1 AV conduction,

atrial flutter must be differentiated from (a) sinus tachycardia, (b) AV nodal reentrant tachycardia, (c) AV reentrant tachycardia, (d) an atrial tachycardia with 1:1 AV conduction, (e) an accelerated AV junctional tachycardia, and (f) sinus node reentrant tachycardia. An atrial rate of 300 beats/min with an ensuing ventricular response of 150 beats/min is suggestive of atrial flutter. In patients with a wide QRS complex tachycardia and underlying bundle branch block, atrial flutter must not only be differentiated from all the above rhythms, but also from ventricular tachycardia.

Other Complementary Diagnostic Approaches

If the diagnosis of atrial flutter is not clear from a 12-lead ECG and circumstances permit, vagal maneuvers (e.g., carotid sinus massage, Valsalva) may be used to transiently block AV conduction while continuously recording the ECG (preferably at least leads II and V_1). This should permit the atrial flutter complexes to be readily identified on the ECG tracing. If the diagnosis remains uncertain despite a vagal maneuver and if the clinical status permits, any of the following diagnostic approaches may be used:

1. Record directly from the atria by (a) placement of an esophageal electrode, (b) transvenous atrial placement of a catheter electrode, or (c) use of a temporary atrial epicardial wire electrode placed during open-heart surgery (mode of choice in patients after open-heart surgery).
2. A pharmacologic agent may be administered, such as adenosine, esmolol, or diltiazem, to transiently block AV conduction, thereby revealing the atrial complexes.

The advantage to the electrode/electrogram strategy is that it permits a definitive diagnosis and also provides an opportunity to treat the atrial flutter with rapid atrial pacing. The advantage to the pharmacologic approach is that it does not require an invasive procedure, and esmolol, verapamil, or diltiazem can be administered intravenously to slow the ventricular rate, giving the clinician additional time to determine the next course of therapy. However, when the patient has a wide QRS complex tachycardia, because the rhythm may represent a ventricular tachycardia and not a supraventricular tachycardia with aberrant ventricular conduction, most interventions using drugs to slow the ventricular rate are fraught with hazard.

Clinical Electrophysiologic Studies

For patients with paroxysms of tachycardia in whom atrial flutter is suspected but has yet to be documented, one of several types of ECG monitoring is recommended. For most patients, particularly those with infrequent episodes of tachycardia, use of an event recorder is preferred to a 24-hour Holter monitor.

At present, electrophysiologic studies have become more important with the advent of catheter-based procedures to cure atrial flutter. Although no standards of programmed stimulation for the initiation of atrial flutter have evolved, the most reliable method is to pace the atria very rapidly to initiate atrial fibrillation and then await the evolution to atrial flutter (92). Initiation of atrial flutter by introducing premature atrial beats after a drive train is a much less reliable technique for inducing atrial flutter. Atrial pacing techniques may not reliably induce atrial flutter even in patients with a known history of atrial flutter.

Electrode catheter mapping studies (101) of atrial flutter are generally performed to help identify the location and type of the reentrant circuit. The mapping study must identify a vulnerable isthmus in the reentrant circuit that can be ablated to ensure success. In most patients with atrial flutter, such a location is thought to be the atrial flutter isthmus between the tricuspid valve orifice and the orifice of the inferior vena cava (19,20 and 21,71,72 and 73). owever, as discussed previously, atrial flutter can operate independent of this isthmus (102,103). Techniques including entrainment mapping, electroanatomic mapping, and virtual electrode mapping play an important role in identifying the vulnerable isthmus.

Acute Treatment

Antiarrhythmic Drugs

When the diagnosis of atrial flutter is established, three acute nonablative options are available to restore sinus rhythm: (a) administer an antiarrhythmic drug, (b) initiate DC cardioversion, or (c) initiate rapid atrial pacing to interrupt atrial flutter. Treatment largely depends on the clinical status of the patient. In the past, the preferred option to interrupt atrial flutter was either DC cardioversion or rapid atrial pacing. However, the recent introduction of ibutilide provides another viable option, as use of that antiarrhythmic drug is associated with a 60% likelihood of converting recent onset atrial flutter to sinus rhythm (18). Antiarrhythmic drugs also may be used before initiating DC cardioversion or rapid atrial pacing for the following purposes:

1. To slow the ventricular response rate using a beta-blocker, a calcium channel blocker, digoxin, or some combination of these drugs
2. To enhance the efficacy of rapid atrial pacing in restoring sinus rhythm by using quinidine, procainamide, disopyramide, or ibutilide (104,105 and 106)
3. To enhance the likelihood that sinus rhythm will be maintained after effective DC cardioversion by using a class IA, class IC, or class III antiarrhythmic agent

For many years, standard initial treatment was administration of a digitalis preparation, usually intravenously, until atrial flutter either converted to atrial fibrillation with a controlled ventricular response rate or to sinus rhythm. This mode of treatment is now not the treatment of choice (5). Whenever rapid control of the ventricular response rate to atrial flutter is desired, intravenous administration of a calcium channel blocker (e.g., verapamil or diltiazem) or of a beta-blocker (usually esmolol, although propranolol or metoprolol can also be used) is usually effective.

Previously, administration of an antiarrhythmic drug to convert atrial flutter to sinus rhythm was not recommended because the antiarrhythmic drugs that were available, such as quinidine or procainamide, frequently only slowed the atrial flutter rate without interrupting the arrhythmia. Ibutilide now provides a reasonable expectation of successful conversion of atrial flutter to sinus rhythm (18). Ibutilide dramatically prolongs ventricular repolarization and consequently the QT interval. Therefore, a low incidence of torsades de pointes is associated with its use (107). However, should these episodes occur, they are usually self-limiting, and because of the short half-life of this drug, the period of risk appears brief (i.e., less than 1 hour). Nevertheless, one should be prepared to administer magnesium and even perform DC cardioversion to treat a prolonged episode of torsades de pointes should it occur when using ibutilide. Flecainide and propafenone, when used intravenously (108,109) or when used orally but in a single high dose (300 mg flecainide or 600 mg propafenone) (110,111), reportedly have been effective in cardioverting this rhythm and atrial fibrillation to sinus rhythm. Again, when using class IC agents, care must be taken to avoid 1:1 AV conduction of a significantly slowed atrial flutter rate.

Direct Current Cardioversion/Rapid Atrial Pacing

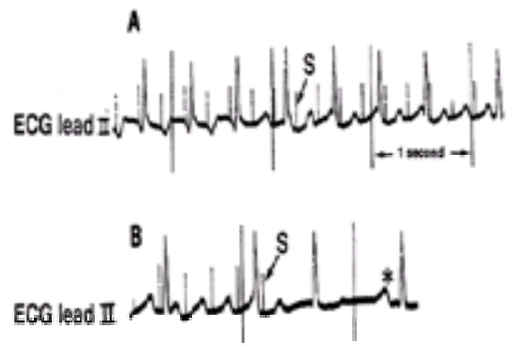
Selecting DC cardioversion, atrial pacing, or antiarrhythmic drugs for acute treatment of atrial flutter depends on the clinical presentation of the patient and on both the clinical availability and ease of applying these techniques. DC cardioversion requires administration of an anesthetic agent. Therefore, this approach may be undesirable in patients who have recently eaten or in patients who have severe lung disease. These patients usually are best treated with antiarrhythmic drugs, rapid atrial pacing, or agents to slow the ventricular response rate. For patients with atrial flutter after open-heart surgery, the use of temporary atrial epicardial electrodes to perform rapid atrial pacing is clearly the treatment of choice (112,113).

Rapid Atrial Pacing to Interrupt Atrial Flutter

When initiating atrial pacing, pacing should be started at a slow rate to demonstrate that ventricular capture is not inadvertently produced. Several effective atrial pacing techniques are available. Pacing should be performed from the high right atrium. A change in the polarity of the atrial complexes (flutter waves in ECG lead II evolve from negative to positive) is the hallmark of interruption of typical atrial flutter (112).

Ramp atrial pacing is the preferred technique. Bipolar atrial pacing is initiated at a rate 10 to 20 beats/min faster than the spontaneous atrial flutter rate while continuously recording ECG lead II. After demonstrating atrial capture, the atrial pacing rate is gradually increased until the atrial complexes in ECG lead II become positive. Atrial pacing may be then either abruptly terminated, or the pacing rate may be rapidly slowed to a desirable atrial pacing rate. The latter permits control of the atrial rhythm in patients with underlying sick sinus syndrome.

Another satisfactory pacing method is the constant rate technique. The most successful rate for interrupting atrial flutter is approximately 120% to 130% of the spontaneous atrial rate (112). When using this technique, atrial pacing is generally initiated at a rate within this range of the spontaneous atrial flutter rate and continued for 15 to 30 seconds, or until the atrial complexes in ECG lead II become positive (eFig. 65.4.2). Pacing is then either abruptly terminated or rapidly slowed to a desirable atrial pacing rate. If pacing at the initially selected rate does not interrupt the atrial flutter, the atrial pacing rate should be increased in increments of 5 to 10 beats/min until atrial flutter is successfully interrupted.



***e*FIGURE 65.4.2 A:** Electrocardiogram (ECG) lead II recorded during high right atrial pacing at a cycle length of 224 ms. Note that with the seventh atrial beat in this tracing, after 22 seconds of atrial pacing at a constant rate, the atrial complexes suddenly became positive. **B:** Electrocardiogram lead II recorded at the termination of atrial pacing in the same patient. With abrupt termination of pacing, sinus rhythm occurs (*asterisk*). Timelines are at 1-second intervals. S, stimulus artifact. (From Waldo AL, Maclean WAH, Karp RB, et al. Entrainment and interruption of atrial flutter with atrial pacing: studies in man following open-heart surgery. *Circulation* 1997;56:737–745, with permission.)

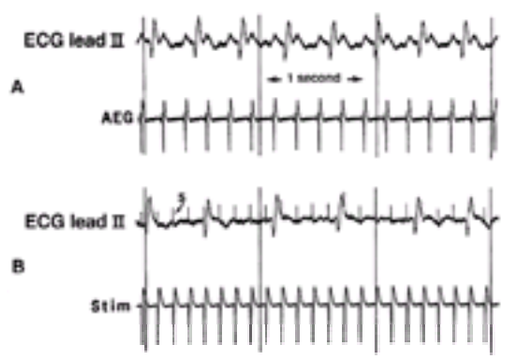
Regardless of the pacing technique used, if the atria are paced at rates faster than the spontaneous rate and the atrial flutter is still not interrupted despite achieving atrial capture, rapid atrial pacing may, in fact, still prove to be successful. This scenario indicates that the selected pacing rates have only transiently entrained the atrial flutter (5,112). Therefore, under the circumstances, successful interruption of atrial flutter will require pacing at a more rapid rate. Atrial pacing rates of more than 400 beats/min occasionally may be required to interrupt atrial flutter, although it should be emphasized that pacing at such a rapid rate usually induces atrial fibrillation. In addition, a critical duration of pacing (average, 11 seconds) at the critical pacing rate is required especially when using the constant rate pacing technique (5,112). Whether using epicardial or endocardial pacing techniques, the stimulus strength required for atrial capture at the rapid rates necessary to interrupt atrial flutter is usually high (113), and either a loss of atrial capture or a failure to capture the atria may occur unless sufficient stimulus strength is applied. It is recommended that pacing be initiated with a stimulus strength of at least 10 mA. However, it is not unusual for up to 20 mA to be required, and on occasion, even stronger stimulus strength may be necessary (5,112,113).

Esophageal Pacing to Interrupt Atrial Flutter

When esophageal pacing is used to interrupt atrial flutter, the suggestions earlier in this section apply with two important exceptions. First, to capture the atria, the stimulus width must be at least 9 to 10 ms, and the stimulus strength needed may be as much as 30 mA (114). Using a pacemaker without these characteristics decreases the chances of successful atrial capture from an esophageal location. Second, because pacing via the esophagus may be somewhat painful (i.e., it usually causes a stinging sensation), pacing should be as brief as possible. Therefore, a pacing rate likely to interrupt atrial flutter should be selected at the outset to minimize the number of pacing attempts required to interrupt atrial flutter.

Precipitation of Atrial Fibrillation (Inadvertent and Deliberate)

Despite appropriate care taken in performing any of these pacing techniques, rapid atrial pacing will provoke atrial fibrillation in some patients. Such atrial fibrillation is usually transient, lasting seconds to minutes, before spontaneously converting to sinus rhythm. When atrial fibrillation persists, it is almost always associated with a slower ventricular response rate than that during atrial flutter. Furthermore, the ventricular rate during atrial fibrillation is usually readily controlled with standard agents. Thus, precipitating atrial fibrillation may be a satisfactory, short-term clinical outcome. In fact, for those patients in whom atrial flutter recurs despite successful interruption by rapid atrial pacing, continuous rapid atrial pacing to precipitate and maintain atrial fibrillation may be indicated (5,112). The latter technique may be especially appropriate in patients who develop transient atrial flutter after open-heart surgery (eFig. 65.4.3) (115).



***e*FIGURE 65.4.3 A:** Electrocardiogram (ECG) lead II recorded simultaneously with a bipolar atrial electrogram (AEG) during typical atrial flutter at a rate of 320 beats/min with 2:1 atrioventricular conduction, producing a ventricular rate of 160 beats/min. After open-heart surgery, the atrial flutter was interrupted successfully on several occasions by rapid atrial pacing but recurred each time. Therefore, as shown in **B**, continuous rapid atrial pacing at 450 beats/min was initiated, which precipitated and sustained atrial fibrillation. This was associated with a slowing of the ventricular rate to approximately 120 beats/min. Continuous rapid atrial pacing to sustain atrial fibrillation to control the ventricular rate was required for 26 hours while antiarrhythmic drugs (digoxin and quinidine) were administered. When rapid atrial pacing was finally terminated, atrial fibrillation spontaneously converted to sinus rhythm. Timelines are 1-second intervals. S, stimulus artifact. (From Waldo AL, MacLean WAH, Karp RB, et al. Continuous rapid atrial pacing to control recurrent or sustained supraventricular tachycardias following open-heart surgery. *Circulation* 176;54:245–250, with permission.)

Direct Current Cardioversion to Convert Atrial Flutter to Sinus Rhythm

DC cardioversion of atrial flutter to sinus rhythm has a very high likelihood of success. It may also require as little as 25 J. However, as 100 J is virtually always successful and virtually never harmful, it should be considered for the initial shock. A high degree of success will thereby avoid the need for delivering a second shock and extending the duration of anesthesia. Low-energy shocks (i.e., less than 3 J and often less than 2 J) delivered between special electrode catheters placed in the coronary sinus and right atrium also have been shown to be highly effective. This latter technique may be applied by using a permanently implanted atrial cardioverter/defibrillator device (116) or during electrophysiology studies to avoid repeated external shocks. It should be noted that when either standard external cardioversion techniques or newer internal cardioversion techniques are used, atrial fibrillation might result. The shock may be delivered during a vulnerable atrial period, as synchronization to the QRS complex is requisite.

Long-Term Treatment

Improvements in the efficacy of catheter-ablation techniques and the long-recognized difficulty in achieving adequate chronic suppression of atrial flutter with drugs have significantly altered the approach to long-term treatment of atrial flutter. In short, if in any patient atrial flutter is an important problem, characterization of the mechanism of atrial flutter followed by catheter ablation (cure) is now recommended.

Antiarrhythmic Drugs

For many years, standard therapy used the class IA antiarrhythmic agents (i.e., quinidine, procainamide, or disopyramide) to prevent recurrence. However, the type IC antiarrhythmic drugs, flecainide and propafenone, appear to be equally, if not more, effective than class IA drugs (15,16). Class IC agents are generally better tolerated and likely have less organ toxicity than class IA agents. Primarily because of serious adverse effects demonstrated in the Cardiac Arrhythmia Suppression Trial I (117), class IC agents should not be used in patients with underlying ischemic heart disease. This notion has generally been extrapolated to include underlying structural

heart disease. However, class IC agents should be considered early on for long-term suppression in patients without structural heart disease.

Moricizine, a class I drug with A, B, and C properties, also may be effective in treating atrial flutter (118). The long-term data from the Cardiac Arrhythmia Suppression Trial II (119) suggested that moricizine and placebo were no different in terms of mortality. Thus, moricizine may be a good choice for patients with atrial flutter and coronary artery disease late (more than 6 months) after myocardial infarction. More data are required to establish efficacy in this clinical setting.

Class III antiarrhythmic agents may also be quite effective (16,17). When using sotalol, care must be taken to avoid QT interval prolongation beyond 500 ms (120) and precipitation of torsades de pointes. Amiodarone appears to be quite effective (17), but several toxicities make widespread use of this drug to treat atrial flutter problematic (121). In fact, several large placebo-controlled studies using low-dose amiodarone (200 mg per day) (although not in patients with atrial flutter) have demonstrated dropout rates as high as 45.0% (122) and 42.5% (123). Thus, using amiodarone as the first-choice drug should be limited to patients with depressed LV function (i.e., an ejection fraction of less than 25%). The safety and efficacy of several other new type III antiarrhythmic agents are currently being evaluated. Dofetilide has recently been marketed for treatment of patients with atrial flutter and fibrillation. Recurrence rates of atrial arrhythmias were similar to sotalol. Like sotalol, caution with regard to QT prolongation and the hazard of torsades de pointes is warranted.

The overall perspective remains that atrial flutter is quite difficult to suppress with drug therapy. In fact, based on available long-term data, drug therapy offers a limited ability to maintain sinus rhythm without occasional to frequent recurrences, even when multiple agents are used (124). Thus, when evaluating drug therapy, an important measure of efficacy should be the frequency of recurrent atrial flutter rather than a single recurrent episode. For instance, recurrence only at long intervals (e.g., once or twice per year) should be classified as successful therapy.

Anticoagulants

The risk of stroke associated with atrial flutter is of concern. An early study (125) found neither evidence of atrial clot formation nor stroke associated with atrial flutter in a relatively small cohort of patients after open-heart surgery. No large prospective studies have been performed to confirm this finding in other patient populations. However, several recent studies (126,127 and 128) indicate that an increased risk of stroke is present in patients with atrial flutter.

Analysis of a Medicare cohort of 17,000 patients with atrial flutter (96) demonstrated a significant increase in the risk of stroke relative to a control population. This risk was concentrated entirely in those patients with atrial flutter who later experienced atrial fibrillation (Fig. 65.5). Unfortunately, no combination of clinical factors in this study could predict which patients with atrial flutter would develop atrial fibrillation. At present there is no consensus statement on the use of anticoagulation in patients with atrial flutter, whether it be acute, ablated, recurrent, or chronic. However, given the above studies, administering warfarin therapy to achieve an international normalized ratio of 2 to 3 is strongly recommended. Anticoagulation for the acute cardioversion of atrial flutter should require the same standards as used for the acute cardioversion of atrial fibrillation.

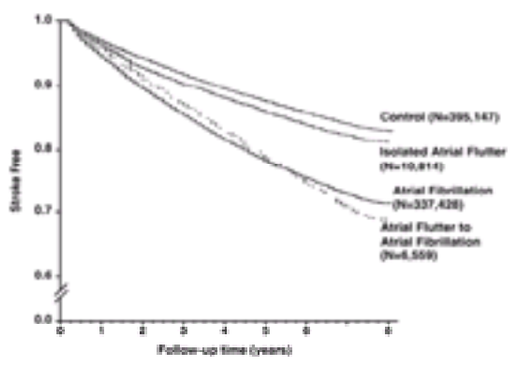


FIGURE 65.5 Medicare patients with an index hospitalization for atrial flutter were followed and compared with atrial fibrillation and control cohorts. The risk of stroke was concentrated almost entirely in the atrial flutter patients, who were rehospitalized at a later time with atrial fibrillation. (From Biblo LA, Yuan Z, Quan KJ, et al. Risk of stroke in patients with atrial flutter. *Am J Cardiol* 2001;87:346–349, with permission.)

Catheter Ablation

Catheter ablation primarily uses radiofrequency energy delivered to selected portions of the heart by an electrode catheter. Initially, success in atrial flutter ablation was reportedly at 60% to 70%, with subsequent recurrence rates of approximately 50% (19,20). However, recent advances in both mapping and ablation techniques have improved efficacy rates to approximately 95%, with little subsequent risk of recurrence (129,130 and 131).

Catheter ablation first involves mapping the atria during atrial flutter to identify a critical isthmus of slow conduction in the atrial flutter reentrant circuit. When this area is identified, usually the atrial flutter isthmus, ablative energy is delivered to create a line of bidirectional block. This isthmus has irregular topography and therefore in some cases may be difficult to ablate successfully. In fact, it was believed that this was the principal cause of most ablation failures. However, combined pacing and mapping techniques have improved, allowing for the reliable determination of complete bidirectional conduction block in this region (132,133,134 and 135).

It must be emphasized that electrode catheter mapping and pacing are necessary not only to demonstrate the completeness of block in the atrial flutter isthmus, but also to confirm the critical participation of the atrial flutter isthmus. Although most types of atrial flutter are isthmus-dependent, atrial flutter can also be due to reentry in the right atrial free wall or in the left atrium. Finally, successful ablation of the atrial flutter reentrant circuit usually does not prevent the occurrence of atrial fibrillation (136,137).

Recently, a catheter ablation experience was reported in patients with left atrial flutter (138). Complete atrial mapping was used to identify a vulnerable isthmus for ablation. Variability was present in circuit locations; however, a left atrial “silent area” characterized most patients with this entity. The area of presumed atrial fibrosis appeared to create a lateral border, stabilizing rotation around the mitral valve.

Ablation has proven effective in lesion reentry atrial tachycardia, as well. In these patients, the lesion is often due to an atriotomy scar after a remote cardiac surgical procedure. Radiofrequency energy is used to extend the scar to a fixed anatomic border (often the tricuspid valve). Thus, rotation of the reentrant circuit around the scar is no longer possible, and the patient is cured of this tachycardia.

For patients in whom the atrial flutter is resistant to catheter ablation, reassessment of the mechanism of the atrial flutter must ensue. Entrainment techniques should be repeated to ensure the proper circuits and mechanisms have been delineated. Resistant atrial flutter (139) is often due to abnormalities in the atrial flutter isthmus region. Anatomic formations such as an unusually large isthmus or a deep, corrugated subeustachian pouch may be present. High-gain, low-noise signals are required to adequately record conduction gaps. Failure rates have declined greatly as a result of these careful and systematic approaches to atrial flutter ablation.

Summary

Atrial flutter is primarily due to reentrant excitation in the right atrium using the subeustachian isthmus. The 12-lead ECG remains the cornerstone for clinical diagnosis. Acute treatment requires control of the ventricular rate and, if possible, restoration of sinus rhythm. Antiarrhythmic drugs to suppress recurrent episodes of atrial flutter may prove useful but are now clearly second-tier therapy in symptomatic patients with atrial flutter. At present, catheter ablation provides a definitive cure, although atrial fibrillation may occur after a successful ablative procedure.

ATRIAL TACHYCARDIA

Background and Classification

The term *atrial tachycardia* encompasses several types of tachycardias that originate in the atria. In the past, classification schemes were largely descriptive and included terms such as *paroxysmal* or *incessant atrial tachycardia* and *atrial tachycardia with block*. Now the term *atrial tachycardia* refers to relatively regular arrhythmias that originate in the atria, do not require participation of the AV node for maintenance, and are neither atrial flutter nor atrial fibrillation. The

subclassifications of atrial tachycardia are based on the mechanisms involved and include reentrant atrial tachycardia, ectopic automatic tachycardia, and triggered atrial tachycardia.

A 57-year-old female patient with atrial tachycardia and 2:1 atrioventricular conduction.

Mechanisms of Atrial Tachycardia

It is generally accepted that there are three different mechanisms responsible for atrial tachycardia: (a) intraatrial reentry, (b) ectopic automaticity, and (c) triggered activity due to delayed afterdepolarizations (DADs). Surprisingly, the details of the reentrant circuit in atrial tachycardia have not been well studied. Consequently, the characteristics of the reentrant circuit are not well delineated.

Atrial tachycardia due to an ectopic automatic focus also has not been well studied. The tachycardias described to date appear to be generated by a focus or foci that cluster around the crista terminalis in the right atrium and around the base of the pulmonary veins in the left atrium (140,141). These tachycardias can be neither initiated nor terminated by atrial pacing.

Triggered activity as a mechanism of atrial tachycardia is thought to be due to DADs largely from digitalis toxicity, but catecholamines can also precipitate atrial tachycardia induced by this mechanism (142). DADs caused by catecholamines have been recorded in the canine heart by microelectrodes placed in atrial fibers of the mitral valve (143), in atrial fibers lining the coronary sinus (144), and in atrial fibers in the inferior right atrium (145). They have also been recorded in human hearts with CM (146).

A recent publication (147) has classified atrial tachycardias as focal or macroreentrant. Focal tachycardia was defined on the basis of (a) centrifugal activation pattern, (b) dissociation of nearly the entire right and left atria from the tachycardia with programmed atrial extra-stimuli, (c) and the absence of entrainment criteria. Macroreentry was defined if initiated or terminated with programmed stimulation and one of the following: (a) continuous electrical activity throughout the cardiac cycle with low-amplitude fractionated signals or (b) any of the entrainment criteria.

The focal versus macroreentrant classification is of benefit in the electrophysiology laboratory but cannot be directly extrapolated to “macroreentrant equals intraatrial reentry” and “focal equals triggered or automatic.” Features consistent with automatic atrial tachycardia were failure to initiate or terminate with programmed stimulation, transient suppression with adenosine, and insensitivity to verapamil. Features consistent with triggered activity were repetitive monomorphic atrial tachycardia, initiation and termination with programmed stimulation, and sensitivity to adenosine and verapamil. Most, but not all, macroreentrant atrial tachycardias were insensitive to adenosine. Those macroreentrant tachycardias that terminated with adenosine were believed to use decremental tissue (outside the AV node).

A new mechanism has also recently been reported: lidocaine-sensitive atrial tachycardia (148). This report describes eight patients with a unique atrial arrhythmia that was suppressed by lidocaine. The arrhythmia could not be initiated or terminated with pacing, making reentry less likely. The arrhythmia occurred at slow heart rates and did not respond to verapamil, making DADs less likely. Overdrive suppression was absent, making automaticity unlikely. The authors speculate that early DAD-like activity in the atria may be responsible for this entity.

Epidemiology and Clinical Significance

The incidence of atrial tachycardia appears to increase with age, reportedly occurring in up to 13% of elderly patients (149,150 and 151). An increased incidence has been reported in patients with myocardial infarction (152,153), nonischemic heart disease (154,155), obstructive lung disease (156), serum electrolyte disorders, and drug toxicity, especially from digitalis (157,158). However, atrial tachycardia may occur in healthy individuals (159,160), and nonsustained episodes have been noted in 2% of healthy young adults (161,162). Most episodes of atrial tachycardia are paroxysmal (usually due to reentry or triggered activity), but some may be incessant (usually due to enhanced automaticity) (163). In patients with incessant tachycardia, a tachycardia-induced CM may result.

Intraatrial Reentry

Patients with reentrant atrial tachycardia often have associated structural heart disease (164,165). In addition, many of these patients have other arrhythmias, specifically atrial fibrillation, atrial flutter, or both. Common symptoms include palpitation, dyspnea, and fatigue. Although patients with this tachyarrhythmia are usually symptomatic, hemodynamic compromise is unusual. Syncope and near-syncope may occur if the underlying heart disease is severe or if the ventricular rate is rapid; however, 2:1 AV conduction very frequently is present so that the ventricular response rate is well controlled (90 to 120 beats/min).

Automatic Atrial Tachycardia

Patients with atrial tachycardia secondary to an automatic mechanism are generally younger, with a mean age of 30 years (165). In fact, automatic atrial tachycardias have been well described in children (166). Automatic atrial tachycardias demonstrate a warm-up phenomenon, do not respond to vagal maneuvers, and often display an incessant nature. When incessant, they are frequently associated with a dilated CM and CHF (165,166).

Triggered Atrial Tachycardia

Atrial tachycardia due to a triggered mechanism appears to be the least common of these tachyarrhythmias. In one series, the mean age of patients was 60 years, and in no instance was the triggered atrial arrhythmia incessant (165). This feature may help clinically distinguish this mechanism from an automatic mechanism, in which the atrial tachyarrhythmia frequently is incessant.

Physical Examination and Associated Hemodynamic Effects

In patients with atrial tachycardia, the findings on physical examination are similar to those of atrial flutter. The atrial rate of the tachycardia will usually determine the ventricular rate. Thus, at relatively slower atrial rates (140 to 150 beats/min) the ventricular response is most often 1:1. With faster atrial rates, variable AV conduction often results, although 1:1 AV conduction at up to rates of 180 beats/min or more may occur. However, with faster atrial rates, 2:1 AV conduction is usually present. The nature of AV conduction may be affected by drugs such as digoxin, calcium channel blockers, or beta-blockers. Adverse hemodynamic effects are more common in patients with 1:1 AV conduction and associated atrial rates of 180 beats/min or more.

Diagnosis

The initial diagnosis of atrial tachycardia is made by the atrial rate (usually 140 to 240 beats/min), on analysis of the 12-lead ECG. However, the range of both the atrial and the ventricular rates may overlap with that of AV nodal–dependent tachycardias and sinus tachycardia. Atrial tachycardia may be confused with atrial flutter if AV conduction is 2:1.

A standard way to determine the presence or absence of an AV nodal–independent atrial tachycardia is to demonstrate that with AV conduction block, the rhythm continues (Fig. 65.6). However, as seen from the following discussion, the confounding effects of many diagnostic interventions can make such differentiation quite

difficult.

FIGURE 65.6 A: A 12-lead electrocardiogram was recorded in a 37-year-old man 29 years after repair of tetralogy of Fallot. The patient noted recurrent palpitation associated with lightheadedness. This 12-lead electrocardiogram documented a tachycardia in which the QRS complex morphology was quite similar to that recorded during sinus rhythm. No P waves could be readily identified. **B:** A Valsalva maneuver induced transient, high-degree atrioventricular block. The underlying atrial tachycardia (cycle length of 360 ms) was then easily demonstrated.

Intraatrial Reentry

In patients with reentrant atrial tachycardia, the rhythm generally can be induced by programmed electrical stimulation. During the arrhythmia, the criteria for either manifest or concealed entrainment usually can be demonstrated, and the interval between the initiating beat and the first beat of the atrial tachycardia is usually inversely related (165). These observations strongly suggest a reentrant mechanism.

As noted in this chapter, terminating a supraventricular tachycardia by a drug that causes transient conduction block (second-degree or third-degree) at the AV node generally would be expected to suggest a diagnosis of an underlying AV nodal–dependent reentrant tachycardia. However, in one reported study (165), adenosine terminated 24 of 27 ostensibly reentrant tachycardias, although in another study (167), in none of the five patients with intraatrial reentrant tachycardia did administration of adenosine affect the tachycardia. The different responses to adenosine observed in these two studies emphasize the need to characterize these rhythms more thoroughly. In any event, termination of an atrial tachyarrhythmia after intravenous administration of adenosine cannot be used per se to characterize the rhythm as AV nodal–dependent. The same seems to be true for beta-blockers, as their use terminated an ostensibly reentrant atrial tachycardia in 13 of 20 patients in one study (165), although they had no effect in three patients reported in another study (167).

Automatic Atrial Tachycardia

Automatic atrial tachycardia may be induced during treadmill testing or after administration of isoproterenol (165,167). Predictably, programmed atrial stimulation will neither initiate nor terminate atrial tachycardia due to this mechanism (145). Propranolol has been shown to suppress putative automatic atrial tachycardias, but neither verapamil nor adenosine has been shown to do so. However, adenosine may transiently slow the atrial rate (165,167).

Triggered Atrial Tachycardia

Triggered atrial tachycardia can be initiated by rapid atrial pacing and has been shown to be cycle length–dependent (165). The onset of the arrhythmia induced by pacing is not pause-dependent. Because these rhythms can be caused by catecholamines, it should not be surprising that isoproterenol and treadmill testing may initiate this form of atrial tachycardia in some patients. Monophasic action potential recording may suggest DADs, and entrainment criteria should not be present. Verapamil and adenosine have been shown to terminate this form of atrial tachycardia.

Summary

The small number of published studies indicates the complexity of identifying the correct underlying mechanism of an atrial tachycardia. Invasive electrophysiologic studies have become an important tool in characterizing the mechanism of this arrhythmia. Induction by programmed stimulation with fulfillment of any of the criteria for entrainment lends support to a reentrant mechanism. The inability to induce or entrain the arrhythmia suggests, but does not prove, either an automatic or triggered mechanism. Thus, when programmed stimulation cannot induce the arrhythmia, successful termination with adenosine suggests a triggered etiology, whereas slowing of the arrhythmia by adenosine suggests an automatic mechanism. Additional insights can be garnered by mapping studies.

Treatment

Reentrant Atrial Tachycardia: Catheter Ablation

For reentrant atrial tachycardia, catheter ablation is now the primary therapy for symptomatic patients. However, radiofrequency ablation appears to be more challenging in these patients than in patients with atrial flutter because the location of the reentrant circuit is not as anatomically consistent as that in most patients with atrial flutter (141). Regardless, if a vulnerable isthmus in a reentrant circuit is found, ablation should prove effective. Reports on catheter ablation for reentrant atrial tachycardia have suggested a success rate of more than 75% (168,169).

Reentrant Atrial Tachycardia: Antiarrhythmic Drugs

Antiarrhythmic drug therapy for reentrant atrial tachycardia is similar to that for atrial flutter and atrial fibrillation. The important message is that overall efficacy as measured by simple recurrence is poor because this rhythm tends to recur in at least half of patients treated. The measure of drug efficacy should be the frequency of recurrence. Occasional arrhythmic recurrences may be quite acceptable in these patients because recurrences are rarely life-threatening and are usually well tolerated. Thus, should the arrhythmia recur and if it does not revert spontaneously, cardioversion to sinus rhythm should be considered. The patient should then be followed on the same antiarrhythmic regimen. When recurrences are too frequent or intolerable, the pharmacologic regimen should be changed. Finally, reentrant atrial tachycardia can be acutely treated with rapid atrial pacing techniques virtually identical to those used to treat atrial flutter.

Nonreentrant Atrial Tachycardia

Patients with nonreentrant atrial tachycardia who have minimal symptoms should be treated with either a beta-blocker or a calcium channel blocker. Automatic atrial tachycardia appears more responsive to beta-blockers, whereas triggered arrhythmias appear to respond best to calcium channel blockers. Extrapolation from acute studies suggests that such therapy is logical (Fig. 65.7). For patients in whom the tachycardia is due to digitalis toxicity, the dose of digitalis should either be stopped or reduced. In patients with clinically important symptomatic or incessant nonreentrant atrial tachycardia, catheter ablation is preferred. A combination of pace mapping, entrainment analyses, and identification of the earliest atrial activation site at electrophysiologic study are complementary methods to ensure an excellent ablative result. Long-term results are excellent (170).

FIGURE 65.7 A 27-year-old woman complained of episodic palpitation. The 12-lead electrocardiogram (ECG) documented salvos of an atrial tachycardia. An echocardiogram was normal. At electrophysiologic study, an arrhythmia was not induced by programmed stimulation. Initial therapy with a beta-blocker proved ineffective, but subsequent therapy with diltiazem resulted in complete suppression of the arrhythmia.

Summary

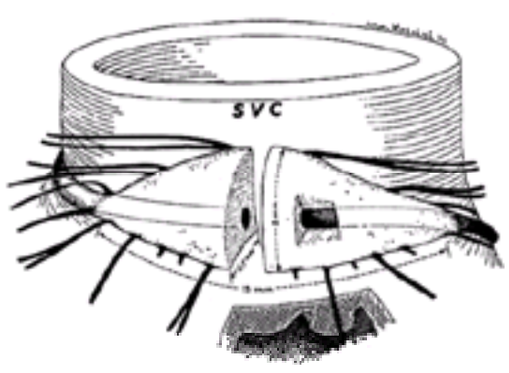
Atrial tachycardia encompasses a wide spectrum of clinical presentations and mechanisms. Current classification schemes focus on mechanism. Therapy should be aggressive for those patients with significant symptoms, and whenever possible radiofrequency ablation is preferable. Despite the mechanistic heterogeneity of atrial tachycardia, radiofrequency catheter ablation is usually successful. Drug therapy remains an acceptable alternative for minimally symptomatic patients with an atrial tachyarrhythmia.

INAPPROPRIATE SINUS TACHYCARDIA

Background

Sinus rhythm is generated by spontaneous phase 4 depolarization of pacemaker cells located in the sinus node. The sinus node lies just beneath the subepicardial surface and is located at the junction of the superior vena cava and the right atrium. As summarized by MacLean et al. (171), the sinus node artery is perhaps the best guide to locating the sinus node. The sinus node artery arises from the proximal 2 to 3 cm of the right coronary artery in 55% of human hearts and from the proximal few millimeters of the left circumflex artery in 45%. Other origins are quite rare. Regardless of origin, the sinus node artery courses along the anterior aspect of the ipsilateral atrial wall to the base of the superior vena cava, which it then encircles.

The exact position of the sinus node varies with the manner of encirclement of the superior vena cava by the sinus node artery. The sinus node is more anterior when the artery courses clockwise when viewed from above. The position of the sinus node can be determined grossly as the point where the artery can no longer be easily dissected from the epicardium. At that point, the sinus node completely surrounds the artery and is located just beneath the epicardium and just below the sulcus terminalis. The anterior margin of the node sits very close (1 to 10 mm) to the crest formed by the junction of the anterior margin of the right atrial appendage and the superior vena cava. The posterior margin is at the junction of the trabeculated right atrium and the sinus intercavarum. The sinus node is shaped like “Napoleon’s hat” and measures approximately 15 mm in length, 5 mm in height, and 1.5 mm in thickness (*e*Fig. 65.7.1). It has neither a head nor a tail, despite common references to these terms. The inferior margins of the sinus node abut on the antrum atrii dextri, which is the endocardial recess between the crista terminalis and the lateral wall of the right atrium.



***e*FIGURE 65.7.1** This drawing illustrates the location and shape of a normal human sinus node and demonstrates the anatomic relationship between the sinus node and the sinus nodal artery. SVC, superior vena cava. (From MacLean WAH, Waldo AL, James TN. Formation and conduction of the cardiac electrical impulse. In: Yu PN, Goodwin JF, eds. *Progress in cardiology*. Philadelphia: Lea & Febiger, 1974:37–74, with permission.)

The sinus node possesses the fastest rate of normal automaticity in the heart. This rate is determined by the rate of rise of phase 4 depolarization, the level of the threshold potential, and the level of the maximum diastolic potential of the pacemaker cell. The sinus rate in humans is normally 60 to 100 beats/min. Alterations in sinus rate primarily depend on the influence of autonomic innervation and secondarily on variations in local environment (e.g., pH, potassium, oxygen partial pressure, calcium, and cardioactive drugs).

Sinus tachycardia is usually the result of an appropriate reflex-controlled response. In adults, *sinus tachycardia* is defined as a rhythm originating from the sinus node at a rate of more than 100 beats/min. The normal maximum heart rate achieved by adults during strenuous exercise is rarely more than 180 beats/min, and it can be calculated using the formula of 220 minus the patient’s age (years). Sometimes during sinus tachycardia, the P-wave morphology in the ECG may change subtly compared with that during sinus rhythm. Such changes associated with rate are thought to represent a shift in the location of the dominant pacemaker cells in the sinus node area, with a consequent change in the initial excitation of the atrium. Treatment of appropriate sinus tachycardia rarely is directed at the sinus node pacemaker, but rather at the underlying trigger. Thus, management first focuses on identifying and then treating the underlying precipitant. A long list of potential causes of appropriate sinus tachycardia includes infection, hypotension, anemia, dehydration, hyperthyroidism, and pheochromocytoma.

In recent years, a syndrome originally called *nonparoxysmal sinus tachycardia* (172), but now called *inappropriate sinus tachycardia*, has been described (173). This entity is characterized by an incessant and symptomatic sinus tachycardia due to inappropriately enhanced automaticity of sinus node pacemaker cells.

Potential Mechanisms

There is only limited information available about the potential mechanisms of inappropriate sinus tachycardia because only a small number of patients have been studied and reported. One study (172) in which inappropriate sinus tachycardia was defined as an atrial rate of more than 100 beats/min on all waking ECGs for 3 months with no demonstrable underlying cause described seven patients with this syndrome. Each patient underwent invasive electrophysiologic testing to exclude a reentrant arrhythmia. Based on resting heart rate responses to propranolol, excessive sympathetic tone was noted in two patients, and deficient resting vagal tone was noted in the other five patients. Three of the seven patients demonstrated an abnormal intrinsic heart rate. The P-wave morphology on the 12-lead ECG was normal.

Another study (173) described six patients with this syndrome. Inappropriate sinus tachycardia was defined as the following:

1. An atrial rate of 100 beats/min or more at rest or with minimal activity
2. A normal P-wave axis and morphology on 12-lead ECG during tachycardia
3. Absence of an underlying cause

The cardiovagal response in these patients as judged by the cold pressor test was blunted compared with that in normal patients. Hypersensitivity to isoproterenol was

noted in all patients. A high intrinsic heart rate (mean of 129 beats/min) was noted in all patients after administration of intravenous propranolol and atropine. Based on the results of complete autonomic blockade, Morillo et al. (173) concluded that the major abnormality in this syndrome appears to be a primary sinus node abnormality exacerbated by autonomic dysfunction.

In still another study of 16 patients (174), the resting sinus rate was not significantly different from the resting heart rate after catheter ablation of the sinus node (85.5 ± 7.8 beats/min versus 79.0 ± 4.9 beats/min). However, the mean baseline measurement of intrinsic heart rate (118.6 ± 8.6 beats/min) was significantly higher than the mean predicted intrinsic heart rate (97.7 ± 1.7 beats/min; p <.01). However, the intrinsic heart rate was within normal range in five of the 11 patients who had a baseline measurement. Patients who underwent exercise treadmill tests had an inappropriate chronotropic response to a light workload (mean heart rate of 141.2 ± 5.1 beats/min after only 1.5 minutes of stage 1 of the Bruce protocol).

In summary, the mechanism of this entity is not well understood, and there is a clear need for improved understanding. It appears that inappropriate sinus tachycardia may be due to enhanced automaticity of sinus node pacemaker cells, a dysautonomia, or both. The dysautonomia appears to include beta-adrenergic hypersensitivity and depression of the efficient cardiovagal reflex, often superimposed on an abnormally high intrinsic heart rate.

Epidemiology and Clinical Significance

Patients with inappropriate sinus tachycardia usually are relatively young and have an abnormally high resting heart rate. This rate increases disproportionately with activity. Patients frequently are disabled by persistent palpitations, extreme dyspnea, chronic fatigue, and near syncope. It is noteworthy that patients frequently have been called neurotic. To date, many of the patients described with this syndrome have been health care employees. Patients reported to date (173,174) have been overwhelmingly female. The heart rate varies with activity but appears to be set 30 to 40 beats/min higher than normal. Surreptitious drug use and Munchausen syndrome must be excluded. During sinus tachycardia, stroke volume is maintained due to a complex interplay of neurohumoral reflexes and changes in peripheral resistance. Thus, in contrast to other atrial tachyarrhythmias, adverse hemodynamic findings are infrequently observed during sinus tachycardia despite rapid rates. Nevertheless, with sustained rapid ventricular rates, a dilated CM may evolve. Although no instances of an inappropriate sinus tachycardia–induced CM have been reported, we have treated one patient with inappropriate sinus tachycardia and an idiopathic CM. In this patient, LV ejection fraction improved from 44% to 67% after radiofrequency modification of the sinus node with associated normalization of the heart rate. The patient also improved clinically from New York Heart Association class III heart failure to class I heart failure.

Diagnosis

To diagnose inappropriate sinus tachycardia, the following criteria should be satisfied:

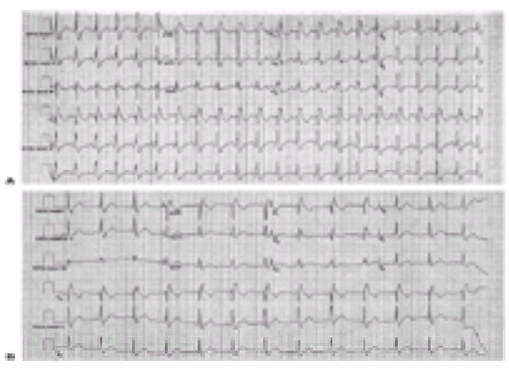
1. The resting heart rate should be 100 beats/min or more or should increase to 100 beats/min or more with minimal exertion (e.g., when rising from the sitting position or when walking slowly).
2. The P-wave morphology and axis in the 12-lead ECG during the tachycardia should be quite similar or, better still, identical to that during sinus rhythm.
3. Secondary causes of sinus tachycardia (e.g., fever, anemia) should be excluded.
4. Symptoms of palpitation, presyncope, or both should be documented to be related to resting or easily provoked sinus tachycardia to differentiate inappropriate sinus tachycardia from severely deconditioned individuals who may otherwise fulfill the above criteria.

Additional testing should prove helpful. Thus, electrophysiologic testing should demonstrate that the tachyarrhythmia could not be initiated or terminated by atrial pacing techniques. In addition, atrial mapping should show that the tachycardia originates from the sinus node region. Producing autonomic blockade to identify the so-called intrinsic sinus rate may not prove helpful to diagnosis because approximately half of patients with this syndrome may have a normal intrinsic sinus rate, which supports the notion that this syndrome may have more than one etiology.

Sinus tachycardia with blocked premature atrial contraction. Premature atrial beat fails to conduct, producing a pause.

Treatment

Finding effective drug therapy for patients with this syndrome is often quite difficult. However, beta-blockers appear to be the most effective for ameliorating symptoms by normalizing heart rate. Effectiveness of therapy is best judged by serial 24-hour ambulatory ECGs (Holter monitor). Sinus node ablation or modification using radiofrequency energy and electrode catheter techniques recently has proven to be effective (174,175). Ablation of the sinus node appears to be more effective when guided by activation mapping (176) to identify the appropriate endocardial ablation sites. Successful sinus node ablation is often associated with a superior shift in the P-wave axis (*e*Fig. 65.7.2). Long-term results vary considerably from institution to institution, with success in up to 66% of patients.



***e*FIGURE 65.7.2 A:** A 40-year-old former health care worker presented with fatigue and dyspnea. The 12-lead electrocardiogram (ECG) documented sinus tachycardia with a right bundle branch block pattern. A 24-hour ambulatory ECG monitor recording showed a mean sinus rate of 120 beats/min. Cardiac catheterization showed normal coronary artery anatomy but a globally dilated left ventricle with an estimated left ventricular ejection fraction of 0.25. **B:** After sinus node modification using catheter-based radiofrequency energy, a 12-lead ECG documented a change in P-wave morphology and rate. A 24-hour ambulatory ECG monitor recording obtained after the ablation documented a mean heart rate of 85 beats/min. This was associated with resolution of all symptoms. Two months later, the left ventricular ejection fraction returned to normal.

Summary

Inappropriate sinus tachycardia is a newly described entity that appears to be rare. The entity remains largely descriptive but may be due to a dysautonomia or a

primary sinus node abnormality. Before initiating definitive therapy, the physician must carefully search for an underlying precipitant.

SINUS NODE REENTRANT TACHYCARDIA

Background

Sinus node reentrant tachycardia is believed to be due to reentry within the tissue in or near the sinus node. This tachycardia is characterized by an atrial rate of 105 to 150 beats/min and a P-wave morphology in the ECG similar to that of sinus rhythm (Fig. 65.8). Marked variation in cycle length during tachycardia is very common.

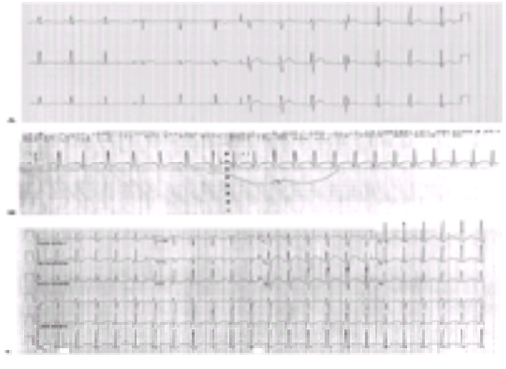


FIGURE 65.8 A: A 64-year-old man complained of episodic palpitation. A baseline 12-lead electrocardiogram (ECG) documented normal sinus rhythm. **B:** A telemetry strip documented the abrupt onset of tachycardia, which proved to be due to sinus node reentry. **C:** A 12-lead ECG obtained during palpitation showed that the P-wave morphology was quite similar to that on the baseline ECG.

Mechanism

As is evident from its name, this rhythm is due to reentry involving the sinus node and perinodal tissue. It usually can be reproduced during electrophysiologic study using standard programmed pacing techniques in the atria. Vagal maneuvers and administration of adenosine or verapamil terminate the arrhythmia (177). A noticeable association with coronary artery disease—specifically with inferior myocardial infarction—has led to speculation that ischemia or infarction in the sinus node area may provide the milieu for reentry.

Epidemiology and Clinical Significance

The majority of patients with sinus node reentrant tachycardia have structural heart disease. Sinus node reentry tachycardia can be associated with any of the classic symptoms associated with any tachycardia, including palpitation, dyspnea, near-syncope, or syncope (see Atrial Flutter: Epidemiology and Clinical Significance) (178,179). Although associated tachycardias have been believed to occur infrequently, one recent study noted one or two additional tachyarrhythmias (atrioventricular nodal reentrant tachycardia, atrioventricular reentrant tachycardia, bundle branch reentrant tachycardia, atrial tachycardia) in nine of 11 patients (179). In patients with prolonged, sustained sinus node reentrant tachycardia, dilated CM may result.

Diagnosis

The rhythm is characterized by rapid rates (usual range of 120 to 150 beats/min) in which the P-wave morphology in the 12-lead ECG is virtually identical to that during sinus rhythm. Its spontaneous onset and offset are abrupt. The tachycardia behaves classically to interventions known to perturb or interrupt ordered reentrant rhythms. Thus, the tachycardia can be initiated or terminated with atrial pacing techniques; it can also be terminated with adenosine or with maneuvers that increase vagal tone. Mapping during electrophysiologic study demonstrates an atrial activation sequence similar to that of sinus rhythm.

Treatment

Intravenous adenosine and verapamil as well as vagal maneuvers have been used over the short term to terminate sustained episodes of sinus node reentry tachycardia. In several small series of studies, radiofrequency ablation of the sinus node region has been shown to prevent recurrence of sinus node reentrant tachycardia (180). Long-term drug therapy has not been systematically studied. However, digitalis, a calcium channel blocker, or a beta-blocker alone or in combination may prove effective.

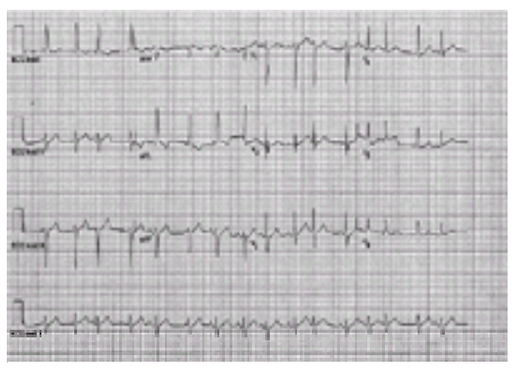
Summary

Sinus node reentrant tachycardia is an infrequent tachyarrhythmia. Definitive therapy with catheter ablation should prove successful.

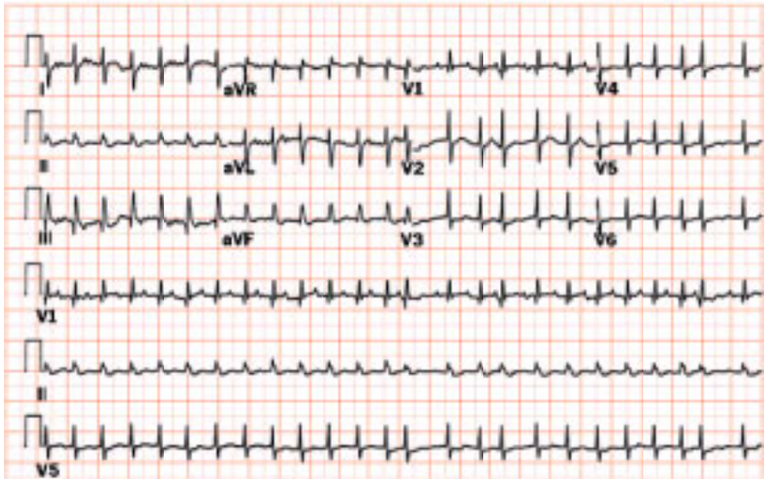
MULTIFOCAL ATRIAL TACHYCARDIA

Background

MAT remains largely a descriptive entity with a need for better characterization (181). MAT is usually diagnosed by ECG criteria that include an atrial rate of more than 100 beats/min with P waves of at least three distinct morphologies. Diagnosing MAT can be difficult. The chaotic nature of its P-wave morphology with varying AV intervals frequently may cause it to be confused with atrial fibrillation (*e*Fig. 65.8.1).



***e*FIGURE 65.8.1** This 12-lead electrocardiogram (ECG), obtained from a 70-year-old man with severe obstructive lung disease, demonstrated multifocal atrial tachycardia. There were more than three different P-wave morphologies. The tachycardia in this example occurs at a relatively slow rate; however, it is shown here because the multiple P-wave morphologies can be well seen.



Multifocal atrial tachycardia. Narrow-complex tachycardia associated with three or more different P-wave morphologies.

Potential Mechanism(s)

The mechanism(s) underlying MAT remain unknown. Several reports have noted that MAT cannot be induced or initiated by programmed stimulation. Thus, reentry seems an unlikely mechanism. Anecdotal reports of successful treatment of MAT with calcium channel blockers or beta-blockers are consistent with both automatic and triggered mechanisms.

Epidemiology and Clinical Significance

MAT is often observed in patients with acute pulmonary disorders and associated hypoxia. Patients with MAT usually are acutely ill and often are receiving beta-agonists or theophylline preparations. As such, both beta-agonists and theophylline have been causally implicated. There are no data to support these observations as more than associations. Regardless, it seems reasonable to discontinue these agents in affected patients. Anecdotal reports have also noted an association of MAT with pulmonary embolism, coronary artery disease, CHF, and electrolyte disturbances.

Treatment

The therapeutic issues revolve around the extent to which the rapid ventricular response rate during MAT affects the clinical condition of the patient. If ventricular response can be controlled, which is usually difficult, MAT per se probably will not affect the patient's clinical course.

The basis for therapy should primarily be correction of the underlying pulmonary problem. DC cardioversion has not proved successful in patients with MAT. Only limited experience has been reported with use of standard antiarrhythmic drugs. Beta-blockers have been used successfully in selected patients. Precipitation of bronchospasm may be a potentially fatal complication when beta-blockers are used in acutely ill patients. Thus, short-acting $beta_1$-specific agents such as esmolol seem most appropriate for initial use. Calcium channel blockers have been used with limited success.

Beta-Blockers

Arsura et al. (182) compared both beta-blockers and calcium channel blockers in a blinded crossover study of patients with MAT. During this 22-month study, 16 of 79 consecutive patients with MAT were randomly assigned to placebo, verapamil, or metoprolol. Of the nonrandomized patients, unstable blood pressure and audible wheezing accounted for most of the exclusions. Patients were given either placebo or verapamil, 5 mg intravenously over 5 minutes, or metoprolol, 5 mg intravenously over 5 minutes. A statistically significant difference in the net decrease in heart rate was observed only when patients treated with metoprolol were compared with patients treated with placebo. Metoprolol-treated patients showed a decrease in heart rate of approximately 25%. Six of the study patients died during hospitalization. Unfortunately, this mortality does not differ from that reported in other studies. Although the data set is obviously small, Arsura et al. (182) cautiously concluded that in selected patients beta-blockers may play a role in the treatment of patients with MAT. It remains questionable whether antiarrhythmic drugs can affect outcome in this dramatically ill group of patients.

Calcium Channel Blockers

Salerno et al. (183) investigated the use of calcium channel blockers in treating patients with MAT. There has been concern regarding use of intravenous calcium channel blockers because of the potential of vasodilation-induced hypotension. Intravenous verapamil was administered at doses of up to 1 mg per minute to 16 consecutive patients with MAT. The mean heart rate decreased from 129 to 101 beats/min. Sinus rhythm was restored in eight patients. Patients who received pretreatment with calcium (1 g of calcium gluconate intravenously over 1 to 2 minutes) showed a systolic blood pressure drop of 11%. However, systolic blood pressure dropped by 27% in those patients who were not pretreated with calcium gluconate. No differences in antiarrhythmic efficacy were observed between the two groups. Salerno et al. (183) concluded that pretreatment with intravenous calcium gluconate was reasonable in patients receiving verapamil for MAT.

Nonpharmacologic Methods

A recent report (184) has advocated AV junction ablation and permanent pacing for those patients with refractory MAT. In this series, both improvement in quality of life and LV function was noted. Of note, right ventricular function did not improve. This study was not powered to examine mortality. Thus, this therapy should be reserved only for extremely symptomatic patients.

Summary

In summary, when precipitating causes of MAT have been corrected, specific drug therapy may be reasonable to help slow the ventricular rate. Although it appears logical that slowing of the ventricular rate would be desirable, there are no data supporting a meaningful change in outcome in these patients by such treatment. MAT remains a paraphenomenon. As such, therapy should not focus on the arrhythmia. The underlying cardiopulmonary substrate must be engaged therapeutically, with little emphasis placed on the arrhythmia.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Clinical Presentation

A chronic or frequent atrial tachyarrhythmia can lead to ventricular dilatation and CHF. The full spectrum of symptoms associated with cardiac dysfunction is possible from pulmonary edema to a nonspecific cough. We believe that this syndrome, tachycardia-induced CM, is grossly unrecognized. Many nonischemic CMs may be entirely due to such an incessant arrhythmia. Equally important, frequent episodes of atrial tachyarrhythmias may exacerbate underlying cardiac disease, resulting in an exacerbation of symptoms and a worsening quality of life. We believe that many physicians attribute such a decompensation to the progression of underlying coronary disease, valve disease, and so forth. The possibility that the frequent arrhythmia is the culprit must be recognized and appropriately treated to ensure the best outcome for each patient. Not only must cardiologists recognize this possibility, but front-line physicians (e.g., internists and family practitioners) must screen for this diagnostic possibility as well.

Therapy

The traditional initial treatment for most AV nodal–independent atrial arrhythmias has been antiarrhythmic drugs. An increasing volume of data has confirmed an excessive mortality risk in those patients with structural heart disease who have been treated with class IA or class III antiarrhythmic drugs. Thus, catheter ablation should assume a greater role as primary therapy for many atrial arrhythmias in these patients.

THE FUTURE

A more thorough understanding of the mechanisms of atrial arrhythmias has brought this field to the forefront of cardiology. More advances in understanding the underlying mechanism(s) of atrial arrhythmias will enable us to better target medications for specific rhythm disturbances. Advances in mapping techniques in the electrophysiology laboratory will further ensure more successful treatment of patients with atrial arrhythmias. Sophisticated mapping systems using a single intracavitary probe or thoracic multielectrode vests will facilitate identification of target sites for successful ablation. A “Star Wars”-like atmosphere has occurred in the electrophysiology laboratory. More advanced systems will decrease the time needed for testing, the radiation exposure to patients and practitioners, and the complication rates to patients undergoing these procedures.

To date, with most atrial arrhythmias, the mechanistic approach has used whole organ physiology. However, a mechanistic approach emphasizing molecular genetics will evolve, and therapies analogous to those under way in patients with long QT syndrome will become commonplace.

OVERVIEW

Atrioventricular (AV) nodal–dependent tachycardias comprise a specific subgroup of rapid, regular supraventricular arrhythmias that critically depend on conduction through the AV node for their perpetuation. The most common are AV reentrant tachycardias that use an accessory pathway (AP) as the retrograde limb of the circuit and AV nodal reentrant tachycardia in which both anterograde and retrograde components of the reentrant substrate are within or near the compact portion of the AV node and neighboring bundle of His. The anatomic location around the mitral or tricuspid annulus of APs can be precisely identified at the time of electrophysiologic testing but can also be predicted with high accuracy based on the morphology of retrograde P waves during tachycardia or characteristic delta waves in those patients in whom these arrhythmias occur as a component of Wolff-Parkinson-White (WPW) syndrome. AV nodal–dependent tachycardias are typically initiated by premature atrial or ventricular extrastimuli and have reasonably specific characteristics that allow their differentiation. Although both are short RP tachycardias, AV reentrant tachycardia must have a ventriculoatrial (VA) or RP interval of at least 70 ms, whereas most AV nodal reentrant tachycardias have intervals of less than 60 ms, with retrograde P waves presenting as a pseudo-R wave in surface electrocardiogram (ECG) lead V_1 during tachycardia. In some patients with APs, a reversed-direction tachycardia with anterograde conduction through the AP may occur, producing a maximally preexcited QRS complex on the surface ECG. Some patients with WPW syndrome are at potential risk for atrial fibrillation degenerating into ventricular fibrillation. APs with unusual conduction characteristics contribute to the occurrence of preexcitation variants, including the permanent form of junctional reciprocating tachycardia and atriofascicular reentry. Because of their dependence on AV nodal conduction for their maintenance, AV nodal–dependent arrhythmias may be acutely terminated by vagal maneuvers or administration of adenosine or verapamil. Wide-complex tachycardias in these patients must be carefully approached without using drugs that accelerate AP conduction, which can lead to ventricular fibrillation. Both pharmacologic and nonpharmacologic therapies may be applied in the long term for managing patients with these arrhythmias. Drug therapy may be directed at the AV node, the AP, or the initiating atrial or ventricular extrastimuli. Ablative therapy has also emerged as the mainstay of nonpharmacologic treatment of these arrhythmias.

GLOSSARY

Anterior fibrous trigone: The region of convergent, dense, fibrous tissue of the posterior aortic and anterior mitral valve annuli.

Antidromic reciprocating tachycardia: A reversed-direction AV nodal–dependent tachycardia in which anterograde conduction occurs through the AP, whereas return retrograde atrial activation proceeds through the normal VA conduction system.

Atriofasciculoventricular Mahaim fiber: An atypical AP with AV node–like properties typically located in the anterior or anterolateral region of the tricuspid annulus. This pathway serves as a bridge between atrial and right bundle branch tissue.

Atriofasciculoventricular or "Mahaim" reentrant tachycardia: A preexcitation variant tachycardia that uses an atriofascicular fiber as its anterograde limb.

AV nodal reentrant tachycardia: An AV nodal–dependent tachycardia in which both anterograde and retrograde components of the reentrant substrate are located within or near the compact portion of the AV node.

AV nodal–dependent tachycardia: A tachycardia that critically depends on conduction through the AV node for its perpetuation.

AV reentrant tachycardia: An AV nodal–dependent tachycardia with the AV conduction system as the anterograde and the AP as the retrograde limb of the tachycardia circuit.

Concealed AP: AP with retrograde-only conduction existing without evidence of anterograde ventricular activation through that pathway.

Discontinuous conduction: Characteristic of dual AV nodal physiology in which a more than 50-ms abrupt prolongation of AV nodal conduction time occurs with a

10-ms decrease in the coupling time of an atrial premature complex (APC), producing anterograde conduction through the AV node.

Dual AV nodal physiology: Electrophysiologic manifestation of two AV nodal pathways with different anatomic and/or physiologic properties that serve as a substrate for AV nodal reentrant tachycardia.

Koch's triangle: A triangular space in the medial portion of the right atrium formed by the septal component of the tricuspid valve annulus, the coronary sinus orifice, and the tendon of Todaro. The AV node lies in the apex of this triangle.

Long RP tachycardia: Tachycardia with a retrograde P wave describing atrial activation occurring close to the succeeding QRS complex. These tachycardias have an RP interval that is more than 50% of the RR interval seen during tachycardia.

Permanent junctional reciprocating tachycardia (PJRT): Preexcitation variant in which retrograde atrial activation occurs through an AP with node-like or decremental electrical conduction properties. These long RP tachycardias may be incessant and show negative P waves in leads II, III, and aVF.

Preexcitation: Early ventricular activation before that proceeding through the normal AV conduction system, as seen in patients with APs.

Short RP tachycardia: Tachycardia with a retrograde P wave describing atrial activation that occurs close to the preceding QRS complex. These tachycardias have an RP interval that is less than 50% of the RR interval seen during tachycardia.

VA interval: The VA interval beginning with the local ventricular activation and ending with earliest retrograde atrial activation. The surface ECG correlate is the RP interval from onset of the surface QRS to the retrograde P wave.

INTRODUCTION

AV nodal–dependent tachycardias comprise a specific subgroup of rapid, regular supraventricular arrhythmias that critically depend on conduction through the AV node for their perpetuation. These arrhythmias typically use the normal AV conduction system as the anterograde limb of the reentrant circuit and therefore present with a narrow QRS complex on the surface ECG, as shown in Figure 66.1. Unlike atrial flutter or atrial tachycardias, which may continue despite the presence of high-grade AV block, AV nodal–dependent tachycardias are typically eliminated by vagal, drug, or nonpharmacologic interruption of AV nodal conduction. As such, with infrequent exceptions (e.g., AV nodal reentrant tachycardia with 2:1 A:V or V:A conduction), AV nodal–dependent tachycardias show a classic 1:1 AV relationship, unlike their AV nodal–independent counterparts that may have a 2:1 or more AV relationship, with or without these interventions (Fig. 66.1).

FIGURE 66.1 Electrocardiogram tracings from atrioventricular (AV) nodal–dependent and AV nodal–independent tachycardias. **A:** Narrow QRS complex tachycardia with a 1:1 AV relationship in a patient with an AV nodal reentrant tachycardia. **B:** Classic atrial flutter persisting despite variable AV block.

The most common of the AV nodal–dependent arrhythmias are AV reentrant tachycardias, in which an AP is used as the retrograde limb of the tachycardia circuit (Fig. 66.2), and AV nodal reentrant tachycardias (Fig. 66.2) in which both anterograde and retrograde components of the reentrant substrate are within or near the compact portion of the AV node and neighboring bundle of His. Some AV nodal–dependent arrhythmias, such as antidromic reciprocating tachycardias, less frequently use the AV conduction system as the retrograde component and an AP as the anterograde limb of the tachycardia circuit. Therefore, the QRS complex on the surface ECG during tachycardia is maximally preexcited.

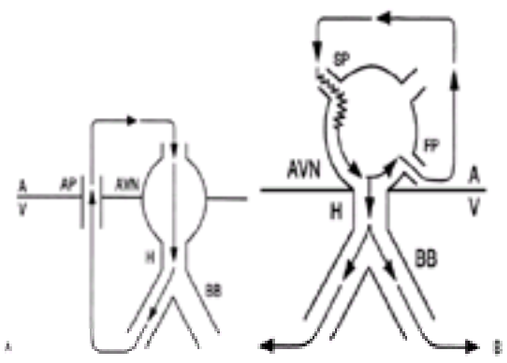

FIGURE 66.2 Mechanism of atrioventricular (AV) reentrant and AV nodal reentrant tachycardias. In both arrhythmias, the AV node serves as a mandatory component of the reentrant circuit. **A:** AV reentrant tachycardia in which the AP serves as the retrograde limb of the reentrant circuit. **B:** AV nodal reentrant tachycardia circuit with anterograde conduction through SP with return retrograde conduction through FP. AP, accessory pathway; AVN, atrioventricular node; BB, bundle branch; FP, fast pathway; H, bundle of His; SP, slow pathway.

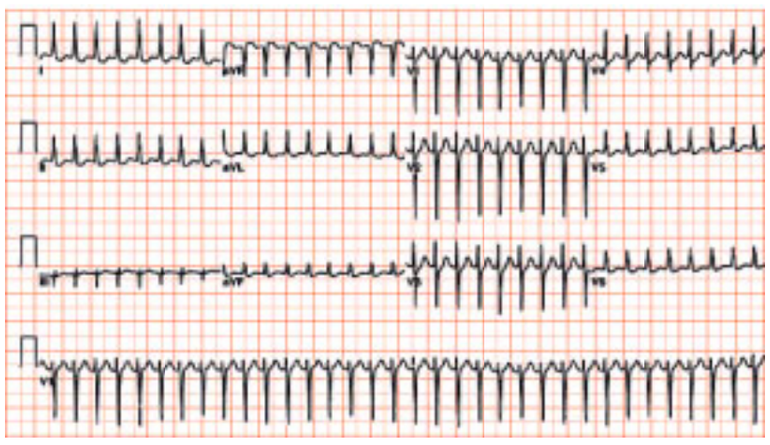
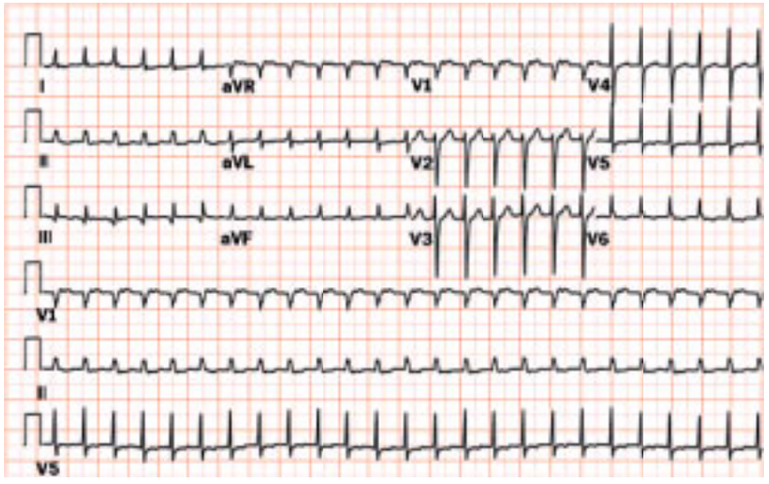
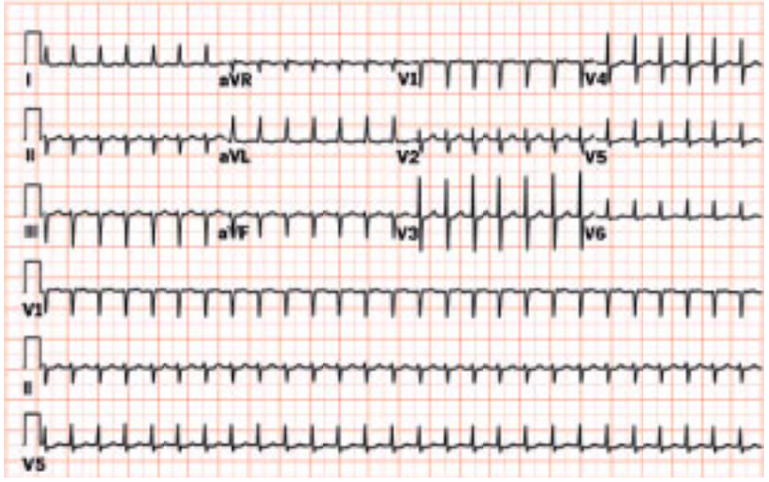


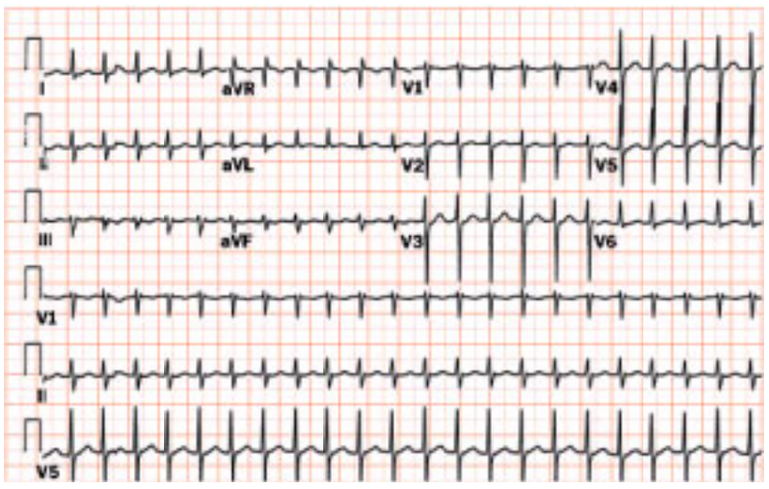
A 58-year-old female patient with supraventricular tachycardia. Arrhythmogenic right ventricular dysplasia diagnosed with electrophysiologic stimulation.



Supraventricular tachycardia. Note narrow QRS complex with short RP interval.



Supraventricular tachycardia. P wave is not visible in this example, suggesting atrioventricular nodal reentry tachycardia.



Atrioventricular nodal reentrant tachycardia. Note retrograde P wave buried within the ST segment.

HISTORICAL PERSPECTIVE

AV nodal–dependent tachycardias have been a focus of extensive clinical interest during the past 100 years and have prompted numerous studies to clarify the underlying electrophysiology. In studying AV conduction, Kent (1) examined a variety of different mammalian hearts and found a “complex system of branching and anastomosing fibers” penetrating the fibrous annular tissue between the atria and ventricles, which we now refer to as the *normal AV conduction system*. Mines provided the first description of reentry in the AV node in 1913, and his explanation of the possible physiologic mechanism of this arrhythmia is essentially what we now refer to as *dual AV nodal physiology* (2). In addition, Kent (3) identified anomalous muscular bundles connecting the auricles and ventricles, which were particularly prevalent at the anterolateral region of the tricuspid ring. Building on Kent’s observations, Mines (4) suggested that such a pathway may serve as a component of a possible reentrant circuit.

By the end of the first decade of the twentieth century, a variety of case reports documented the occurrence of relatively benign, rapid regular tachycardias accompanied by palpitations (5,6,7 and 8). In 1913, Cohn and Frazier (6) reported two patients in whom supraventricular tachycardia (SVT) was documented by ECG recordings for the first time in the United States. The second of these patients had a short PR interval and preexcited QRS complex after vagal termination of the narrow complex tachycardia. Several years thereafter, Wood et al. (7) reported a patient with a short PR interval and prolonged QRS complex who died during an attack of paroxysmal tachycardia. Serial histologic sections of a portion of this patient’s AV groove showed three muscular connections at the right lateral border of the heart between the right auricle and ventricle, as described by Kent (3). Wolferth et al. (5) hypothesized that such accessory connections capable of AV conduction may be responsible for both ventricular preexcitation during sinus rhythm and the paroxysms of tachycardia in these patients. The mechanism depicted in figure 4 of that reference (5) has since been firmly established as underlying these electrophysiologic phenomena.

In 1930, the combination of paroxysmal tachycardias of this type along with a bundle branch block QRS morphology and a short PR interval was codified as WPW syndrome (8). The existence of apparent dual AV nodal physiology as an additional avenue of AV conduction was suggested by others (9,10 and 11), and, in 1962, Kistin postulated the existence of multiple AV nodal pathways in humans (12). Other investigators subsequently also described the possibility of triple or multiple AV nodal pathways (13,14,15,16,17 and 18).

The understanding of the rhythm disorders created by these connections took a giant leap forward with the advent of catheter-based electrophysiologic studies (19,20,21,22,23 and 24). By positioning multiple recording electrodes within the heart and through the use of electrical stimulation techniques, the roles of the AV node and AP in SVTs have been elucidated. Furthermore, this information has also expanded our understanding of macroreentrant arrhythmias in general. In this regard, the AV nodal–dependent SVTs, with their discrete anatomic components, can be viewed as the “schoolmaster” of reentrant arrhythmias. Since then, volumes have been written about the preexcitation syndromes, their accompanying SVTs, and AV nodal reentrant tachycardias (25,26,27 and 28).

These tachycardias also provided the substrate for the first foray into nonpharmacologic therapy for arrhythmias. In the late 1960s, several institutions (29,30) attempted to interrupt APs as a definitive cure for SVT. The first successful division of such a pathway by Sealy et al. (30,31) in 1968 permanently cured a North Carolina fisherman of his recurrent palpitations, firmly established the reentrant nature of AP–dependent arrhythmias, and ushered in the era of nonpharmacologic management of cardiac arrhythmias. Since then, several thousand APs have been surgically interrupted (32,33,34,35,36 and 37).

Building on lessons learned from such surgical interruption of APs, drug therapy for these arrhythmias has been largely supplanted by development of closed-chest, catheter-based ablation of these reentrant circuits. In the early 1980s, ablation of the AV conduction system using direct current energy was applied to patients with AV nodal–dependent tachycardias in whom drug therapy had failed (38,39). Obviously, this approach cured the AV nodal–dependent arrhythmia at the expense of permanent pacemaker dependency. Nevertheless, success with this technique provided incentive for developing the tools to ablate APs directly. Radiofrequency (RF) ablation, originally applied in 1987 (40), has been further refined by a number of investigators (41,42,43,44,45 and 46) and applied to tens of thousands of patients with AV reentrant and other AV nodal–dependent tachycardias. Because of the high success rates and low accompanying risk, this approach has nearly replaced drug therapy as the mainstay of treatment for AV nodal–dependent arrhythmias. Each of these historic milestones marks important progress in both our understanding of these arrhythmias and the development of effective clinical management strategies.

ANATOMIC CONSIDERATIONS

Atrioventricular Conduction System

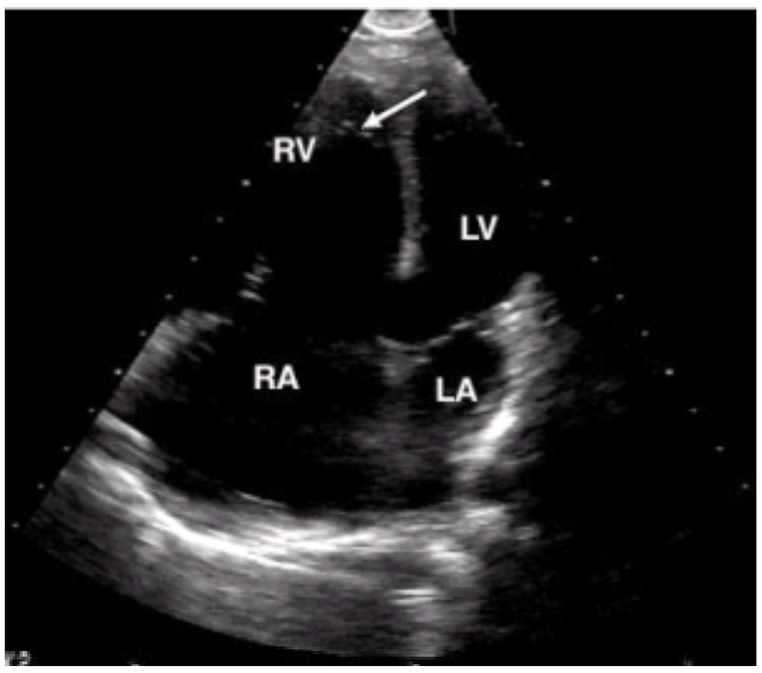
The occurrence of an AV nodal–dependent reentrant tachycardia, like other classic reentrant arrhythmias, requires two anatomically distinct components or pathways to create the tachycardia circuit (4). By definition, the first is the AV nodal conduction system. The AV node is a dense, compact subendocardial structure located in the low, medial portion of the right atrium at the apex of Koch's triangle (47,48,49 and 50), which, in turn, is formed by the septal component of the tricuspid valve annulus, the coronary sinus orifice, and the tendon of Todaro. The bundle of His arises from the distal extent of the AV node and penetrates the superiormost membranous interventricular septum to divide into right and left bundle branches with septal components. Conduction in most AV nodal–dependent tachycardias travels anterogradely through this AV conduction system to produce the classic narrow QRS complex seen on the ECG.

Microscopically, the N cells of the compact AV node are connected to atrial tissue by relatively distinct regions of transitional cell inputs located in the posterior aspect of the AV node along the tricuspid annulus near the coronary sinus orifice, in the anterior and superior aspect of the node near the origin of the bundle of His, and from the left side of the intraatrial septum entering the compact node on its medial aspect. Conduction in the AV node is driven by inward calcium currents and highly modulated by both sympathetic and parasympathetic nerve input, which accelerate or slow conduction, respectively.

Unlike AV nodal tissue, propagation in the His-Purkinje system critically depends on large-amplitude inward sodium currents and is less effectively modulated by autonomic nerve inputs.

Accessory Pathways

APs involved as the retrograde limb of the AV reentrant tachycardia circuit are formed by minute, electrically conducting muscle bundles that transverse the AV groove. These pathways establish a nonnodal avenue for AV or VA electrical propagation across the mitral and tricuspid annuli, which otherwise electrically isolate the atria from the ventricles. These fibers may cross the AV groove directly, proceed on an angle, or in some cases arborize with one or more branch points before insertion into either ventricular or atrial muscle (51,52,53 and 54). Whether atrial or ventricular muscle tissue comprises the AP remains unclear. The observation that APs follow Ebstein's malformation of the tricuspid valve to the anatomic left heart in patients with transposition of the great arteries suggests that the tissue is more likely to be of a ventricular origin.



Ebstein's anomaly of the tricuspid valve. Note marked apical displacement of the tricuspid leaflets, especially the septal leaflet. The arrow designates the septal leaflet of the tricuspid valve.

With the exception of the region near the anterior fibrous trigone between the aortic and mitral valves, which is usually void of APs, these AV connections are distributed anywhere along the mitral or tricuspid annuli. As noted in Figure 66.3, surgical and catheter ablation studies have demonstrated that, on average, 55% of these AV connections serve as a bridge between the left atrium and ventricle in a free wall location. Furthermore, 25% are in the posteroseptal region, 15% are in a right free wall location, and 5% are in the anteroseptal region (33,35,36 and 37,41,43,44 and 45,55). In addition, 7% to 15% of patients may have more than one AP (24,41,43,44 and 45,56,57,58 and 59). More recently, a unique AP involving a connection between the right atrial appendage and right ventricle has been described (60,61,62 and 63). This type of AP may be difficult to ablate with standard techniques endocardially, and successful catheter ablation with a percutaneous epicardial instrumentation approach has been described (61).

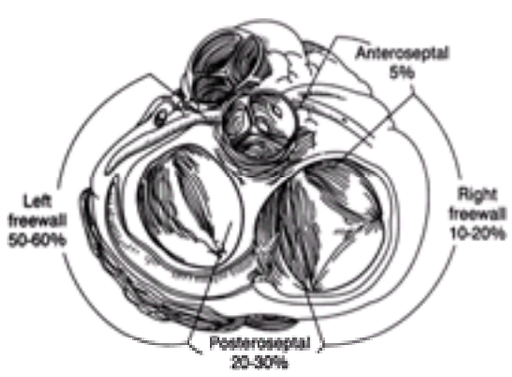


FIGURE 66.3 Distribution of accessory pathways (APs) around the mitral and tricuspid annuli. The left free wall position is the most common AP location.

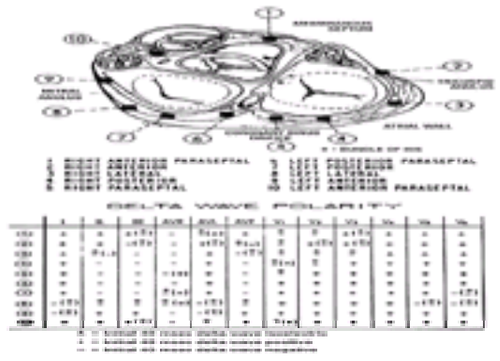
Of all pathways described in reported studies of typically symptomatic patients, 2% to 3% conduct in an anterograde direction only, whereas 20% to 31% conduct in the retrograde/ventricular-to-atrial direction only (41,43,44 and 45,64). These connections are referred to as *concealed APs*. The mechanism of such concealment is further related to atrial and ventricular anatomy or the characteristic electrical properties of conduction through the pathway. Several investigators (65,66) have demonstrated that under certain circumstances, the electrical activity propagating from a small volume of tissue, or "source," into a narrow isthmus of tissue such as AP may be inadequate to bring a larger volume of tissue such as the ventricles, or "sink," to threshold. A potential explanation of this phenomenon is related to the curvature of the wavefront emerging from an AP. Cabo et al. (67) demonstrated a critical relationship between the dimension of the isthmus and the likelihood of bringing a larger "sink" region of tissue to threshold. With small isthmus dimensions, curvature of the wavefront substantially increases, and conduction velocities decrease. These conditions, in turn, may lead to anterograde conduction block out of the isthmus. Propagation into the electrically narrowest of pathways conceivably may increase curvature of the wavefront, leading to anterograde block and therefore concealment. In contrast, wider and effective sources of ventricular activation may produce overt preexcitation.

An alternative mechanism for concealment of a pathway is related to the preferential spread of electrical activation from the normal AV conduction system across the ventricle, and retrogradely into the AP, thus preventing anterograde impulse conduction through the pathway to the ventricle (26,68,69 and 70). The effects of tissue architecture, fiber orientation, and cell-to-cell coupling in the region of the AV grooves undoubtedly further produce directional differences in electrical conduction.

The specific anatomic location of an AP may be inferred from a variety of clinical and electrophysiologic indicators. The most readily available of these is the delta-wave morphology inscribed on the surface ECG. Rosenbaum and colleagues (71) first identified variations in anatomic location based on the precordial QRS morphology and

divided WPW syndrome into type A, with a large R wave in surface lead V_1, and type B, with S or QS morphology in this same lead. Giraud et al. (72) subsequently speculated that the type A pattern was due to posterobasilar preexcitation of the left ventricle, whereas type B was due to right ventricular preexcitation. A variety of different algorithms have since been developed to predict more specifically the anatomic location of single pathways with anterograde conduction based on the surface ECG (73,74,75,76,77 and 78). The earliest of these, developed by Gallagher et al. (64), is shown in *e*Figure 66.3.1.



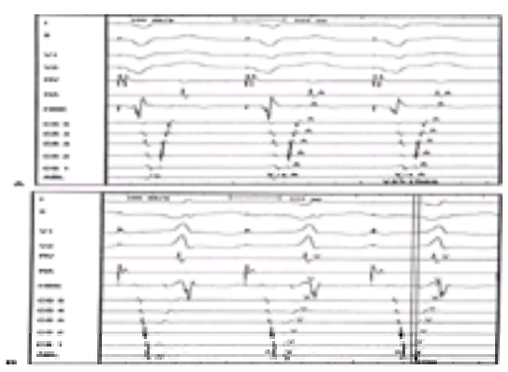
***e*FIGURE 66.3.1** Electrocardiogram algorithm for predicting the location of an accessory pathway based on surface electrocardiogram delta-wave morphology. (From Gallagher JJ, Pritchett EL, Sealy WC, et al. The preexcitation syndromes. *Prog Cardiovasc Dis* 1978;20:285–327, with permission.)

Similarly, pathway location can be discerned from the morphology of the retrograde P wave, when evident. Garcia et al. (79) have shown that a positive P-wave morphology in lead V_1 during SVT is suggestive of a left free wall pathway, whereas a negative deflection is more consistent with a right-sided pathway. Tai et al. (80) have developed a stepwise algorithm for predicting AP location with an accuracy of 88% based on retrograde P-wave morphology in leads I, II, III, aVF, and V_1.

The specific anatomic pathway location is more precisely identified by the earliest site of retrograde atrial activation during tachycardia or ventricular pacing on electrophysiologic testing. As shown in *e*Figure 66.3.2, the location of a free wall AP capable of retrograde conduction is suggested by the presence and site of eccentric atrial activation during tachycardia (22,64). Under normal circumstances, retrograde atrial activation produced by ventricular pacing proceeds through the normal VA conduction system and initially activates concentrically the low, medial aspect of the right atrial septum. All other atrial activation occurs after atrial depolarization at that midline site. In patients with free wall APs, earliest retrograde atrial activation during tachycardia or ventricular pacing emerges from the atrial insertion of the AP. This activation is said to be *eccentric*, or anatomically removed from the midseptal region of the atria. Because this type of atrial activation can be seen with a free wall atrial tachycardia, other markers of pathway presence and participation in the tachycardia must also be established at electrophysiologic testing.

***e*FIGURE 66.3.2** Recording of atrioventricular reentrant tachycardia in a patient with a left free wall accessory pathway. Shown are surface leads I, II, and V_1, as well as intracardiac leads from the right ventricular apex (RVA), high right atrium (HRA), bundle of His region (HBE), and the proximal (P) and distal (D) coronary sinus (CS). An eccentric sequence of retrograde atrial activation with earliest local depolarization along the left free wall is present. Here, the ventriculoatrial interval from the onset of the surface QRS to the local atrial activation is the shortest, as is the local ventriculoatrial conduction time.

More specifically, the pathway site is indicated by the shortest VA conduction time as measured both from the onset of the surface QRS to the earliest atrial depolarization and the point of minimum local conduction time between ventricular and atrial deflections as recorded from a mapping catheter positioned at that site (*e*Fig. 66.3.3). This information is supplemented by the site of earliest ventricular activation and the shortest local AV conduction time during normal sinus rhythm, atrial pacing, or atrial fibrillation, indicating the site of the anterogradely preexciting pathway (*e*Fig. 66.3.3).



***e*FIGURE 66.3.3** Localization of a left free wall pathway during ventricular and atrial pacing. Shown are surface leads I, II, V_1, V_2, and intracardiac electrograms from the right ventricle (RV), right atrium (RA), bundle of His region (HBE) from five pairs of coronary sinus (CS) electrograms, and at the sites of successful pathway ablation (ABL). **A:** Ventricular pacing at cycle length of 500 ms. Again, an eccentric sequence of retrograde atrial activation is seen with a local ventriculoatrial conduction time of 15 ms at the pathway site. **B:** Atrial pacing at a comparable cycle length with moderate preexcitation. The earliest local ventricular activation is seen along the distal CS and precedes the onset of the surface QRS by 20 ms.

PHYSIOLOGIC MECHANISMS OF ATRIOVENTRICULAR NODAL–DEPENDENT TACHYCARDIAS

Tachycardia Initiation

AV nodal–dependent tachycardias require not only the appropriate anatomic substrate for reentry, but also an initiating event. In most cases, initiation is related to the occurrence of atrial or ventricular extrasystolic activity that conducts into and blocks in one of the anatomically distinct components of the reentrant circuit (19,68). An APC, for example, may enter and block within an AP capable of bidirectional conduction (Fig. 66.4). If ventricular activation occurs through the normal AV conduction system, followed by return retrograde atrial activation over the AP back toward the interatrial septum and the AV node, the reentrant circuit is completed. As such, both ventricular and atrial tissue are critical components of the reentrant tachycardia circuit in this arrhythmia. Completing this circuit may be facilitated by delay within the AV node in response to the APC, allowing additional time for the AP to recover before the return impulse arrives at the ventricular end of the pathway (81). Isoproterenol or other adrenergic enhancement may be required to initiate tachycardia in those cases in which AV node conduction under baseline conditions

precludes the onset of arrhythmia.

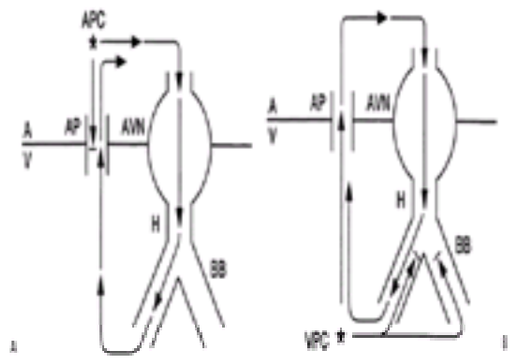


FIGURE 66.4 Initiation of atrioventricular (AV) reentrant tachycardia with an atrial premature complex (APC) or ventricular premature complex (VPC). **A:** APC that conducts into and blocks within the accessory pathway (AP). Additional conduction through the normal AV conduction system followed by return retrograde atrial activation through the AP leads to reentrant arrhythmia. **B**: Similar initiation with a VPC that first blocks retrogradely in both sides of the His-Purkinje system. Subsequent retrograde atrial activation through the AP with return conduction through the normal AV conduction system completes the reentrant circuit. AVN, atrioventricular node.

AV reentrant tachycardia can also be initiated by a ventricular premature complex (VPC) or pacing. Here, the initiating VPC typically blocks retrogradely in both sides of the His-Purkinje system, conducts to the atrium through the AP, and completes the circuit by reactivating the ventricles through the normal anterograde AV conduction system, as shown in Figure 66.4 (82,83).

Tachycardia Maintenance

Although ventricular activation occurs rapidly through the His-Purkinje system, the distance of the AP from the bundle of His region dictates that the time from onset of the surface QRS to the local atrial activation at the site of the pathway, referred to as the *VA interval*, must be at least 65 to 70 ms (64,84). For this reason, the ECG correlate of this VA interval, the “RP” interval, from the onset of the QRS complex to the P wave is usually more than 80 ms in duration. This specific VA activation time predicts that the inscription of the retrograde P wave will occur early in the ST segment or on the upslope of the T wave of the surface ECG, closer to the preceding than the succeeding QRS complex, as shown in Figure 66.5. If the RP interval is less than 50% of the RR interval from one QRS complex to the next, the tachycardia is considered to be a short RP tachycardia (Fig. 66.6).

FIGURE 66.5 Narrow complex supraventricular tachycardia due to an atrioventricular reentrant mechanism. Note the retrograde P waves inscribed in the inferior and precordial ST segments and the short RP tachycardia appearance.

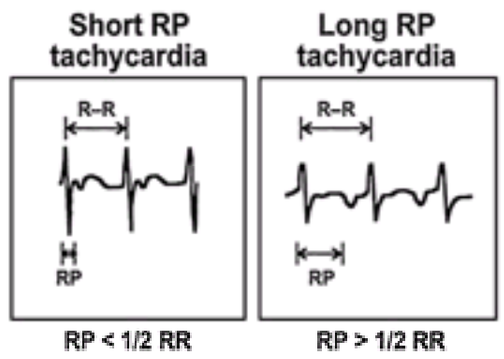

FIGURE 66.6 Classification of short and long RP tachycardias. The left panel shows a retrograde P wave in tachycardia that occurs closer to the preceding than succeeding QRS. Supraventricular arrhythmias with such an RP interval of less than 50% of the RR interval are designated “short” RP tachycardias. The right panel shows a retrograde P wave closer to the following QRS due to prolonged retrograde conduction time. An RP interval longer than 50% of the RR cycle length qualifies as a “long” RP tachycardia.

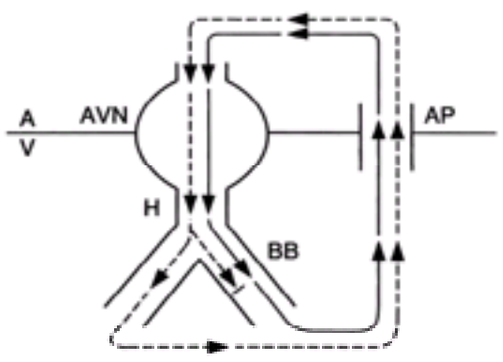
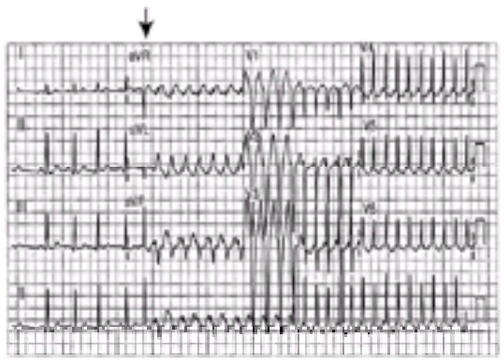
These VA or RP intervals during tachycardia typically use an AP and are relatively constant. An important exception to this is the more than 35-ms prolongation of the VA interval seen with the emergence of bundle branch block ipsilateral to the AP during the AV reentrant arrhythmia, as shown in *e*Figure 66.6.1 (85,86), because ventricular activation in the presence of bundle branch block must proceed through the contralateral bundle branch, with subsequent slower transseptal conduction and return propagation to the ventricular origin of the AP through ventricular muscle. For example, patients with left free wall pathways who develop left bundle branch block show classic prolongation of the VA interval during tachycardia. The alternative is true in patients with right free wall pathways who develop right bundle branch block. Unless this activation slowing is offset by reciprocal acceleration of conduction through the normal AV conduction system, the tachycardia in such patients is slowed. Conversely, acceleration of the tachycardia with abrupt resolution of bundle branch block, as seen on the surface ECG in *e*Figure 66.6.2, is virtually pathognomonic for an AP-related tachycardia. In contrast, patients with posteroseptal pathways show VA interval changes of 10 to 30 ms only with the emergence of left bundle branch block, whereas patients with anteroseptal pathways may develop a comparably limited VA interval change during onset of right bundle branch block (85).

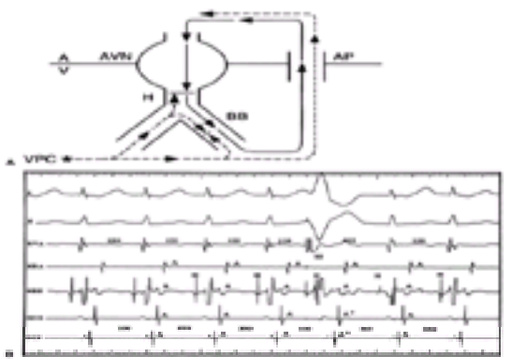


***e*FIGURE 66.6.1** Change in the ventriculoatrial (VA) interval with development of bundle branch (BB) aberration during tachycardia. During normal conduction (*solid line*), the interval from the onset of the surface QRS to the earliest retrograde atrial activation (VA interval) is at least 70 ms because of the component conduction properties. With BB block ipsilateral to the pathway, the additional conduction time due to transseptal and intramyocardial propagation (*dashed line*) to the accessory pathway (AP) prolongs the retrograde VA conduction time. AVN, atrioventricular node; H, bundle of His.



***e*FIGURE 66.6.2** Electrocardiogram showing transition from left bundle branch block to normal QRS supraventricular tachycardia. Atrioventricular reentrant tachycardia with left bundle branch block morphology begins with an atrial premature complex (*arrow*). Midway through the V_1 to V_3 precordial leads, the left bundle branch block resolves, resulting in a decrease in tachycardia cycle length from 300 to 250 ms (200 to 240 beats/min). This is indicative of tachycardia using an ipsilateral or left free wall accessory pathway.

An additional indication of an AP that is participating in a narrow QRS complex tachycardia that can be elucidated on electrophysiologic testing is based on the response to VPCs introduced during the tachycardia. An AP is present if a VPC introduced late in the tachycardia diastolic interval advances or preexcites retrograde atrial activation without changing the atrial activation sequence (87,88). As shown in *e*Figure 66.6.3, such advancement occurs through an AP, because the VPC cannot retrogradely penetrate the AV node or bundle of His, as the immediately preceding anterograde impulse during tachycardia placed these tissues into a state of refractoriness. Furthermore, termination of tachycardia by a premature impulse at a time when the bundle of His is refractory that does not produce retrograde atrial activation must occur within ventricular or His-Purkinje tissue, thus establishing such tissue as critical components of the reentrant circuit. This is even stronger evidence that narrow complex tachycardias critically depend on an AP as their retrograde limb (26,27 and 28).



***e*FIGURE 66.6.3** Retrograde atrial preexcitation with a ventricular premature complex (VPC) introduced during atrioventricular (AV) reentrant tachycardia. Panel **A** diagrammatically shows a VPC introduced from the right ventricular apex (RVA), which collides retrogradely (*dashed line*) in the His-Purkinje system with an anterograde impulse (*solid line*) from the previous tachycardia cycle. Retrograde atrial activation thereafter proceeds exclusively through the accessory pathway (AP), advancing the tachycardia circuit. **B:** Intracardiac tracings demonstrating an AV reentrant tachycardia with a cycle length of 350 ms. With the introduction of a critically timed VPC (S_2) at a coupling interval of 235 ms, retrograde atrial activation (*asterisk*) is advanced by 20 ms without altering the atrial activation sequence. Note that the VPC occurs at a time when the bundle of His (H) is refractory. Shown are surface leads I and II as well as intracardiac leads with a similar configuration, as shown in *e*Figure 66.3.2 and *e*Figure 66.3.3. AVN, atrioventricular node; BB, bundle branch.

Physiology of Preexcitation

When the AV reentrant tachycardia occurs in a patient with early or “preexcited” anterograde ventricular activation through the AP during normal sinus rhythm, a delta wave and a short PR interval are evident on the surface ECG (Fig. 66.7), and the criteria for WPW syndrome are met (8). The degree of accompanying preexcitation observed on a surface 12-lead ECG, however, depends on relative local ventricular activation proceeding through the normal AV conduction system versus that through the AP. This in turn depends on the relative time required for a propagating impulse from the sinus node to reach and traverse the AV node and His-Purkinje system or the AP (*e*Fig. 66.7.1). The additional activation time required to reach an AP well removed from the sinus node along the far left lateral region of the mitral annulus decreases the likelihood of expressing ventricular preexcitation during normal sinus rhythm with this pathway location. In the setting of increased sympathoadrenergic tone as that which accompanies exercise, ventricular activation through the normal AV conduction system is enhanced and can precede that which occurs through the AP (*e*Fig. 66.7.1). During such circumstances, no or minimal ventricular preexcitation may be evident. At the other extreme, ventricular activation through the pathway, yielding moderate or marked preexcitation, may be more evident with pathways closer to the sinus node or in those conditions in which conduction through the AV node is slowed by intrinsic nodal factors, withdrawal of sympathetic tone, or heightened vagal tone (*e*Fig. 66.7.1). In some cases, the rapid intravenous (i.v.) administration of 6 to 12 mg of adenosine as a diagnostic maneuver exposes an anterograde AP by blocking or slowing AV node conduction (89,90). As such, the presence and degree of ventricular preexcitation in patients with WPW syndrome depend dynamically on a variety of different factors, chief of which is the autonomic modulation of the AV node.

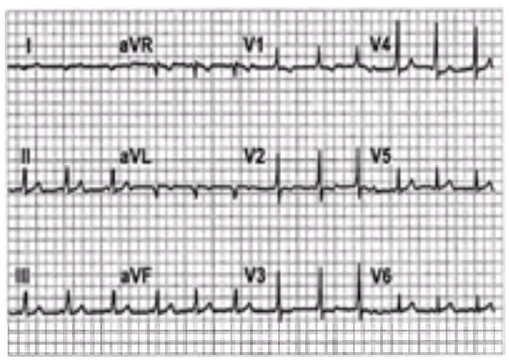


FIGURE 66.7 Electrocardiogram with ventricular preexcitation across a left free wall accessory pathway. Note the widened QRS complex with a slurred upstroke and a shortened PR interval consistent with a diagnosis of Wolff-Parkinson-White syndrome.

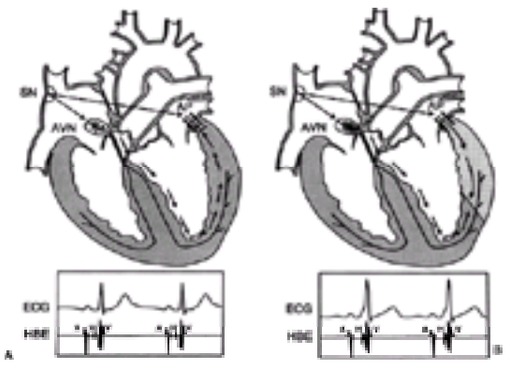
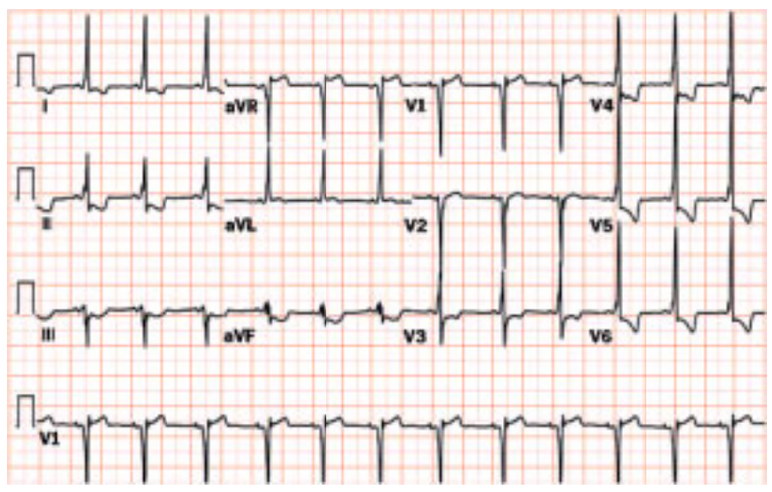


***e*FIGURE 66.7.1** Variable preexcitation dependent on relative conduction through the atrioventricular (AV) node and accessory pathway (AP). **A:** Minimal preexcitation in the setting of enhanced AV nodal conduction and an accessory pathway distant from the sinus node (SN). Prolonged conduction time to this site provides a relative advantage to ventricular activation through the AV node. Note the normal AV interval of 40 ms on the diagrammatic electrogram **(inset)**. **B:** Moderate to marked preexcitation related to relatively greater ventricular activation through the accessory pathway. Here, conduction time through the AV node is prolonged, yielding a relative advantage for conduction through the accessory connection. The His deflection occurs after the onset of ventricular activation through the pathway. A, atrial electrogram; AVN, atrioventricular node; ECG, electrocardiogram; H, bundle of HIs; HBE, bundle of His electrogram; V, ventricular electrogram.



Wolff-Parkinson-White syndrome. Eleven-year-old patient with manifest preexcitation consistent with Wolff-Parkinson-White.

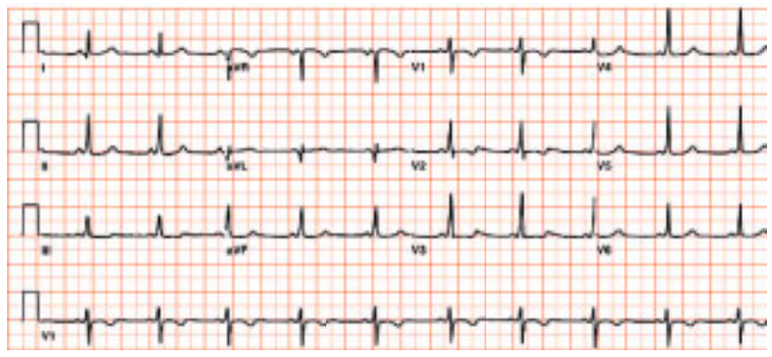
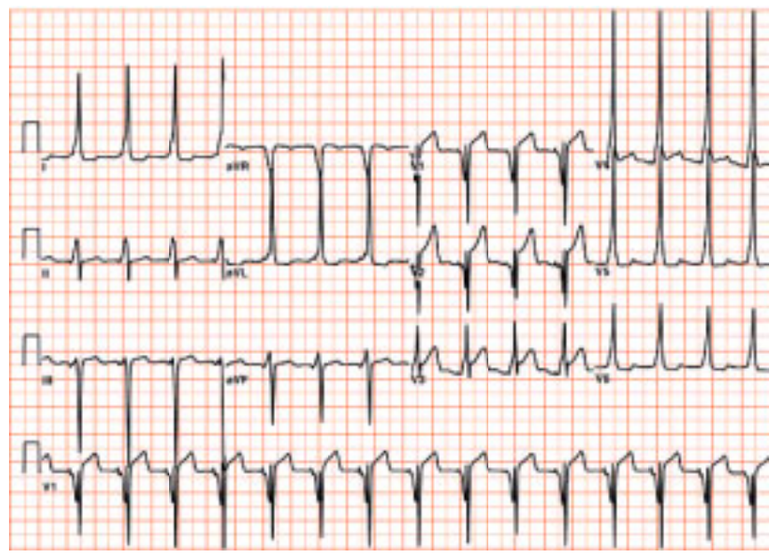
Intermittent delta wave. Intermittent conduction via accessory pathway is noted (*arrow*).



A 44-year-old female patient with Wolff-Parkinson-White syndrome.



A 16-year-old male patient with Wolff-Parkinson-White syndrome.

The degree of preexcitation can also be enhanced with atrial pacing, as performed on electrophysiologic testing (28). With pacing directly over the AP, inherent intraatrial conduction delay from the sinus node to the atrial origin of the AP is eliminated. In addition, increments in rapid atrial pacing rates increase preexcitation by progressively slowing or decrementing conduction within the normal AV conduction system. The QRS complex thereby becomes more preexcited unless block in the AP occurs and the QRS complex narrows as conduction proceeds exclusively through the normal AV conduction system.

Preexcited Atrioventricular Nodal–Dependent Tachycardias

Although most AV nodal–dependent tachycardias use the AV conduction system as the anterograde limb of the tachycardia circuit, the reentrant circuit is reversed in the presence of antidromic reciprocating tachycardia, as seen in Figure 66.8. With this arrhythmia, the AV node is the requisite retrograde limb of the circuit, and ventricular activation proceeds through the AP, producing maximum QRS preexcitation (Fig. 6.9). This tachycardia can be induced on electrophysiologic testing in 6% to 8% of patients with an AP (55,91,92 and 93), although only 2% to 3% of patients clinically develop this arrhythmia (55,91,93).

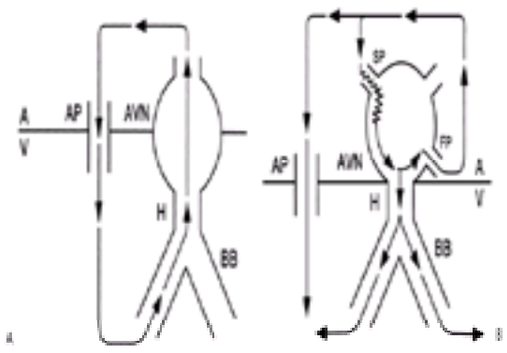


FIGURE 66.8 Mechanisms of preexcited atrioventricular (AV) nodal–dependent tachycardias. **A:** Antidromic reciprocating tachycardia with anterograde conduction through the accessory pathway (AP) and retrograde atrial activation through the normal ventriculoatrial conduction system. **B:** AV nodal reentry with a classic mechanism involving anterograde conduction through the slow pathway (SP) and retrograde or return atrial activation through the fast pathway (FP). Preexcitation occurs because of additional bystander conduction through the neighboring AP. AVN, atrioventricular node; BB, bundle branch; H, bundle of His.

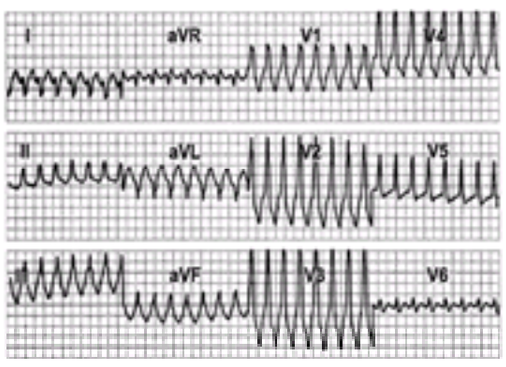

FIGURE 66.9 Antidromic reciprocating tachycardia with marked preexcitation. This electrocardiogram pattern occurs because of exclusive ventricular activation through the accessory pathway. Retrograde activation occurs through the normal ventriculoatrial conduction system.

AV nodal reentry with bystander conduction through a coexistent AP is a second preexcited AV nodal–dependent tachycardia. In this arrhythmia, perpetuation of the tachycardia depends on classic AV node reentry using anterograde and retrograde limbs found within or near the compact portion of the AV node. The wide or preexcited QRS morphology seen on ECG is due to concomitant ventricular activation through an AP. Ablation of the AP, although eliminating preexcitation, would not necessarily eliminate the tachycardia. Although AV nodal reentrant tachycardia may be seen in 10% to 20% of patients with an AP (94,95,96 and 97), concurrent anterograde conduction through an AP is seen in less than 2% of patients (96). When evaluating patients with these types of AV nodal–dependent tachycardias, alternative mechanisms of preexcited tachycardias such as any atrial tachycardia or flutter with ventricular activation through an AP should be considered. Well-defined criteria for differentiating these types of tachycardias from antidromic reciprocating tachycardia have been established (93,98).

Pathophysiology of Atrial Fibrillation

Regardless of whether a patient has antidromic tachycardia, the greatest concern in patients with WPW syndrome is the possibility of onset of atrial fibrillation with a rapid ventricular response rate and further degeneration into ventricular fibrillation. This requires both the onset of atrial fibrillation and the propensity for rapid conduction through the pathway. Although atrial fibrillation may develop as an isolated or primary process in WPW patients, the disorganization of AV reentrant tachycardia is a more likely mechanism for its occurrence in patients with an AP (99,100 and 101). In one-third of patients, atrial fibrillation arises in the region of the AP during AV reentrant tachycardia (99). This raises the possibility of disorganizing reentrant wavelets within the pathway apparatus itself. Atrial fibrillation, however, emerges more frequently at a distance from the pathway (99,100 and 101). Even in these patients, the presence of the rapid, pathway-dependent tachycardia produces electrophysiologic changes in the atria that facilitate the onset of atrial fibrillation. Rate-dependent decreases in atrial refractoriness along with additional increases in the inhomogeneity of electrophysiologic properties accompanying the increasing left and right atrial pressures observed during tachycardia have been reported. In this regard, rapid tachycardia that uses an AP appears to contribute to the onset of atrial fibrillation but is not always sufficient for atrial fibrillation to emerge. The role of the AP or tachycardia in this process is also inferred from the substantial reduction in clinical atrial fibrillation after curative surgical or catheter-ablative procedures (102,103,104 and 105). Evidence that AV reentrant tachycardia is not mandatory for onset of atrial fibrillation, however, is the occurrence of atrial fibrillation in patients who do not have AV reentrant tachycardia and in whom pathways are capable of only anterograde conduction (103).

CLINICAL PRESENTATION

General Considerations

Screening 12-lead ECG studies reveal that 1.0 to 1.5 in 1,000 patients demonstrate preexcitation. Population-based studies (106) have suggested that 50% to 60% of these patients show symptoms ranging from palpitations to syncope. In others, tachycardia may be accompanied by dyspnea, decreased exercise tolerance, chest pain or tightness, anxiety, dizziness, presyncope, or syncope. The latter is more likely in AV nodal reentrant tachycardia in which atrial and ventricular contractions accompanying respective electrical activation occur nearly simultaneously. Atrial contraction at the time of mitral valve closure may limit cardiac output and be accompanied by increases in right and left atrial pressure. These increases in turn may precipitate a posttachycardia diuresis due to release of atrial paracrine factors such as atrial natriuretic peptides. Of those patients with symptomatic arrhythmias, 85% have underlying AV reentrant tachycardias that use the AP as a retrograde limb (28,55,64). Only 2% to 3% of patients show clinical antidromic reciprocating tachycardia (93,107,108), whereas 30% to 40% of patients develop atrial fibrillation (55,64,109,110,111 and 112).

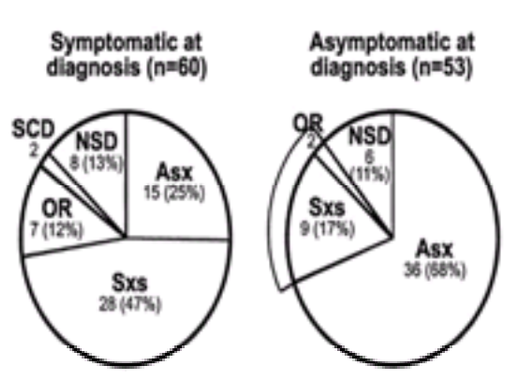
Unlike most ventricular tachycardias, which occur in patients with pump dysfunction, most AV nodal–dependent tachycardias occur in the absence of any other organic heart disease. Any underlying process that does occur, such as mitral valve prolapse or hypertrophic cardiomyopathy, is therefore a chance occurrence. The one exception is coexistent Ebstein's malformation of the tricuspid valve and an AP (55,64,95). Of those patients with APs reported in larger studies (113,114), 7% to 10% have this coexistent structural abnormality. This finding is of clinical importance because these patients typically have a higher prevalence of multiple APs and the success rate of RF ablation in patients with tricuspid valve abnormalities is lower.

Natural History of Atrioventricular Reentrant Tachycardias

Predicting the likelihood and frequency of recurrent arrhythmias would be useful in deciding which patients should be treated for supraventricular arrhythmias. Unfortunately, the natural history of patients with AV nodal–dependent arrhythmias remains unestablished. Available data are limited and contradictory. Several small studies have suggested that recurrent tachycardia after a first event is common and is related to several factors. After monitoring 40 patients for an average of 24 years, Lundberg (115) established younger patient age at the time of diagnosis and the presence of preexcitation as predictors of recurrent tachycardia. For example, 65% of infants with manifest preexcitation had recurrent tachycardia. This was more common than the 46% incidence in youngsters aged 1 to 10 years, the 53% incidence in children older than 10 years, or the 50% incidence of tachycardia in those patients in their third decade of life. In contrast, of those patients studied who had no ventricular preexcitation, 46% of infants, 6% of children aged 1 to 10 years, 9% of children older than 10 years, and 25% of patients in their third decade of life had recurrent tachycardia. In another longitudinal study, Chen et al. (116) followed 113 older patients over a 9-year period and found that the original tachyarrhythmias disappeared over time in 10% of patients, whereas 15% developed other arrhythmias, and 38.5% of patients developed atrial fibrillation. This latter occurrence was significantly more likely in those with manifest anterograde pathway conduction. In still another study of recurrent tachycardia (117), 17 of 31 patients showed a decrease in frequency of tachycardia, five had more frequent episodes, and nine patients reported no clear change over the course of 21 years of follow-up. Fifteen of these patients also continued to show ECG preexcitation during normal sinus rhythm.

In contrast, in a review of patients with symptomatic SVTs, Clair et al. (118) found that older patients were more likely to suffer recurrent episodes of tachycardia. Of 57 patients younger than 38 years, 30% suffered a recurrent episode of premature SVTs in the first 30 days of follow-up. In contrast, nearly 70% of the 56 older patients suffered a recurrent episode of arrhythmia over the same period. These findings are similar to those described by other investigators (119).

Population-based studies, however, suggest a substantially lower rate of recurrent arrhythmia. In an analysis (106) of 113 patients with WPW syndrome in Olmsted County, Minnesota, 60 (53%) were symptomatic at the time of first diagnosis. Over the course of 11.8 years of long-term follow-up, 28 (47%) remained symptomatic, 15 (25%) became asymptomatic, and seven (12%) required surgery (eFig. 66.9.1). The difference between this study and others reflects differences between general populations of patients and those selected by increasing symptoms requiring referral for medical evaluation.



***e*FIGURE 66.9.1** Long-term follow-up in a population-based evaluation of Wolff-Parkinson-White syndrome. The left panel shows the outcome in 60 patients with symptoms at the time of diagnosis of Wolff-Parkinson-White during long-term follow-up. The right panel shows follow-up over 1,338 patient-years in 53 patients who were asymptomatic at the time of initial diagnosis of Wolff-Parkinson-White. Asx, asymptomatic; NSD, noncardiac sudden death; OR, surgery; SCD, sudden cardiac death; Sxs, symptomatic. (From Munger TM, Packer DL, Hammill SC, et al. A population study of the natural history of Wolff-Parkinson-White syndrome in Olmsted County, Minnesota, 1953–1989. *Circulation* 1993;87:866–873, with permission.)

In contrast, other patients with APs remain asymptomatic throughout life (120,121). In examining the persistence of preexcitation in 63 asymptomatic patients with ECG delta waves, Leitch et al. (120) demonstrated a 95% probability of remaining arrhythmia-free and a 50% loss of preexcitation over 232 patient-years of follow-up (average, 3.6 years). Similarly, in a population-based study involving 1,338 patient-years of follow-up, Munger et al. (106) demonstrated that only 11 of 53 (21%) patients who were asymptomatic at the time of initial diagnosis developed symptoms over time (eFig. 66.9.1), whereas 36 (68%) remained symptom-free. Consistent with the findings of Leitch et al. (120), Munger et al. (106) also demonstrated that an asymptomatic patient older than 40 years was highly unlikely to develop progressive symptoms thereafter.

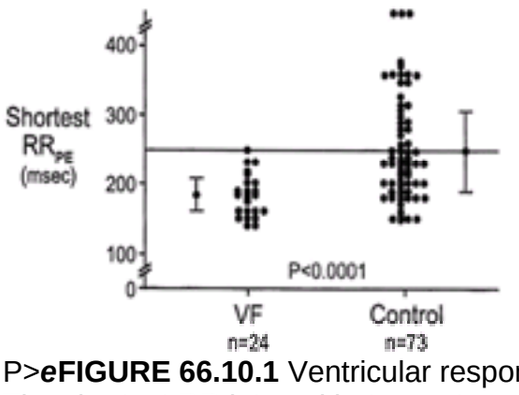
Therefore, taken together, these data suggest several characteristics of patients likely to have recurrent tachycardias. First, the bimodal distribution of symptomatic arrhythmia predicts an initial decrease in symptoms during childhood followed by an increase in tachycardia in young adulthood. Second, the presence of anterograde conduction through an AP increases the likelihood of recurrence. Third, although 25% of patients become asymptomatic over time, more than one-half of patients with an episode of AV reentrant tachycardia will experience a recurrence. Fourth, arrhythmia occurrence is unlikely to occur in asymptomatic patients with no preexcitation, particularly those older than 40 years. Obviously, more extensive longitudinal studies are required to establish the accuracy of any of these or other predictors.

Risk Stratification in Patients with Wolff-Parkinson-White Syndrome

Atrial fibrillation occurs in 30% to 40% of patients with WPW syndrome. Of greatest concern is the propensity of rapid conduction through the AP with accompanying risk for atrial fibrillation degenerating into ventricular fibrillation (Fig. 66.10). The degree of risk is related in part to the symptom status of the patient at the time of initial evaluation. In symptomatic patients from tertiary referral centers, the prevalence of patients with a history of aborted sudden cardiac death (SCD) is 2% to 11% (64,106,122). In contrast, population-based studies (106) demonstrate a lower incidence of SCD—0.0015 events per patient year, or approximately 0.15% per year—occurring exclusively in previously symptomatic individuals. Several other studies (106,120) have also shown that patients who are asymptomatic at the time of diagnosis are unlikely to suffer a subsequent cardiac arrest. This is related to relatively benign AP conduction capabilities in these patients (63,120,123).

FIGURE 66.10 Atrial fibrillation with a rapid ventricular response rate during Wolff-Parkinson-White syndrome. Initial atrioventricular reentrant tachycardia degenerates into atrial fibrillation (*arrow*). The shortest RR interval in this case was 240 to 250 ms, which indicates an increased risk for sudden cardiac death.

A variety of testing methods have been proposed for stratifying the risk for atrial fibrillation degenerating into ventricular fibrillation, including ambulatory recordings, exercise testing, and the response to drugs. The most direct method of assessment is the actual induction of atrial fibrillation and determination of the propensity for rapid conduction as judged by the interval between consecutively preexcited QRS or "RR" complexes. Klein et al. (124) showed that those patients who survived a prior episode of ventricular fibrillation had the shortest preexcited RR intervals (i.e., less than 250 ms in duration) (eFig. 66.10.1). Although this has been regarded as a highly sensitive marker for risk, it is of lower specificity. As such, the positive predictive value of this finding is only 20% over short-term follow-up. On the other hand, the shortest preexcited RR interval of more than 250 ms has a negative predictive value of more than 95%. Other indicators of risk include an average RR interval during atrial fibrillation of 360 ms or less (125). A posteroseptal AP with accompanying rapid AV conduction capability and prior atrial fibrillation also suggests a higher risk (122,125).



P>***eFIGURE 66.10.1*** Ventricular response intervals in patients with ventricular fibrillation (VF) and without a history of VF and aborted sudden cardiac death (control). The shortest RR interval between two consecutive complexes was 250 ms or less in patients with a history of VF. Intervals of more than 250 ms occurred exclusively in those patients with no history of VF. (From Klein GJ, Bashore TM, Sellers TD, et al. Ventricular fibrillation in the Wolff-Parkinson-White syndrome. *N Engl J Med* 1979;301:1080–1085, with permission.)

Other findings on noninvasive testing, if present, indicate a lower risk for SCD. The demonstration of intermittent preexcitation on a 12-lead ECG or ambulatory monitor strip as shown in Figure 66.11 indicates the presence of precarious conduction through an AP (126). It must be noted, however, that the term *intermittent preexcitation* specifically denotes the *abrupt* loss of preexcitation from one beat to the next on a rhythm strip or ECG; it cannot be extended to include the loss of preexcitation on an ECG from one office visit to the next. Depending on the effect of autonomic tone on AV nodal conduction, ventricular activation may proceed exclusively through the normal AV conduction system, thus masking the anterograde conduction capability of the pathway on an ECG. The next ECG, if obtained at the time of heightened parasympathetic tone, alternatively may show increased preexcitation due to preferential ventricular activation through the pathway. This variability is of no predictive value and is of particular concern in patients with left free wall pathways in which the distance of the pathway from the sinus node decreases the chance of manifest preexcitation.

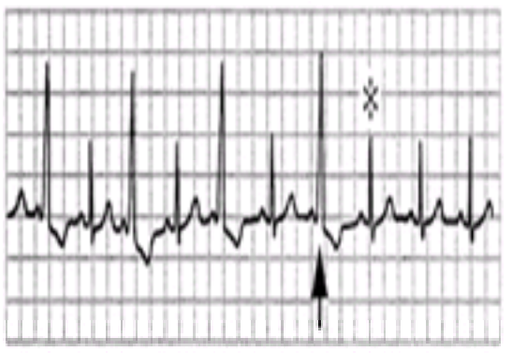


FIGURE 66.11 Rhythm strip showing intermittent preexcitation in a patient with Wolff-Parkinson-White syndrome. Both preexcited (*arrow*) and nonpreexcited (*asterisk*) QRS complexes are seen. Note the loss of QRS preexcitation from one beat to the next.

Exercise testing has also been proposed as a means of identifying patients with long AP refractoriness (127,128). Although several groups have shown that the *abrupt* loss of preexcitation during exercise (Fig. 66.12) is indicative of a low propensity for rapid conduction through an AP, this is an infrequent finding. Preexcitation more frequently disappears gradually during exercise because of enhanced conduction through the normal AV conduction system. Because of the low likelihood of an abrupt loss of preexcitation on exercise testing, persistent preexcitation during exercise testing is reasonably sensitive for identifying patients at risk for an untoward event. Unfortunately, the specificity for excluding those who are not at risk is less than 30%, which is substantially less than that of the shortest RR interval between two preexcited QRS complexes of 250 ms or less. Furthermore, the predictive accuracy of exercise testing is even lower than possible with the induction of atrial fibrillation (128).

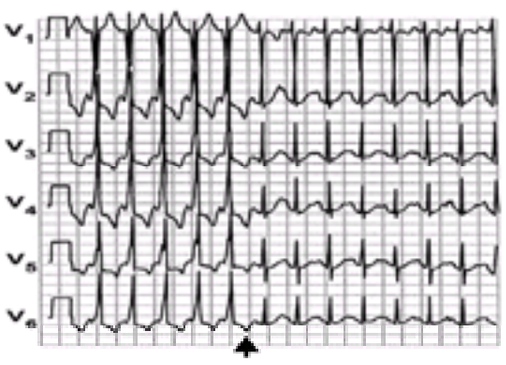

FIGURE 66.12 Electrocardiogram rhythm strip of leads V_1 to V_6 recorded during exercise in a patient with a left free wall accessory pathway. With an increasing workload, an abrupt loss of preexcitation (*arrow*) was seen. This indicates a low-risk pathway. Gradual loss of preexcitation accompanying exercise-induced enhancement of atrioventricular nodal conduction is of no prognostic significance.

Others have reported the use of drug testing measures to stratify risk. This is based on the presumption that the loss of AP conduction with administration of an agent such as procainamide or ajmaline (129,130) indicates a low-risk pathway. Again, however, findings using such testing maneuvers appear to be falsely reassuring (28,128,130,131). In a previous report (130), the response to 10 to 12 mg per kg of procainamide in 56 patients with WPW syndrome failed to support infusion of this medication for establishing risk. Risk stratification is discussed in greater detail in other studies (28).

The most direct means of stratifying risk in symptomatic patients is initiation of atrial fibrillation. This can be performed in a relatively noninvasive way with atrial pacing using an esophageal lead (90,132,133). In those patients in whom risk stratification is important, this allows direct determination of risk at the level of ventricular response rate during atrial fibrillation. This is preferable to using surrogate indicators of risk available on ambulatory recordings or exercise testing or to the response to drugs that only indirectly predict pathway effective refractoriness or ventricular rates in atrial fibrillation.

Furthermore, the overall risk of an untoward event in an asymptomatic patient is clearly not zero but appears to be sufficiently low that additional evaluation of asymptomatic individuals showing ventricular preexcitation on 12-lead ECG is unnecessary (134). The risks associated with drug or ablative therapy in these patients may be equal to or greater than the risks associated with an underlying AP. Potential exceptions to this include patients with a family history of SCD, competitive athletes, and patients with high-risk occupations whose performance may be unacceptably impaired by the unlikely occurrence of tachycardia or atrial fibrillation, with or without rapid ventricular response rates. In contrast, symptomatic patients, particularly those with a history of atrial fibrillation, are at higher risk for more rapid conduction through an AP during atrial fibrillation and warrant further evaluation (109,112,125).

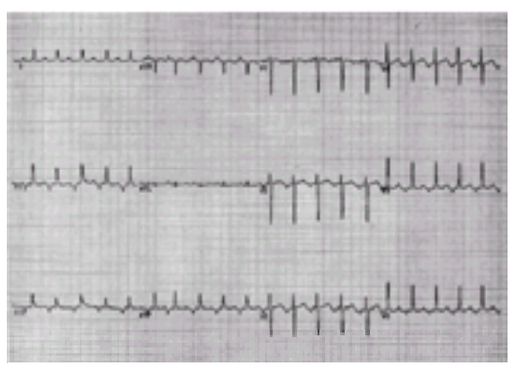
PREEXCITATION VARIANTS

Unlike the more classic presentations seen in most patients with WPW syndrome, other individuals have arrhythmias related to atypical APs with distinctive anatomic and physiologic characteristics. The most common of these are PJRT and preexcited tachycardia related to atriofascicular fibers. The hallmark of these preexcitation variants is the presence of unusual APs that show node-like or decremental electrical conduction properties. Here, progressively slower conduction across the pathway occurs with faster stimulation rates.

PERMANENT JUNCTIONAL RECIPROCATING TACHYCARDIA

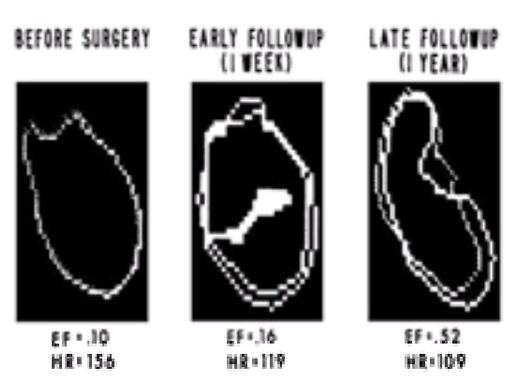
Most patients with PJRT have posteroseptal APs within 1 cm of the coronary sinus orifice (25,135,136), although free wall pathway locations have been described (136,137). Like more typical APs, these connections also participate as the retrograde limb of an AV nodal–dependent tachycardia. In addition to characteristic decremental conduction properties, these pathways also have a long circuitous route from ventricle to atrium, contributing to prolongation of retrograde conduction times (138,139). These pathways also appear to conduct in the retrograde direction only, although several instances of emergent anterograde conduction and more classic ventricular preexcitation have been reported after ablation of the normal AV conduction system (140). This suggests that preablation anterograde conduction into the pathway is blocked in part by retrogradely concealing penetration of impulses into the pathway from the ventricular end of the normal AV conduction system during sinus rhythm. Unlike typical reentrant tachycardias, this arrhythmia may occur spontaneously with alterations of the sinus rate without preceding APCs or VPCs. In such cases, return conduction through the AP and subsequent reactivation of the anterograde AV nodal limb of the circuit perpetuate the tachycardia (25,135).

Slow reverse VA conduction results in inscription of the retrograde P wave in late diastole or closer to the succeeding QRS than the preceding QRS, as shown in eFigure 66.12.1 (25,135). The finding of an RP interval of more than 50% of the RR tachycardia interval invokes the descriptor, long RP tachycardia. Because the low atrial septum is most frequently the first site of atrial activation, P waves during PJRT are typically negative in leads II, III, and aVF, indicating a low-to-high retrograde atrial activation sequence.



***e*FIGURE 66.12.1** Twelve-lead electrocardiogram showing tachycardia in a patient with permanent junctional reciprocating tachycardia. Inspection of leads II, III, and aVF demonstrate the presence of a long RP tachycardia with negative P waves indicative of a low- to high-atrial activation sequence.

Many patients with this process develop rapid, nearly incessant, tachycardias, hence the designation PJRT. Because of the incessant nature of the tachycardia, the development of a tachycardia-induced cardiomyopathy (eFig. 66.12.2) that resolves after elimination of the pathway is not uncommon (141). Other patients with this type of pathway show only frequent paroxysmal junctional reciprocating tachycardia.



***e*FIGURE 66.12.2** Serial radionuclide studies demonstrating resolution of a tachycardia-induced cardiomyopathy in a patient with permanent junctional reciprocating tachycardia. The ejection fraction (EF) was initially 10% but showed progressive improvement to 52% 1 year after interruption of the accessory pathway. HR, heart rate. (From Packer DL, Bardy GH, Worley SJ, et al. Tachycardia-induced cardiomyopathy: a reversible form of left ventricular dysfunction. *Am J Cardiol* 1986;570:563–570, with permission.)

Atriofascicular (Mahaim) Reentrant Tachycardias

Another type of tachycardia, referred to as *atriofascicular*, or *Mahaim, reentrant tachycardia*, is due to a similar decrementally conducting AP located in the right anterior or anterolateral aspect of the tricuspid annulus. When first described (142,143), these pathways were believed to originate in the upper portion of the AV node, with distal insertion in the ventricle or right bundle branch system. lectrophysiologic studies (144,145) have demonstrated more recently that the vast majority of patients with left bundle branch block left-axis deviation Mahaim tachycardias have pathways located several centimeters away from the AV node, as suggested in Figure 66.13. Local His-like potentials are usually seen when recording immediately over this pathway site. As with the normal AV node, conduction in these pathways is strongly altered by adenosine or verapamil. This pathway, which also shows progressively longer conduction times at faster pacing rates, inserts into the right bundle branch system (146), giving a left bundle branch block left-axis deviation QRS morphology on the surface ECG during tachycardia (eFig. 66.13.1). In addition, small,

sharp R waves are typically seen in lead V_1, and the transition from negative to positive QRS morphology seen in the precordial leads typically occurs after V_4 (108). Like antidromic reciprocating tachycardias, the VA conduction system serves as the retrograde limb of this circuit. Because of its left bundle branch block appearance, this arrhythmia must be differentiated from other tachycardias with a left bundle branch block morphology, such as any atrial or AV nodal–dependent tachycardia with bundle branch aberrancy, antidromic tachycardias using a right free wall AP, right ventricular tachycardia as seen in patients with arrhythmogenic right ventricular dysplasia, and bundle branch reentrant ventricular tachycardias.

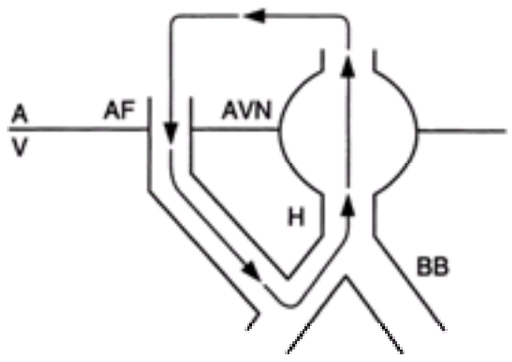


FIGURE 66.13 Mechanism of atriofascicular (AF) (Mahaim) reentrant tachycardias. Anterograde preexcitation typically occurs through a right anterolateral, decrementally conducting accessory pathway (AP) or AF pathway that inserts into the region of the right bundle branch (BB). Retrograde atrial activation occurs through the normal bundle of His (H) and atrioventricular (AV) node (AVN).

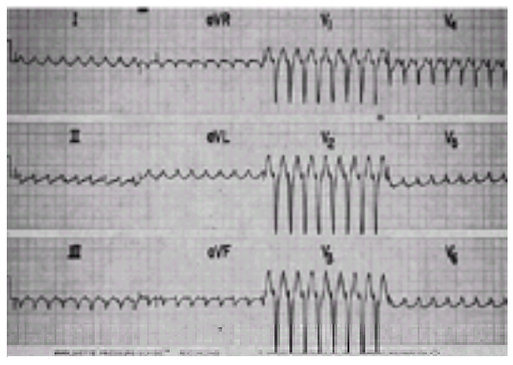

***e*FIGURE 66.13.1** Wide complex tachycardia through an atriofascicular fiber. Because of the distal insertion of the extra connection in the region of the right bundle branch block, the tachycardia shows a left bundle branch block left-axis–deviation morphology with small, sharp R waves in lead V_1. Note also the characteristic late transition of QRS complexes in the precordial leads.

Fasciculoventricular Mahaim Fibers

A final variant of the preexcitation syndromes is created by a fasciculoventricular Mahaim fiber (64). Here, a conducting strand of tissue bypasses the distal component of the His-Purkinje system, resulting in earlier ventricular activation than expected through the normal His-Purkinje network. This is manifested at the time of electrophysiologic testing by a shortened HV interval recorded on the bundle of His electrogram. Unlike with atriofascicular fibers, bundle of His pacing fails to eliminate this preexcitation because pacing at these sites is upstream from the site of the bypassing fiber.

ATRIOVENTRICULAR NODAL OR JUNCTIONAL REENTRANT TACHYCARDIAS

Anatomic Considerations

The most common mechanism of AV nodal–dependent tachycardia is AV nodal or junctional reentry, as shown in Figure 66.14. Approximately 60% (147,148 and 149) of all narrow QRS complex SVTs seen in the clinical setting are due to reentry within at least two parallel components in or near the AV nodal portion of the normal AV conduction system. The precise anatomic construction of these pathways remains a subject of controversy, with debate centering on the existence of common pathways both at the entry and exit points of the AV conduction system. It had been accepted that two pathways with differing conduction properties were confined to the compact portion of the AV node, as shown in Figure 66.14. Recently other investigators have argued that at least a portion of the circuit lies outside the compact region of the AV node, as shown in Figure 66.2B (42,49,150,151).

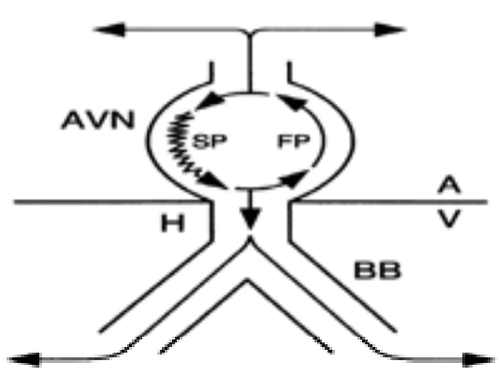

FIGURE 66.14 Microanatomy of atrioventricular (AV) nodal reentrant tachycardia. Here, dual physiologically or anatomically dissociated AV nodal pathways are confined to the compact portion of the AV node (AVN). Note the upper and lower final common pathways at the proximal and distal ends of the compact node. This is in contrast to the AV nodal reentrant circuit involving extranodal atrial tissue seen in Figure 66.2B, where the retrograde atrial activation proceeds through the fast pathway (FP), which exits near the distal portion of the compact AV node. A variable portion of the atrium is subsequently traversed by a reentrant impulse that then reenters the AV conduction system through a posterior slow pathway (SP). H, bundle of His.

In addition, early studies suggested that these functionally, if not anatomically, separate pathways joined at the upper and lower regions of the compact AV node to exit into the surrounding atrial or His-Purkinje tissue, respectively, through single, final, common pathways. This concept is supported by the uncommon occurrence of atrial dissociation from the remaining portion of the AV nodal reentrant circuit during tachycardia (147,152,153). Additional evidence for a final, lower, common pathway is found in the occurrence of dissociation of the ventricles from the tachycardia circuit, as well as the inability to retrogradely preexcite the atria when introducing a VPC at a time when the His-Purkinje system is refractory.

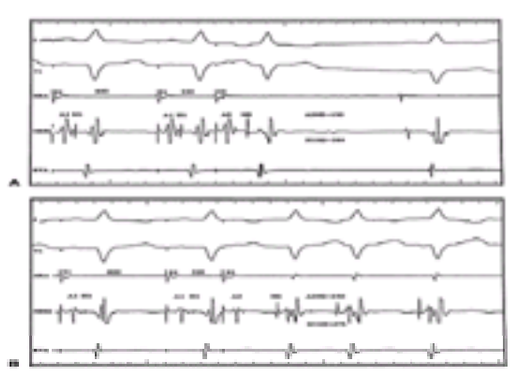
In contrast, other investigators (42) have argued that at least a component of the reentrant circuit lies outside the compact region of the AV node, passing through atrial tissue, as depicted in Figure 66.2B. The presence of a different retrograde atrial activation sequence with conduction through a fast pathway (FP) versus a slow pathway (SP) further argues against a final common upper pathway, as do recent pacing studies (154). Both surgical- and catheter-based studies have demonstrated that retrograde activation through the FP typically exits the compact portion of the AV node both anteriorly and superiorly to the distal portion of the AV node near the origin of the bundle of His. In contrast, earliest retrograde activation through the SP occurs 2 to 3 cm further posteriorly along the tricuspid annulus near the coronary

sinus orifice (42,49,150,151). Investigators have described an unusual occurrence of atypical AV nodal reentrant tachycardia with eccentric retrograde left-sided activation that may be confused with AV reentrant tachycardia using a concealed left AP. Interestingly, these tachycardias were cured with catheter ablation at the posteroseptal region of the right atrium (155). Catheter ablation of the AV nodal SP for typical AV nodal reentrant tachycardia from the left atrial septum via a transseptal approach when conventional right-sided techniques failed has also been described (156,157). Both left and right posterior extensions of the human compact AV node have been described from human autopsy studies and have been speculated to be involved in SP conduction (158).

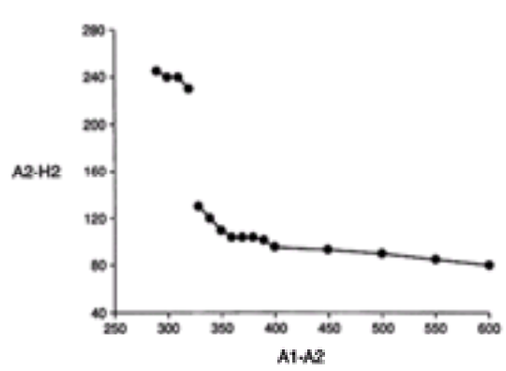
The response to extrastimulus testing has also been proposed as an indication of separate pathways connected by atrial tissue. The advancement of bundle of His activation with an APC introduced in the posterior part of the intraatrial septum near the coronary sinus orifice at a time when the anterior portion of the septum near the FP has already been activated suggests an atrial component of the circuit external to the AV node (42).

Physiologic Mechanisms

Regardless of the anatomy of the circuit, pacing studies clearly demonstrate physiologically discontinuous, or longitudinally separate, conduction through the two or more components of the involved AV conduction system (10,11,16,150,159,160). During sinus rhythm, during slow atrial pacing, or with the introduction of late coupled APCs, AV conduction typically occurs through the faster of the dual functionally or anatomically distinct AV nodal pathways. Here, conduction times are short, and the PR interval inscribed on the surface ECG may be less than 140 ms. With faster pacing or with the introduction of progressively earlier APCs, a critical point of refractoriness or effective recovery time within the FP is reached. With subsequent decrements in the timing of the APC, AV conduction switches to the “slower” component of the dual AV conduction system, typically with a more than 50-ms prolongation of the AH interval conduction time through the AV node, as shown in *e*Figure 66.14.1. This jump from the FP to the SP over a 10-ms decrease in the APC coupling time produces a discontinuity in the plot of the trans-AV nodal conduction time or the AH interval given as a function of the timing of the premature impulse or A_1 to A_2 interval (*e*Fig. 66.14.2); hence, the descriptor, *discontinuous conduction*. Some patients may have several discontinuities, suggesting multiple SPs. Furthermore, the presence of such conduction may not, in and of itself, be “abnormal,” because up to 70% of patients undergoing electrophysiologic testing who do not have clinical AV nodal reentrant tachycardia reportedly have such anterograde or retrograde conduction discontinuities (161,162 and 163).

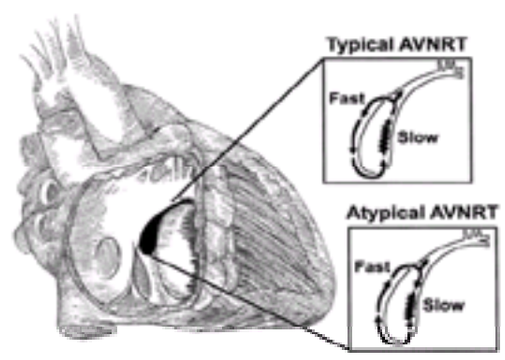


***e*FIGURE 66.14.1** Intracardiac tracings showing dual atrioventricular (AV) nodal physiology and initiation of AV nodal reentrant tachycardia. Lead configurations are similar to those seen in *e*Figure 66.3.2 and Figure 66.3.3. An atrial premature complex introduced with an A_1 to A_2 interval of 330 ms conducts through the fast pathway **(A)**. **B:** With a 10-ms decrement to 320 ms, block is followed by conduction through the slow pathway and a 100-ms prolongation of the A_2 to H_2 interval. Thereafter, AV nodal reentrant tachycardia with a ventriculoatrial interval of 40 ms is observed. HBE, bundle of His region; HRA, high-right atrium; RVA, right ventricular apex.



***e*FIGURE 66.14.2** Discontinuous atrioventricular (AV) nodal conduction curves resulting from dual AV nodal physiology. The abrupt prolongation in the A_2 to H_2 interval with a decrease in the A_1 to A_2 interval from 320 to 310 ms, which indicates a jump from the AV nodal fast pathway to slow pathway is readily apparent. Some patients may have multiple discontinuities, which indicates more than one slow pathway.

In 85% to 95% of patients, a slow/fast–type AV nodal–dependent tachycardia is seen in which the SP with the longest conduction time of the two AV nodal tracts comprises the anterograde limb of the reentrant circuit. This pathway is typically encountered in or near the posterior aspect of the compact portion of the AV node. Return or retrograde impulse propagation, as shown in *e*Figure 66.14.3, proceeds through the FP with a shorter conduction time located in the anterior and medial aspect of the compact portion of the AV node near the origin of the bundle of His. The inscription of a rapid electrogram deflection immediately after local atrial activation during sinus rhythm along the posterior aspect of the tricuspid annulus near the coronary sinus orifice has been shown to emanate from the SP. Similarly, a high-frequency deflection can also be observed before atrial activation during retrograde conduction through the SP (41). The exact origin of these potentials is unclear, however, as they may also result from the specific atrial architecture underlying the posteroseptal region (164,165 and 166).



***e*FIGURE 66.14.3** Mechanisms of typical slow/fast and atypical fast/slow atrioventricular nodal reentrant tachycardia (AVNRT). **Top inset** shows anterograde conduction occurring through the slow pathway with return retrograde atrial activation through the fast pathway. The completion of the return portion of the circuit occurs simultaneously with or shortly after concomitant conduction through the His-Purkinje system to activate the ventricle. **Bottom inset** shows atypical fast/slow AVNRT in which the direction of the reentrant circuit is reversed. Because of the prolonged atrial activation times through the slow pathway, a long RP tachycardia is present.

In 3% to 20% of patients, the tachycardia circuit direction is reversed and a fast/slow or atypical type of AV nodal reentrant tachycardia is observed, as shown in *e*Figure 66.14.3 (16,167,168,169,170 and 171). In this case, anterograde conduction proceeds down the faster of the two pathways, with return activation through the SP. Given the potential of multiple SPs and therefore multiple discontinuities, the circuit involved in this atypical arrhythmia may not be the same as that involved in the

slow/fast type of AV nodal reentrant tachycardia seen in the same patient. Furthermore, up to 9% of individuals also display a slow/slow type of AV nodal reentrant tachycardia in which both anterograde and retrograde conduction occurs through such multiple SPs (14,151,160,169,170,172).

Initiation of Tachycardia

AV nodal reentrant tachycardia is most frequently initiated when a critically timed APC blocks in the FP with longer refractoriness and conducts through the SP. If the impulse then returns retrogradely to the atria through the FP, which has since recovered from the anterogradely conducting and blocking APC, the reentrant circuit is completed. This is facilitated by the substantive delay within the SP, giving the FP sufficient time to recover from the original block created by the APC (10,81,159,173,174).

AV nodal reentrant tachycardia is initiated less frequently by a VPC that conducts to the atria through the retrograde FP but reenters with return conduction through the SP (175). This mechanism of initiation is also more common in atypical or fast/slow AV nodal reentrant tachycardia. In such cases, retrograde activation after the VPC proceeds through the slower AV nodal pathway, with return ventricular activation through the faster of the dual AV nodal physiologic or anatomic pathways.

Presentation on Electrocardiogram

Because return atrial activation and P-wave generation during typical AV nodal reentrant tachycardia is rapid, the earliest atrial deflection on the bundle of His electrogram during tachycardia is usually less than 60 ms (84). Although such a short VA interval excludes the possibility of a reentrant tachycardia using an AP, longer VA intervals do not eliminate the possibility of AV nodal reentrant tachycardias that use an SP as the retrograde limb of the reentrant circuit. As such, a short VA interval for diagnosing all AV nodal reentrant tachycardias is not completely sensitive, although its positive predictive value is very high.

Therefore, a retrograde P wave is inscribed within or at the end of the QRS complex or ECG. This dictates that this arrhythmia is a short RP tachycardia (46,84,149,176,177). If the P wave occurs at the end of the QRS complex on the surface 12-lead ECG, a pseudo–R-wave deflection in V_1 not present during normal sinus rhythm may be seen, as shown in Figure 66.15 (80,176,177). This is a highly sensitive and specific indicator of AV nodal reentry as the mechanism for a narrow QRS complex tachycardia (80,149,177).

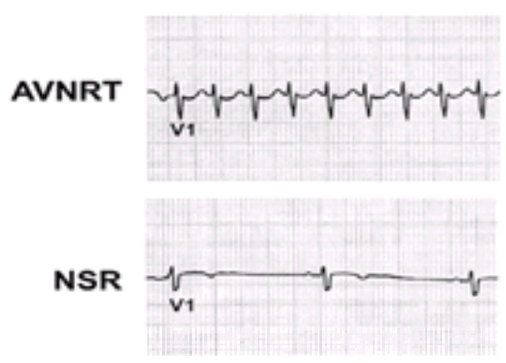


FIGURE 66.15 V_1 rhythm strips showing pseudo rSR' QRS configuration in a patient with atrioventricular nodal reentrant tachycardia (AVNRT). In the **upper panel**, the short ventriculoatrial conduction time during tachycardias results in inscription of the retrograde P wave at the end of the QRS complex, giving the “rSR prime” configuration. In the **lower panel**, normal sinus rhythm in the same lead shows resolution of that component. This is highly indicative of atrioventricular nodal reentry as the mechanism of the arrhythmia.

In contrast, atypical AV nodal reentrant tachycardia with retrograde conduction through the SP, such as PJRT, inscribes its retrograde P wave later in the RR diastolic interval, more closely coupled to the following QRS complex (42,148,168,170). Thus, criteria for a long RP tachycardia are met. By virtue of the posteroseptal site of retrograde atrial activation, retrograde P waves typically observed during this arrhythmia are negative in leads II, III, and aVF, again indicating a low-to-high atrial activation sequence.

This arrhythmia and PJRT must be distinguished from other long RP tachycardias (80,178). Sinus tachycardia, sinus node reentry, and a variety of atrial tachycardias in the absence of marked PR interval prolongation also show a close association between the P wave and the subsequent QRS complex. Given their AV nodal–independent mechanisms, these atrial tachycardias persist when higher-grade AV block occurs spontaneously or after vagal or drug interventions. Furthermore, many of these tachycardias show a high-to-low atrial activation sequence, unlike that seen with PJRT or atypical AV nodal reentry.

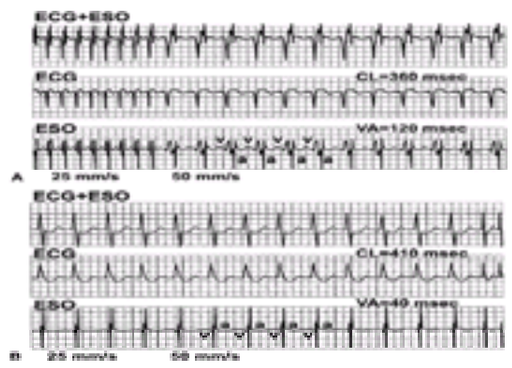
DIFFERENTIATING ATRIOVENTRICULAR NODE REENTRANT FROM ATRIOVENTRICULAR REENTRANT TACHYCARDIAS

Distinguishing AV reentrant from AV nodal or junctional reentrant narrow-complex tachycardias is important in planning therapeutic strategies for these tachycardias. An understanding of these aforementioned mechanisms provides the needed clues for such differentiation. It was once believed that both the tachycardia rate and the presence of QRS alternans were useful in establishing a diagnosis of AV reentrant tachycardia (149). Although AV reentrant tachycardias may be faster in some patients, the overlap in heart rates with these two mechanisms makes this factor unhelpful in establishing a diagnosis of AV reentrant tachycardia. Furthermore, the presence of QRS alternans, as shown in Figure 66.16, has since been shown to be a function of heart rate and not of the specific underlying mechanism (46).

FIGURE 66.16 QRS alternans during reciprocating tachycardia. Note the alternating amplitude of the R wave in leads V_1 and V_4. This is a rate-related process and is not predictive of the underlying mechanism.

The positions of the P wave and the RP intervals in tachycardia are more useful in distinguishing these two reentrant mechanisms (46,80,176,177). P waves inscribed within the ST or T segments observed in AV reentry (46,68,149,176,179,180) contrast with the even shorter RP intervals and accompanying P waves producing the r' in lead V_1, which is highly predictive of an AV nodal reentrant mechanism (80,176,177). Obviously, in some cases the P waves are not obvious on the surface ECG, and recordings using an esophageal lead are required to determine the RP or VA interval.

*e*Figure 66.16.1 shows representative tracings from patients with AV reentrant and AV nodal reentrant tachycardias. The patient in the left panel had a VA interval of 120 ms, consistent with retrograde conduction through an AP. In contrast, the right panel shows a VA conduction time of 40 ms, which is too short for occurrence through an AP. This was recorded from a patient with AV nodal reentrant tachycardia.



***e*FIGURE 66.16.1** Esophageal lead tracings in patients with atrioventricular (AV) reentrant and AV nodal reentrant tachycardias. Shown here are the surface electrocardiogram (ECG), esophageal (ESO), and combination ECG and ESO recordings at a paper speed of 50 mm per second. The retrograde ventriculoatrial conduction time is 120 ms in the patient with AV reentrant tachycardia seen in **(A)**. Panel **B** shows a retrograde ventriculoatrial conduction time of 40 ms in a patient with AV nodal reentrant tachycardia.

Finally, it should be noted that 10% to 20% of patients with WPW syndrome also have AV nodal reentrant tachycardia with a narrow QRS morphology (94,96,97,162,181,182). Therefore, the presence of a narrow QRS SVT in a patient with WPW syndrome does not necessarily indicate AV reentrant tachycardia. In these patients, clarification of the precise mechanisms of arrhythmias requires more detailed electrophysiologic evaluation.

PRINCIPLES OF MANAGEMENT

Short-Term Therapy for Narrow Complex Tachycardias

The dependence of both AV reentrant and AV nodal reentrant tachycardias on AV nodal conduction has important implications for the short-term management of patients with these arrhythmias. As reviewed in Figure 66.17, the simplest approach to tachycardia termination takes advantage of vagal modulation of AV nodal conduction. In many patients, a Valsalva maneuver, carotid sinus massage, or application of ice water to the face will terminate the tachycardia by increasing vagal tone. If these approaches prove unsuccessful, the use of drugs with significant negative dromotropic effects on the AV node may also readily terminate either type of SVT. Adenosine, administered in a rapid bolus at an initial dosage of 6 mg i.v. (Fig. 66.18), will terminate 62% of tachycardias, whereas 91% of these tachycardias respond to 12 mg of adenosine from a peripheral i.v. site (183). Alternatively, 5 to 10 mg of i.v. verapamil will terminate up to 90% of tachycardias (184,185 and 186). The high success rate of these i.v. drugs has supplanted the use of edrophonium (a short-acting cholinesterase inhibitor), phenylephrine, or beta-blockers, which had been used at one time for this purpose. Although i.v. esmolol, a short-acting beta-blocker, may also be effective, accompanying hypotension has been reported (187). The use of these drugs or of vagal maneuvers is also useful to the diagnosis because the development of higher-grade AV nodal block during tachycardia, as shown in Figure 66.1 and Figure 66.19, virtually excludes the presence of an AV nodal–dependent tachycardia. It should be noted that under rare circumstances AV nodal reentrant tachycardia may show 2:1 AV block due to physiologic impairment of infra-His conduction; however, this is unlikely to occur with vagal or drug interventions.

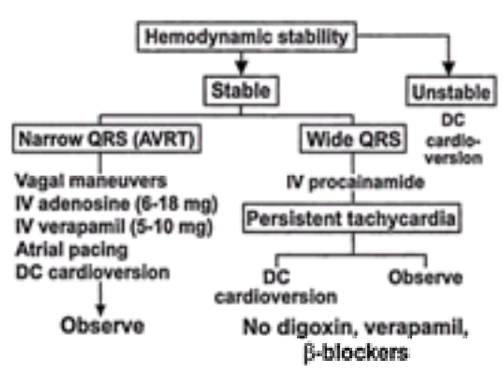


FIGURE 66.17 Algorithm for the acute management of patients with atrioventricular nodal–dependent tachycardias. AVRT, atrioventricular reentrant tachycardia; DC, direct current.

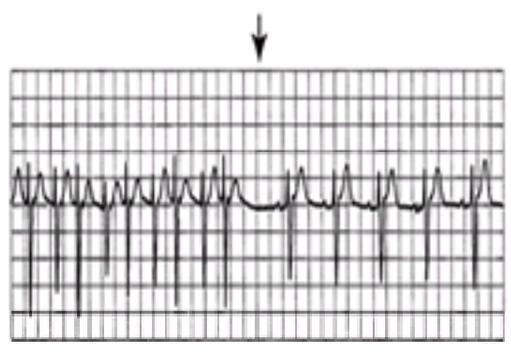

FIGURE 66.18 Termination of supraventricular tachycardia with adenosine. Twelve mg of adenosine given intravenously results in abrupt termination of narrow complex tachycardia in a patient with atrioventricular nodal reentry. Note the alternating tachycardia cycle lengths before termination.

FIGURE 66.19 Effect of carotid sinus massage on atrioventricular conduction in a patient with an ectopic atrial tachycardia. On the left side of the figure, a narrow QRS complex tachycardia was observed with a 1:1 atrioventricular relationship, as seen in leads V_1 to V_3. With carotid sinus massage, high-grade atrioventricular nodal block, which readily discloses the continuing atrial tachycardia, appears as 1:1 conduction and resumes after resolution of the carotid sinus massage effect.

Intravenous flecainide, propafenone, sotalol, or amiodarone may also prove effective in restoring sinus rhythm, although these drugs may take longer to produce

clinically relevant effects. Although i.v. ibutilide is effective in terminating the acute onset of atrial fibrillation and its class III properties may effectively block AP conduction, the safety and efficacy of this agent for treating narrow, complex AV nodal–dependent tachycardia have not been established. The same is true for dofetilide and azimilide, which have been studied almost exclusively in atrial fibrillation and atrial flutter, the latter of which is not available in i.v. forms in the United States.

Nonpharmacologic therapies for patients with narrow, complex SVTs are also available to restore normal sinus rhythm. Atrial pacing using an esophageal lead positioned behind the atria proves routinely effective in terminating AV nodal–dependent tachycardia (38,188,189 and 190). With this approach, current strengths of 10 to 20 mA with pulse widths between 10 and 20 ms may be required. Although this approach is effective, it also produces some esophageal discomfort and can initiate atrial fibrillation. Administration of a low-energy direct current shock to stop tachycardia is an alternative, but it is rarely required, given the efficacy of pharmacologic and other nonpharmacologic measures.

Short-Term Management of Wide-Complex Tachycardias

The presence of a wide QRS complex tachycardia warrants careful consideration of several additional issues. Although the prolongation of the QRS complex may simply represent aberrancy accompanying an AV nodal–dependent tachycardia, the diagnosis of ventricular tachycardia should be carefully considered. The presence of underlying coronary artery disease or prior myocardial infarction has an accuracy of more than 90% in predicting a ventricular mechanism for wide-complex arrhythmias (191). These issues are reviewed in greater detail in Chapter 60. An additional mechanism of wide QRS tachycardia in patients with AV nodal–dependent arrhythmias is that of an antidromic reciprocating tachycardia that uses an AP as its anterograde limb, atrial fibrillation, or other atrial tachycardias with ventricular preexcitation through the accompanying pathway. Each of these arrhythmias should be manifest by their characteristic slurred upstroke delta waves seen in the first 40 ms of the wide QRS complex. During atrial fibrillation with a rapid ventricular response rate, however, the characteristic preexcited QRS pattern may be difficult to discern. Preexcitation may be most evident in the QRS complexes after the longest RR intervals during irregular tachycardias. Ventricular activation during atrial fibrillation in patients with multiple APs may proceed by several alternating avenues, thus mimicking torsades de pointes on a single rhythm strip. As with evaluation of any wide-complex arrhythmias, a surface 12-lead ECG is indispensable in correctly identifying the underlying mechanism.

The short-term treatment of wide-complex tachycardia first and foremost depends on the patient's underlying hemodynamic status. In the presence of hemodynamic compromise, direct current cardioversion after appropriate anesthesia is warranted. It is not uncommon for direct current cardioversion to require at least 200 J to restore normal sinus rhythm in patients with WPW syndrome and atrial fibrillation. In the presence of stable hemodynamics, several different i.v. antiarrhythmic agents are available. Intravenous procainamide has been most widely used for this purpose. This agent not only alters propagation through the APs, but it may also directly restore normal sinus rhythm. Use of beta-blockers (187,192,193,194 and 195) and lidocaine (192,196,197) is not effective for either purpose. Intravenous propafenone, flecainide, and sotalol are effective in both slowing the ventricular response rate during atrial fibrillation and restoring normal sinus rhythm in patients with APs. These drugs, however, are not commercially available in the United States. Intravenous amiodarone is also effective, although the time to conversion with this agent may be longer, and the overall conversion rate may be low. Intravenous ibutilide may also restore normal sinus rhythm, although its safety and efficacy in this setting have not been documented.

Several i.v. agents can also accelerate AV conduction through an AP, causing atrial fibrillation to degenerate into ventricular fibrillation. Digoxin, although slowing atrial fibrillation in some patients, clearly accelerates the ventricular response rate in others (198). This deterioration has also been described after use of i.v. verapamil (199,200,201,202 and 203). A similar reduction in the shortest RR interval during atrial fibrillation has also been observed after i.v., but not oral, diltiazem (13). This acceleration may be due to direct pathway effects, enhancement of peripheral sympathetic activity related to the precipitation of hypotension, or the reduction in retrograde concealment into the AP by generation of higher-grade AV nodal block. In the presence of atrial fibrillation in a patient with an anterogradely conducting AP, ventricular activation proceeds through the pathway or the normal AV conduction system. The latter avenue of propagation may be accompanied by impulse propagation across the ventricle in a reverse direction into the pathway. This retrograde penetration or concealment blocks ventricular activation proceeding anterogradely through the pathway because of impulse collision. This produces a net effect of slowing ventricular activation. Higher-grade AV nodal block can reduce this beneficial effect by withdrawing retrograde concealment. Ventricular fibrillation after adenosine administration in a patient with WPW syndrome and atrial fibrillation has also been reported (204). Because of this and the potential hemodynamic deterioration of ventricular tachycardia, these drugs should not be routinely used in patients with wide-complex tachycardias. This does not mean that their use is prohibited in patients with narrow QRS complex tachycardias, although the possibility of degeneration of such arrhythmias into atrial fibrillation dictates that facilities dealing with such unlikely transitions should be available.

Long-Term Therapy for Atrioventricular Nodal–Dependent Tachycardias

Drug Therapy

In selecting appropriate therapy for patients with supraventricular arrhythmias, several general principles should be carefully considered. The inherent risk for untoward events accompanying the target arrhythmia, as well as its impact on the patient's quality of life, must be carefully weighed against the anticipated treatment's efficacy and accompanying risks. Furthermore, the effectiveness and risks, including side effects, of a given strategy must be carefully compared with those of other treatment options. In the case of increased risk for SCD in symptomatic patients with WPW syndrome, aggressive evaluation and treatment are warranted. Here, the risks of intervention are likely to be small compared with the risks associated with the underlying arrhythmia. These patients are best treated with definitive ablative procedures. This is in part because of the relatively limited efficacy of antiarrhythmic therapy on AP conduction in those patients with the most rapid underlying conduction capabilities (205). This is a particularly true of class Ia antiarrhythmic agents.

In contrast, in the absence of a propensity for rapid anterograde conduction through an AP during atrial fibrillation or of marked neurologic symptoms, such as presyncope or syncope, the majority of AV nodal–dependent tachycardias are relatively benign. As such, therapy is warranted if prevention of symptomatic arrhythmia improves quality of life and can be accomplished without undue risk to the patient. The benefit of achieving such arrhythmic suppression must be weighed against possible side effects, the proarrhythmic risk from drug therapy, or complications from ablation. In those cases of single or infrequent tachycardia episodes with relatively mild symptoms, expectant observation without treatment or with sole use of vagal maneuvers to terminate tachycardia, where effective, may suffice. In such cases, ablative therapy is unnecessary. Patients with frequently recurring palpitations clearly related to an AV nodal–dependent tachycardia, those with problematic, associated cardiac or central nervous system symptoms, those in whom drugs are either ineffective or accompanied by side effects, or individuals facing lifetime medical therapy are best treated with catheter ablation. The exception to this approach is those patients in whom the risks associated with catheter ablation may be greater than the risk of the underlying arrhythmia. For example, patients with an AP located close to the normal AV conduction system in which the risk for high-grade or complete heart block is high may be better treated with medical therapy. Obviously, if such therapy proves ineffective or if the patient is at risk for SCD the potential complications of catheter ablation may be unavoidable to provide symptomatic relief and protection for the patient.

Other patients will benefit from the more readily available drug therapies. In the absence of anterograde preexcitation or atrial fibrillation, patients with AV reentrant tachycardia may be effectively managed using calcium channel blockers, such as verapamil or diltiazem (13,206,207 and 208), or any one of a number of beta-blockers (187,193) that target the AV node, as shown in Figure 66.20. The latter may be useful in those patients with exercise-related tachycardia. These agents are also effective in modifying conduction within the SP in AV nodal reentrant tachycardia and within the AP involved in PJRT or atriofascicular reentrant tachycardia. Efficacy rates of 40% to 50% in eliminating or significantly reducing the frequency of AV nodal–dependent tachyarrhythmias have been reported. Furthermore, the risk for proarrhythmia using these agents is very low and most of these drugs can be administered in single daily doses.

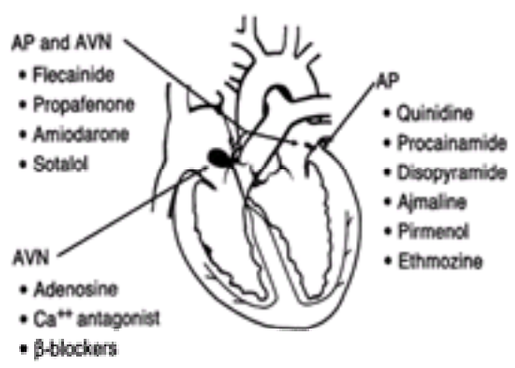

FIGURE 66.20 Antiarrhythmic drug effects in patients with Wolff-Parkinson-White syndrome. Shown here are drugs with exclusive accessory pathway (AP) effects, with exclusive atrioventricular nodal (AVN) actions, and with both AP- and AVN-modifying properties. Pharmacologic modulation of the fast pathway in AVN reentrant tachycardia is similar to that of an AP. The slow pathway behaves in a manner similar to that of AVN tissue.

In contrast, class Ia agents such as quinidine (209,210), procainamide (209,210 and 211), or disopyramide (212,213) produce beneficial effects on the AP but not on the normal AV conduction system. Other class I agents such as propafenone (214,215,216 and 217), flecainide (218,219,220,221 and 222), and moricizine and class III drugs such as sotalol (223,224,225 and 226) and amiodarone (71,227,228,229,230 and 231) have demonstrable effects on both the AV conduction system and the AP (Fig. 66.20). Because the FP used as the retrograde limb of AV nodal reentrant tachycardia has many properties similar to those of APs, class I agents also produce beneficial effects on both the frequency and severity of this arrhythmia (208,232,233,234,235 and 236). Class Ic and class III drugs may also sufficiently modify the anterograde SP to reduce the occurrence of arrhythmias. These agents produce additional beneficial effects in patients with either type of AV nodal–dependent arrhythmia by reducing tachycardia-induced atrial or ventricular ectopy. Regardless of the specific underlying mechanism, the efficacy of these agents in treating AV nodal–dependent arrhythmia is 60% to 80% over short-term follow-up.

The choice of a specific membrane-active antiarrhythmic agent for use in patients with AV reentrant tachycardia depends on several factors. These include (a) the presence or absence of structural heart disease or other organ system problems; (b) the presence of preexcitation; and (c) the side effect profile of a given agent, including organ toxicity, negative inotropic effects, and propensity for proarrhythmias. In the absence of underlying heart disease, any one of the class Ic, III, or Ia drugs may be effective in managing AV reentrant tachycardias. Of these, flecainide, propafenone, disopyramide, and sotalol are less likely to produce organ toxicity or nuisance side effects. In this setting, the risk of a proarrhythmic event is low and ranges from 0.5% to 2.0%. In the presence of underlying heart disease, those agents such as disopyramide and flecainide, and to a lesser extent, propafenone and sotalol, that may have significant negative inotropic effects, should be used with caution, if at all. Although these agents are not absolutely contraindicated in patients with EFs of 30% to 45%, the presence of congestive heart failure should dictate an alternative choice of therapy. In the presence of congestive heart failure or prior myocardial infarction, amiodarone is least likely to produce a proarrhythmic effect. The risk for proarrhythmia with other class I and class III drugs may be as high as 5% to 8%, particularly with the class Ia agents producing significant QT interval prolongation in the presence of underlying heart disease. Specific drug therapy for these tachycardias and dosing strategies are reviewed in greater detail in other studies (26,27 and 28).

Nonpharmacologic Therapy: Radiofrequency Ablation

Although drug therapy was the mainstay of treatment for AV nodal–dependent tachycardias for many years, the advent and improvement of surgical techniques in the 1970s ushered in an era of nonpharmacologic therapy. Those patients with an AP who were at risk for SCD, those in whom antiarrhythmic therapy had failed because of inefficacy or side effects, or those patients who faced lifelong medical therapy were increasingly managed with surgical ablation. During the past 6 years, even this approach has been replaced by RF ablation. As described in greater detail in Chapter 73, success rates of 90% to 98% are routinely possible (41,43,44). A 5% to 8% recurrence rate of AP conduction nevertheless may occur (41,43,44). This ablative approach is accomplished at low risk, and the benefits to patients are achievable at lower cost and substantially less hospitalization and recovery times than are possible with surgical ablation. Hence, RF ablation is a reasonable first-line modality in patients with recurrent arrhythmias. Again, potential exceptions to this approach are encountered in patients who are at higher risk for complete heart block due to pathways in close proximity to the AV conduction system or to other factors that increase the risks of invasive procedures.

In patients with AV nodal reentrant tachycardias, similar success rates are now possible with ablation of the SP or atrial approaches to that pathway, which lies posteriorly along the tricuspid annulus. The risk for heart block in these patients is 0.5% to 3.0%, depending to some extent on the experience of the perator and on the apparent SP location. This approach has virtually supplanted the alternative ablation of the FP, which has been accompanied by heart block rates of 5% to 25% (42,46,237,238).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Risk Stratification in Patients with Asymptomatic Preexcitation

Although much of the physiology of the AV nodal–dependent arrhythmias has already been elucidated and management and treatment methods established, several areas of controversy remain. It is the opinion of the author (D.L.P.) that risk stratification in patients with asymptomatic preexcitation is not necessary, unless extenuating circumstances exist. Some clinicians, however, continue to be strong proponents of risk stratification in all patients. As discussed above, the likelihood of rapid conduction through an AP in the absence of symptoms is low; moreover, the risk of SCD has been shown in population-based studies to be very low. Still, the risk for an untoward event is not zero. On rare occasions, patients present with ventricular fibrillation as their first manifestation of WPW syndrome. As such, clinicians cannot give patients a blanket guarantee of freedom from untoward events over the long term. It is important that this uncertainty be discussed with patients to provide them with the necessary understanding needed to make informed decisions about proceeding with additional evaluation and treatment and any accompanying risks, if they are asymptomatic. If risk stratification is to be undertaken, it should be by direct initiation of atrial fibrillation and assessment of the ventricular response rate. Noninvasive methods are insufficiently predictive to be of any significant use. If rapid conduction through an AP is identified, the patient should have sufficient information to either accept the risks associated with such rapid conduction or the risks associated with ablation of the offending AP. When presented with the juxtaposition of the risks associated with no intervention versus those of catheter ablation, some patients may well opt for conservative follow-up. Others may wish to face the risks of ablation immediately rather than confront continued pathway-related risks, no matter how low, over time.

Anatomy of Atrioventricular Nodal Reentrant Tachycardias

Another area of controversy is outlined previously in this chapter. Some clinicians argue that the circuit resides within the compact portion of the AV node. Others argue that at least a component of the reentrant circuit lies outside the compact region of the AV node. In the latter case, the SP is viewed as arising from atrial tissue, with insertion into the compact AV node. Given the various considerations on both sides of this argument, it seems most likely that an appreciable component of the reentrant circuit resides outside the AV node within atrial tissue. In fact the FP and SP may even be variable manifestations of anisotropic tissue architecture in the interatrial septum. It is therefore likely that the anterograde limb of the circuit is actually composed of both the atrial tissue inputs into the posterior region of the AV node and a component of AV nodal tissue itself. As such, successful SP ablation may simply mean that the atrial inputs into the AV node have been sufficiently modified to make onset of tachycardias unlikely.

Radiofrequency Ablation as First-Line Therapy for Atrioventricular Nodal–Dependent Tachycardia

Finally, in some quarters, the propriety of RF ablation as first-line treatment for AV nodal–dependent arrhythmias remains controversial. Some clinicians believe that patients with AV reentrant tachycardia in the absence of manifest preexcitation and those with AV nodal reentrant tachycardias should be managed with antiarrhythmic drugs that target the AV node. Ablative therapy is reasonable first-line therapy if (a) a patient faces lifelong medical therapy, (b) there is an arrhythmia refractory to previous medical treatment, (c) the patient is at risk for an untoward event, or (d) the patient resides in an area where medical therapy for tachycardia is less readily available. Again, the risks of this therapy must be weighed against the alternative of using membrane-active antiarrhythmic drugs. Although most of these agents are reasonably tolerated when appropriately administered, constitutional side effects and the risk of potentially lethal proarrhythmia remain a reality. In the hands of experienced interventionalists, the risks associated with ablation remain very low; moreover, ablation has the added advantage of curing the arrhythmia. RF catheter ablation of SVT has been shown to be cost-effective and improve quality of life for patients with WPW who survive cardiac arrest or who experience SVT or AF (239) and for highly symptomatic patients with AV nodal reentrant tachycardia or AV reentrant tachycardia using a concealed AP (240). Here again, patients should be informed of their options so they may participate in choosing an approach that best meets their needs.

CONCLUSIONS

Over the past 15 to 20 years, substantial progress has been made in the treatment of AV nodal–dependent tachycardias. This has been facilitated by the development of catheter-based electrophysiology study techniques that elucidate the underlying arrhythmic mechanisms, the development of better drugs for acute and chronic management, and the refinement of nonpharmacologic therapy such as RF catheter ablation for curing these arrhythmias. This progress has not only elucidated these arrhythmias, but has also provided the foundation for extrapolating these refinements to the more complicated AV nodal–independent atrial and ventricular tachycardias. An appreciation of these issues should improve the efficacy of therapies and reduce their risk in patients with AV nodal–dependent tachycardias.

THE FUTURE

Substantial progress has already been made in the area of AV nodal–dependent tachycardias. Excellent therapies are already available and have been applied successfully in thousands of patients. In the future, however, we will undoubtedly better define the cost-effectiveness of the various treatment modalities through outcome-based studies. A better understanding of the natural history of AV nodal–dependent arrhythmias will be forthcoming. Technology will be developed to facilitate noninvasive substrate localization and establishment of mechanisms. Nonfluoroscopic multisite mapping for creating three-dimensional maps of specific arrhythmias and improved energy sources and delivery techniques will also be forthcoming. With the anticipated progress during the next 5 to 10 years, it would not be surprising if arrhythmogenic substrate could be eliminated through energy delivery from the body surface.

OVERVIEW

Ventricular tachyarrhythmias are a major cause of sudden cardiac death, which makes up approximately 50% of all cardiac-related deaths. Most ventricular tachycardias are due to a reentrant mechanism but focal automatic as well as triggered automaticity play a role in certain types of ventricular tachycardias. The most common cause of ventricular tachycardia in the Western world is ischemic coronary artery disease. Both ischemia and the scarred tissue of old myocardial infarction can contribute to the initiation and sustainment of ventricular tachycardia in the setting of coronary artery disease. After a myocardial infarction, several clinical factors appear to indicate a high risk of spontaneous occurrence of ventricular tachycardia or sudden death in a patient. Depressed left ventricular function, presence of nonsustained ventricular tachycardia, occurrence of syncope, presence of late potentials on the signal-averaged electrocardiogram (ECG), decreased heart rate variability, presence of microvolt T-wave alternans, and inducible sustained ventricular tachycardia during an electrophysiologic study are all predictors of this risk. Antiarrhythmic drug therapy is used infrequently as a primary therapy for sustained ventricular tachycardia in the setting of structural heart disease. When used, amiodarone and sotalol are the most common medications. The implantable cardioverter-defibrillator (ICD), especially with the improved technology that allows transvenous implantation of the electrode and pectoral implantation of a small generator, is the most reliable approach to reduce arrhythmic deaths. Catheter ablation is a modality that is useful for special circumstances.

Wide complex tachycardia. Atrioventricular dissociation confirms ventricular origin.

Reentry using the His-Purkinje system is seen more often as the cause of sustained ventricular tachycardia in patients with nonischemic cardiomyopathy than in postmyocardial infarction patients. Recognition of this type of ventricular tachycardia is important because of the comparable ease of ablating this reentrant circuit when compared with ablation of myocardial scar–related ventricular tachycardia.

Both monomorphic and polymorphic types of tachycardias can occur in patients with otherwise structurally normal hearts. For the monomorphic varieties, radiofrequency catheter ablation in well-trained hands has a high success rate in eliminating the tachycardia. Long QT syndrome is a major cause of the polymorphic varieties. These tend to have a more malignant presentation, with syncope and sudden death. New genetic discoveries of the molecular defects associated with long QT syndrome can dramatically change our approach to treatment of this entity. The acquired form of polymorphic ventricular tachycardia associated with long QT is related to drug therapies and electrolyte imbalances that delay repolarization of the action potential and prolong the QT interval on the ECG. Treatment of these malignant arrhythmias is accomplished by removal of the offending drug, correction of electrolyte imbalance, and temporary pacing as needed.

A variety of inflammatory and infiltrative diseases can cause ventricular tachycardia. The most prominent are arrhythmogenic right ventricular dysplasia, sarcoidosis, acute myocarditis, muscular dystrophies, and Chagas' disease.

GLOSSARY

Delayed afterdepolarization (DAD): The normal action potential in the myocardium returns to the resting membrane potential after repolarization brought on by phase 3. Under abnormal conditions, which can be produced by digitalis toxicity and sympathetic stimulation, an oscillation of the transmembrane potential can occur after full repolarization, which can depolarize the membrane back up to threshold and cause repetitive generation of action potentials. These late depolarizations that occur after full repolarization of the transmembrane potential are called *delayed afterdepolarizations*.

Dispersion of refractoriness: The refractory period is the time after initiation of an action potential at a particular myocardial site during which another action potential cannot be elicited. *Dispersion of refractoriness* refers to the termination of refractory periods at different myocardial sites at varying times such that some areas of the myocardium may still be refractory, whereas others are ready for activation.

Early afterdepolarization: Early afterdepolarizations occur with membrane depolarization starting from the early portion of phase 3 of the action potential. Phase 3 is the repolarization phase driven mostly by potassium current. These early depolarizations take off from the early portion of phase 3. The onset of the afterdepolarizations can bring repetitive firing of action potentials. Drugs and electrolyte changes that prolong the action potential duration have a tendency to activate these afterdepolarizations. They are called "early" afterdepolarizations to distinguish them from the "delayed" type, which are activated after full membrane

repolarization.

Monomorphic ventricular tachycardia: Ventricular tachycardia in which the QRS morphology of each beat remains constant in any particular ECG lead. To make that assessment, it is best to compare QRS complexes that are 2 to 3 seconds apart rather than adjacent ones. Occasionally, the changes in QRS morphology may be quite subtle on a beat-to-beat basis. Over several beats, however, these subtle changes become quite obvious.

Polymorphic ventricular tachycardia: Ventricular tachycardia in which the QRS morphology of each sequential beat changes such that over multiple beats, the QRS morphology distinctly changes in at least one ECG lead. Furthermore, the QRS morphology of a polymorphic ventricular tachycardia continues to change over time. The demarcation between polymorphic ventricular tachycardia and ventricular fibrillation is unclear. In general, however, one can visually appreciate distinct initiation and termination of QRS complexes on the surface ECG in polymorphic ventricular tachycardia despite their changing morphologies, whereas that distinction cannot be appreciated during ventricular fibrillation.

QT prolongation: The QT interval changes in relationship to the heart rate, being longer at slower rates and faster at higher rates. Thus, an absolute value cannot be used to define a prolonged QT interval. The corrected QT interval is normalized to the heart rate and can be derived by the Bizet's formula, QTc (ms) = QT (ms)/[RR (sec)]$^{1/2}$, where RR is the cycle length of the heart rate measured in seconds. The upper limits of normal for the QTc is 440 ms.

Reentry: Propagation of a single action potential wavefront, or multiple simultaneous wavefronts, along a path or paths that allows reactivation of individual sites repetitively.

Sustained and nonsustained ventricular tachycardia: The demarcation of what constitutes sustained versus nonsustained ventricular tachycardia is somewhat arbitrary. In most literature describing induction of ventricular tachycardia during programmed ventricular stimulation, a sustained tachycardia is defined as one that lasts at least 30 seconds or one that caused significant hemodynamic compromise such that it needed termination by pacing or direct current cardioversion before 30 seconds. Tachycardias that terminate spontaneously in less than 30 seconds are considered nonsustained.

INTRODUCTION

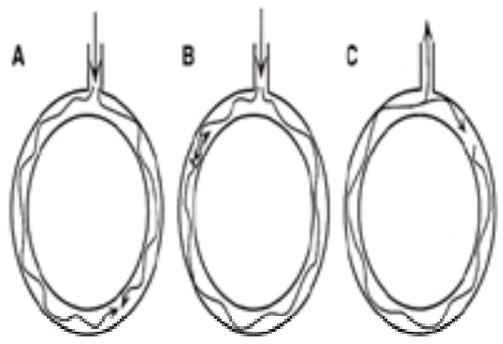
The recognition of the underlying causes of ventricular tachycardia and the available options for treatment have dramatically changed since the early 1970s. Before that time, treatment of ventricular tachycardia was restricted to the use of a small number of antiarrhythmic medications that are now generally recognized as having limited efficacy in the treatment of most common forms of ventricular tachycardia. Although there was an appreciation of the association of ventricular tachycardia with various forms of cardiac disease, there was unclear understanding of the functional mechanisms and the microanatomic substrate responsible for these tachycardias. The last three decades have indeed seen a substantial growth in this understanding. With this understanding, there has also been a growth in the tools available to treat ventricular tachycardia and to prevent sudden cardiac death. Newer medications such as amiodarone and sotalol may have a higher efficacy rate than those available before them. The development of the ICD has dramatically altered the risk-versus-benefit analysis of using antiarrhythmic medications for the prevention of sudden cardiac death. Surgical resection and cryoablation of ventricular tachycardia sources, although not used frequently now, remains a viable option for treating ventricular tachycardia in special circumstances. Lastly, catheter ablation techniques together with enhanced mapping technologies have offered curative therapies that eliminate the substrate for tachycardia and could be all the therapy needed in some circumstances. Indeed, curative ablation therapies now offer perhaps the best option for treatment of monomorphic ventricular tachycardia in structurally normal hearts afflicting younger, otherwise healthy patients.

SIGNIFICANCE OF VENTRICULAR TACHYCARDIA

It is estimated that approximately half of the deaths due to cardiac diseases are sudden (1,2). Ambulatory ECG recordings of sudden deaths have indicated that these are mostly due to ventricular tachyarrhythmias (3,4). Thus, ventricular tachyarrhythmias are the immediate cause of a large number of deaths, estimated at approximately 300,000 annually in the United States. Death occurs through its interference with the cardiac pumping function.

MECHANISM OF VENTRICULAR TACHYCARDIA

Most clinical ventricular tachycardias are related to reentry over a fixed reentrant circuit, usually involving diseased tissue generating slow conduction of impulses, which allows sustained reentry to occur. Several electrophysiologic conditions are required for initiation and sustainment of reentry. The first requirement for sustainment of a reentrant ventricular tachycardia is the existence of a circuit made up of electrically active tissue that can complete a reentrant path. During normal rhythm, cardiac impulses usually enter these reentrant circuits at one or more points and propagate through the tissues of the reentrant pathway. However, an impulse entering this circuit at a point will propagate in both directions and will extinguish itself when the two limbs of propagation collide with each other some place within the circuit (*e*Fig. 67.0.1A). An initiating mechanism must exist to begin a circulatory movement of electrical activation within the reentrant circuit. Therefore, a second requirement is the initiating "trigger." This is generally supplied as a premature beat. However, it could occur during spontaneous regular rhythm. Such a trigger beat must penetrate the reentrant circuit. Its propagation down one limb of the circuit must be blocked at some point of the circuit. The propagation down the other limb of the reentrant circuit must achieve adequate conduction delay so that arrival of this impulse at the site where the opposing impulse blocked is late enough to allow tissue recovery and continued propagation (*e*Fig. 67.0.1B). This sequence of events initiates the first reentrant beat. However, a sustained reentrant propagation of an impulse around the reentrant circuit can occur only when a third requirement is achieved: Every link of the reentrant circuit is capable of repeated activation at the cycle length of the tachycardia (*e*Fig. 67.0.1C). These three requirements apply in general to all reentry and can form the framework of analyzing reentrant tachycardias whether they are supraventricular or ventricular in origin. Some forms of reentrant tachyarrhythmias may not require a fixed reentrant circuit—that is, their reentrant pathways may be continuously changing. Ventricular fibrillation, as well as some forms of polymorphic ventricular arrhythmias, may fall into this category. The exact pathways over which electrical propagation occur may change from moment to moment. New pathways may develop while existing pathways extinguish. However, the rhythm will sustain itself as long as at least one electrical wavefront continues to propagate.



***e*FIGURE 67.0.1** The three electrophysiologic requirements for initiating and sustaining a reentrant tachycardia. **A** indicates the presence of a reentrant circuit. With every nontachycardia beat, the wavefront depolarizing the heart can enter the reentrant circuit and propagate via both limbs of the reentrant circuit. Reentry does not occur, however, as a result of collision and annihilation of the impulses propagating down both pathways. **B** illustrates the initiation of the first reentrant beat. The impulse entering the circuit again enters into both limbs. It must block in one direction (superior direction in this illustration) and propagate in the opposite direction. The time for the conducting impulse to arrive at the site of block must be long enough to allow sufficient recovery at the blocked site so that the propagating impulse can conduct through this site of block and complete the first reentrant beat. Once the first reentrant beat occurs, the tachycardia can continue as long as every site within the reentrant circuit can maintain conduction at the cycle length of the tachycardia, as illustrated in **C**.

Several electrical mechanisms causing tachyarrhythmias are believed to be focal in nature. Enhanced automaticity may be the cause of the so-called accelerated idioventricular response. Enhanced automaticity is generally ascribed to phase 4 depolarization of the action potential. It is more often seen in the His-Purkinje tissues of the ventricle but can also occur in the myocardium under abnormal metabolic conditions.

DADs are spontaneous depolarizations that develop after complete repolarization of an action potential. These depolarizations can achieve a high enough transmembrane voltage that repeated action potentials are triggered (5). DADs occur as a result of calcium loading of the cell. Experimentally, these can be elicited in isolated tissue or myocyte preparations by digitalis and sympathetic stimulation. Calcium channel blockers can suppress these arrhythmias (6).

Early afterdepolarizations occur during the recovery phase of the action potential. During the repolarization process, a renewed depolarization can occur when the repolarizing current is weak or when a strong enough depolarizing current persists. Drugs that interfere with the repolarization process such as the type I antiarrhythmic medications that block the potassium channels can cause this type of afterdepolarization (7). Quinidine is a typical type Ia antiarrhythmic drug that can produce these early afterdepolarizations that are enhanced by bradycardia and are suppressed with increased extracellular potassium and magnesium concentrations (8). Thus, electrolyte imbalances such as hypokalemia and hypomagnesemia may contribute to this mechanism in the clinical setting. This mechanism is probably involved in the initiation of some forms of tachyarrhythmias such as torsades de pointes during antiarrhythmic drug therapy (9).

ANATOMIC SUBSTRATE OF VENTRICULAR TACHYCARDIA RELATED TO ISCHEMIC MYOCARDIAL DISEASE

Because ischemic heart disease is still the most common cardiac disease in North America, ischemic myocardial scars remain the most common substrate for sustained monomorphic ventricular tachycardia. When arterial blood supply is interrupted to a portion of the ventricular myocardium, causing myocardial infarction, not all the muscle fibers die within that region. Especially within the subendocardial and subepicardial layers, surviving muscle fibers can be electrically active and may even generate normal-appearing action potentials. However, because of the interweaving of scar tissue within these muscle fibers, propagation of electrical impulses through this tissue may take a circuitous route. Cell-to-cell propagation may also be slowed due to a variety of factors associated with the scarring process and persistence of ischemia. Refractory periods within regions of surviving muscle in the scar may also be prolonged in comparison with the surrounding normal muscle. Recordings of electrical propagation in these scarred areas tend to show fractionated, low-amplitude, and prolonged signals. These properties form the basis of unidirectional block and slow conduction necessary for initiation and sustainment of a reentrant wavefront (10,11 and 12).

Risk Factors for Ventricular Tachyarrhythmia and Sudden Death in Ischemic Heart Disease

Patients who have experienced a myocardial infarction have the potential for reentrant ventricular tachycardia. Several clinical factors are useful for assessing the risk of experiencing sustained ventricular tachycardia. The probability that sustained ventricular tachycardia or sudden death would occur in a person after a myocardial infarction appears to be directly related to the size of the infarct and the consequent reduction in systolic ventricular function. Several reports have described a direct relationship between ventricular dysfunction and increased mortality rates in post–myocardial infarction patients (13,14). Sudden deaths make up a significant proportion of this mortality and are largely due to ventricular tachycardia and ventricular fibrillation. The extent of myocardial damage, as reflected by the patient's left ventricular ejection fraction and functional class, is probably the most important predictor of sudden arrhythmic deaths.

The occurrence of syncope, the presence of late potentials on a signal-averaged ECG, decreased heart rate variability, the presence of T-wave alternans, the occurrence of high-grade ventricular ectopy and nonsustained ventricular tachycardia, and the inducibility of sustained ventricular tachycardia during programmed ventricular stimulation are also predictors of mortality and occurrence of clinical sustained ventricular tachycardia (15,16,17,18 and 19).

A signal-averaged ECG is a high-gain ECG that attempts to detect low-voltage electrical propagation through scarred areas of the myocardium extending beyond the QRS. Although having low amplitudes, these signals tend to have high-frequency content. Because such conduction is slowed through a scarred region of the myocardium, late activation of cells in this region can occur after the completion of the QRS complex on the surface ECG. The presence of such "late potentials" indicates the existence of substrate for a potential reentrant circuit. These late potentials are generally too low in amplitude to be appreciated on a standard 12-lead ECG. The use of signal-averaging techniques to reduce electronic noise permits high-amplification recording and detection of these potentials. Such techniques were first applied to human ECG recordings in the early 1980s (20,21). Subsequent studies have demonstrated a correlation between the presence of these late potentials on a signal-averaged ECG and the inducibility of sustained monomorphic ventricular tachycardia as well as the clinical occurrence of sustained ventricular tachyarrhythmia (15,22,23 and 24). In these studies, the absence of late potentials on the signal-averaged ECG after myocardial infarction was associated with a low incidence of sudden death or clinical occurrence of sustained ventricular tachycardia, in the range of 4% over a 2-year period. On the other hand, the presence of late potentials was associated with a 16% to 28% incidence of sudden death or sustained ventricular tachycardia. In two of these studies (15,23), patients with a combination of left ventricular ejection fraction of less than 40% and the presence of late potentials on the signal-averaged ECG had around a 35% incidence of sudden death or sustained ventricular tachycardia during a mean follow-up of 12 to 14 months.

The variability of heart rate during sinus rhythm on a beat-to-beat basis reflects the presence of vagal tone, which may have a protective effect against the triggering of ventricular arrhythmias. Such variability can be quantified using short-term (minutes) or long-term (24 hours) ECG recordings. The absence of normal heart rate variability has been found to be a predictor of mortality in patients after myocardial infarction (25). In patients with congestive heart failure, heart rate variability appears to be an independent predictor of mortality, especially in those patients with moderately reduced functional status (26,27). In fact, even in patients without overt cardiac disease, lower heart rate variability appears to be associated with a higher probability of developing coronary heart disease and mortality (28).

Another noninvasive test currently being investigated that may demonstrate clinical usefulness is the detection of T-wave alternans, especially during a stress test. Alternating T-wave amplitudes of small magnitudes occurring on an every-other-beat basis may be a marker for potential malignant ventricular arrhythmia in the presence of ischemia (29). These microvolt alternations in T-wave amplitude reflect alternation in repolarization gradients within the myocardium. Such gradients are linked to the vulnerability of the heart to initiation of ventricular tachycardia and ventricular fibrillation in response to a triggering premature beat (30,31). Several smaller studies have demonstrated increased mortality associated with increased T-wave alternans (32,33). Large-scale clinical evaluation of this test will be needed to demonstrate its clinical usefulness in predicting sudden arrhythmic deaths.

Programmed electrical stimulation of the heart during an electrophysiologic study has also been used to assess the risk of a patient experiencing sustained ventricular arrhythmias. Several studies have shown an increased risk of sudden death or sustained ventricular tachycardia if such arrhythmias can be induced with programmed stimulation in patients after myocardial infarction (34,35 and 36). In these studies, the predicted risk of a sustained ventricular arrhythmic event was low (2% to 7%) in those who had no inducible sustained ventricular tachycardia, whereas that risk was quite high, approximately 30%, in those who had induced sustained ventricular tachyarrhythmia.

The occurrence of syncope in patients who have previously suffered myocardial infarctions should be a warning sign that they may be experiencing rapid ventricular tachycardia. Syncope in patients with significant heart disease, particularly if accompanied by congestive heart failure, appears to be a strong predictor of sudden death (37,38). In patients with both ischemic as well as nonischemic dilated cardiomyopathy, the occurrence of syncope appears to portend an increased risk of arrhythmic death (39,40). An electrophysiology study can be helpful in identifying an arrhythmic cause of syncope in such patients. Inducible sustained ventricular tachyarrhythmias in patients with syncope correlates with a high incidence of ICD therapy for sustained ventricular tachycardia (41). If electrophysiology study is unsuccessful in identifying a cause of syncope, ECG patient-actuated event recorders can be used and are generally more helpful than Holter monitors. In addition, implantable loop recorders, a thin, thumb-size device capable of automatic recording of cardiac rhythm during tachycardia or bradycardia, as well as patient-actuated recordings, can be very helpful in revealing a cardiovascular or a neurologic cause of syncope (42).

The largest risk factor for arrhythmic death appears to be the prior occurrence of sustained ventricular tachyarrhythmia, especially one that causes hemodynamic collapse requiring resuscitation.

Ischemia as a Cause of Ventricular Tachycardia

During ischemia, myocardial cells may undergo changes in their action potentials that could promote ventricular tachycardia. Depending on the degree of ischemia, refractoriness can be prolonged, action potentials can shorten, myocytes can become electrically uncoupled, or the cell can become electrically inert (43). Metabolic changes such as increased extracellular potassium concentration and acidosis can further affect cellular electrical activation. Toxic lipid metabolites can accumulate in the ischemic area to provoke ventricular arrhythmias (44). The ventricular tachycardia seen during the acute ischemic event generally tends to be polymorphic ventricular tachycardia or ventricular fibrillation rather than a sustained monomorphic ventricular tachycardia. Marked ischemia can cause prolongation of the QT interval, usually associated with inversion of the T wave. QT interval prolongation, for example, can be seen during an acute myocardial infarction. However, myocardial ischemia may not prolong the QT interval. In fact, the presence of polymorphic ventricular tachycardia, sustained or nonsustained, in the absence of QT prolongation should be a clue that ischemia is likely to be an underlying cause (Fig. 67.1). Although nonischemic causes of polymorphic ventricular tachycardia can occur as described below, they are rare in comparison. Thus, high-grade coronary disease should be the first consideration in an adult patient with any coronary risk factor who manifests polymorphic ventricular tachycardia without QT prolongation.

FIGURE 67.1 Polymorphic ventricular tachycardia related to cardiac ischemia. This figure illustrates the initiation of sustained polymorphic ventricular tachycardia resulting from ischemia without evidence of ST elevation. This polymorphic ventricular tachycardia should be distinguished from torsades de pointes (see Fig. 67.9). Note that the QT intervals were not prolonged, and initiation of polymorphic ventricular tachycardia was not preceded by a long RR interval.

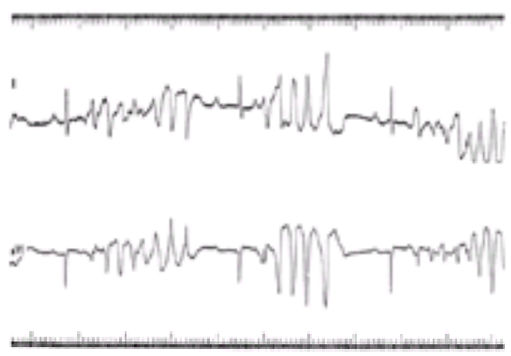


FIGURE 67.9 Typical characteristics of torsades de pointes. The initiation of the first ventricular ectopic beat of the tachycardia tends to occur after a pause. The QRS of this first beat initiates on the T wave, making it difficult to appreciate where the T wave ends. There is a beat-to-beat change in the QRS axis in a sinusoidal pattern. The rate of the tachycardia tends to be slower than the polymorphic ventricular tachycardia seen during cardiac ischemia, as shown in Figure 67.1 and Figure 67.3.

FIGURE 67.3 Polymorphic ventricular tachycardia related to coronary spasm. **A**, **B**, and **C** show Holter electrocardiographic tracings from a 38-year-old patient in the hospital after a cardiac arrest at home where ventricular fibrillation was documented. He had complained of chest pain just before the cardiac arrest. **A:** Baseline rhythm. **B:** Beginning of ST elevation. One minute later, the ST segments are markedly elevated **(C)**, accompanied by short nonsustained runs of polymorphic ventricular tachycardia. Cardiac catheterization in this patient showed minimal coronary disease, and the ischemic events were attributed to coronary spasm. Note that the QT intervals in Figure 67.2 and this figure are not prolonged. Although QT interval may prolong during acute ischemia, especially with T-wave inversion, it is not a common accompanying finding in ischemia-induced polymorphic ventricular tachycardia.

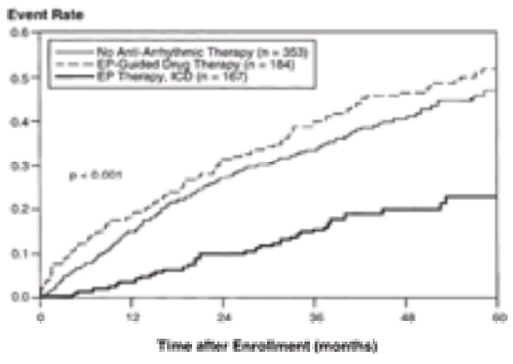

FIGURE 67.2 Survival of patients in the Multicenter Unsustained Tachycardia Trial: comparison of antiarrhythmic drug therapy, no therapy, and implantable cardioverter-defibrillator (ICD) therapy. The study enrolled post–myocardial infarction patients who had left ventricular ejection fraction of 40% or less and inducible sustained ventricular tachycardia during electrophysiology study. Patients who were treated with antiarrhythmic drugs had no better outcome than those who were not treated at all. Those treated with an ICD had significantly improved survival. EP, electrophysiologic. (From Buxton AE, Lee KL, Fisher JD, et al. A randomized study of the prevention of sudden death in patients with coronary artery disease. Multicenter Unsustained Tachycardia Trial Investigators. *N Engl J Med* 1999;341:1882, with permission.)

Animal models have shown that acute ischemia is associated with prolongation of activation time in the ischemic region, resulting in the dispersion of activation from site to site, which may be directly related to the onset of ventricular tachycardia (45). Multiple studies have shown that the presence of an open artery, even in an infarcted area of myocardium, appears to have a protective effect against ventricular arrhythmias. The Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries I Trial demonstrated that restoring brisk coronary artery blood flow (thrombolysis in myocardial infarction grade 3) early, within 90 minutes, reduces 30-day mortality by 50% (46). Similarly, reocclusion of an initially opened artery was associated with a tenfold higher 30-day mortality (47). One can argue that early reperfusion improves survival due to reduction of infarct size and improvement of residual ventricular function. However, other studies have demonstrated a survival benefit of late patency of the artery supplying an infarct site even when there is no appreciable impact on residual ventricular function (48,49). Thus, continued patency of an infarct-related artery may have beneficial effects such as improved electrical stability of the area (50), especially in the border zone of the infarct where ischemic but viable tissue may generate unstable ventricular tachyarrhythmias.

Assessment of Risk after a Myocardial Infarction

The assessment of risk for ventricular tachycardia and sudden death in a patient after myocardial infarction is a multifactorial process. At the minimum this should include an assessment of left ventricular function and the presence of nonsustained runs of ventricular tachycardia on ECG monitoring. An assessment of any persistent ischemia either surrounding the infarct zone or in another portion of the myocardium unrelated to the infarct artery should be made. The use of a signal-averaged ECG may provide additional information to enhance or reduce the apparent risk of a particular patient. The other noninvasive tests such as heart rate

variability and T-wave alternans, as discussed above, may prove to be good risk assessments. Those patients who appear to be at high risk as determined by the above noninvasive testing should undergo electrophysiologic testing. The inducibility of sustained ventricular tachycardia during an electrophysiologic study confirms the high risk, whereas the inability to induce sustained tachycardia suggests a lower risk.

Prevention and Treatment of Ventricular Tachycardia after Myocardial Infarction

As a general approach to the prevention of sustained ventricular tachyarrhythmia, patients who have an ischemic cardiomyopathy should have optimal therapy to relieve congestive heart failure and ischemia. The proper use of diuretics, potassium and perhaps magnesium supplements, angiotensin-converting enzyme inhibitors, beta-blockers, and digoxin as needed should form the basis of heart failure therapy. Significant ischemia should be relieved, where possible, by revascularization and minimized with drug therapies, especially beta-blockers. Beta-blockers and angiotensin-converting enzyme inhibitors in some studies have been shown to improve overall as well as arrhythmic mortality in this population (51,52 and 53).

With the possible exception of amiodarone, the use of antiarrhythmic medications has not improved or has worsened survival. Several clinical trials with amiodarone have demonstrated no detrimental effects and may, in selected subgroups, improve survival.

Large-scale and smaller clinical trials have demonstrated the potential harmful effects of type I antiarrhythmic medications given to suppress ventricular premature beats in post–myocardial infarction patients. The Cardiac Arrhythmia Suppression Trial (54) represents the most prominent of these trials. Other trials have demonstrated the lack of beneficial effects of type Ia and Ib medications (55,56). Teo et al. provided an excellent summary of these trials, reviewing the outcomes of 138 trials involving 98,000 patients (57). None of these trials showed a beneficial effect of type I antiarrhythmic drugs in post–myocardial infarction patients. The only post–myocardial infarction survival trial reported so far with a “pure” type III antiarrhythmic, D-sotalol, showed a higher mortality in the drug treatment limb than in the placebo arm (58). The results of another study, Azimilide Post-Infarct Survival Evaluation Trial, using azimilide, are pending (59).

Although earlier studies (60) have suggested that amiodarone may be beneficial in lowering arrhythmic mortality, a more recent report, the Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure (61), did not show a significant advantage in using this medication as prophylactic therapy to prevent arrhythmic deaths in a large group of patients with congestive heart failure, including patients with ischemic heart disease. Two trials of empiric amiodarone in post–myocardial infarction patients (Canadian Myocardial Infarction Amiodarone Trial and European Myocardial Infarct Amiodarone Trial) were recently completed. The European Myocardial Infarct Amiodarone Trial enrolled more than 1,400 post–myocardial infarction patients with a left ventricular ejection fraction of 40% or less. They were randomized to treatment with amiodarone or placebo. Despite a reduction of mortality classified as arrhythmic, overall mortality and cardiac mortality did not differ significantly (62). Further subgroup analyses have suggested that those patients in the European Myocardial Infarct Amiodarone Trial who had greater reduction of left ventricular ejection fraction (30% or less), faster resting heart rates, or less heart rate variability or who were treated with beta-blockers may have an improved overall mortality when treated with amiodarone (63,64). The Canadian Myocardial Infarction Amiodarone Trial enrolled 1,202 post–myocardial infarction patients who had more than ten premature ventricular complexes per hour. They were also randomized to treatment with amiodarone or placebo. The trial, however, was designed to assess the primary end point of resuscitated ventricular fibrillation or arrhythmic death and was not powered to assess all-cause mortality differences. The trial demonstrated that patients treated with amiodarone had a significant reduction in risk of experiencing the primary end point of resuscitated ventricular fibrillation or arrhythmic death (65). However, the difference in all-cause mortality between the amiodarone-treated patients and those who received placebo did not reach statistical significance. Of particular interest, a combination of beta-blockers with amiodarone may have a synergistic survival benefit, as suggested in a combined analysis of the European Myocardial Infarct Amiodarone Trial and Canadian Myocardial Infarction Amiodarone Trial (66).

In contrast to the antiarrhythmic drug studies, two studies have now reported improved survival in high-risk post–myocardial infarction patients treated with an ICD. The Multicenter Automatic Defibrillator Implantation Trial demonstrated that patients with nonsustained ventricular tachycardia after a myocardial infarction who have left ventricular ejection fractions of 35% or less and who have inducible sustained ventricular tachycardia at electrophysiologic study are best treated with an ICD rather than with antiarrhythmic medications. The antiarrhythmic medication used in this trial consisted primarily of amiodarone (74%), with a small number of patients taking sotalol (7%). Patients treated with the implanted device had approximately one-half the mortality of the drug-treated group (67). The Multicenter Unsustained Tachycardia Trial (MUSTT) enrolled 704 post–myocardial infarction patients with left ventricular ejection fractions of 40% or less who had nonsustained ventricular tachycardia on monitoring and inducible sustained ventricular tachycardia during electrophysiologic testing. In contrast to the Multicenter Automatic Defibrillator Implantation Trial, MUSTT contained a no-therapy arm. Antiarrhythmic treatment consisted of medications guided by the results of programmed ventricular stimulation or the ICD. Forty-six percent of the patients receiving therapy were given an ICD. The group of patients receiving the ICD had the best arrhythmic and all-cause mortality. Patients receiving antiarrhythmic drug therapy did no better than those who received no antiarrhythmic therapy (Fig. 67.2) (68). These two studies taken together have demonstrated that the particular group of patients characterized by prior myocardial infarction, reduced left ventricular ejection fraction, clinical nonsustained ventricular tachycardia, and inducible sustained ventricular tachycardia are at high risk for arrhythmic mortality and that treatment with an ICD results in lower arrhythmic and overall mortality.

Patients who have already experienced a clinical episode of sustained ventricular tachycardia or ventricular fibrillation are at the highest risk of recurrence (69). Unless one can clearly demonstrate that such an occurrence was associated with a reversible cause, a reliable therapeutic approach should be used to minimize the risk of sudden death. The therapy of choice is now clearly the ICD. Publication of several studies have demonstrated that ICD therapy yields better survival outcomes in these patients when compared with antiarrhythmic drug therapy with sotalol or amiodarone.

The Antiarrhythmic Versus Implantable Defibrillator Trial, published in 1997, enrolled 1,016 patients who were resuscitated from cardiac arrest and had clinical sustained ventricular tachycardia with syncope or with a left ventricular ejection fraction of 40% or less. These patients were randomized to treatment with ICD or with antiarrhythmic drugs, predominantly amiodarone. The survival outcome was clearly better in the ICD arm of the study (70). The Canadian Implantable Defibrillator Study is a smaller study that enrolled 659 patients who had prior cardiac arrest, sustained symptomatic ventricular tachycardia, or syncope with documentation of ventricular tachycardia on monitoring or during electrophysiology study. These patients were randomized to treatment with amiodarone or with an ICD. The study showed a trend toward improved arrhythmic and overall survival in the ICD-treated patients, but this trend did not reach statistical significance (71). A subanalysis demonstrated that those patients with the lowest left ventricular ejection fraction, older age, and the worst New York Heart Association class benefitted the most from ICD therapy (72). A metaanalysis of three different trials (Antiarrhythmic Versus Implantable Defibrillator Trial, Canadian Implantable Defibrillator Study, and Cardiac Arrhythmia Study Hamburg) comparing the ICD with drug therapy in the prevention of arrhythmic deaths in patients who had already experienced a prior major ventricular arrhythmic event revealed that the risk of overall mortality was 28% lower in the ICD group. This lower mortality was largely due to a 50% decrease in the risk of arrhythmic mortality (73).

The assessment of an antiarrhythmic medication for its ability to suppress clinical recurrence of ventricular tachycardia is problematic. The utility of the electrophysiology study to test drug suppression of ventricular tachycardia as a means of predicting clinical efficacy has been questioned by the results of the Electrophysiologic Study Versus Electrocardiographic Monitoring Trial (74). With the publication of MUSTT, programmed ventricular stimulation as a means of predicting antiarrhythmic drug efficacy for preventing sustained ventricular tachycardia has been seriously challenged. Given the poor outcomes of post–myocardial infarction patients in that study who were treated with antiarrhythmic drugs guided by programmed stimulation, one can no longer recommend this approach (68).

Although use of antiarrhythmic medications as the sole method of preventing recurrence of sustained ventricular tachyarrhythmia is declining, its use as adjunctive therapy with an ICD is still quite common. Approximately 50% of patients with ICDs are on antiarrhythmic medications (75,76). Antiarrhythmic medications are used for preventing atrial fibrillation as well as decreasing the frequency of ventricular tachycardia causing reception of shocks by the patient.

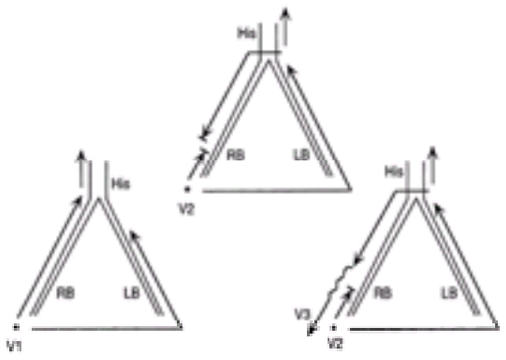
An alternative to drug therapy of ventricular tachycardia associated with ischemic heart disease is catheter ablation. Current approaches mainly use radiofrequency energy. Success in eliminating a particular reentrant ventricular tachycardia is in the 50% to 70% range by most reports (77,78). At present, this technique is still mostly used as an adjunctive therapy for patients who have an ICD already but are having frequent or slow ventricular tachycardias that complicate device therapy.

Ischemic Ventricular Tachycardia Unrelated to Atherosclerotic Coronary Artery Disease

Although not related to atherosclerotic obstruction of the coronary arteries, several other causes of sudden death, presumably from ischemic polymorphic ventricular tachycardia and ventricular fibrillation, should be considered, especially in competitive athletes (79). Anomalous takeoff of the left coronary artery from the right coronary cusp or the right coronary artery from the left coronary cusp are potential, although rare, etiologies. Anatomically, this anomalous takeoff can result in compression of the artery, resulting in ischemia. Hypertrophic cardiomyopathy and other causes of myocardial hypertrophy such as aortic stenosis may also trigger ventricular fibrillation by an ischemic mechanism. Embolic occlusion of coronary arteries can also occur from blood clots or vegetations generated by endocarditis. Lastly, coronary spasm can induce ischemic polymorphic ventricular tachycardia and cardiac arrest (Fig. 67.3). In all these entities, the therapeutic approach is to prevent or alleviate the conditions leading to ischemia. Although medications may be helpful in cases such as coronary spasm, an ICD should be considered as back-up protection should medications fail to completely prevent ischemia.

VT RELATED TO HIS-PURKINJE DISEASE

The His bundle and the bundle branches together with the Purkinje network and the myocardium form a potential reentrant pathway that could become the substrate for ventricular tachycardia. The ability of the normal His-Purkinje to generate reentrant beats during right ventricular premature stimulation was first described in the 1970s (80,81). It had been recognized that a stimulated right ventricular premature beat (V2) was frequently followed by another ventricular beat (V3) that had a QRS morphology similar to that of V2. Akhtar and colleagues (80,81) demonstrated that the reentrant circuit of the V3 phenomenon involved the bundle branches as shown in eFigure 67.3.1. These reports were the first demonstration that the normal human His-Purkinje/myocardial system was capable of acting as a reentrant circuit. However, the electrophysiologic characteristics of the normal His-Purkinje system, fast conduction and long refractory periods, prevent sustainment of this reentrant process. When these normal electrophysiologic characteristics are altered by disease processes, however, this reentrant circuit can become the substrate for sustained tachycardia.



***e*FIGURE 67.3.1** Schematic mechanism of bundle branch reentrant beats elicited by right ventricular premature stimulation. Programmed ventricular stimulation is usually done by delivering a string of constant cycle length pulses (six or eight) followed by one or more premature pulses. The ventricular depolarization associated with the constant cycle length stimulation pulses are called *V1s*, whereas the ventricular depolarization associated with a premature pulse is labeled *V2*. In this figure, the left panel demonstrates electrical activation of the bundle branches during the V1 complexes. Because the stimulation is done in the right ventricle, the wavefront propagates up the left bundle later than it propagates up the right bundle due to the additional transseptal conduction time. The middle panel shows the conduction pattern of the premature beat (V2) that blocks retrogradely in the right bundle. When V2 occurs with sufficient prematurity, its conduction up the right bundle is blocked due to normal refractory properties of the right bundle. Transseptal propagation of V2 can then invade the left bundle branch system and propagate retrogradely to activate the bundle of His. Because of the longer propagation path of V2 from the site of stimulation to the bundle of His, the interval between V2 to His bundle activation (V2–H2) is longer than that seen in the left-sided panel (V1–H1). In the middle panel, the wavefront activating the bundle of His can also antegradely activate the right bundle and propagate down to the site of retrograde block. With sufficient V2–H2 conduction delay, this antegrade right bundle wavefront can penetrate through the area of retrograde V2 block and conduct to the myocardium, generating a reentrant ventricular complex, V3. LB, left bundle branch; RB, right bundle branch.

Several reports have defined the specific criteria useful in identifying the bundle branch reentrant mechanism in a ventricular tachycardia (82,83,84 and 85). In these reports, all patients had underlying His-Purkinje system disease as demonstrated by prolonged HV conduction time during sinus rhythm and the presence of intraventricular conduction defects on their surface 12-lead ECGs. Many had enlarged hearts due to various underlying cardiac diseases. However, there are reported cases in which isolated conduction system disease without other significant structural heart diseases can be the sole underlying cause of sustained bundle branch reentrant ventricular tachycardia (86). Myotonic dystrophy with its associated conduction system disease has been associated with bundle branch reentrant ventricular tachycardia (87). In the largest reported series (88), approximately half of the patients had nonischemic dilated cardiomyopathy; the other half had ischemic cardiac disease. However, when one looks at the frequency of bundle branch reentry as a mechanism of sustained tachycardia in these disease categories, the differences are quite striking. Bundle branch reentry can be the mechanism of tachycardia in 30% to 50% of patients with nonischemic dilated cardiomyopathy who have inducible sustained monomorphic ventricular tachycardia during programmed stimulation, although the incidence of inducing this tachycardia is no more than 5% to 6% in patients who have ischemic cardiac disease.

The tachycardia rate of bundle branch reentry tends to be fast, frequently above 200 beats/min. The most common clinical and laboratory-induced tachycardias have a left bundle branch block pattern (Fig. 67.4). Only isolated cases of right bundle branch block QRS morphologies have been reported. His-Purkinje system reentry generating a right bundle branch block QRS morphology on the surface ECG can also be due to fascicular reentry.

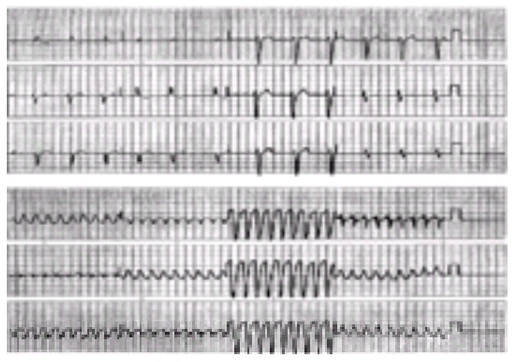


FIGURE 67.4 Electrocardiographic characteristics of a typical bundle branch reentrant ventricular tachycardia. This 12-lead electrocardiogram shows the typical characteristics of the common form of bundle branch reentrant ventricular tachycardia (*lower panel*). The anterior chest leads have a left bundle branch block QRS morphology with rapid downstroke of the S wave. The tachycardia is rapid. The QRS in sinus rhythm (*upper panel*) shows an intraventricular conduction defect of the left bundle branch type.

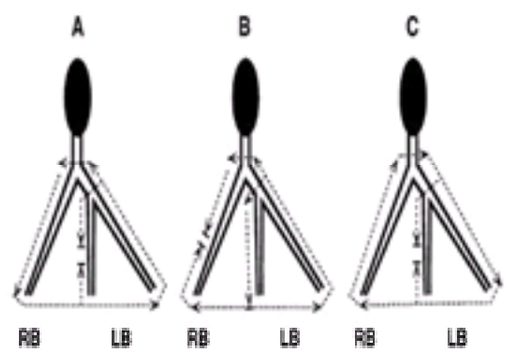
His-Purkinje system reentrant circuits can be classified into three different types, as shown in eFigure 67.4.1 (89). Type A involves retrograde conduction via the left bundle branch and antegrade conduction via the right bundle branch. The QRS morphology of type A reentry has a typical left bundle branch block pattern. Type B is a fascicular reentry in which retrograde conduction occurs via a left-sided fascicle and antegrade conduction is via the other fascicle. Because the ventricles are activated via the left bundle system, the QRS has a right bundle branch block morphology. Because this reentrant circuit is entirely contained within the left bundle branch, the right bundle is not necessary for reentry and may be activated strictly as a bystander. This form of tachycardia is quite infrequently seen but should be suspected when a typical right bundle branch block QRS morphology is seen during a sustained tachycardia in a patient with His-Purkinje system disease. Type C is the reversed circuit of type A and involves retrograde propagation via the right bundle branch and antegrade ventricular activation via the left bundle branch. This tachycardia would also have a right bundle branch block QRS on the surface ECG but can be differentiated from type B during electrophysiologic study. Because of the electrophysiologic properties of retrograde conduction via the right and left bundle branches (70), this form of tachycardia is quite rare, probably because initiation of this reentrant circuit is difficult with ventricular premature beats. Coexistence of two types of His-Purkinje system reentrant tachycardias, bundle branch reentry and fascicular reentry, has been reported in the same patient (90).



***e*FIGURE 67.4.1** The three types of His-Purkinje system reentrant circuits. Type A is the most commonly seen type of bundle branch reentrant ventricular tachycardia, both clinically as well as in the electrophysiology laboratory. Retrograde conduction occurs via the left bundle branch (LB) and antegrade conduction occurs via the right bundle branch (RB). This yields a ventricular tachycardia in which the QRS has a left bundle branch block pattern as seen in Figure 67.4. Type B is a fascicular reentrant ventricular tachycardia, in which the retrograde limb of the reentrant circuit is one of the fascicles, whereas the antegrade limb is the opposing fascicle. Because the ventricle is activated via the left bundle branch, the QRS has a right bundle branch block morphology. The QRS axis will depend on which fascicle serves as the antegrade route of ventricular activation. The right bundle is activated in a bystander fashion and is not necessary for sustaining the tachycardia. Type C is a reentry using the bundle branches in the opposite direction as shown for type A. Because ventricular activation occurs via the left bundle, the QRS morphology will also be right bundle branch block as in type B. Electrophysiologic distinction between the two types is important, because right bundle ablation will be curative for type C but will have no effect on type B tachycardia. (From Mehdirad AA, Keim S, Rist K, et al. Asymmetry of retrograde conduction and reentry within the His-Purkinje system: a comparative analysis of left and right ventricular stimulation. *J Am Coll Cardiol* 1994;24:177, with permission.)

Although one can suspect the presence of bundle branch reentry as a mechanism of tachycardia based on clinical presentation and ECG characteristics, its diagnosis can be made only during a careful electrophysiologic study. Several studies have detailed the diagnostic criteria that have been summarized in a review of the topic (91).

The therapy of choice for this tachycardia is radiofrequency catheter ablation, usually of the right bundle branch (92,93). Left bundle ablation should be pursued only when there is a clear indication that antegrade conduction down the left bundle is not reliable. These patients frequently have an already depressed left ventricular function that can be further compromised with the development of complete left bundle branch block.

Long-term survival in these patients depends ultimately on the underlying cardiac disease and identification and appropriate treatment of other ventricular tachycardia. A report (94) of survival among 16 patients undergoing radiofrequency ablation of the right bundle and followed for a mean duration of 22 ± 10 months showed one sudden death and one death due to congestive heart failure. Three of those patients had ICDs, two of which were implanted before the ablation. Two patients underwent heart transplant during their follow-up.

MONOMORPHIC VENTRICULAR TACHYCARDIA IN AN OTHERWISE NORMALLY FUNCTIONING HEART

Primary electrophysiologic abnormalities of the heart can be associated with ventricular tachycardia with no hint of heart disease or dysfunction on the echocardiogram or the ECG during sinus rhythm. These ventricular tachycardias are sometimes referred to as “normal heart” ventricular tachycardias. It is important to recognize the source of these tachyarrhythmias, as some of them respond to calcium channel blockers and, thus, may mistakenly be called supraventricular tachycardia. Two distinct types of normal heart monomorphic ventricular tachycardias are described. One type originates from the outflow tract regions near the pulmonic and the aortic valves. On the 12-lead ECG, this tachycardia has a characteristic appearance of left bundle branch block and inferior axis (Fig. 67.5), a QRS morphology typically seen with outflow area pacing.

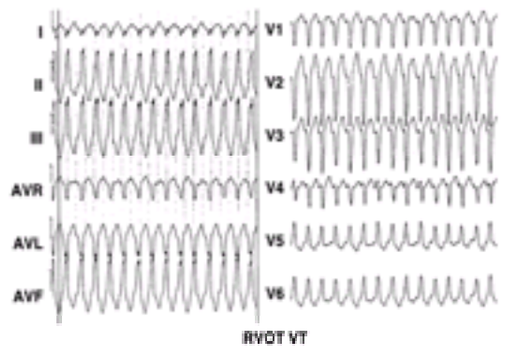


FIGURE 67.5 Twelve-lead electrocardiogram of a ventricular outflow tachycardia (RVOT). The ventricular outflow tract tachycardia typically seen in structurally normal hearts has a characteristic QRS morphology that is similar to that seen with pacing at the pulmonic and aortic valve regions. The QRS has a left bundle branch block morphology with an inferior right axis. This QRS morphology is diagnostic for ventricular tachycardia (VT), as it is highly unusual for aberrant conduction to manifest this type of QRS.

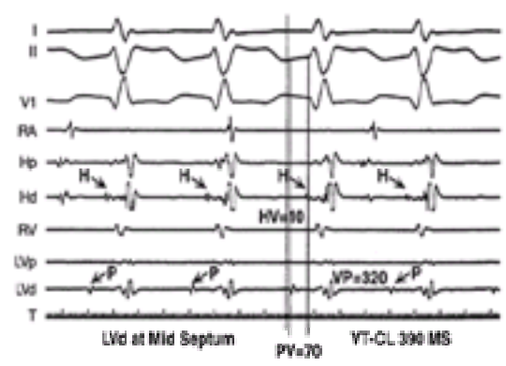
Several electrophysiologic characteristics of this tachycardia suggest that it originates from an automatic focus, perhaps related to delayed afterdepolarizations (94,95 and 96). The occurrence of the afterdepolarizations is enhanced by calcium loading and adrenergic stimulation (97,98 and 99). Clinically, these tachycardias can be exercise-induced or occur at other times of adrenergic stimulation. At times, these may manifest as frequent and virtually incessant ventricular premature beats to the extent that the patient may be in ventricular bigeminy constantly. A variation of the sustained tachycardia originating from the ventricular outflow region is the syndrome of repetitive monomorphic ventricular tachycardia. This syndrome is characterized by repetitive bursts of nonsustained ventricular tachycardia. These have also been shown to respond to calcium channel blockers, beta-blockers, as well as adenosine (100). Although the original descriptions suggested that the right ventricular outflow and the pulmonic valve area are the source of these ventricular tachycardias and premature ventricular complexes, more recent reports have found that the origin may also be located on the left side of the heart near the aortic valve (101,102). This type of ventricular tachycardia may respond to calcium channel blockers, beta-blockers, or a combination of both. However, they may also respond to a variety of antiarrhythmic agents, including type Ia and Ic agents. They may also be sensitive to adenosine, suggesting that cyclic adenosine monophosphate may function as an intracellular mediator (103,104).

Because of its focal nature, catheter ablation has an excellent chance of obtaining a cure when the tachycardia can be reproduced within the electrophysiologic study (105,106). Alternatively, drug therapy with verapamil, diltiazem (107), beta-blockers, or another antiarrhythmic agent may prevent clinical recurrence of this tachycardia. This ventricular tachycardia does not appear to associated with a progressive myopathy or other diseases of the heart except where it is incessant and could cause a tachycardia-mediated myopathy. The outflow-tract tachycardias should be distinguished from other right ventricular tachycardias that could be due to bundle branch reentry or to right ventricular dysplasia (see below).

A second type of normal heart ventricular tachycardia originates near the apex of the left ventricle. On the 12-lead ECG, this tachycardia has a typical right bundle branch block QRS morphology with a superior axis (Fig. 67.6). The earliest reports of this ventricular tachycardia described the typical response to verapamil treatment by slowing and terminating (108,109). However, other antiarrhythmic medications may also suppress it. The tachycardia originates from within the left-sided His-Purkinje system and has been described as a fascicular tachycardia in normal hearts (110). Success in ablating this tachycardia in competent hands is near 100%, and long-term survival after ablation is excellent (111).

FIGURE 67.6 Ventricular tachycardia originating from the left ventricular apex in a structurally normal heart. The left ventricular origin of this ventricular tachycardia generates a typical right bundle branch block QRS morphology on the 12-lead electrocardiogram. Early ventricular activation occurs in the apical inferior septal region of the ventricle, giving the QRS a superior axis.

This tachycardia is most likely reentrant in nature, using decrementally conducting tissue that inserts into the Purkinje network and is sensitive to calcium channel blockade (112,113). This tachycardia does not appear to be a part of a progressive cardiac disease, although when incessant, it can cause a tachycardia-mediated cardiomyopathy. Radiofrequency applications during ablation can be targeted to early ventricular activation sites or to the Purkinje source of the tachycardia. Fractionated potentials and slower-frequency components in the mid-diastolic time during tachycardia have been recorded, perhaps representing activation within the slow conduction zone (*e*Fig. 67.6.1).



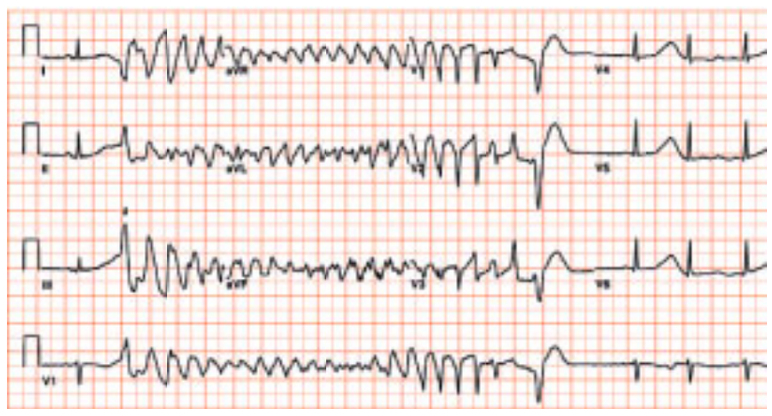
***e*FIGURE 67.6.1** Electrophysiologic recordings of mid-diastolic potential in a normal heart with left ventricular tachycardia. This tracing is from an electrophysiologic study and shows the mid-diastolic potential recorded from the left ventricular septum during ventricular tachycardia. There is a bundle of His electrogram in front of each V electrogram, but the HV interval is only 10 ms, much shorter than during normal antegrade activation. The bundle of His is passively activated retrogradely just before ventricular activation, indicating the fascicular origin of this tachycardia. The site of mid-diastolic potential (P), which is recorded 70 ms before ventricular activation, is also the site of successful radiofrequency ablation of this tachycardia, demonstrating that this potential is associated with the structure responsible for the mechanism of tachycardia.

Lastly, occasional monomorphic ventricular tachycardias are seen in normal hearts that do not necessarily fit into the two categories listed above. Some may originate in the left ventricle but do not have the typical QRS morphologies described above. Others are located at the mitral or tricuspid annulus. These tachycardias usually respond to type Ic agents such as flecainide, calcium channel blockers, or beta-blockers. They can also be treated with catheter ablation.

An 81-year-old male patient with ventricular tachycardia.

POLYMORPHIC VENTRICULAR TACHYCARDIA AND FIBRILLATION IN THE NORMAL HEART

Polymorphic ventricular tachycardia and ventricular fibrillation can also occur in the setting of a structurally normal heart. Whereas the monomorphic varieties typically do not present with syncope and cardiac arrest, the polymorphic varieties are more malignant and are associated with a high incidence of syncope and sudden death. These can be categorized into two general classes, those associated with prolonged QT intervals and abnormal-appearing T waves and those apparently unassociated with QT abnormality.



A 51-year-old female patient with torsades de pointes.

Jervell and Lange-Nielsen (114) reported in 1957 a family with congenitally deaf children, prolongation of the QT interval, and sudden death. Subsequent reports have demonstrated an autosomal recessive inheritance of this syndrome. Romano et al. (115) and Ward (116) subsequently reported familial clustering of sudden death and long QT without deafness. This more common form of long QT syndrome is inherited in an autosomal recessive pattern. In addition to these two reported inherited syndromes, there are occasional cases of new mutation causing this syndrome in a person who has no family history of such a genetic abnormality.

Recent advances in the genetics of long QT syndrome have revealed that they are associated with abnormalities of transmembrane ion channels causing the repolarization abnormality. Mutations associated with at least six genes coding for ion channel functions have been identified that cause clinical long QT syndrome. Within each gene or genetic locus, there can be multiple specific mutations that interfere the function of the ion channels. Each one of these mutations is usually seen

in a particular family. The clinical long QT syndromes associated with these mutated genes or chromosomal loci have been named sequentially in order of their discovery, long QT syndrome 1 to long QT syndrome 6 (Table 67.1).

	Gene (alternate names)	Chromosome	Affected cardiac channel/current
LQT1	*KvLQT1 (KCNQ1)*	11	Potassium/I_{Ks}
LQT2	*HERG (KCNH2)*	7	Potassium/I_{Kr}
LQT3	*SCN5A*	3	Sodium/I_{Na}+
LQT4	Not identified	4	Unknown
LQT5	*minK (KCNE1, IsK)*	21	Potassium/I_{Ks}
LQT6	*MiRP1 (KCNE2)*	21	Potassium/I_{Kr}

LQT, long QT syndrome.

TABLE 67.1 GENETIC ABNORMALITIES ASSOCIATED WITH LONG QT SYNDROME

Long QT syndrome 1 and long QT syndrome 2, the first two to be identified, are associated with mutations on chromosome 11 and 7, respectively (117,118,119 and 120), and demonstrate abnormalities of potassium channels responsible for the repolarization current in myocardial cells. The gene associated with long QT syndrome 1, called KvLQT1 or KCNQ1, codes for an ion channel involved in the delayed rectifier potassium current, I_{Ks}. Long QT syndrome 2 is associated with abnormalities of the *HERG* gene (human ether-a-go-go–related gene), which codes for a protein involved in another delayed rectifier current, I_{Kr}.

Long QT syndrome 3 is due to a mutation of the sodium channel gene. The mutation was initially mapped to a locus on chromosome 3 (121) and later identified as a mutation on the gene *SCN5A* (122). The mutation, although not affecting activation of the channel, prevents proper inactivation of the sodium channel after phase 0 of the action potential. The persistence of some inward sodium current during the plateau phase of the action potential causes prolongation of the action potential. Interestingly, mutations of the same gene causing improper activation of the sodium channel have been identified as the cause of Brugada syndrome (see below).

Long QT syndrome 4 appears to be a rare syndrome associated with a mutation mapped to chromosome 4 (123), but the exact gene has not yet been identified. The gene for long QT syndrome 5, known as *minK*, codes for a potassium channel protein, which, when combined with the *KVLQT1* gene product, forms the slowly activating delayed rectifier current I_{Ks}. The mutated gene causes prolongation of action potential by delaying repolarization. Long QT syndrome 6 has been correlated with an abnormality in the *MiRP1* gene, also located on chromosome 21 (124). This gene codes for a potassium channel protein that coassembles with the *HERG* gene product to form the delayed rectifier current I_{Kr}.

Correlation of the genetic abnormality with ECG T-wave pattern has revealed characteristic patterns that seem to be associated with different forms of the long QT syndrome (Table 67.1). Moss et al. (125) have described three different ECG QT patterns associated with long QT syndrome 1, long QT syndrome 2, and long QT syndrome 3 (Fig. 67.7). These different types of long QT syndromes also appear to have different responses to heart rate acceleration. In long QT syndrome 3, increase in heart rate appears to markedly shorten the QT interval; such is not the case in long QT syndrome 2 (92). The different forms of long QT syndrome also respond differently to pharmacologic interventions aimed at shortening the QT interval. In long QT syndrome 2, in which the defect is in a delayed rectifier potassium channel, potassium loading appears to shorten the QT interval (126). On the other hand, in long QT syndrome 3, in which the defect is in the persistent opening of an abnormal sodium channel, mexiletine, a sodium channel blocker, appears to shorten the QT interval (92).

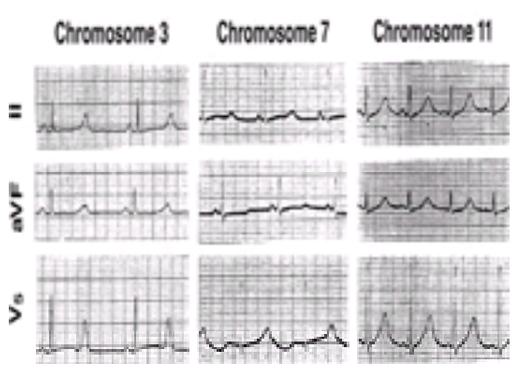


FIGURE 67.7 The QT abnormalities associated with long QT syndrome 1, long QT syndrome 2, and long QT syndrome 3. This figure shows some of the characteristic ST- and T-wave abnormalities associated with some of the long QT syndromes. The electrocardiogram in long QT syndrome 1, associated with an abnormality on chromosome 11, shows broad-based T waves with robust amplitudes. The T wave in long QT syndrome 2, associated with a genetic abnormality on chromosome 7, is also broad-based but tends to have lower amplitudes. Long QT syndrome 3, which comes from an abnormality on chromosome 3, shows a late-initiating and late-peaking T wave with a rather narrow base. (From Moss AJ, Zareba W, Benhorin J, et al. ECG T-wave patterns in genetically distinct forms of the hereditary long QT syndrome. *Circulation* 1995;92:2929, with permission.)

The greatest clinical concern with patients who have long QT syndrome is sudden death and syncope. Those patients who have already experienced such an event appear to be at the highest risk. Patients with long QT interval and first-degree family members who have experienced sudden death are also at significantly increased risk (127). Treatment of high-risk patients with the long QT syndrome may soon be undergoing a marked change as the molecular abnormalities associated with specific channel proteins are identified. Traditionally, the treatments have used beta-blockers (98), pacemakers (128), cervicothoracic sympathectomies (129), careful avoidance of drugs that could prolong the QT interval (Table 67.2), and ICDs. Sympathetic tone, especially when associated with sudden arousal, may be a potent stimulant for the development of polymorphic ventricular tachycardia in these patients. Beta-blockers serve to block this effect of sympathetic tone. Pacemakers can prevent bradycardia, which may be another trigger for polymorphic tachycardia. Left-sided sympathectomy may function in a similar manner as beta-blocker therapy but limits its effect to neurally mediated sympathetic stimulation of the heart. However, this approach is no longer used commonly. ICDs, of course, are intended as rescue devices rather than prevention of the arrhythmia. With the pacing function available in current devices, ICDs could potentially perform a dual role of prevention as well as rescue. These traditional approaches, however, may be quickly changing. Recent advances in the understanding of the different manners in which long QT syndrome 3 and long QT syndrome 2 respond to heart rate acceleration, sodium channel blockers, potassium loading, and potassium channel openers, for example, may dramatically alter our approach to therapy and may provide a more rational approach to selection of the traditional therapies in conjunction with possible new pharmacologic approaches.

Antiarrhythmic medications
Type Ia: quinidine, procainamide, disopyramide
Type Ic: encainide (due to metabolites)
Type III: sotalol, amiodarone, ibutilide, dofetilide, *N*-acetyl procainamide
Type IV: bepridil
Antibiotics
Erythromycin, trimethoprim-sulfamethoxazole, ketoconazole, pentamidine
Antihistamines
Terfenadine, astemizole
Psychoactive compounds
Phenothiazines, haloperidol, tricyclic and tetracyclic antidepressants
Chloral hydrate
Miscellaneous
Diuretics (hypokalemia and hypomagnesemia related)
Probucol, cisapride
Corticosteroids
Organophosphate poisoning

TABLE 67.2 DRUGS ASSOCIATED WITH QT PROLONGATION AND TORSADES DE POINTES

The occurrence of polymorphic ventricular tachycardia and fibrillation in the absence of prolonged QT interval, cardiac ischemia, or marked metabolic abnormalities has been called *idiopathic ventricular fibrillation*. Three syndromes have been described and many isolated cases reported. Brugada and Brugada (130) reported a group of patients with recurrent polymorphic ventricular tachycardia leading to cardiac arrest who had characteristic ECG abnormalities during sinus rhythm. The precordial recordings in the standard 12-lead ECG showed ST elevation mimicking a right bundle branch block (Fig. 67.8). A genetic abnormality of the sodium channel has been identified with this syndrome (131).

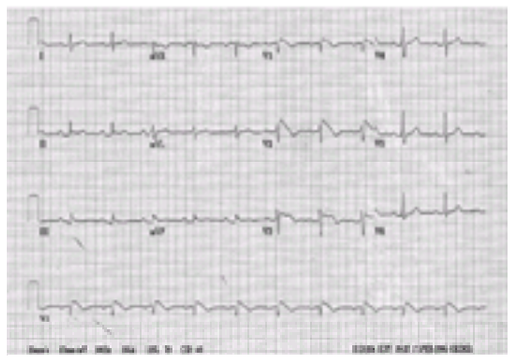

FIGURE 67.8 A 12-lead electrocardiogram from a patient with the Brugada syndrome. Note the ST elevation in the anterior chest leads, especially V1, which mimics the appearance of right bundle branch block. The ST segment slopes gently downward into the inverted T wave, giving the so-called saddleback appearance.

Interestingly, the same gene, *SCN5A*, is implicated in both long QT syndrome 3 and the Brugada syndrome. In contrast to the “gain-of-function” mechanism in long QT syndrome 3, whereby the sodium channel persists in conducting the sodium current by not inactivating adequately, the sodium channel in Brugada syndrome does not generate an adequate sodium current through several different mechanisms: slower recovery from inactivation by a prior depolarization, faster inactivation during depolarization, and a more “sluggish” response to membrane voltage changes (132). In the anterior right ventricular region of the epicardium, this reduced sodium current during phase 0 of the action potential together with the enhanced repolarization current of phase 1 (ITO) seen in the epicardium aborts the usual plateau (phase 2) of the action potential in this region. The voltage gradient between this region and the adjacent myocardium causes the “ST elevation” seen on the ECG. This voltage/repolarization gradient can generate premature ventricular beats and allow wavefront reentry, leading to ventricular fibrillation (133). Although different genetic abnormalities of the *SCN5A* gene have been identified in both the long QT syndrome 3 and Brugada syndrome, a single genetic abnormality may generate both ECG findings, prolonged QT interval and ST elevation, under differing physiologic conditions (134).

The ECG findings of Brugada syndrome may not be persistent and administration of a sodium channel–blocking agent such as flecainide or ajmaline may be necessary as a challenge to reveal this abnormality (135). In symptomatic patients with ventricular fibrillation or syncope, treatment with an ICD is indicated. Asymptomatic patients with the ECG abnormality, either persistent or induced with drug challenge, who have a family history of sudden death at a young age should be treated as well. However, there is a low prevalence (0.05% to 0.10%) of this abnormal ECG finding in the general population without any symptoms or associated family history. Whether any treatment of these individuals is needed remains controversial (136).

Leenhardt et al. (137), reported on a group of young patients who had documented clinical polymorphic ventricular tachycardia and ventricular fibrillation. These arrhythmias appear to be triggered by sympathetic tone and can be reproduced with exercise testing. They frequently present with syncope and seizure-like events. Symptoms are generally triggered by physical or emotional stress. These children have no underlying heart disease and have normal resting ECGs and echocardiograms. The tachyarrhythmia responds well to beta-blocker therapy and a long-acting beta-blocker such as nadolol is the therapy of choice.

Leenhardt and co-authors (138) also reported a syndrome they termed “short-coupled variant of torsades de pointes.” The QT interval is not prolonged. The polymorphic ventricular tachycardia is typically triggered by early ventricular premature beats with short coupling intervals of approximately 250 ms. These patients also have no structural heart disease, but they have a high incidence of sudden death. Beta-blockers do not seem to suppress these arrhythmias. Verapamil may have a beneficial effect. However, an ICD appears to be the most reliable means of preventing sudden death.

DRUG-INDUCED MONOMORPHIC AND POLYMORPHIC VENTRICULAR TACHYCARDIA

Ventricular tachycardia can be seen in certain toxic or idiosyncratic reactions generated by drugs or electrolyte imbalances. Polymorphic ventricular tachycardia associated with drugs that prolong the QT interval is an example. The term “torsades de pointes” was coined by Dessertenne (139) to describe polymorphic ventricular tachycardia where the QRS axis appears to be twisting around a baseline. Torsades has been associated with a variety of antiarrhythmic drug therapies, electrolyte disturbances, and bradycardia due to heart block and hypothyroidism (140,141,142 and 143). A long cycle length, the pause, typically precedes the initiation of this arrhythmia (144) and appears to be a hallmark of drug-induced torsades de pointes (Fig. 67.9). This malignant arrhythmia frequently progresses to sustained ventricular fibrillation and cardiac arrest. Many of the drugs that produce marked QT prolongation in susceptible individuals appear to affect the *HERG*/I_{Kr} potassium repolarization current (145). Thus, a genetic predisposition is most likely present. When QT intervals prolong to 600 ms or when the QTc prolongs more than 500 ms, there is a significant incidence of torsades. Interestingly, amiodarone, although capable of prolonging the QT interval, appears to have a low incidence of causing torsades de pointes (146,147). Table 67.2 lists some of the medications and other conditions that have been shown to produce QT prolongation and torsades de pointes. The list of drugs that could cause QT prolongation and torsades de pointes, especially in patients with the prolonged QT syndrome, is frequently updated and can be obtained from the Georgetown Center for Education and Research on Therapeutics by accessing their Web page on the International Registry for Drug-Induced Arrhythmias (http://georgetowncert.org/qtdrugs_torsades.asp). Besides medications, hypokalemia, hypomagnesemia, hypocalcemia, bradycardia associated with hypothyroidism, and heart block are also potential causes of torsades de pointes. Clinically, torsades de pointes appears to have a predilection for the female gender (148). The cause of this predilection is unclear but may be related to a protective effect of testosterone.

Two potential mechanisms contribute to torsades de pointes. Prolongation of the action potential duration by suppressing the repolarizing transmembrane potassium current is associated with the development of early afterdepolarizations. Myocytes in the middle layers of the ventricular myocardium (M cells) have the longest action potential durations at baseline and may be the source of these afterdepolarizations when the heart is exposed to an agent that prolongs repolarization (149). These early afterdepolarizations are bradycardia-dependent in a similar manner as torsades de pointes. The persistence of the polymorphic ventricular tachycardia and its degeneration into ventricular fibrillation may result from reentry facilitated by the dispersion of repolarization seen in the myocardium when the QT interval is prolonged (150). Interestingly, although amiodarone can prolong QT intervals as readily as other antiarrhythmics, it seems to generate less dispersion of repolarization, perhaps explaining its low associated incidence of torsades de pointes (114).

Treatment of acquired torsades de pointes involves a two-pronged approach—acute therapy to prevent a cardiac arrest and removal of the offending factors generating the prolonged QT interval. Electrolyte levels, specifically those of potassium, magnesium, and calcium, should be checked and corrected to a normal range. Offending drugs should be stopped. Bradycardia due to sinus slowing or atrioventricular block should be corrected quickly with temporary pacing or isoproterenol infusion. Bringing the heart rate up to 100 beats/min is generally adequate to suppress the onset of polymorphic ventricular tachycardia. Intravenous magnesium has been found useful in acutely suppressing torsades de pointes, as it has been demonstrated to suppress early afterdepolarizations in experimental preparations (151). Two grams can be given over 10 to 15 minutes intravenously and repeated if needed. Raising the serum potassium level into the high normal range may also be helpful, as extracellular potassium is known to inhibit the potassium channel–blocking activity of antiarrhythmic drugs (152). These measures should be maintained until the etiologic factors can be removed. In the case of drugs, this may take several days or even longer if amiodarone is the offending agent.

Digitalis toxicity can also induce a ventricular tachycardia, although it is typically a monomorphic ventricular tachycardia. The mechanism by which digitalis causes ventricular tachycardia is through the generation of delayed afterdepolarizations. In experimental preparations, digitalis is one of the agents known to enhance DADs (153). The combination of digitalis toxicity and enhanced sympathetic tone may be a particularly potent stimulus for DADs. Rarely, digitalis toxicity can manifest as a bidirectional ventricular tachycardia. More commonly, it is monomorphic. Clinically, these often manifest as automatic fascicular tachycardias that respond to verapamil but not to adenosine. Because fascicular tachycardia can sometimes have a somewhat narrow QRS and because this tachycardia can respond to verapamil, it is

sometimes misdiagnosed as supraventricular tachycardia (Fig. 67.10). Although the tachycardia will acutely respond to calcium channel blockers such as verapamil, the definitive therapy is to remove digoxin from the tissue through the infusion of digoxin antibody fragments.

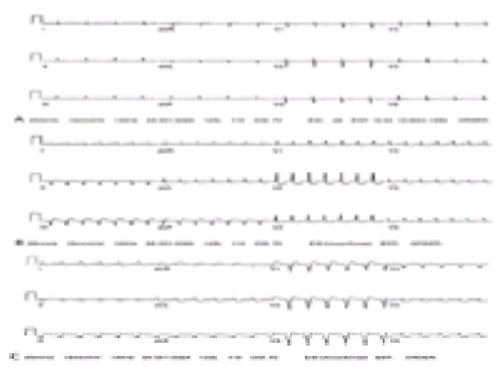

FIGURE 67.10 Ventricular tachycardia induced by digoxin toxicity. This figure illustrates ventricular tachycardia resulting from digoxin toxicity. This patient was in an intensive care unit as a result of acute exacerbation of chronic obstructive lung disease. Digoxin was being administered orally and intravenously because of episodes of atrial fibrillation. **A:** Sinus rhythm. **B,C:** Two different ventricular tachycardias that were initially mistaken for supraventricular tachycardias because of the relatively narrow QRS in **B** and the termination of these tachycardias with intravenous infusions of verapamil. The response of a tachycardia to verapamil cannot be used to indicate the involvement of the atrioventricular node in the tachycardia, as several forms of ventricular tachycardia can respond to this drug. At the time of occurrence of these ventricular tachycardias, the patient's digoxin level was higher than 5 ng per mL.

In the case of drug-facilitated ventricular tachycardia, the underlying substrate such as a reentrant circuit within the scarred portion of the myocardium already exists and may even be able to sustain a reentrant tachycardia. However, the electrophysiologic characteristics of the circuit may make the tachycardia difficult to initiate and sustain. In the presence of a drug that modifies these electrophysiologic characteristics, the tachycardia may become more easily initiated and sometimes can even become incessant. The most frequent cause of drug-facilitated ventricular tachycardia is antiarrhythmic medications that slow conduction of the action potential—that is, class I drugs with sodium channel–blocking activity. When such a drug causes frequent or incessant tachycardia, the best therapy is to discontinue the drug. However, clinical management of the patient may be difficult while the drug is being eliminated. Another cause of ventricular tachycardia in susceptible patients comes from the injection, ingestion, or inhalation of sympathomimetics or bronchodilators such as ephedrine (154) or terbutaline (155). Most likely, these patients have a sympathetic-mediated ventricular tachycardia as described above associated with structurally normal hearts. Under more intense sympathetic stimulation while receiving these drugs, the ventricular tachycardia may become sustained for the first time.

MISCELLANEOUS CAUSES OF VENTRICULAR TACHYCARDIA AND VENTRICULAR FIBRILLATION

Arrhythmogenic Right Ventricular Dysplasia

Arrhythmogenic right ventricular dysplasia, an entity first described in the 1970s and better characterized in the early 1980s (156), is a cardiomyopathy that begins in the right ventricle. It is characterized by right ventricle dilation, decreased contractile function, fatty infiltration and scarring of the myocardium, and ventricular tachycardia. The disease process is progressive and eventually affects the left ventricle as well (157,158). Ventricular tachycardia is frequently the first clinical presentation. The tachycardia is most likely reentrant in nature and arises from the right ventricle. Epicardial mappings have shown late potentials in the right ventricular free wall, and signal-averaged ECGs are generally positive for late potentials (159), both indicating that slow activation of parts of the myocardium occur as a result of the fatty infiltration and scarring of the myocardium. This slow conduction forms the substrate for reentry.

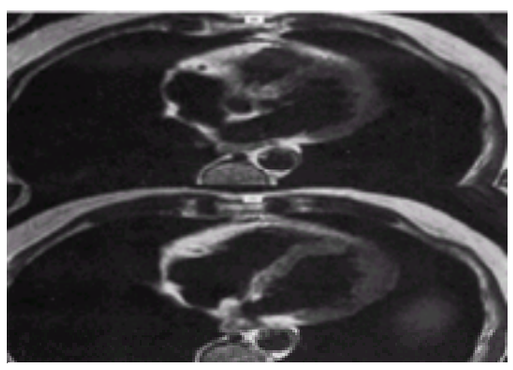
VIDEO

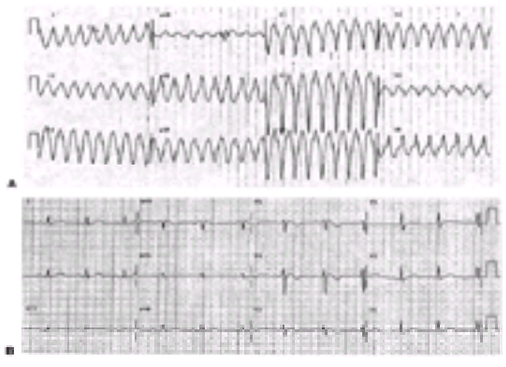
Video 67.1 Arrhythmogenic right ventricular dysplasia (transaxial). Thinning of the right ventricular wall with dyskinesia of the right ventricular free wall during systole is due to fibrous replacement of the myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The pathology of the myocardium can be appreciated by magnetic resonance imaging (eFig. 67.10.1), computed tomography, and direct biopsy. The enlargement of the right ventricle with hypocontractile areas can also be observed on magnetic resonance imaging, by right ventricular angiography, and sometimes on the echocardiogram. The right ventricular angiogram demonstrates a characteristic scalloped appearance of the endocardial outline. The ventricular tachycardia usually has a left bundle branch block pattern due to its origin in the right ventricle. However, it does not usually have the typical appearance of a left bundle branch block QRS, as seen in bundle branch reentrant ventricular tachycardia (eFig. 67.10.2A). The 12-lead ECG during sinus rhythm typically has inverted T waves in the anterior precordial leads (eFig. 67.10.2B), and occasionally one can appreciate a notching of the terminal portion of the QRS, suggesting an incomplete right bundle branch block. This notching has been termed an *epsilon wave*. The generalized infiltration process within the myocardium can create multiple different reentrant circuits. Although there are many sporadic cases, there are also familial clusters of right ventricular dysplasia as well as concurrent presence of the disease in twins, suggesting a genetic abnormality as the etiology (160). Several specific genetic loci have been associated with familial right ventricular dysplasia (161,162 and 163). Thus, there may be multiple genetic abnormalities contributing to this entity. In one family, the genetic abnormality was identified as the mutated plakoglobin gene responsible for generating a protein important in cell-to-cell adhesion, suggesting that disruption of cell junction may play a role in the etiology of this syndrome (164).



***e*FIGURE 67.10.1** Two transverse sections from a gated magnetic resonance image of the thorax in a patient with right ventricular dysplasia. The upper panel shows the right atrium to the left, the right ventricle at the top, and the left ventricle below and to the right. There is increased intensity of the image at the right atrioventricular

groove surrounding the right coronary artery consistent with the fat pad normally seen surrounding the blood vessels of the groove. This increased intensity extends into the right ventricular free wall, indicating infiltration of the free wall with fatty tissue. Near the apex of the right ventricle, there is thinning of the free wall. The lower panel shows a section just below the level of the upper panel, demonstrating that there is extensive fatty infiltration of the entire right ventricular free wall. Note the normal appearance of the left ventricular free wall on these two images. (Images courtesy of Dr. Richard White, The Cleveland Clinic Foundation.)



***e*FIGURE 67.10.2** Electrocardiographic characteristics of arrhythmogenic right ventricular dysplasia. **A:** Twelve-lead electrocardiogram of a ventricular tachycardia having a left bundle branch block QRS morphology and a left axis deviation. This indicates that the tachycardia is originating from the apex of the right ventricle. This patient had extensive dysplasia of the right ventricle with fatty infiltration. **B:** The 12-lead electrocardiogram in the same patient during sinus rhythm. Note the inverted T waves across the anterior chest leads and the slurring of the terminal portions of the QRS in the same leads, suggestive of an incomplete right bundle branch block. This slurring has been called an *epsilon wave*.

Contrary to early descriptions of the disease in middle-aged patients, there is a considerable risk of arrhythmic death in patients who are found to have this disease at a younger age, especially in childhood (165). The risks of ventricular tachycardia and sudden death appear to correlate with the extent of right ventricular involvement (166). Sympathetic stress such as exercise may trigger ventricular tachycardia. Patients who have experienced sustained ventricular tachycardia, syncope, or cardiac arrest are at the highest risk and need to be treated. Large-scale clinical trials comparing various therapies are not available. Among the antiarrhythmic medications, sotalol appears to be most effective, perhaps because of its beta-blockade properties in combination with type III antiarrhythmic effects (167). The usual type I antiarrhythmics appear to have very little success. Amiodarone at higher doses can also work well but may not be well tolerated chronically. Catheter ablation can be used to ablate a particularly frequent or incessant tachycardia. However, because of the multifocal nature of the disease, other tachycardias are frequently present or become manifest later. Thus, catheter ablation can be a palliative therapy but is unlikely to be a curative treatment. ICDs may be the only reliable therapy for the prevention of sudden death in these patients. Despite concerns regarding the safety of implanting an ICD lead into the right ventricle in these patients, experience with ICDs in patients with hemodynamically compromising ventricular tachycardia or cardiac arrest has been positive (168,169).

Sarcoidosis

Cardiac sarcoidosis can cause a variety of cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and complete heart block (170). Occasionally, sudden death may be the presenting symptom. Sarcoidosis in general and its cardiac involvement seem to affect women more than men.

Cardiac involvement with sarcoidosis can be confirmed with nuclear imaging such as thallium-201, gallium-67, or technetium-99m pyrophosphate scans. Magnetic resonance imaging has also been reported to be useful (171). Patients presenting with ventricular tachycardia, syncope, or aborted sudden death are at particularly high risk. Early in the disease process, corticosteroids and other immunosuppressive therapy may be helpful in resolving ventricular arrhythmias (126,172). However, in most patients presenting with sustained ventricular arrhythmias, steroid therapy appears to have no suppressing effects on the arrhythmia (173). Sustained ventricular tachycardia is usually inducible with programmed ventricular stimulation. Drug suppression of inducibility, as in other etiologies of ventricular tachycardia, does not necessarily translate to clinical prevention of recurrence. The main approach to antiarrhythmic drug therapy is the use of amiodarone and sotalol. However, some have advocated the ICD as the best approach in combination with drug therapy as needed in this high-risk group of patients (129,174).

Acute Myocarditis

Acute myocarditis has been associated with both polymorphic as well as monomorphic ventricular tachycardia. Conduction disturbances, ST-segment changes, and T-wave abnormalities can all be seen in acute myocarditis. Some authors have reported favorable responses to steroid therapy (175). Others have reported mixed results, in which ventricular arrhythmias persist even after resolution of acute myocarditis after steroid therapy (176). A combination of antiarrhythmic drug therapy with an attempt at suppressing the inflammation with steroid therapy appears to be needed in these patients.

Muscular Dystrophies

Ventricular arrhythmia and conduction system disturbances have been associated with some of the muscular dystrophies. In particular, Duchenne's muscular dystrophy and myotonic dystrophy have a high incidence of ventricular arrhythmia and occasional sudden death (177,178). In both these entities, signal-averaged ECGs have shown late potentials consistent with delayed cardiac activation, probably originating from myocardium affected by the disease process (179,180). Whereas patients with Duchenne's dystrophy tend not to survive beyond the teenage years, patients with myotonic dystrophies generally survive well into adulthood. In myotonic dystrophy, conduction system disease is a prominent component of its myocardial involvement. This can lead to the development of bundle branch block as well as complete heart block. Besides ventricular tachycardia originating from the affected myocardium, bundle branch reentry and fascicular reentry resulting from the conduction system disease have been reported in these patients (181).

Chagas' Disease

Chagas' disease, a chronic infection with the parasite *Trypanosoma cruzi*, causes a cardiomyopathy secondary to chronic multifocal myocarditis (182). Patients chronically infected with this agent can develop congestive heart failure, conduction system disease, and ventricular tachycardia. The signal-averaged ECG is frequently positive for late potentials in patients with ventricular tachycardia (183). There is a high incidence of sudden death among these patients, probably due to ventricular tachycardia, although complete heart block may contribute to some of these sudden deaths (184,185). Patients with more advanced congestive heart failure are at the highest risk for sudden death. Treatment includes drug eradication of the parasite, therapy for the congestive heart failure, antiarrhythmic drug therapy, pacemakers, and ICDs (186). Catheter ablation of ventricular tachycardia can be successful (187), although recurrence of tachycardia from other foci is frequent.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Although the last 30 years have seen the development of a deeper understanding of the mechanisms of ventricular tachycardia and of several technologies for the treatment of ventricular tachycardia, the application of such technologies is frequently the subject of debate among physicians. With the publication of the Multicenter Unsustained Tachycardia Trial, extending the results of the Multicenter Automatic Defibrillator Implantation Trial, it is now generally accepted that high-risk patients with inducible sustained ventricular tachycardia form a group who are best treated with the ICD as opposed to currently available antiarrhythmic medications.

The use of the electrophysiology study, however, is a costly and invasive means of assessing increased risk for arrhythmic deaths in post–myocardial infarction patients. Whether less invasive means such as T-wave alternans, heart rate variability, and signal-averaged ECG may substitute as well are questions that remain to be answered. Furthermore, debate remains as to whether patients with decreased ventricular function, due to coronary disease or other processes, are all at a high enough risk for arrhythmic deaths to benefit from antiarrhythmic drug or ICD therapy. Several ongoing clinical trials may answer this question in the near future.

How to approach treatment to prevent sudden arrhythmic deaths among patients with nonischemic dilated cardiomyopathy is still undergoing debate. Besides ejection fraction, functional class, prior resuscitation from cardiac arrest, and perhaps the clinical occurrence of syncope, there are no other clinical factors that have a strong predictive value for arrhythmic deaths. Although the presence of nonsustained ventricular tachycardia appears to be associated with increased mortality (188,189), it is unclear whether this increase is due to sudden arrhythmic deaths (190) or if the predictive value of such a finding will be useful (191). Clinical studies have not demonstrated significant benefit of amiodarone in this population as a whole in preventing sudden death. Similarly, no studies exist on the use of ICD implantation. Yet,

given the known increased risk of sudden death among these patients with poor ventricular function, should one consider ICD therapy because of its demonstrated ability to lower sudden death rates in other patients? Some would argue that such an approach is not justifiable until the extent to which life can be usefully prolonged by this approach has been demonstrated by clinical study. Clinical trials specifically aimed at this patient population may yield an answer to this question.

THE FUTURE

Despite a number of unanswered and perhaps unanswerable questions, the direction in which therapy of ventricular tachycardia has moved in the past three decades indicates that it will have an exciting future. The development of preventive medicine aimed at eliminating the underlying disease processes that generate the substrate for ventricular tachycardia is already well under way for coronary artery disease. Similar preventive treatments may develop for the nonischemic cardiomyopathies. Treatment of congestive heart failure with better drugs, transplants, and mechanical hearts may considerably lessen if not eliminate the problem of arrhythmic sudden deaths in these patients. For those who are still at risk, the development of a very small ICD that is relatively inexpensive to insert will minimize the risk of sudden arrhythmic death at an acceptable cost. New mapping technologies that are now being explored combined with new ablation approaches perhaps using different energy sources will make catheter ablation of ventricular tachycardia a reliable and highly successful tool in selected patients. Lastly, the blossoming understanding of the molecular and genetic basis of certain syndromes such as long QT syndrome will allow the application of genetic cures or drug therapies targeted specifically at the molecular defects that promote ventricular arrhythmias and cause sudden deaths in these patients. Those advances would provide not only treatments but also an understanding of those physiologic properties that promote a stable rhythm as opposed to those that facilitate the development of lethal tachyarrhythmias.
