HISTORICAL PERSPECTIVE

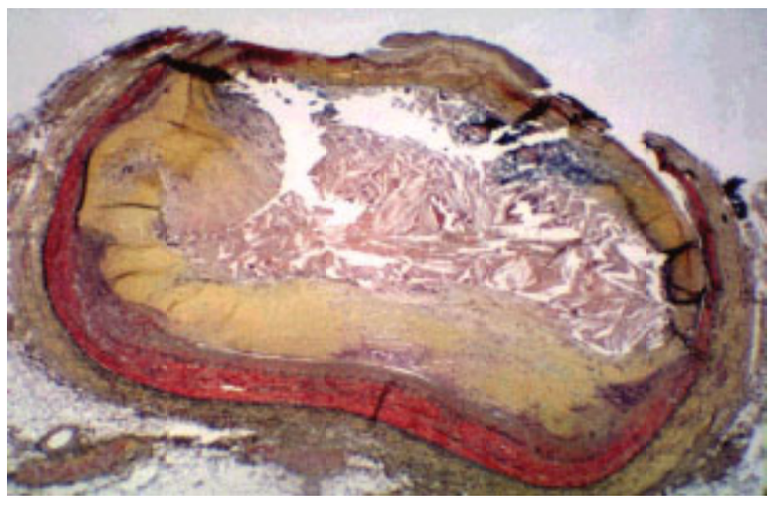
Evolution of Direct Coronary Artery Surgery

Now in its fourth decade, surgical myocardial revascularization has benefited millions of patients. Excellent early and late results are attributable to improvements in technology rather than selection of lower-risk patients. The surgical achievements relate to advances in myocardial protection, use of arterial conduits for bypass grafting, and postoperative intensive care management. The original coronary artery bypass operation as popularized by Favaloro (1) and Johnson and colleagues (2) and performed earlier by Garret and colleagues (3) involved aortocoronary saphenous vein grafts. Later, after surgeons acquired the necessary technical expertise, internal thoracic arteries (4) and other arterial conduits were successfully used. Anesthesiologists deserve a large part of the credit for advances in myocardial protection, intraoperative stabilization, and intensive care management. Improvements in anesthetic agents, afterload reduction, and ventilation management have contributed to reduction of complications, shorter hospitalization, and lower cost.

SELECTION OF CANDIDATES FOR SURGERY

Current Indications

Advanced age affects selection for surgical procedures and has stimulated risk assessment. At age 70, clinically detectable coronary atherosclerosis occurs in 15% of men and 9% of women; by age 80, this figure rises to 20% in both sexes. In addition, increasing age is associated with increasing prevalence of diabetes, peripheral vascular and cerebrovascular disease, cardiac dysfunction, and left main narrowing (5).



Severe atherosclerosis of saphenous vein graft. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

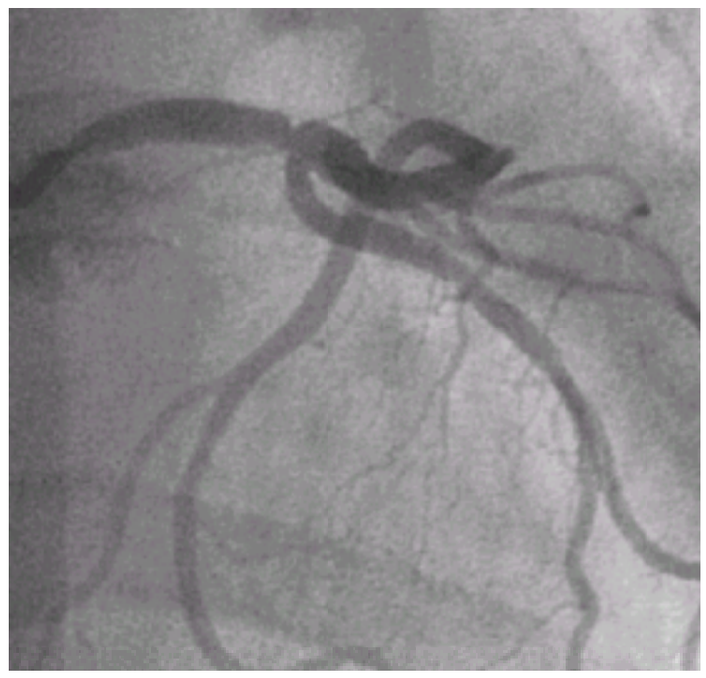
In 1967, the mean age for coronary artery surgery patients was approximately 50 years, and today it has risen to 66 years; nearly 30% of patients are older than age 70, and 10% are older than age 80. The national rate of bypass surgery in octogenarians is increasing rapidly (up 67% during a recent 4-year period), and early results are similar to those of the Medicare population overall (6), despite the complicated and frequently multisystem atherosclerosis typical in older people. In the elderly, there is a greater incidence of silent ischemia, unrecognized myocardial infarction, and diastolic dysfunction (7). Stress echocardiography with pharmacologic testing or positron emission tomographic scanning may be required to document ischemia because exercise capacity is often limited (see Chapter 50).

Age and left ventricular performance are the most important prognostic indicators for late outcome, regardless of the type of treatment (8). Men tend to manifest clinically detectable coronary atherosclerosis at a younger age than women; however, after menopause, the rates of atherosclerosis among men and women are approximately the same.

Chronologic age is a crude measure and is less important than physiologic age. Older age is fraught with the above-mentioned comorbidities, yet these do not encompass all factors in selection. Postoperative hospitalization is longer in those older than age 70 years compared with that of patients ages 65 to 70 years, and

hospital costs and charges are also greater. The four As—age, attitude, activity, and associated diseases—are helpful in assessing risk versus benefit (9).

Given that the patient is an acceptable candidate based on clinical characteristics and evidence of myocardial ischemia, the next important step is coronary arteriography. The location(s) of myocardial jeopardy influences the decision about the type of revascularization. Left main and proximal anterior descending narrowing of 50% or more of lumen diameter impacts the prognosis for adverse events and death more than lesions in other arteries. Patients with angina or ischemia and two-vessel coronary atherosclerosis with a proximal anterior descending lesion or proximal three-vessel disease should be considered for surgery (10). When viable myocardium is demonstrated, poor left ventricular function is not a contraindication to surgery, provided the target vessels are graftable.



A 64-year-old male patient with severe ostial and moderate distal left main trunk stenosis.

Lessons from Clinical Trials

The lessons learned from clinical trials of coronary bypass surgery compared with medical treatment and with angioplasty are the bases for selection of the surgical candidate. In low-risk patients (i.e., those with marginal lesions and no ischemia or with narrowing in small branch coronary arteries) medical treatment is effective. Coronary bypass surgery is indicated for patients with multivessel disease and is most appropriate in patients with left main and proximal anterior descending lesions as part of a complicated atherosclerotic pattern (Fig. 82.1) (11,12,13 and 14). As left ventricular performance worsens, survival with surgical treatment tends to be better than that with medical treatment (15). Angioplasty may yield equivalent results in single-vessel and selected two-vessel disease in the intermediate term, but more complicated atherosclerotic plaques and calcification in diffuse coronary atherosclerosis make standard balloon angioplasty less effective. In calcified vessels, rotational atherectomy combined with balloon angioplasty has been successful, as well as atherectomy performed before stent placement. Stents have reduced but not eliminated the restenosis problem.

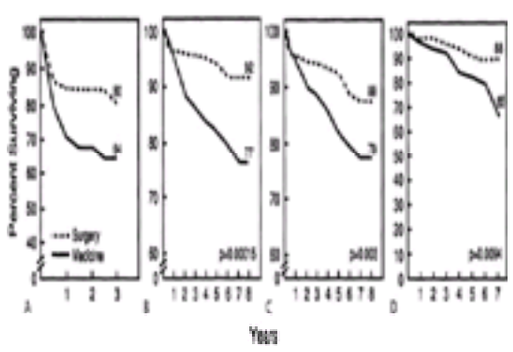


FIGURE 82.1 Survival from published randomized trials comparing coronary artery bypass surgery with medical treatment. **A:** The original Veterans Administration Coronary Arterial Disease Study, which randomly allocated 113 patients with severe left main coronary narrowing to medical or surgical treatment from 1970 to 1974. The 3-year survival was 80% for surgery and 64% for medicine. **B:** Long-term results of two- and three-vessel disease patients from the European Coronary Surgery Study Group are depicted in this panel. Actuarial survival curves for three-vessel disease patients who had an 8-year survival of 92% for surgery and 77% for medicine (p = .00015). **C:** In the subgroup of patients with more than 50% narrowing in the proximal third of the anterior descending coronary artery, there was a highly significant difference in favor of surgery in both two- and three-vessel disease subsets. **D:** Seven-year cumulative survival rates for surgery and medical patients from the randomized trial of the coronary artery surgery study. The surgical survival of 88% was significantly better (p = .012) than medical treatment when the left ventricular ejection fraction was under 0.50. (Data from Takaro T, Hultgren HN, Lipton MJ, et al. The VA Cooperative randomized study of surgery for coronary arterial occlusive disease II. Subgroup with significant left main lesions. *Circulation* 1976;54[Suppl III]:III107–III117; European Coronary Surgery Study Group. A randomized trial of coronary artery bypass surgery: survival of patients with a low ejection fraction. *N Engl J Med* 1985;312:1665–1671.)

Contraindications

Contraindications to coronary artery surgery are relative and include patients with no signs of ischemia, especially those with poor left ventricular function and clinical evidence of heart failure; very elderly patients who are inactive and have absent or mild symptoms; and patients who exhibit noncompliant behavior or are otherwise mentally impaired.

In patients with noncardiac conditions whose coronary atherosclerosis warrants revascularization, coronary artery surgery should precede noncardiac procedures (16). Extensive guidelines for physicians involved in preoperative, operative, and postoperative care of patients undergoing noncardiac surgery are available (17). Their purpose is to formulate a stepwise, cost-effective approach to diagnostic testing and management.

Selected Subsets

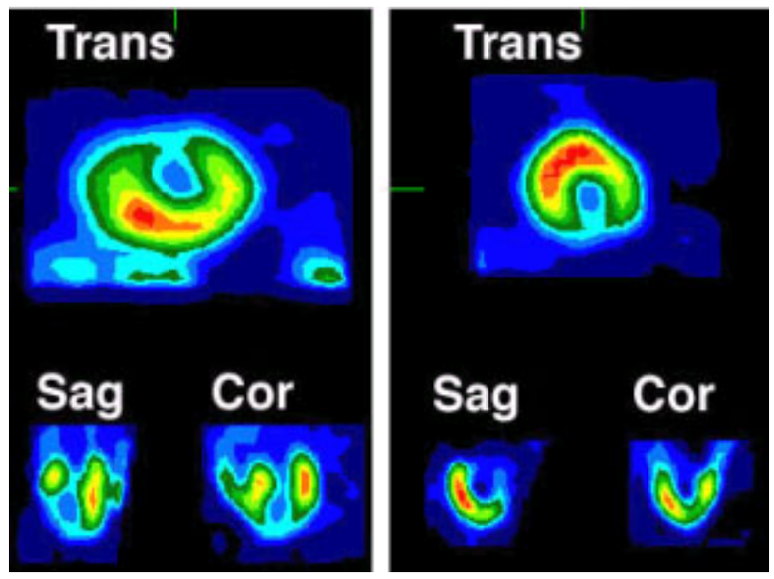
Younger Age

Young age is generally defined as age younger than 40 years. Premature atherosclerosis may be severe and require coronary artery bypass grafting followed by strict lipid modification therapy and diabetic management when indicated (18,19). Coronary risk factors tend to be more prevalent in this population. Only arterial bypass conduits should be used as grafts—that is, bilateral internal thoracic artery grafts are often used for the anterior descending and circumflex arteries, and, when the right coronary artery is small and subtotally or totally occluded, the gastroepiploic artery or other arterial conduit may be useful to revascularize the inferior wall. Larger patent but stenotic right coronary arteries may be treated with the radial artery or selectively by the *in situ* right internal thoracic artery grafted to a major branch, usually the posterior descending. The radial or inferior epigastric artery may be used as a Y or T graft for circumflex revascularization from the left internal thoracic artery or as an aortocoronary bypass graft (20).

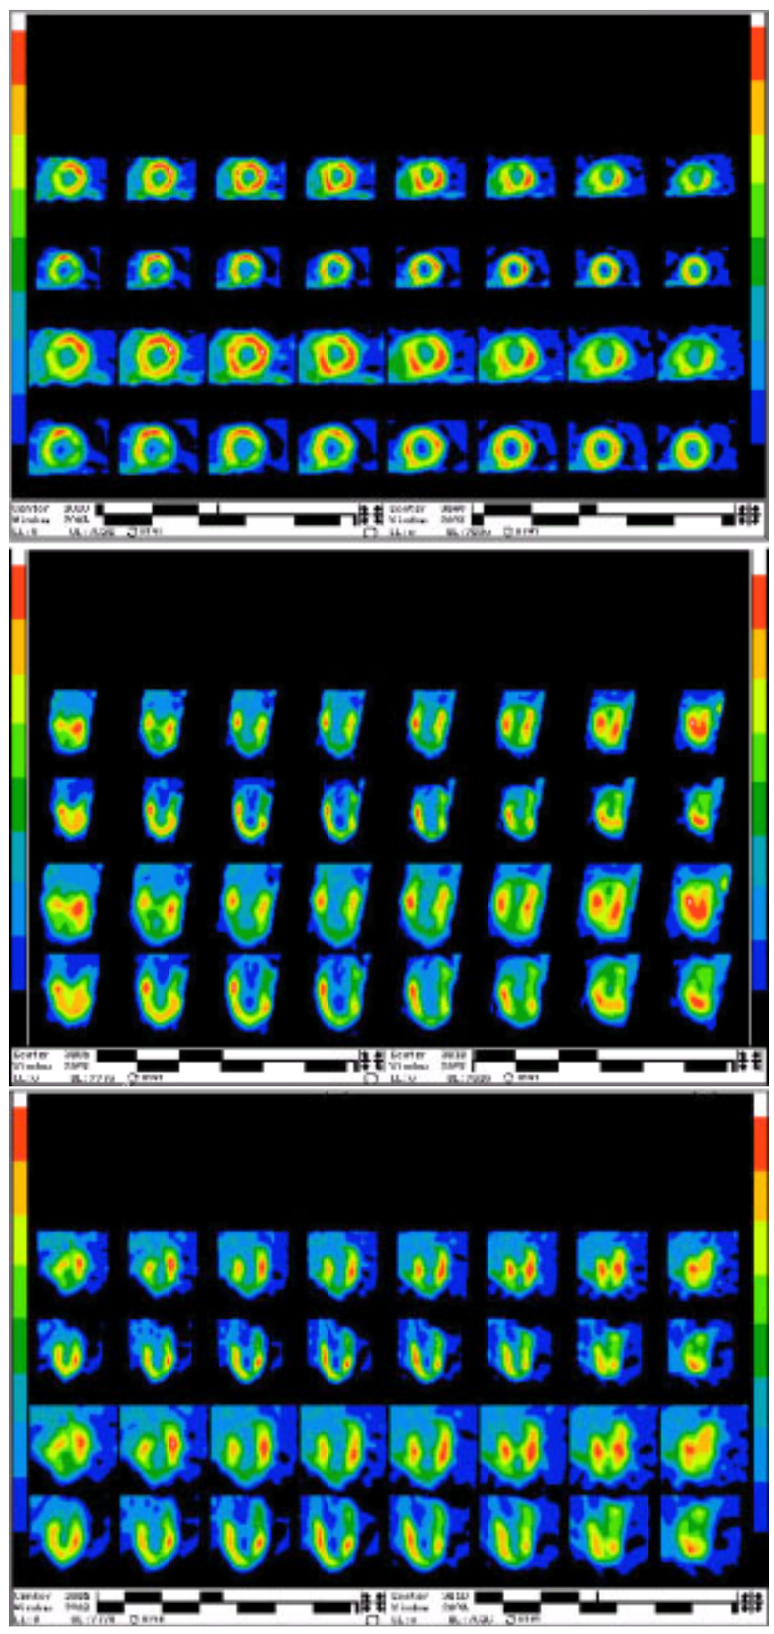
Hibernating Myocardium

Hibernating myocardium, a potentially reversible condition, indicates impaired contraction caused by chronically reduced myocardial blood flow (21). Hibernating

myocardium may be identified by demonstrating contractile reserve after administration of dobutamine, by showing preserved metabolism in abnormal regions through positron emission tomography, and by thallium uptake indicating preserved myocardial function. Of these alternatives, positron emission tomographic myocardial imaging is the most sensitive predictor of functional recovery. In contrast, stunned myocardium occurs after restoration of normal flow after a period of myocardial ischemia (22). Stunning may occur after vasospasm, myocardial infarction, angioplasty, or coronary bypass surgery. Stunning is not innocuous and may reduce contractile function to the point where the left or right ventricle is incapable of supporting the systemic circulation (see the section Reduced Left Ventricular Function). With recent technological advances, magnetic resonance imaging has become a valuable method for the detection of viable myocardium (23).



Matched resting rubidium (*left set*) and radiolabeled fluoro-deoxyglucose positron emission tomographic (*right set*) images. Transverse, sagittal, and coronal positron emission tomographic images demonstrating myocardial hibernation in the left anterior descending artery territory.



Resting rubidium-82 with fluorinated deoxyglucose viability positron emission tomographic scanning in a 63-year-old patient in the transverse (*first image*), sagittal (*second image*), and coronal (*third image*) plane images demonstrating hibernating myocardium involving the mid and distal anterior, mid and distal anteroseptal, and distal septal segments. Matched perfusion and metabolic defects are seen involving the apical and inferoapical segments. The right anterior oblique left ventriculogram (*first video*) also shows the presence of hibernating myocardium, due to occlusion of a "wrap around" left anterior descending coronary artery. The mid and distal anterior, apical, and inferior apical walls are akinetic. The anteroposterior cranially angulated angiogram (*second video*) demonstrates subtotal occlusion of a large "wrap around" left anterior descending coronary artery in the same patient with a dominant left coronary artery.

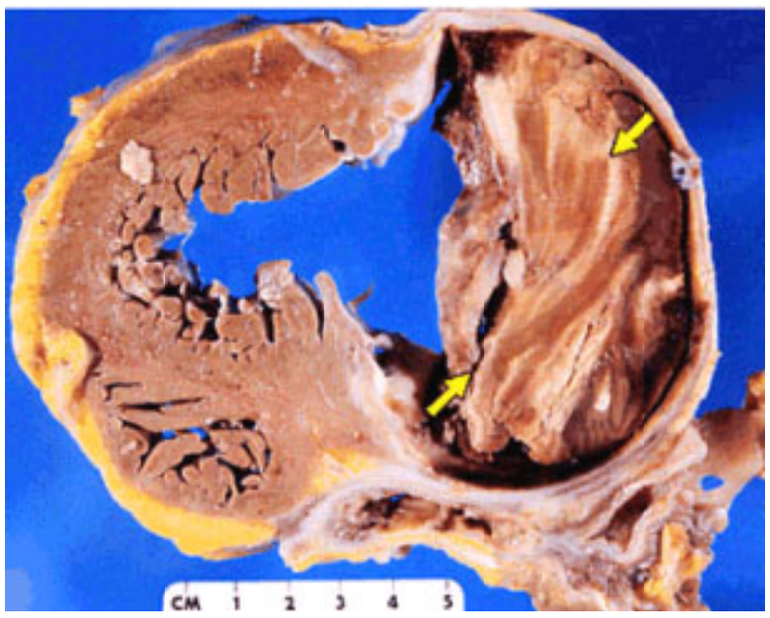
Ventricular Aneurysm

Ventricular aneurysm is irreversible true scar formation that is most frequently due to anterior descending coronary artery occlusion (24). Approximately 3% to 4% of cardiac aneurysms occur posteriorly between the papillary muscles (25). The scarred region is thin-walled and frequently adherent to the pericardium. Angina, heart failure, and tachyarrhythmias are the indications for surgery. Adherent organized ventricular thrombi are seen in 50% of ventricular aneurysm cases. Embolism is rare, and left ventricular thrombus *per se* is not an indication for surgical removal. The great majority of patients have multivessel disease. Endoaneurysmorrhaphy appears more physiologic than linear repair because of a more favorable effect on measured ejection fraction and improved long-term clinical outcome (26). The best surgical treatment is to have aneurysm exclusion by ventricular patch combined with coronary bypass surgery. Several techniques for geometric preservation of the ventricle have been advanced and are characterized by a reduction in chamber volume to provide greater systolic shortening (27,28).

A 78-year-old with left ventricular aneurysm status post anterolateral myocardial infarction.

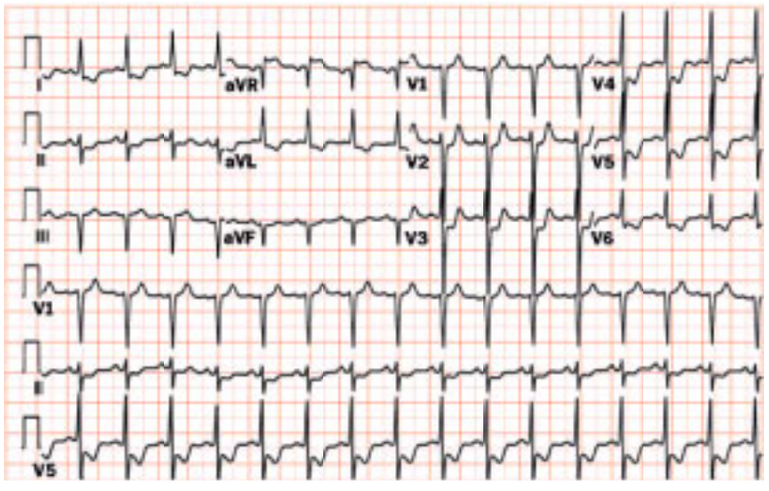
Aneurysm repair in a patient with a recent lateral wall myocardial infarction. "Packing material" is evident overlying the area of repair (*yellow arrow*).



Healed, atrophic posterolateral infarct and ventricular aneurysm containing a mural thrombosis (*yellow arrows*).

Acute Ischemic Syndromes

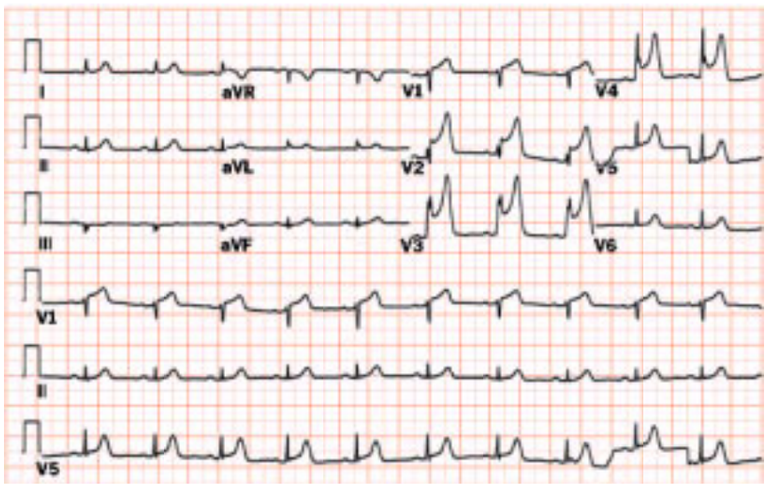
Acute ischemic syndromes include the spectrum from unstable angina to myocardial infarction. Unstable angina is a broadly interpreted condition. New and progressive angina may be categorized as unstable, but a stricter definition includes pain at rest with electrocardiographic evidence of ischemia (29). Most such patients can be stabilized, but approximately 10% experience myocardial infarction. Necropsy studies indicate that unstable angina patients frequently have severe coronary atherosclerosis. A ruptured atherosclerotic plaque has been linked to persistent instability. Refractory unstable angina may lead to early coronary arteriography and intervention. Multivessel graftable coronary atherosclerosis is an indication for coronary bypass surgery, preferably when the patient is stable. Operations in the face of acute symptoms, especially with ischemic electrocardiographic change, are associated with a higher perioperative myocardial infarction rate and associated risk (30).



Subendocardial ischemia. Anterolateral ST-segment depression is consistent with diffuse subendocardial ischemia versus non–Q-wave myocardial infarction.

Unstable angina vs. non–Q-wave myocardial infarction. ST-segment depression in leads V_2 through V_5 supports acute ischemic syndrome.

Reports on emergency surgery for acute myocardial infarction demonstrated good intermediate-term results (31); however, thrombolytic therapy and angioplasty have largely supplanted emergency surgery. Today, emergency coronary bypass surgery is generally reserved for patients who have severe left main coronary atherosclerosis, who fail angioplasty intervention, or who have mechanical defects. The greatest decrease in risks for operative mortality and perioperative myocardial infarction occurs within 48 hours of infarction, and there is little to be gained by delaying surgery longer (32). Patients with non–Q-wave infarction may, with appropriate indications, undergo bypass surgery with relative safety at any time.



Acute anteroseptal myocardial infarction. Dramatic ST segment elevations in leads V_1 through V_5 with associated hyperacute T-wave changes are noted.

Data collected from 19 Seattle hospitals showed that, among patients who underwent emergency or urgent surgery during myocardial infarction, there was no difference in mortality for patients operated on during the first 24 hours compared with those operated on later in the hospital course (8.3% vs. 7.2%) (33). Over the next 3 years, there were few cardiac events in the surgical population; the 3-year survival of 83% was better than the 66% survival rate in those treated medically. Other studies have reported a hospital mortality as low as 4% in patients operated on less than 24 hours after infarction.

As might be expected, given higher event rates among patients with left anterior descending lesions, emergency surgery for myocardial infarction is more beneficial for

anterior infarctions than for inferior infarctions (34). Multicenter trials indicate that in-hospital and 1-year results, event-free survival, angina status, and health status are similar for emergency bypass surgery and treatment by successful thrombolysis and angioplasty. Patients who have survived cardiac arrest secondary to myocardial infarction should be evaluated by electrophysiologic testing and coronary arteriography (35). Commonly, multivessel coronary artery disease is found, and surgical revascularization is considered. The result depends on preoperative left ventricular status and the potential for surgery to suppress inducible ventricular arrhythmias.

The results of emergency surgery today far surpass those of the early 1970s. Although preoperative cardiogenic shock is the leading risk factor for hospital death after emergency revascularization, techniques of controlled surgical reperfusion have reduced the mortality in that subset to 10% (36). As myocardial protection improves through better reperfusion strategies, the treatment of acute coronary occlusion should be reevaluated because ischemic muscle may be salvaged at time intervals beyond limits previously thought to cause irreversible damage.

Mechanical Complications of Myocardial Infarction

Cardiac rupture is documented at autopsy in 8% of patients after myocardial infarction. Cardiac rupture occurs more frequently in women, in the elderly, after recurrent myocardial infarction, and in patients with multivessel disease (37). Free wall rupture occurs 3 to 10 times more frequently than ruptured papillary muscle or ventricular septal defect and is a more frequent cause of acute hemopericardium than is aortic dissection (38). Rupture of the free wall, most commonly the anterior or lateral wall, usually occurs during the first week after infarction, but approximately one-third of ruptures occur in the first 24 hours. Free wall ruptures may occur after thrombolytic therapy and present subacutely. Death is often instantaneous, but in up to 40% of patients, death occurs over a matter of hours. If the rupture is contained and is recognized, surgical repair should proceed immediately (39). Conventional surgery involves bolstered primary closure or patching, and both carry high mortality due to the precarious emergency situation and necrotic muscle. Recently, patching with a biocompatible synthetic glue without direct suturing has been successful (40).

Cardiac rupture after acute transmural anteroseptal myocardial infarction. The yellow arrow indicates the site of rupture.

The pseudoaneurysm cavity is contained by pericardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

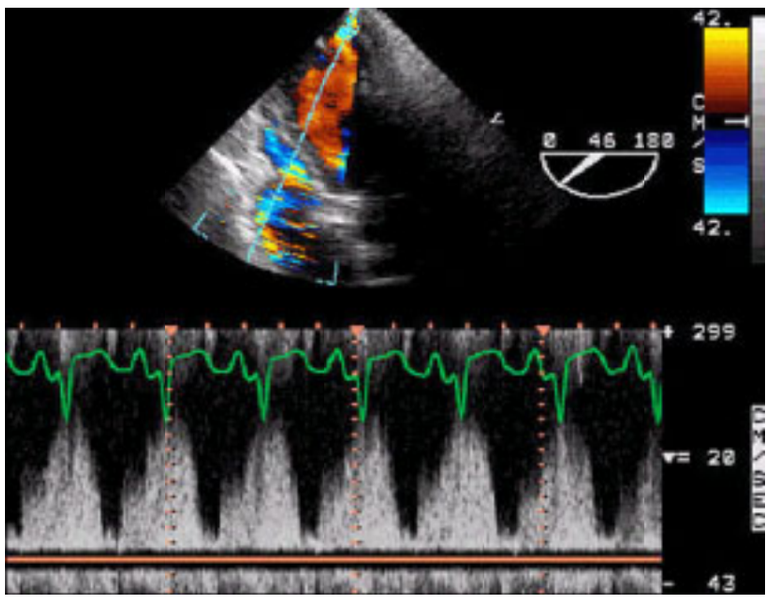
Ventricular septal defects account for 20% of cardiac ruptures secondary to myocardial infarction. Ideally, repair is performed at 6 weeks, when the defect edges have become more fibrous and hold sutures better. However, this situation is infrequent; most patients with acute septal rupture are hemodynamically unstable and require emergency surgery. These patients should be treated expeditiously with vasopressor and intraaortic balloon pump support and should have coronary angiography before emergency surgery. The traditional surgical treatment has been infarctectomy and incorporation of septal and ventricular wall polyethylene terephthalate (Dacron) fabric patches (41).



Doppler recording of flow through an ischemic ventricular septal defect before surgical repair.

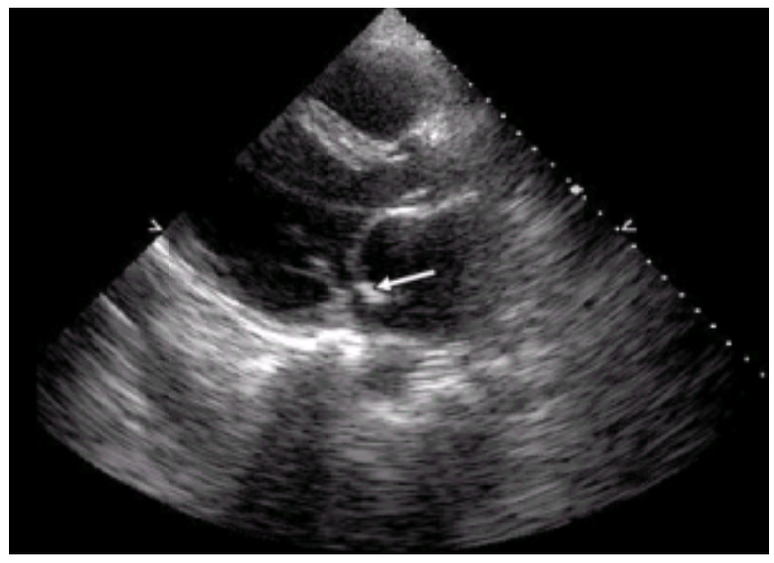
More recently, introduction of a glutaraldehyde-fixed bovine pericardial patch sewn to the endocardium around the infarcted muscle has been introduced. This technique of repair by bioprosthetic endocardial patch is easy to accomplish technically and has resulted in lower operative mortality (14% operative mortality and 66% 6-year survival in the largest reported series) (42). The advantage of this approach is restoration of left ventricular geometry and preservation of right ventricular muscle. Regardless of surgical technique, the greatest risk factors in patients with postinfarct ventricular septal defects are cardiogenic shock and right ventricular dysfunction.

Ischemic Mitral Regurgitation

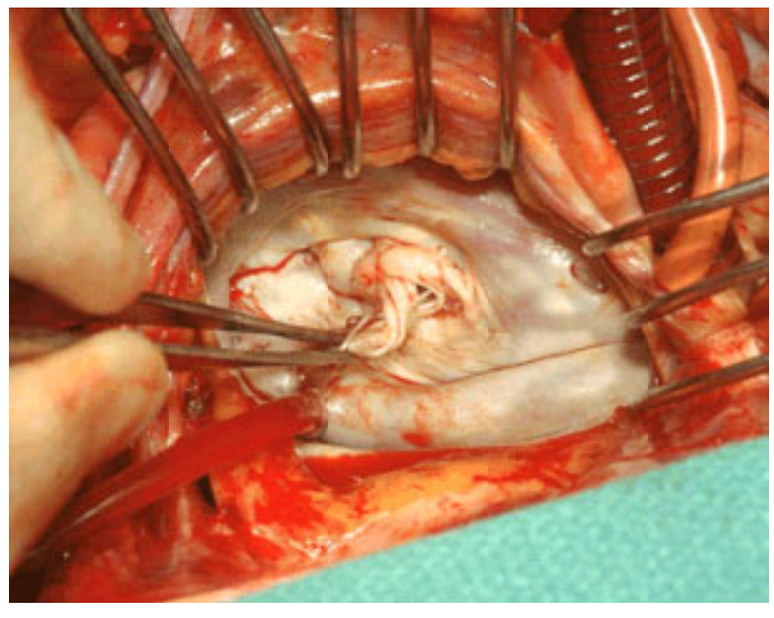
In ischemic mitral regurgitation, the mitral leaflets and chordae are normal, and the regurgitation is a consequence of ischemic disease of the myocardium. Although published classification schemes for this entity are confusing, classification by mechanism of mitral valve dysfunction is straightforward. Some patients have transient mitral regurgitation caused by intermittent ischemia. In such patients, mitral regurgitation is relieved by revascularization alone. In most cases, however, ischemic mitral regurgitation can be corrected only by mitral valve repair or replacement. In such cases, ischemic mitral regurgitation has one of three causes: (a) ruptured papillary muscle, (b) infarcted but unruptured papillary muscle, and (c) functional ischemic mitral regurgitation (43). Patients with a ruptured papillary muscle usually present with acute pulmonary edema and require urgent surgery. Patients with an infarcted but unruptured papillary muscle generally have a fibrotic, elongated papillary muscle. This causes leaflet prolapse and mitral regurgitation. The majority of patients with ischemic mitral regurgitation has functional ischemic mitral regurgitation. In such patients, alterations in ventricular and annular geometry produce restricted leaflet motion and a jet of mitral regurgitation that is frequently central or eccentric.

Video 82.10 Parasternal long-axis view of a ruptured papillary muscle after myocardial infarction. Note the bright mass (papillary muscle) attached to the tip of the anterior mitral leaflet as it flails into the left atrium. This resulted in severe mitral regurgitation. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Parasternal long-axis view of a papillary muscle rupture after myocardial infarction. Note the piece of papillary muscle attached to the tip of the anterior mitral leaflet as it flails into the left atrium (demonstrated by the arrow).

Surgical pathology specimen demonstrating a torn papillary muscle seen to the lower right of the screen, attached via chordae to a portion of the anterior mitral leaflet. Note the torn "ragged edges" at the bottom of the papillary muscle head.



Intraoperative field demonstrating a mitral valve with a torn papillary muscle prolapsing across the mitral valve into the left atrium. The surgeon has the papillary muscle in forceps demonstrating the chordae attached to the posteromedial commissure, predominantly attached to the anterior mitral leaflet. (The patient's head is to the left of the screen and feet to the right.)

Surgical treatment of ischemic mitral regurgitation consists of mitral valve repair or replacement, generally with concomitant coronary artery bypass grafting. In most patients, there is a survival advantage to mitral valve repair over mitral valve replacement (43). When mitral valve replacement is performed, the subvalvular apparatus should be preserved. Hospital mortality is 10% to 20%, and 5-year survival is approximately 50% (43). These unfavorable results are attributable to left ventricular dysfunction in this subset of patients.

Coronary Artery Aneurysms

Ectasia and Kawasaki disease exhibit aneurysmal coronary arterial changes. The term *ectasia* denotes a diffuse ballooning of the coronary artery probably related to atherosclerosis, although some of these cases may be traced to past Kawasaki disease. Kawasaki coronary artery disease (also known as *mucocutaneous lymph node syndrome*) is a self-limited vasculitis of unknown etiology, occurring in children younger than 5 years of age and more commonly in males (44). Asian children are seven times more susceptible than non-Asians. The pathology is aneurysm formation, which may manifest itself 20 years or more after the acute illness. In many patients, obstructions develop at the aneurysm site. Coronary artery bypass surgery is indicated for multiple coronary artery narrowing and ischemia (45). Many of these patients are young, and extended internal thoracic artery bypass grafting is a better alternative than vein grafts, both for long-term patency and for reduction of late cardiac death. Excision of coronary artery aneurysms is rarely indicated.

Physical features in Kawasaki's disease. These are capillary hemangiomas (*yellow arrow*).

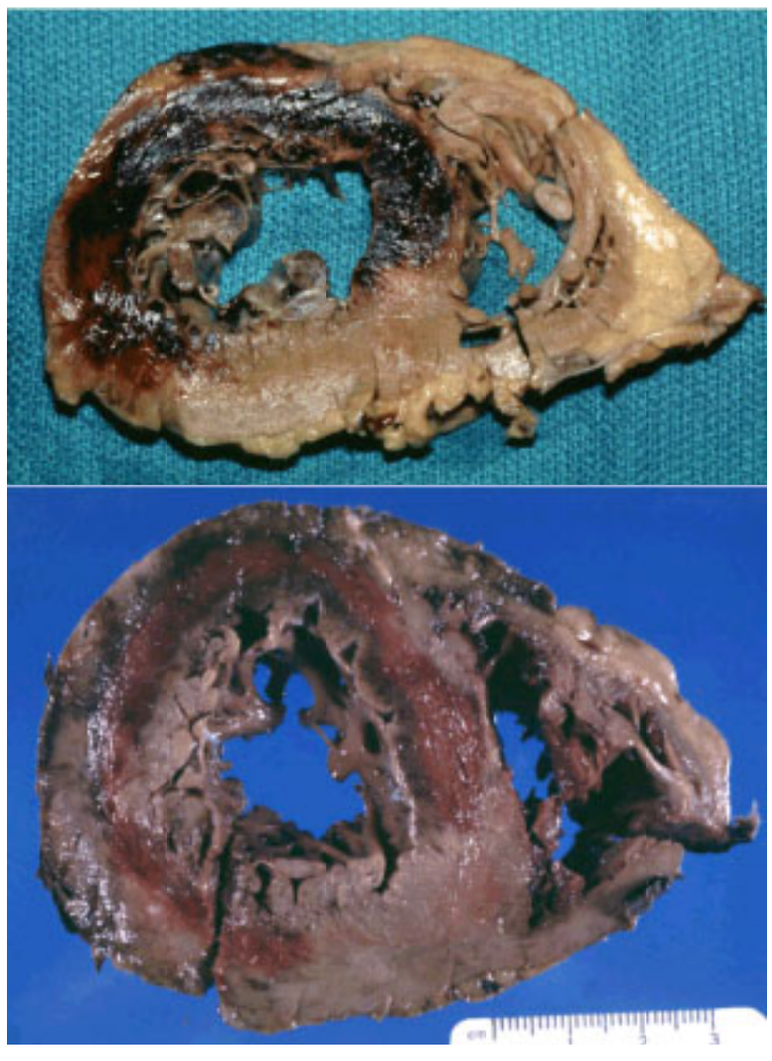
Reduced Left Ventricular Function

Poor left ventricular function is defined as a left ventricular ejection fraction of less than 0.30. Coronary bypass surgery may be indicated when such patients have angina or demonstrable ischemia coupled with critical lesions and bypassable vessels (46,47). Reversal of hibernating myocardium may be dramatic with adequate revascularization. Patients with heart failure only and poor ventricular function are rarely candidates for isolated revascularization, although selected patients may require bypass combined with ventricular aneurysmectomy. In addition to the clinical presentation, coronary pathoanatomy, and evidence of ischemia, identification of myocardial viability is important in assessing surgical candidacy of patients with impaired left ventricular function. Between 25% and 40% of patients with coronary atherosclerosis and left ventricular global dysfunction show improved contraction after revascularization. The physiologic markers used to demonstrate contractile reserve include positron emission tomographic imaging in which enhanced fluorine 18-fluorodeoxyglucose is measured relative to myocardial blood flow, thallium single-photon emission computed tomography, and dobutamine echocardiography. Each method has its proponents (see Chapter 47, Chapter 50, and Chapter 52) (48).



Hemorrhage after left main infarct (A,B). (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Cardiac transplantation is reserved for younger patients who cannot be helped by catheter interventions or coronary bypass surgery. Dynamic cardiomyoplasty may be an option for patients with contraindications to transplantation (49). In cardiomyoplasty, the pedicled latissimus dorsi muscle flap is mobilized into the chest and wrapped around the ventricles of the failing heart (50). The muscle is stimulated electrically to contract synchronously with the heart. Dynamic cardiomyoplasty is still controversial, because the clinical improvement tends to be greater than the improvement in hemodynamic parameters. To date, left ventricular ejection fraction improvement has been slight (51). Only a few centers perform this operation.

Peripheral and Cerebrovascular Disease

Peripheral and cerebrovascular disease is common in patients with coronary atherosclerosis. In the evaluation of patients with peripheral atherosclerosis, history of prior myocardial infarction, congestive heart failure, angina, and age older than 70 years predicts presence or absence of coronary atherosclerosis with 94% to 96% accuracy (52). Conversely, severe carotid artery stenosis with or without neurologic symptoms is found in approximately 6% of coronary patients (53). Most reports on the efficacy of carotid endarterectomy do not take into context the occurrence of simultaneous carotid and coronary atherosclerosis. The North American Symptomatic Carotid Endarterectomy Trial found that when carotid stenosis was greater than 70% in patients who had already experienced either transient ischemic attacks or minor strokes with good functional recovery, carotid endarterectomy reduced the stroke rate by 75% over 2 to 3 years compared with nonsurgical treatment (54). Moderate symptomatic carotid stenosis is generally not treated surgically unless the patient has neurologic symptoms attributed to microemboli from an ulcerated plaque despite antiplatelet therapy (55). The Asymptomatic Carotid Atherosclerosis Study concluded that asymptomatic patients with internal carotid narrowing of more than 60% had stroke reduction after carotid endarterectomy (56). This was the first trial to reach that conclusion in asymptomatic patients.

Severe left internal carotid artery stenosis in a 67-year-old male patient with transient ischemic attacks (A) and after implantation of a self-expanding stent (B).

Doppler ultrasound (duplex) scans are used to evaluate asymptomatic cervical bruits. Angiography is reserved for those who have severe carotid stenosis, regardless of symptomatology. There are no randomized clinical studies identifying the optimal strategy for combined coronary and carotid disease. Retrospective clinical data support a strategy of combined coronary artery bypass grafting and carotid endarterectomy in two groups of patients, those with symptomatic and severe disease in both systems and those with symptomatic carotid disease and severe coronary artery disease (57,58 and 59). The approach to patients with severe coronary artery disease and asymptomatic carotid stenosis is controversial (59). Although some authors support a combined procedure in those with coronary artery disease and asymptomatic carotid stenosis of 80% or more (60,61), analysis of the available literature neither supports nor refutes this strategy (62). This subset of patients awaits randomized controlled studies to guide treatment recommendations. Pending such studies, most patients with severe asymptomatic carotid lesions are treated by staged surgical procedures.

Combined coronary artery bypass grafting and carotid endarterectomy is associated with 5% mortality and 5% stroke risk (57,58,63). These risks are higher than for either procedure alone (52). There is evidence, however, that in properly selected patients, this strategy is superior to a staged approach (57,61).

Recently, angioplasty and stenting of internal carotid stenosis have been reported. Primary stenting appears more reliable than angioplasty alone. The University of Alabama (63) reported good reduction of stenosis in 126 stents deployed in 107 patients. There were two major and seven minor strokes, one death, and a 5% recurrence rate in asymptomatic patients at 6 months. Other groups have documented similar clinical results (64,65 and 66). Furthermore, the feasibility of safe carotid stenting in patients with cardiac disease has been demonstrated (67). Because carotid stenting generally requires days to weeks of postprocedure platelet inhibitors, the strategy of carotid stenting before cardiac surgery may necessitate a delay in the treatment of the cardiac lesions. Trials comparing elective endarterectomy and stenting for symptomatic stenosis will define the role of carotid stenting in patients with carotid artery stenosis.

Radiation-Induced Atherosclerosis

In the absence of conventional risk factors, mediastinal irradiation may lead to aortic and coronary atherosclerosis and cardiac valve disease. In one report, the prevalence was 33 of 16,364 patients over a 6-year period (68). The great majority was radiated for lymphoma. The mean interval between radiation and cardiac surgery was 14 years. Pericarditis may be encountered. Calcifications of the aorta, aortic valve, and proximal coronary arteries are generally found, and radiation may damage the internal thoracic arteries. Ostial stenosis and proximal arterial calcification may require bypass surgery. Wound healing may be jeopardized, perhaps because of obliteration of lymphatic channels and effects on sternal blood supply. Despite higher risk, coronary artery surgery is not contraindicated in patients with mediastinal irradiation, and outcome of revascularization is satisfactory.

Valve Disease

Concomitant valve disease most frequently combines aortic stenosis with multivessel coronary atherosclerosis. In men, the surgical risk (1% to 2%) is approximately the same as for isolated valve replacement. However, for elderly women the risk is higher. Except in patients younger than 40 years of age who have no history of coronary artery disease, coronary arteriography is indicated for patients undergoing evaluation for valve surgery. The absence of angina does not exclude coronary atherosclerosis. Almost all aortic valve lesions are treated with valve replacement, and most cases of mitral regurgitation are treated by mitral valve repair, which carries a lower surgical risk than mitral valve replacement (69).

Advanced age, female gender, elevated creatinine, advanced New York Heart Association class, moderate to severe left ventricular dysfunction, mitral regurgitation, extensive coronary atherosclerosis, severe cardiac rhythm disorders, and prolonged intraoperative ischemia are the most important predictors of adverse clinical outcome of combined valve operation and coronary artery bypass grafting (70). Reoperative valve replacement after previous coronary artery surgery is fraught with higher hospital mortality than either primary or reoperative coronary artery surgery. Therefore, it has been suggested that liberal criteria for selection be used for valve repair or replacement in those undergoing myocardial revascularization for the first time (71).

Coronary Reoperation

Reoperation may be required for recurring symptoms (ischemia) and angiographic evidence of vein graft atherosclerosis, progressive coronary atherosclerosis, or both. Late stenosis in an anterior descending vein graft predicts a higher death and event rate than late stenosis in vein grafts to other coronary arteries and is an indication for further revascularization (Fig. 82.2) (72). For appropriately selected patients, coronary artery reoperation offers improved longevity compared with medical treatment (73).

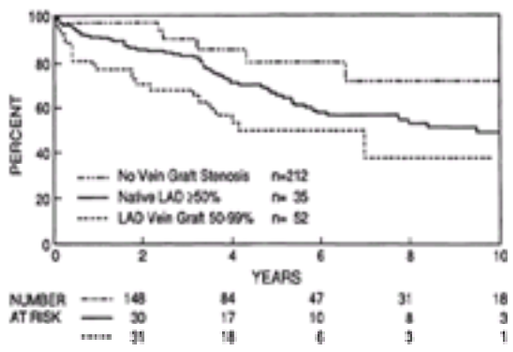


FIGURE 82.2 Patients with late stenoses and vein grafts to the anterior descending coronary artery have worse survival compared to that of either patients with native coronary anterior descending or patients with no stenotic vein grafts. LAD, left anterior descending. (From Lytle BW, Loop FD, Taylor PC, et al. Vein graft disease: the clinical impact of stenoses in saphenous vein bypass grafts to coronary arteries. *J Thorac Cardiovasc Surg* 1992;103:831–840, with permission.)

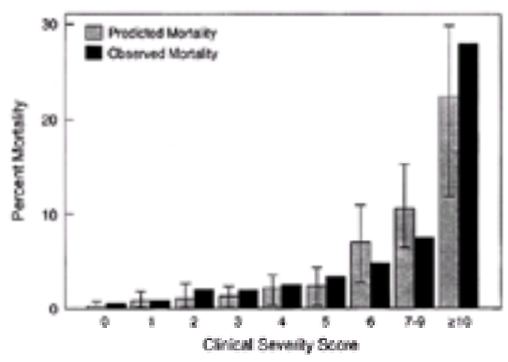
In the presence of severe diffuse coronary atherosclerosis, most patients with vein graft atherosclerosis are better served by reoperation than by catheter interventions. The exceptions are fibrous lesions or intimal hyperplasia causing graft stenosis that occurs within 18 to 36 months after the first operation. In selected cases, an isolated vein graft with a discrete lesion may be well suited for percutaneous revascularization. In general, however, angioplasty of saphenous vein grafts with or without stenting has a high rate of complications and unsatisfactory late results (74,75).

The method of revascularization hinges on the age of the graft, the location of the stenosis, the status of left ventricular performance, and overall clinical characteristics. After coronary artery surgery, four arteriographic situations warrant consideration for angioplasty or stenting: (a) progressive atherosclerosis in nonbypassed major coronary arteries when bypass grafts to other major vessels are patent; (b) distal anastomotic stricture that is less than 3 years old; (c) saphenous vein graft lesions less than 3 years old; and (d) native vessel narrowing distal to an open graft accessible via a fully patent, nondiseased graft (76). Angioplasty or stenting of early vein graft lesions or for progressive coronary artery stenoses is more successful than intraluminal dilatation of late vein graft atherosclerosis.

Risk Assessment

Preoperative risk scoring is based on clinical, angiographic, and surgical data. The scoring methodologies are more predictive of mortality than of morbidity (eFig. 82.2.1) (77). The risk factors for hospital mortality are generally considered to be advanced age, emergency surgery, elevated serum creatinine level, left main coronary artery disease, female gender, anemia, and moderate to severe left ventricular dysfunction (78,79 and 80). Adjusted for comorbid conditions, advanced age is associated with a greater risk of procedural death and complications with both coronary artery surgery and catheter-based revascularization.



***e*FIGURE 82.2.1** Clinical and angiographic risk variables are weighted by a logistic regression formula and stratified from low risk through high risk. This clinical severity score predicts mortality by the preoperative variables. This severity score ranges from 0 (lowest risk) to 10 or more (highest risk). The actual predicted and observed mortalities are shown in the bar graphs. (From Higgins TL, Estafanous FG, Loop FD, et al. Stratification of morbidity and mortality outcome by preoperative risk factors in coronary artery bypass patients: a clinical severity score. *JAMA* 1992;267:2344–2348, with permission.)

Smaller body size, more typical of women, is associated with increased operative mortality (81,82). Women, as bypass candidates, also tend to be older than men as bypass candidates and thus have more comorbidity. Because of generally smaller size, their coronary arteries frequently have narrower diameter. Most reports indicate women have more extensive coronary atherosclerosis but overall better preoperative left ventricular function. After adjusting for preoperative risk factors and body size, technical factors, inadequate myocardial protection, and lack of internal thoracic artery grafting contribute to higher risk in women (83) and may explain why gender remains an independent risk factor for operative mortality and low-output syndrome (84). There is recent evidence that bypass surgery mortality for women is decreasing compared with earlier reports (85).

The risk of stroke for patients who undergo cardiac surgery can also be estimated. A stroke risk index has been developed using the variables of age, history of neurologic disease, diabetes, history of vascular disease, previous coronary artery surgery, unstable angina, and history of pulmonary disease. Carotid occlusion, with or without contralateral stenosis, may be another risk factor. Of these clinical characteristics, previous stroke, vascular disease, and diabetes have the most weighted importance (86).

Prediction of risk is more complicated than simple preoperative assessment. Risk changes in response to surgery. The preoperative risk score may be affected by the type and conduct of surgery, including the volume of blood transfusion, cardiopulmonary bypass time, the type of myocardial protection, conduits used, and whether an intraaortic balloon pump is required (87). Rescoring of risk after admission to the postoperative intensive care unit indicates that two-thirds of preoperative high-risk patients are converted to low risk and 95% of those stratified in the low-risk category preoperatively remain classified as low risk in the immediate postoperative period. The contribution of the preoperative clinical and angiographic characteristics, the operating room events, and the physiologic measurements at intensive care unit admission converge postoperatively and change the predicted outcome.

Estafanous and colleagues from The Cleveland Clinic Foundation found that the prevalence of high-risk patients is increasing, and yet the surgical morbidity adjusted for preoperative risk score has fallen in the last 10 years (88). These findings are likely attributable to better myocardial protection and wider use of arterial bypass grafts.

SURGICAL PRINCIPLES

Basic Strategies

The design of the operation is based on estimated risk and a review of revascularization techniques, including availability and type of bypass conduit. The objective is to provide safe, durable, and complete revascularization with a low probability of complications. Same-day admission is safe and cost-effective and avoids at least 1 day of hospitalization (89,90). Patients may continue on beta-blockers, calcium channel blockers, antihypertensives, and nitrate therapy until the day of surgery. Aspirin should be discontinued 7 to 10 days before elective surgery. We use pulmonary artery catheters in all patients (approximately $35 total cost) to monitor hemodynamic changes and to facilitate management. An increasing number of patients have heparin-induced platelet antibodies preoperatively due to prior heparin exposure (91). These patients are at risk for thrombotic complications with additional heparin exposure.

Blood Conservation

A blood conservation protocol is important to reduce transfusion requirements and decrease the incidence of transfusion-induced complications (92). Red cell volume and patient age are the best predictors of the need for transfusion. Hematocrit levels of 20% to 25% are tolerated in young, good-risk patients intraoperatively and

postoperatively. However, in patients with impaired left ventricular function, older age, and serious preoperative comorbidities, target hematocrit levels of 28% to 30% allow better perfusion pressure and hemodynamic stability (93). As the population of surgical candidates ages, with attendant comorbidities, transfusion requirements rise.

Most intraoperative and postoperative bleeding is directly related to the surgery, but causes of bleeding are often multifactorial and relate to the use of antiplatelet drugs preoperatively, prolonged operating time, the number of transfusions of blood and blood products, previous cardiac surgery, and, very infrequently, a preoperative coagulopathy. Aspirin is associated with increased incidence of postoperative bleeding, increased use of blood and blood products, and longer intensive care unit hospitalization (94). Aspirin should be discontinued in advance, but this is not always possible in emergency situations.

Aprotinin is an effective drug for reduction of bleeding; however, there is controversy about vein graft thrombosis and increased risk of myocardial infarction (95,96). Anaphylactic reactions to aprotinin, which are infrequent, may be reduced by (a) giving a test dose (10,000 KIU) in all aprotinin patients; (b) delaying the first dose until onset of cardiopulmonary bypass; (c) prescribing H_1/H_2 blockade in reexposures; and (d) avoiding reexposure for at least 6 months (97). Preoperative and intraoperative administration of epsilon-aminocaproic acid has been reported to reduce postoperative cardiac surgical bleeding (98,99), and the cost of approximately $3 to $5 per case is small compared with $900 to $1,200 for aprotinin. Fibrin sealant has been used, largely in Europe, for small bleeding points. More than 2,000 clinical papers on its use in approximately 1 million patients attest to its safety (100).

Myocardial Protection

Current cardioprotective methods include core cooling, antegrade and retrograde cardioplegia, and continuous retrograde warm blood cardioplegia. Chemical cardioplegia initiates potassium arrest. Blood cardioplegia delivers oxygen; causes less systemic hemodilution; and provides endogenous buffers, free radical scavengers, and proteins for controlling oncotic pressure (101). Retrograde cardioplegia delivery through the coronary sinus is useful in patients with totally obstructed vessels, in patients with diffuse coronary atherosclerosis, and in reoperation cases with patent but atherosclerotic vein grafts or patent internal thoracic artery grafts.

A combination of antegrade and retrograde cardioplegia, cold or warm, provides the optimum cardioplegic distribution. Because aortic atheroma is predictive of cerebrovascular events, a single cross-clamp technique, which involves less manipulation of the ascending aorta, may reduce the stroke rate (102). Controlled reperfusion techniques of antegrade and retrograde cardioplegia using warm amino acid–enriched blood cardioplegia, combined with total vented cardiopulmonary bypass, have reduced mortality in cardiogenic shock (36). The method of reperfusion may be more important than the interval between occlusion and reperfusion. Blood cardioplegia has been correlated with a reduction of morbid events, shorter intensive care unit stay, shorter hospitalization, and reduced hospital cost (103).

Future cardioprotective strategies will be directed to the vascular endothelium rather than the myocyte. Endothelium-derived nitric oxide may prevent vasospasm and thrombus formation through its vasodilator and antiaggregant properties (104). Nitric oxide may protect against cell damage during ischemia/reperfusion by blocking hydroxyl radicals and terminating free radical chain reactions within the lipid membrane (105).

Conduits in Coronary Bypass Surgery

Vein grafts develop endothelial proliferation as soon as they are placed in arterial circulation and after a few years tend to develop atherosclerosis with thrombus formation. Low- or regular-dose aspirin therapy may prevent platelet thrombi, the release of platelet mediators, and consequent platelet aggregation in vein grafts (106). Dipyridamole has antithrombotic and vasodilating capabilities, but the addition of dipyridamole to aspirin does not improve vein graft patency (107). Also, compared with aspirin, oral anticoagulants do not improve patency. Aspirin that is begun early postoperatively and continued indefinitely does not prevent atheroma formation. Reports on serial postoperative angiograms from Montreal (108) and from The Cleveland Clinic (109) are complemented by an angiographic investigation of 1,388 Canadian military personnel operated on in the 1970s (110), in which approximately 5,000 bypass grafts were reexamined by angiography at 1 year, 5 years, and 15 years or more after surgery. These latter results are the latest available and concur with the classic studies from Montreal and Cleveland. Vein graft patency was 88% early and 81%, 75%, and 50% at 1, 5, and 15 years or more. Approximately half of the grafts showed luminal defects at 5 years, and 81% had lumen irregularities at 15 years or more (Fig. 82.3).

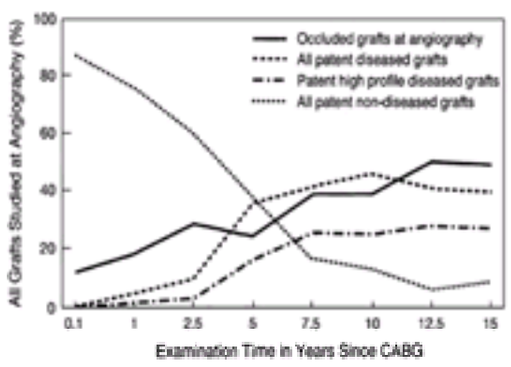


FIGURE 82.3 The latest and longest serial study of aortocoronary vein grafts has classified vein grafts through angiographic findings. High-profile lumen irregularities are defined as more than 59% graft stenosis. Note that the rate of vein graft occlusion progresses after 25 years. Vein graft occlusion rate was 2.1% per year after the first postoperative study. CABG, coronary artery bypass surgery. (From Fitzgibbon GM, Kafka HP, Leach AJ, et al. Coronary bypass graft fate and patient outcome: angiographic follow up of 5,065 grafts related to survival and reoperation in 1,388 patients during 25 years. *J Am Coll Cardiol* 1996;28:616–626, with permission.)

Vein graft atherosclerosis is characterized by diffuse involvement of the venous conduit, circumferential atheroma instability, and fragility (111). Vein graft atherosclerosis begins as a deposition of foam cells followed by plaque formation that varies in extent of fibrosis, lipid deposition, thrombosis, and even calcification. Late thrombosis is a frequent cause of graft closure and may form slowly or suddenly after plaque rupture (112).

In diffuse native-vessel atherosclerosis wherein the artery is completely obstructed or exhibits diffuse distal involvement, coronary endarterectomy may be performed to improve arterial runoff (113,114). Endarterectomy is rarely successful in small arteries that have been completely occluded for a long time. Anterior descending endarterectomy requires an extended arteriotomy to clean out all side branches, whereas a right coronary endarterectomy is accomplished by a distal arteriotomy and dissection of the plaque from the two main branches. It is generally concluded that there is a higher rate of perioperative infarction after endarterectomy and that vein graft patency is slightly lower in endarterectomized arteries.

In the past 15 years, the internal thoracic artery graft has displaced the saphenous vein graft as the conduit of choice. There are three reasons for this change: (a) lower hospital mortality (115), (b) higher long-term patency rate (116), and (c) favorable effect on longevity (116,117). Even in patients with diffuse multisystem atherosclerosis, the internal thoracic artery is rarely affected by atherosclerosis. Metabolism in the arterial wall confers immunity compared with the more inert saphenous vein, which is prone to atherosclerotic degeneration. Coronary arteries narrowed an estimated 50% or more may be grafted with an internal thoracic artery; progression of the proximal native lesion is less after internal thoracic artery grafting than with vein grafts (118). This conduit used in young patients with Kawasaki disease has also shown growth on serial angiography (119). Competitive flow from a major coronary artery not critically narrowed may account for the infrequent internal thoracic artery “string sign” (120) on postoperative angiograms. Whether an internal thoracic artery graft with this diffuse narrowing will progress to subsequent graft closure or reopen later is not known. However, this no-flow situation was reexamined by temporary occlusion of the recipient coronary artery with a percutaneous transluminal coronary angioplasty balloon (121). The internal thoracic artery with a demonstrable string sign reopened, showing anatomic patency. Therefore, it appears that the string sign may be a reaction to reduced demand and not an intrinsic problem.

Whenever feasible, the internal thoracic artery should be the conduit of choice for anterior descending and other major arteries that supply large regions of myocardium (117,122). This recommendation is particularly important for the anterior descending artery, because severe proximal stenosis in this vessel has greater prognostic importance than stenoses elsewhere in major coronary arteries except for the left main coronary artery (123).

The relative contraindications for use of internal thoracic artery grafts include radiation-induced atherosclerosis, extensive brachiocephalic atherosclerosis, reoperation in patients who have patent large-diameter atherosclerotic vein grafts (replacement of which by a smaller-diameter internal thoracic artery may result in hypoperfusion) (124), and some unusually high-risk situations such as emergency surgery after resuscitation or other instances of cardiogenic shock. In our experience, emphysema does not constitute an absolute contraindication. In these cases of overinflated lungs, free (aortocoronary) internal thoracic grafts may be

used instead of *in situ* grafts.

The internal thoracic artery used for anterior descending grafting has consistently shown patency of greater than 90% 10 to 15 years postoperatively. Early anastomotic stenosis may be treated by angioplasty with good results (125). Late occlusions occur infrequently from progressive native-vessel atherosclerosis beyond the distal anastomosis. Rarely, a subclavian steal may occur when the proximal subclavian artery narrows or occludes proximally and blood flows from the coronary circulation retrograde through the internal thoracic artery into the distal subclavian distribution.

Increasing use of bilateral internal thoracic artery grafts has expanded arterial grafting further. Free (126), sequential, and Y or T grafts (127) increase versatility by extending graft length and by avoiding the crossing of the midline. Long-term patency of free grafts is 69% to 77%, whereas patencies of sequential and Y or T grafts are consistently 90% or greater. One series of free grafts demonstrated a 95% patency in 40 free right internal thoracic artery grafts studied an average of 40 months postoperatively (128). A study of more than 10,000 patients having primary coronary artery bypass grafting at The Cleveland Clinic has demonstrated that two internal thoracic arteries are better than one (129). This study concluded that patients who received two internal thoracic artery grafts had decreased risks of death, reoperation, and angioplasty. Although this result held for all patient subgroups, further analysis revealed that in high-risk patients, the benefit of two internal thoracic artery grafts on freedom from intervention was eroded considerably by death (130). The conclusions of these large studies support the use of bilateral internal thoracic artery grafting in most patients having primary coronary artery bypass grafting.

Some of the previous concerns about infection related to internal thoracic artery grafting have been dispelled by better techniques of internal thoracic artery dissection and wound closure. Bilateral internal thoracic artery grafting is still associated with a higher wound infection rate in diabetic patients (131). Nevertheless, the sternal blood supply in patients with diabetes is not reduced, compared with nondiabetics. Wound complications may be minimized by good surgical techniques, including a minimum of electrocautery, short operating time, blood conservation, and meticulous wound closure. Diabetes is not a contraindication to use one or both internal thoracic arteries as bypass grafts.

The gastroepiploic artery (Fig. 82.4A) may be used for revascularization of right coronary artery branches and, less frequently, the circumflex branches or the anterior descending (132,133). In addition, using the gastroepiploic artery as a composite graft by attaching it to a segment of radial artery allows grafting of two or three coronary arteries with gastroepiploic inflow (134). Previous laparotomy and severe obesity complicate procurement of this artery. The patency reported from the largest series is 80% at 5 years and 62% at 10 years (135). Once the gastroepiploic artery is perfectly anastomosed to a coronary artery with tight proximal stenosis and good runoff, late patency is good and new stenosis in both the gastroepiploic artery trunk and the anastomotic site was uncommon. The severity of the stenosis of the target artery should be high because retrograde coronary artery–to–gastroepiploic artery flow may occur if the native vessel narrowing is modest.

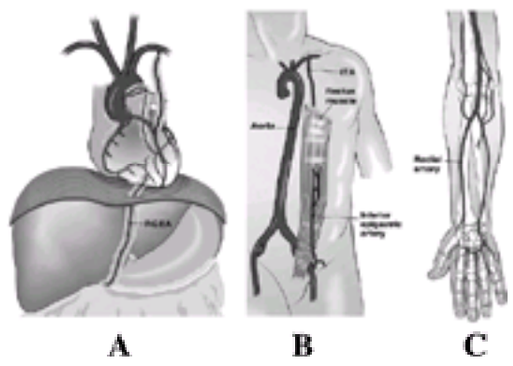

FIGURE 82.4 A: The gastroepiploic artery is mobilized from the greater curvature of the stomach and generally brought anterior to the liver through the diaphragm and grafted to one of the two branches of the right coronary artery. The conduit is small and prone to spasm. Using it to graft a large coronary artery may result in hypoperfusion. **B:** The inferior epigastric artery lies behind each rectus muscle and is removed through a midline incision. This conduit is used infrequently today but may be advantageous as a Y graft sewn proximally to an arterial conduit and distally to a secondary target. **C:** The radial artery is removed with its venae comitantes. Today, it is the second arterial graft of choice after both internal thoracic arteries, and it may be used as an aortocoronary graft or attached as a Y graft. ITA, internal thoracic artery; RGEA, right gastroepiploic artery.

The inferior epigastric artery (Fig. 82.4B), generally 10 to 12 cm in length, is located behind the rectus muscle. This artery is generally used as a Y or T graft and is often connected to secondary targets such as branch vessels (136). The intermediate-term patency of the inferior epigastric artery graft is lower (75%) than that reported for pedicled internal thoracic artery grafts. Today, it is probably the least frequently used arterial conduit (137).

The radial artery (Fig. 82.4C) has enjoyed widespread resurgence after early reports that showed a high incidence of spasm leading to focal intimal hyperplasia (138,139). Improved results in the current era have been attributed to improved harvesting technique and use of calcium channel blockers or other vasodilators to prevent perioperative spasm of the graft (139). Patients with radial artery grafts are treated today with calcium antagonists and postoperative use of aspirin. Dihydropyridine calcium antagonists are most effective at reducing radial artery spasm (140,141). Preoperative noninvasive assessment of forearm collateral flow may be accomplished by a modified Allen test, pulse volume recordings, oximetric plethysmography with calculated perfusion index, and Doppler scanning. Most agree that a modified Allen test and calculation of perfusion index suffice. Procurement is performed delicately to avoid damage of the intima, which may suffer focal endothelial damage (142). For patients undergoing unilateral radial artery procurement, the contralateral extremity is used for intravenous and arterial monitoring lines. When bilateral radial arteries are harvested, left femoral or axillary arterial lines are placed for monitoring. Intravenous nitroglycerin or calcium channel blockers are administered intraoperatively. Postoperatively, oral nitrates or calcium channel blockers are administered for 6 months or longer.

Radial artery patency is reported to be 94% at 9 months (143). Five-year patency has been reported to be 84% to 92% (144,145). Given these encouraging results, some groups have recommended performing multiple distal anastomoses with the radial artery to increase the number of arterial bypasses (146,147 and 148). Although intermediate-term results support a role for the radial artery in coronary artery bypass operations, it is premature to conclude that this conduit is equivalent to a second internal mammary artery.

REOPERATION

A number of factors influence the rate of reoperation; the single greatest determinant is the type of conduit used in the first operation. Patients with only vein grafts have a much higher and earlier reoperation rate than do patients with one or more arterial grafts. Other factors that increase the probability of reoperation include young age at the first operation, incomplete revascularization, one- or two-vessel grafting initially, and good left ventricular function. Young age, less extensive coronary disease, and normal ventricular function are markers of a good prognosis, which allows the patient to survive to eventual reoperation. The cumulative incidence of reoperation was 3% 5 years after the original surgery, 10% at 10 years, and 30% at 15 years (149).

In the past 10 years, the evolution of catheter intervention techniques has reduced the number of reoperation candidates, although the effects of angioplasty, atherectomy, and stents are not fully elucidated. Patients who are protected by patent grafts but who require native-vessel dilatation or early catheter manipulation after the original bypass operation tend to be referred for catheter intervention, whereas patients at higher risk with diffuse graft atherosclerosis or compromised left ventricular function tend to be referred for surgery rather than for angioplasty (150).

The most frequent indication for reoperation is vein graft atherosclerosis. Atherosclerosis in an anterior descending saphenous vein graft is associated with a particularly poor prognosis (72). We recommend strong consideration for reoperation in those cases. Lesions in old saphenous vein grafts are friable and are not treated consistently well by catheter intervention techniques; the restenosis rate is upward of 50% to 70%. Stenting probably results in less restenosis than does angioplasty, but stent implantation in vein grafts has not been associated with a particularly good 5-year clinical outcome, with high event rates due to infarction, repeat surgery, and repeat angioplasty (151,152). Directional, rotational, and transluminal extraction catheter atherectomy used in atherosclerotic vein grafts have been shown to cause more distal embolization than conventional angioplasty (153).

The hospital mortality for second operations is less than 5% in centers reporting large series (149,154). Emergency surgery, poor left ventricular performance, older age, and female gender influence higher in-hospital mortality. Manipulation of old vein grafts at reoperation may cause atheroembolism and myocardial infarction. Ideally, vein grafts should be replaced with arterial grafts; however, there is a risk of hypoperfusion when large patent but atherosclerotic vein grafts are replaced with *in situ* internal thoracic artery grafts. Adequacy of perfusion depends on the size of the vessel and the arterial runoff and the size of the left ventricular region perfused. In older patients, re-replacement with saphenous veins generally suffices, but younger patients should have every consideration for arterial grafting for the most critical areas of ischemia. The use of an internal thoracic artery graft at the first operation does not increase the risk of reoperation, and the use of an internal thoracic artery

graft at reoperation does not increase hospital mortality or morbidity (155).

TRANSMYOCARDIAL LASER REVASCULARIZATION

Transmyocardial laser revascularization (TMR) has been applied in patients with angina and ischemia who are not candidates for conventional revascularization techniques (156). The laser is used to create transmural channels in areas of critically ischemic tissue. Encouraging results have been reported from clinical trials using the carbon dioxide, holmium:YAG, and excimer lasers. The laser energy may be delivered to the heart via thoracotomy, thoracoscopy, or percutaneously.

VIDEO

Video 82.12 Intraoperative transesophageal echo of a patient undergoing laser transmyocardial revascularization. Note the gas production as the laser beam penetrates the myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

TMR is used solely for relief of intractable angina in patients who have failed or cannot undergo standard treatment. In several randomized trials, TMR combined with medical therapy has been shown to be superior to medical therapy alone for angina relief (157,158,159,160 and 161). These trials report similar results, with approximately 50% of TMR patients having important symptomatic improvement at 1 year. Other reported benefits include improved exercise tolerance, improved quality of life, and decrease in number of hospital admissions (157,160,161). Given these results, in August 1998 the U.S. Food and Drug Administration fully approved TMR for the sole treatment of patients with class III and IV chronic stable angina not treatable by conventional means.

TMR via thoracotomy is associated with important morbidity and mortality. Hospital mortality ranges from 1% to 9% (157,158,159,160,161 and 162). Morbidity occurs in 35% of patients (163). Morbidity and mortality are more common in patients with unstable angina (163). Therefore, TMR should be reserved for patients with disabling chronic stable angina. Although encouraging results have been reported, the efficacy and role of percutaneous laser therapy are not yet well defined (164).

TMR has also been used as an adjunct to coronary artery bypass grafting to treat ischemic myocardial regions lacking suitable targets for bypass grafting (165,166). Although the addition of TMR did not improve anginal class when compared with patients having bypass grafting alone, TMR was associated with a survival advantage in one trial (166). The reason for this is unclear, and this result requires confirmation by larger studies.

The mechanism for the improvement in angina with TMR is unclear. Both clinical and experimental work suggest that it is unlikely that the channels remain patent (167,168). Experimental models demonstrate that TMR causes increased myocardial expression of vascular endothelial growth factor (168,169). Most clinical studies, however, do not demonstrate important increases in myocardial perfusion, left ventricular function, or survival (158). Other possible mechanisms include a placebo effect, myocardial denervation, and infarction of ischemic myocardium. Further investigation will be necessary to define the precise mechanism for TMR.

In current practice, TMR is not an alternative to medical therapy, percutaneous intervention, or coronary artery bypass grafting. It is reserved for the small group of patients who cannot be treated successfully by the above means. Furthermore, it is used only for relief of chronic stable angina. It has not been demonstrated conclusively to improve ventricular function or longevity when compared with other therapies.

GENE THERAPY AND THERAPEUTIC ANGIOGENESIS

An alternative approach to inducing myocardial angiogenesis is direct myocardial injection of angiogenic genes or proteins. This approach is currently under investigation as treatment for patients with severe coronary artery disease who are unsuitable for medical therapy or traditional techniques for revascularization (170,171). There is a growing body of experimental work to support the hypothesis that injection of the gene for vascular endothelial growth factor causes angiogenesis in ischemic myocardium (170,171 and 172).

Recent reports document the safety of gene therapy to treat myocardial ischemia in humans. Rosengart performed adenovirus-mediated transfer of human vascular endothelial growth factor cDNA in 21 patients with reversible myocardial ischemia (173). In this phase I study, gene therapy was used as an adjunct to coronary artery bypass grafting or as sole therapy via mini-thoracotomy. Coronary angiography and stress sestamibi scan 30 days after therapy suggested improved perfusion in the area of vector administration (173). At 6-month follow-up, there were trends toward improvement in anginal class and xercise treadmill testing (174). In another phase I trial, Symes and colleagues injected plasmid DNA encoding vascular endothelial growth factor into the myocardium of patients with coronary artery disease (175). They demonstrated improved perfusion, as documented by angiography and single-photon emission computerized tomography sestamibi scans. In that study, all patients reported reduced angina.

As with TMR, gene therapy for myocardial ischemia is currently a therapy only for patients who fail standard medical therapy and cannot have revascularization by conventional means. The intermediate and long-term efficacy of gene therapy remains unproven. Ongoing trials are likely to clarify the role of gene therapy and therapeutic angiogenesis in the treatment of coronary artery disease.

MINIMALLY INVASIVE CORONARY ARTERY BYPASS SURGERY

Off-Pump Coronary Artery Bypass Grafting

The most dramatic change in coronary artery surgery during the last decade has been the resurgence of coronary artery bypass grafting on the beating heart. Off-pump approaches to coronary artery bypass grafting seek to eliminate morbidity and mortality associated with cardiopulmonary bypass, hasten patient recovery, and reduce cost. Initial widespread use of off-pump techniques was limited to revascularization of the left anterior descending coronary artery using the left internal thoracic artery via a small left anterior thoracotomy, so-called minimally invasive direct coronary artery bypass grafting (MIDCAB). Although technically difficult, this procedure is feasible and provides optimal revascularization of the left anterior descending coronary artery. Early concerns over graft patency using this procedure have been answered, and early patency generally exceeds 95% (176,177,178 and 179). In addition, nonocclusive early angiographic abnormalities frequently disappear during the first postoperative year (176,179). Long-term patency with this approach is superior to that attained with angioplasty (180).

MIDCAB has been used in conjunction with percutaneous interventions to offer a hybrid approach to coronary revascularization (181,182,183,184 and 185). In this approach, the left internal thoracic artery is used to revascularize the left anterior descending coronary artery, and other stenotic vessels are treated by angioplasty with or without stenting. In most cases, surgery is performed first and percutaneous intervention follows in hours to days. Advantages to the patient include a small incision and no cardiopulmonary bypass. Although initial results with this strategy have been promising, its place in coronary revascularization remains to be defined.

Although there is no demonstrable benefit in survival with MIDCAB when compared with on-pump coronary artery bypass grafting, there is some suggestion that this approach may decrease morbidity in the most seriously ill patients (186). Postoperative atrial fibrillation remains a problem with this approach (187). Costs associated with MIDCAB are less than those for standard on-pump surgery and similar to those for percutaneous coronary interventions (188,189 and 190).

Technological improvements in coronary artery stabilization and surgical advances in coronary artery exposure have enabled widespread application of multivessel off-pump coronary artery bypass grafting. Using current techniques, virtually all patients are candidates for multivessel off-pump coronary artery bypass grafting. This procedure is performed through a sternotomy but without cardiopulmonary bypass. Aortic manipulation is limited to a single application of a clamp to perform proximal anastomoses. All coronary artery targets are accessible, and conduits used may include all arterial and venous grafts used for on-pump surgery.

As with MIDCAB, the question of anastomotic patency with multivessel off-pump coronary artery bypass grafting has been answered. Studies performed before the advent of modern coronary stabilizer platforms suggested reduced anastomotic quality (191). However, in a large prospective study that involved postoperative catheterization of all patients, Puskas et al. found graft patency after off-pump surgery comparable to that documented after on-pump surgery (192). Long-term patency results are not yet available, however.

Advances in anastomotic techniques are likely to reduce the difficulty of off-pump coronary artery bypass surgery, widening its appeal to surgeons and applicability to patients. Several companies have developed anastomotic coupling devices that replace standard suturing techniques. Use of such devices for distal anastomoses will reduce the difficulty of off-pump surgery. Application of such devices for proximal anastomoses will eliminate the need to place a clamp on the aorta;

this may further reduce neurologic morbidity associated with coronary artery bypass grafting.

Although there are suggestions that off-pump surgery reduces hospital mortality in the elderly and sick (193,194), a survival advantage to this approach remains speculative (195). Nevertheless, there are several advantages to multivessel off-pump coronary artery bypass grafting when compared with conventional on-pump surgery. These include decreased cardiac damage (196), decreased inotrope requirement (196), decreased blood loss (194,197), decreased inflammation and infection (198), and decreased hospital length of stay (194,199). Most important, there appears to be decreased neurologic damage, as demonstrated by decreased cerebral edema (200), decreased cerebral microemboli (201,202), decreased serum S-100 protein (202), and decreased neurocognitive dysfunction (202). Nearly all patients experience some neurocognitive dysfunction after cardiopulmonary bypass. Occasionally, patients develop a temporary confusional state, termed “pump head.” Reduction of neurologic insults, coupled with the other aforementioned advantages, tends to result in reduced hospital costs for off-pump surgery as compared with on-pump surgery (188,203). However, atrial fibrillation still occurs with high frequency after off-pump surgery (204).

Port-Access Coronary Artery Bypass Grafting

An alternate approach to multivessel coronary artery revascularization is the port-access technique. This operation, which relies on cardiopulmonary bypass, entails a small left thoracotomy through which all coronary targets are accessible. Arterial return for cardiopulmonary bypass is attained by cannulation of the aorta or femoral artery.

Results with this approach have been comparable to those obtained using a median sternotomy and cardiopulmonary bypass (205,206,207,208 and 209). Although there may be some benefit in terms of reduced postoperative atrial fibrillation with the port-access technique (206), this remains controversial (202). The need for additional instrumentation and disposable products increases the cost of this approach by $2,000 (209). Because cardiopulmonary bypass is still used, there is some question as to whether port-access surgery is truly minimally invasive. In current practice, off-pump surgery has emerged as the preferred less-invasive surgical approach to multivessel coronary artery disease.

Endoscopic and Robotic Coronary Artery Bypass

A truly minimally invasive approach to coronary artery bypass grafting will entail a combination of endoscopic visualization, off-pump techniques, and robotic assistance. Robotically assisted endoscopic coronary artery bypass grafting has been performed in humans (210,211). Thus far, these operations require cardiopulmonary bypass. Even with cardiopulmonary bypass, these operations are technically demanding and time-consuming. Development of sutureless anastomotic techniques will greatly facilitate these efforts (212). The applicability of robotically assisted endoscopic coronary artery bypass grafting in patients with multivessel disease remains to be demonstrated.

HOSPITAL RESULTS OF CONVENTIONAL CORONARY ARTERY BYPASS SURGERY

Mortality and Morbidity

Hospital mortality varies from 1% or less in good-risk patients to approximately 5% overall in the elderly or infirm. High-risk subsets exist with mortality up to 15% to 30%, but these cases are few in number and generally are associated with cardiogenic shock or extensive, combined reoperative cardiac reconstruction and coronary bypass surgery.

Preoperative factors that prolong length of hospitalization include reoperation, combined coronary plus valve surgery, congestive heart failure, prolonged intensive care unit stay, renal failure, and insulin-dependent diabetes mellitus. Postoperatively, major complications that prolong hospitalization include perioperative myocardial infarction, bleeding requiring reoperation, respiratory insufficiency, wound infection, stroke, and renal failure. Patients who experience one or more complications have up to 10 times greater probability of mortality compared with those who sustain no complications. Patients who develop the complications of wound infection, pneumonia, respiratory insufficiency, and arrhythmias tend to remain hospitalized the longest (213).

Lower-risk patients may qualify for a fast track, with the objective of reducing cost through shorter length of stay. These patients are mobilized quickly, treated aggressively with diuretics, and started in rehabilitation early. Discharge planning is begun immediately on discharge from the recovery area or intensive care unit (214).

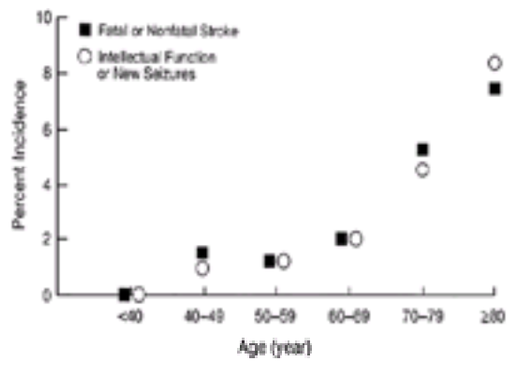
Today, perioperative myocardial infarction is infrequent. Most patients who have new Q waves along with cardiac enzyme elevation do not exhibit hemodynamic instability. The perioperative infarction rate averages 2% to 5%; the intermediate-term course of those who sustain myocardial damage is essentially the same as that of those without myocardial infarction, and the subset in which infarction affects outcome involves those who require intraaortic balloon pumping.

Balloon counterpulsation—the most frequently used form of mechanical circulatory-assist device—acts by augmenting diastolic aortic pressure and coronary blood flow while reducing the resistance (afterload) against which the heart must pump. Intraaortic balloon pumping is used in 1% to 5% of coronary bypass patients, most frequently in emergency cases and in patients requiring combined coronary artery and valvular procedures. Indications are preoperative ischemia and postoperative left ventricular failure (low cardiac output and high filling pressures). Cardiogenic shock refractory to intraaortic balloon pumping may require a ventricular-assist device. Patient selection is important, and even under the best circumstances, overall mortality in patients requiring left ventricular–assist devices for postcardiotomy cardiogenic shock is 25% to 50%. Younger patients with no underlying preoperative comorbidity and isolated left ventricular failure are the best candidates. These patients should qualify for heart transplantation if cardiac failure is not reversible.

Postoperative bleeding is most frequently surgical in origin (i.e., one or more bleeding points related to the operation). Aspirin in the immediate preoperative period is associated with a higher postoperative bleeding rate. Certain drugs such as aprotinin and epsilon-aminocaproic acid decrease postoperative bleeding. Reexploration for bleeding is an independent risk factor for mortality, renal failure, respiratory distress syndrome, sepsis, and atrial arrhythmias, and it is especially dangerous in those who have undergone complex procedures, including reoperations (215).

Wound infections are classified as superficial or deep. Deep intrathoracic or mediastinal infections are life-threatening. Most deep infections are detected during the first 10 days but may occur as late as 6 weeks postoperatively. Treatment involves sternal and mediastinal débridement, drainage, and either primary closure or rotational muscle flaps to fill any sternal defect. These infections are often associated with generalized sepsis and other complications and are fatal in 10% to 30%. Wound infections increase hospital costs more often than any other nonfatal complication because of protracted hospitalization. The infection rate in most centers ranges from a fraction of 1% to approximately 5% and depends on preoperative risk factors and length and type of operation.

Stroke is most frequently attributed to atheroemboli arising from the ascending aorta (216). The incidence of detected aortic atheromas rises with advancing age. In fact, patients who have a history of unexplained embolic events should have transesophageal echocardiography, magnetic resonance imaging, or computed tomographic scanning to evaluate the thoracic aorta (217). A multicenter study reviewed adverse neurologic outcomes after coronary artery surgery. Overall, the stroke rate was 6.1% (*e*Fig. 82.4.1) (218). Predictors of major stroke (focal injury, stupor, or coma at discharge) were proximal aortic atherosclerosis, history of neurologic disease, and older age. Other defined stroke (deterioration in intellectual function, memory deficit, and seizures) occurred more frequently with older age, systolic hypertension, pulmonary disease, and excessive use of alcohol. Stroke tends to occur more often in patients with a previously documented stroke.



***e*FIGURE 82.4.1** Incidence of different types of neurologic deficits occurring after coronary artery surgery according to age of patient. (Data from Roach GW, Kanchuger M, Mangano CM, et al. Adverse cerebral outcomes after coronary bypass surgery. *N Engl J Med* 1996;335:1857–1863.)

Atrial fibrillation is the most frequent minor postoperative complication. The prevalence of preoperative atrial arrhythmia is approximately the same for men and women but does increase with advancing age (219): Approximately 30% of patients aged 65 to 74 and approximately 45% of those older than age 75 years develop postoperative atrial fibrillation. Most patients are returned to sinus rhythm by chemical or electrical cardioversion.

The majority of patients with postoperative renal dysfunction has underlying renal disease, and most have preoperative elevation of serum creatinine. The common denominator is postoperative cardiac instability, often low cardiac output. Every effort should be made to maintain stable hemodynamics and adequate renal perfusion in the perioperative period. Progressive liver dysfunction combined with renal failure portends a uniformly poor prognosis.

Infrequent complications include the following. Peripheral nerve trauma may result from compression of the brachial plexus between the clavicle and the first rib and involve the median nerve. Horner's syndrome may result from first rib fracture. Infarction of the bowel tends to occur with multisystem failure and is associated with high mortality. Acute cholecystitis is coincidental and rare and may require cholecystectomy. Pancreatitis is also rare but may occur, especially in patients with low cardiac output, in those with a history of pancreatitis, and in those who have received large doses of calcium chloride during the surgical procedure (220). Complications related to saphenous vein procurement sites are unusual, but lower extremity cellulitis may occur in diabetic patients.

Hospital and Operator Outcomes

State and region databases periodically survey results of coronary bypass surgery. New York (221), Pennsylvania (222), and New England (223) have reported results and correlate declining mortality rates to the introduction of outcome reporting. There has been wide variation in outcomes and charges. Although the results are showing a satisfactory trend, these improvements have been attributed to coding creep and outmigration (224).

The question is whether the extra resources demanded by statewide projects are justified. The majority of physicians surveyed indicate that these consumer guides have no relevance. Recently, investigators from Massachusetts pointed out that despite absence of statewide outcome reporting, in-hospital mortality after coronary artery bypass has decreased (225). Our experience supports this view.

LATE RESULTS

Coronary artery surgery has been influenced by randomized clinical trials that were initiated during the 1970s (Fig. 82.1). Surgery has provided improved longevity in subsets of patients with left main narrowing, proximal two- and three-vessel disease (with proximal anterior descending stenosis), and multivessel disease combined with compromised left ventricular function.

The Coronary Artery Surgery Study registry followed approximately 7,000 patients operated on from 1974 to 1977. After 4 to 6 postoperative years, patients with multivessel disease and poor left ventricular function (226), patients with three-vessel disease with proximal arterial stenoses (227), patients with multivessel disease with severe angina or mild angina (228,229), and patients 65 years of age or older (230) all showed an improved survival with surgery compared with patients who received medical treatment. The disparity in the survival outcomes of the two groups widened with increasing left ventricular dysfunction (i.e., poor left ventricular function adversely affected medically treated patients more than it did surgical patients). The myocardial infarction–free survival was improved by coronary bypass surgery rather than medical treatment in patients with severe angina and in patients with mild angina (231).

Most studies show a 5-year survival rate of 90% to 95%, 10-year, 80% to 90%, and 15-year, 65% to 75% (232). Completeness of revascularization is a strong univariate and multivariate predictor of survival (233). A metaanalysis of the major clinical trials of surgery versus medical treatment indicates that surgery produced lower mortality at 5, 7, and 10 years. In pooled data from all major randomized trials of bypass surgery, Yusuf and colleagues (234) reported a risk reduction of 39% at 5 years in the bypass surgery group despite a crossover rate from medical therapy of 23%. The best differentiation in favor of surgery occurred in patients with left main and three-vessel disease with left ventricular dysfunction; however, patients with focal proximal three-vessel disease with normal left ventricular function and patients with proximal anterior descending disease also showed higher survival with surgery than with medical treatment (Fig. 82.5).

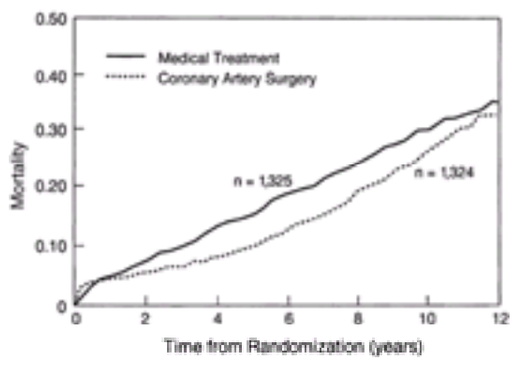


FIGURE 82.5 Results from a metaanalysis of seven randomized trials that have compared coronary artery bypass surgery with initial medical therapy. The risk reduction favored coronary surgery at 5 years, 39%; 7 years, 32%; and 10 years, 17%. The mortality curves are shown for each treatment group. The coronary artery surgery patients had significantly lower mortality than the medical group at all years surveyed. The risk reduction was greatest among left main disease patients than in those with three-vessel or one-or two-vessel disease (odds ratio at 5 years, 0.32, 0.58, and 0.77, respectively). (From Yusuf S, Zucker D, Peduzzi P, et al. Effect of coronary artery bypass graft surgery on survival: overview of 10-year results from randomised trials by the Coronary Artery Bypass Graft Surgery Trialists Collaboration. *Lancet* 1994;344:563–570, with permission.)

In 15-year studies, it has been shown that performance of the left internal thoracic artery graft to the anterior descending is a more important predictor of survival than progression of native coronary atherosclerosis (Fig. 82.6) (117). Patients who received internal thoracic artery grafting at either the first or the second operation fare significantly better than those who had vein grafts. Because internal thoracic artery grafting to the anterior descending is the single most important determinant of survival and event-free survival, it should not be withheld from any group of patients. The only relative contraindications were noted earlier.

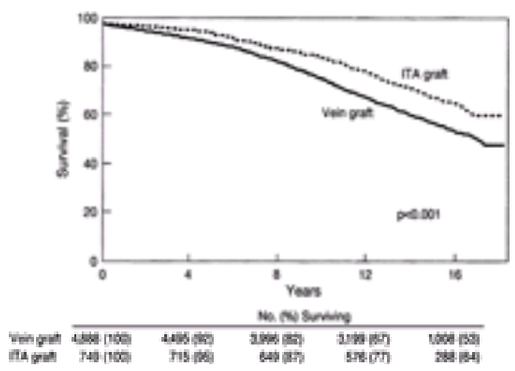

FIGURE 82.6 Actuarial survival up to 18 years comparing cohorts of patients with internal thoracic artery (ITA) bypass grafts and those with vein grafts. After 5 postoperative years, the differences in survival favor patients with ITA grafting and consistently reach statistical significance. (From Cameron A, Davis KB, Green G, et al. Coronary bypass surgery with internal-thoracic-artery grafts—effects on survival over a 15-year period. *N Engl J Med* 1996;334:216–219.)

Coronary atherosclerosis is a highly degenerative disease, and after the fifth year, the number of angina-free patients becomes progressively less due to native

coronary and conduit atherosclerosis. Typical results show 1-, 5-, and 10-year angina-free survival of 98%, 92%, and 81%, respectively (235). Recurring angina relates also to hypertension, diabetes, obesity, and other comorbidities. By the tenth to twelfth year, approximately half of the patients originally angina-free remain so. Late angina correlates with type of conduit, hyperlipidemia, and hypertension (236).

Continued cigarette smoking after surgery is the greatest determinant of early vein graft thrombosis (237). Smokers are at higher risk of myocardial infarction and reoperation compared with patients who stop smoking. Patients who continued to smoke 1 year after surgery had more than twice the risk for myocardial infarction and reoperation compared with patients who stopped smoking before surgery. Patients who were still smoking 5 years after surgery had even greater risk for myocardial infarction and reoperation and had a higher rate of recurring angina pectoris compared with patients who stopped smoking before surgery and patients who never smoked (238).

These and other older reports do not reflect the trend toward arterial grafting, nor do they compare surgery with current catheterization interventions. In general, the highest-risk patients (defined by severity of angina, extent of coronary artery disease, and left ventricular dysfunction) showed higher survival with surgery than with medical treatment. Lower-risk patients (mildly symptomatic, less extensive coronary atherosclerosis, and normal or near normal left ventricular function) showed less differentiation from medical treatment, although approximately 40% eventually underwent surgery over a 10-year period (239).

COMPARISON WITH ANGIOPLASTY AND STENTING

The nine major randomized trials comparing angioplasty and bypass surgery have shown no significant differences in intermediate-term mortality (240,241,242,243 and 244). However, the cardiac event rates, notably additional revascularization procedures and recurring angina, favor bypass surgery for multivessel disease. Patients in these trials were selected by the feasibility of either angioplasty or surgery, which excluded patients with left main narrowing, those with totally obstructed major vessels, and those with previous revascularization. Thus, these trials enrolled approximately 5% of multivessel coronary atherosclerosis revascularization candidates. Application of conclusions from these studies to all patients with multivessel coronary artery disease is problematic. Patients in the randomized angioplasty/surgery trials have tended to be of low risk; less than 10% had significant impairment of left ventricular function. Approximately half had one- or two-vessel disease, and thus those enrolled in these trials were not among those for whom a benefit from bypass surgery had previously been documented.

Most trials found that there were no differences in early mortality or combined end point of death and nonfatal myocardial infarction comparing surgery with angioplasty, but they did show repeat revascularization was more common by several-fold in patients receiving initial angioplasty (241,242,243 and 244). The angina relief, which favored surgery, abated as early as the third year, and the costs of the therapies were equivalent by the third to fifth year (241,242,243 and 244).

The Bypass Angioplasty Revascularization Investigation (BARI), the largest clinical trial with the longest follow-up, demonstrated improved survival for surgery patients at 7-year follow-up (245). This difference could be explained by the patients with treated diabetes, for whom estimates of 7-year survival were 76.4% for surgery and 55.7% for angioplasty. Among nondiabetics, survival was similar by assigned treatment (86.4% for surgery, 86.8% for angioplasty). The angioplasty group had substantially higher subsequent revascularization rates than the surgery group (59.7% vs. 13.1%). Of patients initially randomized to angioplasty, 35.5% had bypass surgery over the next 8 years.

The BARI finding that treated diabetics with multivessel coronary artery disease have excess mortality with an initial treatment strategy of angioplasty has been challenged (246,247). It is clear that diabetes is an independent risk factor for death with both strategies of revascularization (245,247,248). However, careful analysis of the BARI results (245,246) and recent reports from other studies support a strategy of initial bypass surgery in treated diabetics with multivessel disease (248,249,250 and 251).

BARI investigators analyzed medical care costs and quality of life (252). Initially, the mean cost of angioplasty was 65% of that of surgery ($21,113 vs. $32,347; p <.001), but after 5 years, the difference narrowed to only 5% ($56,225 vs. $58,889; p = .047). The cost differences favored angioplasty for two-vessel but not three-vessel disease. Surgery was especially cost-effective in diabetic patients. In the first 3 years, surgery, more so than angioplasty, was associated with improved physical function (253).

In the largest study examining death and revascularization after surgery or angioplasty, New York's surgery and angioplasty registries were used to identify nearly 30,000 people undergoing each treatment (254). Patients with single-vessel disease not involving the left anterior descending coronary artery had improved survival with angioplasty. Patients with proximal left anterior descending coronary artery disease had better 3-year survival with surgery regardless of the number of coronary vessels diseased. Also, patients with three-vessel disease had better 3-year survival with surgery than with angioplasty. These results, which reflect clinicians' decision making rather than enrollment in a randomized trial, support an initial strategy of surgery in patients with proximal left anterior descending coronary artery disease or three-vessel disease.

Other studies of one-vessel disease are noteworthy. Patients with single proximal left anterior descending stenoses were randomized to medicine, angioplasty, or surgery (255). All interventions resulted in symptom relief; however, the incidence of totally asymptomatic patients was 32% for the medically treated patients, 82% after angioplasty, and 98% after surgery. An internal thoracic artery graft to the anterior descending was associated with greater event-free probability at 3 years than was either angioplasty or medical treatment. Another study of one-vessel anterior descending revascularization found that 86% of surgically revascularized patients and 43% of angioplasty patients were free of adverse events after a mean follow-up of 2.5 years (256). Recent 5-year results of a randomized study support this, with 62% of angioplasty patients and 91% of surgery patients free of repeat revascularization (257). In each of these studies, there was no difference in cardiac death or myocardial infarction rate between surgery and angioplasty. In a study comparing different treatment modalities for isolated left anterior descending coronary artery disease, at a mean follow-up of 27 months repeat revascularization was necessary in 30% of patients having percutaneous transluminal coronary angioplasty, 24% of patients having percutaneous transluminal coronary angioplasty with stent, and 5% of patients having surgery with a left internal mammary artery (258).

Finally, a comprehensive prospective nonrandomized treatment comparison was conducted from 1984 to 1990 on 9,263 patients referred to cardiac catheterization at Duke University (Fig. 82.7) (259). In patients with three-vessel coronary atherosclerosis, coronary artery surgery provided a consistent 5-year survival advantage over angioplasty and medical treatment. For less severe coronary disease (i.e., some two- and one-vessel disease), there was a trend toward a relative survival advantage of angioplasty over medical treatment.

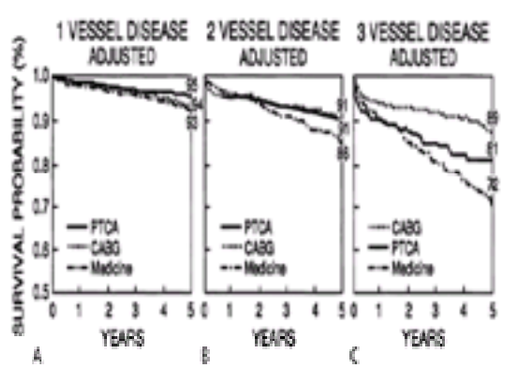

FIGURE 82.7 Survival curves for one-, two-, and three-vessel disease showing adjusted comparisons of angioplasty [percutaneous transluminal coronary angioplasty (PTCA)], coronary artery surgery [coronary artery bypass surgery (CABG)], and medicine. **A:** For one-vessel disease, there is a slight but insignificant trend toward higher survival in the angioplasty group: PTCA, 95%; CABG, 93%; medicine, 94%. **B:** Patients with two-vessel disease showed adjusted 5-year survivals of PTCA, 91%; CABG, 91%; medicine, 86%. **C:** In three-vessel disease, CABG was superior to medicine and PTCA: CABG, 89%; PTCA, 81%; medicine, 72%. (From Mark DB, Nelson CL, Califf RM, et al. Continuing evolution of therapy for coronary artery disease: initial results from the era of coronary angioplasty. *Circulation* 1994;89:2015–2025, with permission.)

How angioplasty alters the natural history of coronary arthrosclerosis depends on the selection criteria for balloon intervention. Using Rand appropriateness selection criteria, the acute success rate for angioplasty was significantly less in patients who have "necessary" revascularization compared with patients undergoing angioplasty for "uncertain" revascularization criteria. Patients undergoing angioplasty for "necessary" indications had a significantly different 5-year survival (97.8%) compared with patients who had unsuccessful, "necessary" angioplasty (85.5%). In patients classified as having "uncertain" criteria, there was no difference in survival between successful and unsuccessful cases (94.8% vs. 94.4%) (260).

Conclusions from the medical literature may be summarized as follows. Patients who have moderate to high risk of death or cardiac events, including those with diffuse

multivessel disease, are generally better off with surgery because of the high restenosis rate of angioplasty and its less consistent results. For patients who qualify for angioplasty, approximately two-thirds will avoid subsequent revascularization, including surgery within the first 3 to 5 years. In multivessel disease patients selected by angioplasty criteria, coronary bypass surgery and angioplasty have similar mortalities up to the first 7 years postprocedure. Surgery offers more complete revascularization because of the greater ability to graft totally obstructed coronary arteries; however, the morbidity is higher and hospitalization is longer. Excepting restenosis, the intermediate term after angioplasty has shown a high rate of revascularization, a higher rate of recurring angina, more use of antianginal drugs, and a trend toward higher mortality compared with surgery for multivessel disease (Table 82.1).

Coronary artery bypass grafting		Percutaneous transluminal coronary angioplasty	
Advantages	Disadvantages	Advantages	Disadvantages
Established differences			
Results in more complete revascularization	Involves major surgery (possible perioperative problems)	Major surgery avoided in 70% of patients (at 5 yr)	Results in less complete revascularization
Provides excellent relief of angina	Requires longer hospitalization and high initial costs	Associated with shorter hospitalization and lower initial costs	Angina may recur
			Associated with more subsequent procedures
Possible differences			
Possibly better long-term survival	Associated with more early infarctions	Associated with fewer periprocedural infarctions	Possibly poorer long-term survival

From Simoons ML, Myocardial revascularization—bypass surgery or angioplasty? N Engl J Med 1996;335:275-277, with permission.

TABLE 82.1 DIFFERENCES BETWEEN CORONARY ANGIOPLASTY AND SURGERY

Randomized trials comparing coronary artery surgery to angioplasty with stenting are under way (261,262). It is clear that coronary stent implantation reduces the restenosis rate associated with angioplasty in favorable lesions (263,264). Initial results of the Arterial Revascularization Therapies Study and the Stent or Surgery trials are encouraging for multivessel stenting compared with bypass surgery, but only 1-year follow-up has been reported. The addition of platelet glycoprotein-IIb/IIIa blockade to percutaneous coronary interventions has also had an important impact (265,266 and 267). As long-term results of coronary stenting become available and results of randomized trials are published, it will be important to remember that clinical results in selected patients may not apply to all patients with multivessel coronary artery disease.

LATE MANAGEMENT

All revascularization is palliative. After coronary artery surgery, lifelong attention should focus on limiting progressive disease. Patients who demonstrate progressive atherosclerosis have an increased risk of future clinical coronary events (268,269). Stabilization of the atheromatous lesion, rather than marked regression of disease, most likely determines reduction of cardiac events (270,271). Whether by diet or drugs, cardiac events and mortality related to ischemic heart disease are significantly reduced by lowering of serum cholesterol levels (272). Metaanalyses of lipid-lowering trials suggest that at least 2 years of a 10% reduction in serum cholesterol levels results in a 17% to 24% reduction in cardiac death and a 22% reduction in coronary events (273,274 and 275). These findings are consistent with those of a large, randomized, placebo-controlled study that concluded that a 25% lowering of cholesterol correlated with a 34% reduction in the combined outcome of cardiac death and onfatal myocardial infarction, a 42% reduction in coronary-related mortality, and a 37% reduction in revascularization procedures 5 years after treatment with no evidence of increased mortality from noncardiovascular causes (276). Subjects with normal serum cholesterol values (less than 240 mg per dL and a low-density lipoprotein level of 115 to 174 mg per dL) may also benefit from lipid lowering (277). In this double-blind trial, a 25% reduction in total cholesterol resulted in a 24% reduction in cardiac death and nonfatal myocardial infarctions and a 27% reduction in coronary bypass or angioplasty. Both of these most current studies revealed similar reductions in risk for those younger or older than age 60 years. Reduction in risk for women (a small percentage of participants) was approximately 25%, including approximately a 30% reduction in angioplasty and bypass surgery procedures as well as cardiac event rates over 5 years.

The above data are relevant but must be applied to patients on an individual basis. Although dietary modifications are important, more so in younger patients, a restrictive diet is less likely to benefit a very elderly patient, and compliance is less with advanced age. A lipid profile should be checked annually to monitor and adjust treatment.

Patients with aortocoronary vein bypass grafts who had low-density lipoprotein cholesterol levels between 130 and 175 mg per dL and were treated with lovastatin and, when necessary, cholestyramine showed less progression of atherosclerosis and late graft occlusion (278). The mean percentage of grafts with progressive change was 27% when low-density lipoprotein was aggressively lowered, compared with 39% with moderate treatment. Warfarin had the same effect as placebo, as documented by angiography. There was also a 29% reduction in the rate of revascularization procedures (average 4 years later) for the aggressive group compared with the moderate treatment group. However, regression does not continue at the same rate year after year. Approximately 20% to 40% of subjects treated with cholesterol-reducing drugs show some progression despite what was thought to be adequate therapy.

The wealth of data on the effects of smoking is convincing both in native-vessel and vein graft disease. Cigarette smoking is one of the greatest determinants of vein graft thrombosis. Cessation of smoking results in a 50% reduction in recurrent cardiac events and must be strongly and, if necessary, repeatedly recommended. Of all measures, smoking cessation is the most cost-effective preventive intervention (279).

Hypertension adversely affects postoperative longevity, and accurate management of diabetes is crucial for retardation of progressive coronary and peripheral atherosclerosis. Platelet antiaggregants should be continued for at least 1 year postoperatively in patients with vein or radial artery grafts. Low-dose warfarin has not been effective in reducing vein graft disease. Early recurring angina is unusual but may require full investigation. After the fifth postoperative year, surveillance should be annual, especially for those who had vein grafts. In view of the propensity for vein graft degeneration, patients with vein grafts to major vessels should have repeat angiography, in our opinion, regardless of symptoms or noninvasive test results, at 10 years.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Coronary artery revascularization is changing at an increasingly rapid pace. In the past 30 years, the operation has advanced to provide more complete revascularization, more durable conduits, and a positive effect on later survival and incidence of cardiac events. The heterogeneity of coronary atherosclerosis pathoanatomy and patient characteristics has made clinical trials difficult to design and generally not applicable to the population of patients regularly seen in practice.

Early clinical trials that compared medical and surgical treatment of unstable angina showed that conservative treatment of patients with repeated attacks of angina that ultimately required coronary artery surgery resulted in more cost than a strategy of early surgery under stable conditions. The same will be found when repeated catheter-based interventions culminate in coronary artery surgery.

In the past decade, the number of percutaneous revascularization procedures have eclipsed the number of coronary bypass procedures. Percutaneous coronary intervention has a secure place in the armamentarium of revascularization. However, there remain the problems of restenosis in stents and after angiography, the inability to approach chronic occlusions in most patients, and addressing diffuse multivessel disease.

THE FUTURE

Cardiac surgery offers a large menu of arterial conduits that can be used to provide consistent high-quality, long-lasting, biologically better conduits that are affected only by distal progression of native atherosclerosis. The whole field is moving rapidly toward minimally invasive techniques that will compete effectively for revascularization of complicated proximal anterior descending or ostial stenosis, which is often difficult to dilate or stent with consistently good results. In addition, off-pump surgery is likely to reduce the morbidity and mortality of multivessel coronary artery bypass grafting, particularly in patients with multiple comorbidities. In the near future, vein grafts, even in older patients, will be supplanted by all arterial grafting performed through small ports. Virtually every subset of coronary atherosclerosis patients in whom myocardial jeopardy and ischemia of large regions are conclusively demonstrated deserves consideration for coronary bypass surgery. In each of these subsets—even in patients with advanced age, previous coronary artery surgery, and poor ventricular function—the results have consistently shown advantages for patients receiving internal thoracic artery grafting for the anterior descending artery. More recent evidence suggests advantages of expanded arterial grafting for younger patients.

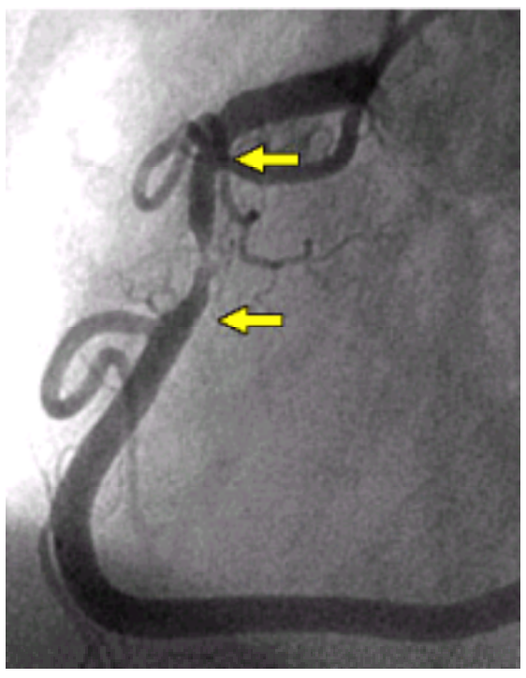
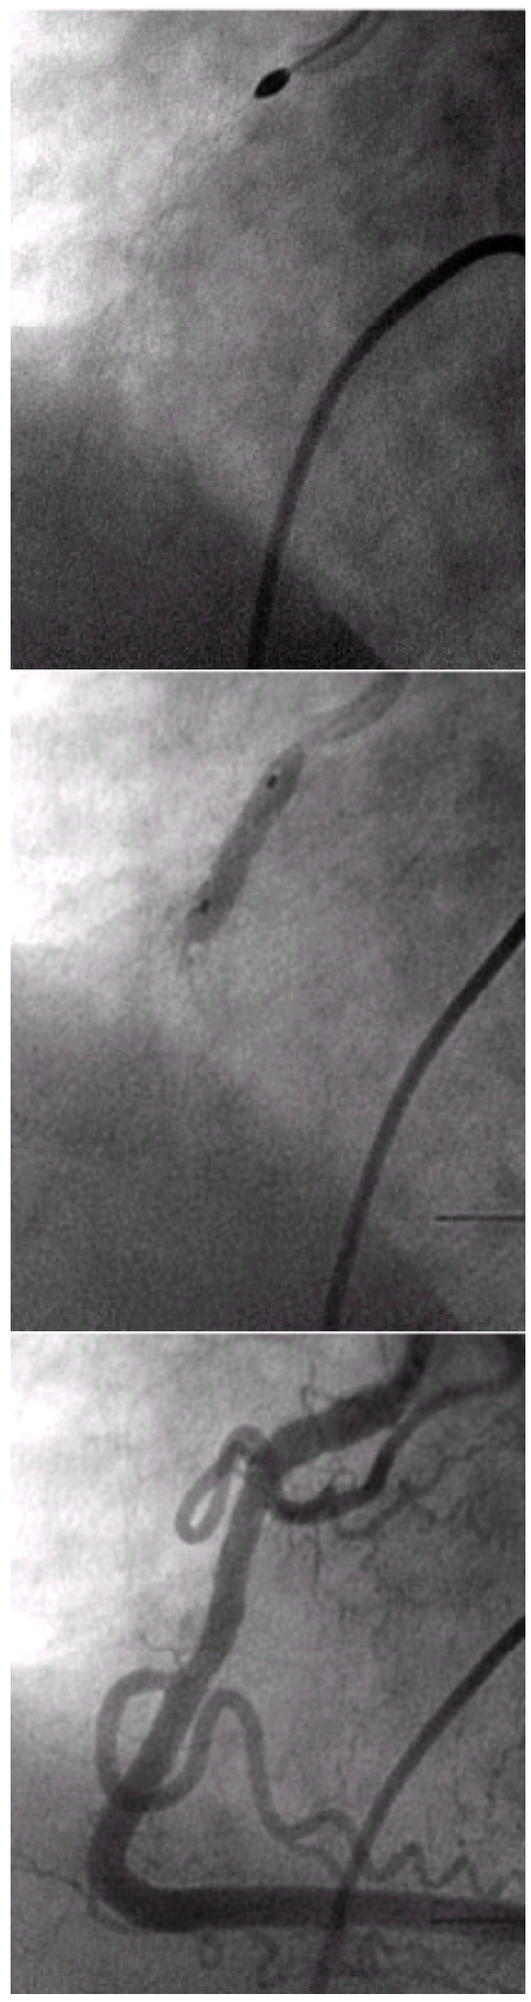
OVERVIEW

Percutaneous coronary revascularization is an increasingly attractive alternative to medical therapy and surgical revascularization for coronary artery disease. The leading drawback continues to be the occurrence of restenosis within 6 months. The epidemiology of restenosis after balloon angioplasty has been studied in many clinical trials, and several predictors of restenosis have been consistently identified: diabetes mellitus, unstable angina, preprocedural and postprocedural minimum lumen diameter, chronic occlusions, lesion length, reference vessel diameter, ostial stenoses, and lesions in saphenous vein grafts. The mechanisms of restenosis include a combination of vessel recoil, vascular remodeling, thrombus transformation, and neointimal proliferation. As indicated by intravascular ultrasonography, remodeling is the predominant mechanism after balloon angioplasty and neointimal hyperplasia dominates in in-stent restenosis. Substantial progress has been made over the past 5 years in lowering the rate of restenosis as vessel recoil and remodeling have been nearly eliminated by the use of intracoronary stents.

Restenosis occurs in one-fourth to one-third of patients within 3 to 6 months of percutaneous revascularization. Most patients with restenosis have symptom recurrence, whereas the minority have silent restenosis, and myocardial infarction is rare. Symptom status alone has weak predictive value for stenosis recurrence, so the optimal method of evaluation is stress myocardial imaging studies. For prophylaxis of restenosis, numerous pharmacologic therapies, including antithrombotics, vasodilators, lipid-lowering agents, and growth factor inhibitors, have been tested but have failed. Likewise, use of several atherectomy catheters (rotational, directional, laser) has been studied, again without consistent improvement noted in the occurrence of restenosis.

Now stents are commonly used to safely maximize postprocedural lumen diameter and decrease the incidence of angiographically identified restenosis and the need for target vessel revascularization. Compared to balloon angioplasty, intracoronary stent placement has been shown to improve the rate of restenosis in nearly all patients and for nearly all lesion subsets. On the other hand, a new disorder, in-stent restenosis, has been created, although it is less common than restenosis after balloon angioplasty. The neointimal proliferation produced by stents has required the development of agents, techniques, and equipment to address it when vessel renarrowing occurs. Radiation and cell-cycle inhibitors hold the current promise in treating in-stent restenosis.





Rotational atherectomy to treat in-stent restenosis. Diffuse restenosis within a previously placed Palmaz-Schatz stent (A, *arrows*) is treated with rotational atherectomy (B), followed by adjunctive stent placement (C). The postintervention result is shown in D.

HISTORICAL PERSPECTIVE

As percutaneous coronary revascularization has evolved over the past 25 years, it has become an increasingly attractive alternative to medical therapy and surgical revascularization for coronary artery disease. During this time most of the advancement in the field of interventional cardiology has been to make the procedure safer and more immediately successful while expanding the treatment to progressively more complex coronary arterial lesions. The leading drawback to percutaneous coronary intervention (PCI) has been and continues to be the recurrence of stenosis within 6 months, or restenosis. Among the first 169 patients in whom percutaneous transluminal coronary angioplasty (PTCA, balloon angioplasty) was performed by Gruentzig in Zurich, 31% of those undergoing repeat angiography at 6 months were noted to have recurrence of stenosis (1).

Currently, well over 1 million percutaneous coronary interventions are performed each year throughout the world (2,3,4 and 5). The majority of these procedures is performed in the United States and Western Europe, and the rate on both sides of the Atlantic continues to nearly double every 5 to 8 years (Fig. 83.1). Of these angioplasty cases, approximately one-fourth involve lesions previously treated by PCI. In the United States alone, restenosis still occurs in approximately 150,000 patients annually, which translates into over $3 billion of medical expenditures (6). With an increasing number of PCI procedures performed each year, the absolute number of patients who will be affected by restenosis will rise until successful treatments to prevent restenosis are discovered and implemented.

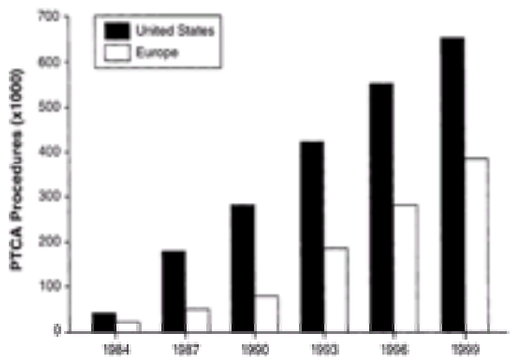

FIGURE 83.1 The number of percutaneous revascularization procedures performed in Europe and the United States has steadily increased over time, and well over 1 million procedures are now carried out each year worldwide. PTCA, percutaneous transluminal coronary angioplasty. (Data from Gruentzig AR, King SD, Schlumpf M, et al. Long-term follow-up after percutaneous transluminal coronary angioplasty: the early Zurich experience. *N Engl J Med* 1987;316:1127–1132; Bittl JA. Advances in coronary angioplasty. *N Engl J Med* 1996;335:1290–1302; Windecker S, Maier-Rudolph W, Bonzel T, et al. Interventional cardiology in Europe 1995. *Eur Heart J* 1999;20:484–495; and American Heart Association. 2001 heart and stroke statistical update. Available at: http://www.americanheart.org/statistics/index.html. Accessed September 4, 2001.)

Historically, early reports of restenosis showed a broad range in the incidence and prevalence of restenosis. This occurred because a number of arbitrary definitions existed for angiographically determined restenosis, and many early clinical studies were small and their results were confounded by problems of incomplete revascularization, withdrawal bias, and limited follow-up. Finally, the technique and technology of percutaneous revascularization have continually evolved, which perhaps limits assessments of restenosis to snapshots in time, rather than providing a dynamic perspective. This chapter reviews issues involved in the epidemiology of restenosis and contemporary efforts to prevent restenosis after coronary intervention.

PATHOPHYSIOLOGY

The response of the vessel to coronary interventions is complex (Fig. 83.2 and Fig. 83.3) (7)—with injury to the intima and media likely occurring in all patients during angioplasty, even if to a small extent—and is detailed in Chapter 105 (8). Briefly, restenosis can be broadly divided into three interrelated facets: vessel wall recoil and remodeling, thrombus formation and organization, and neointimal growth. Studies report that many patients (15% to 65%) have a 10% or greater increase in the diameter of stenosis within 2 days of balloon angioplasty (9,10,11,12,13 and 14), and some patients (10%) have a substantial early renarrowing (more than 50% acute loss) (10). This vessel wall recoil may represent elastic rebound of the arterial wall or plaque, abnormal vasoconstriction, the presence of a thrombus, or a combination of these factors. Regardless of the underlying mechanism, this very early vessel wall response affects the likelihood of subsequent restenosis. Vessel wall remodeling also occurs over the long term, and the vessel may adaptively enlarge (positive remodeling) in response to atherosclerosis or may shrink (negative remodeling) in response to the trauma of angioplasty (Fig. 83.2) (15,16 and 17).

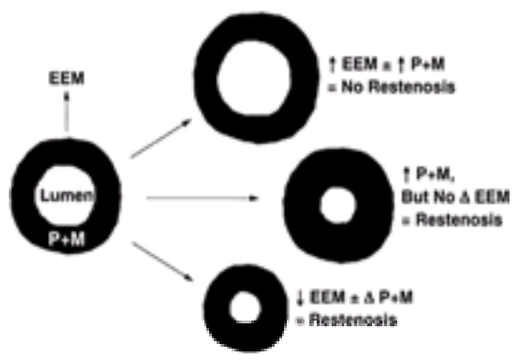

FIGURE 83.2 Restenosis can occur by several interrelated mechanisms. As shown in the schematic of the “doughnut and the hole,” neointimal proliferation can decrease lumen area by increasing the plaque plus media (P+M) cross-sectional area. If the overall vessel area (external elastic membrane, or EEM) increases adequately (compensatory arterial dilatation or favorable arterial remodeling), no restenosis will occur. Alternatively, if (a) neointimal growth is excessive, (b) arterial remodeling is inadequate, or (c) negative arterial remodeling (arterial contracture) occurs, then restenosis ensues. ↑, increase; ↓, decrease; D, change. (Adapted from Mintz G, Popma J, Pichard A, et al. Arterial remodeling after coronary angioplasty: a serial intravascular ultrasound study. *Circulation* 1996;94:35–43, with permission.)

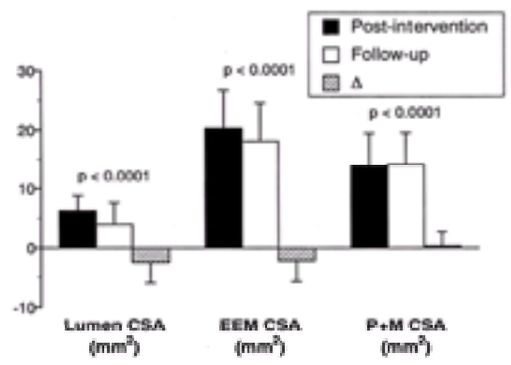
FIGURE 83.3 Pathophysiologic mechanisms of restenosis after percutaneous revascularization. After balloon angioplasty, recoil occurs followed by activation of growth factors and smooth muscle cell proliferation. These lead to vessel contracture or negative remodeling in some patients. After intracoronary stent placement, the majority of lumen loss is from neointimal hyperplasia. In most cases, the mechanisms of restenosis are likely interrelated. bFGF, basic fibroblast growth factor; EDRF, endothelium-derived relaxing factor; EGF, epidermal growth factor; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); PDGF, platelet-derived growth factor; PGI_2, prostacyclin; TGF-b, transforming growth factor-b.

To directly investigate the importance of arterial remodeling in restenosis after angioplasty, Mintz and coworkers (18) performed serial intravascular ultrasonographic studies of 212 native coronary lesions. By carefully measuring changes in the vessel cross-sectional area components (lumen area and plaque plus media area) (eFig. 83.3.1), they were able to demonstrate that 73% of the loss in lumen area among those with restenosis was attributable to loss in the overall vessel wall cross-sectional area. The remaining 27% was attributable to growth of the plaque or neointimal area. Of the 212 lesions studied, 78% had some decrease in overall size (negative remodeling), whereas 22% increased in overall size. Finally, lesions that demonstrated negative remodeling were 2.4 times more likely to have angiographically identified restenosis (62% vs. 26%).



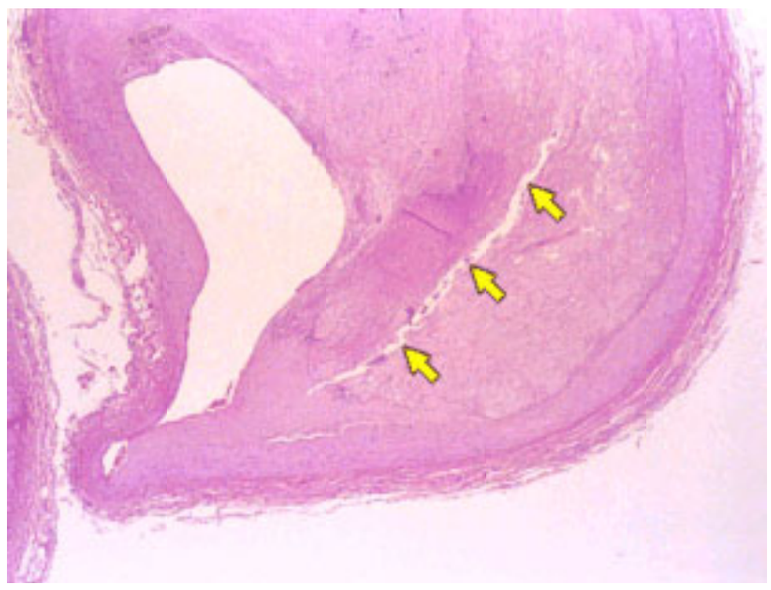
***e*FIGURE 83.3.1** Measurements of the cross-sectional areas (CSA) of the overall vessel [external elastic membrane (EEM)], plaque plus media (P+M), and lumen by serial intravascular ultrasonography demonstrated that 73% of the lumen area lost in the restenotic process was as a result of a decrease in the EEM CSA (i.e., negative remodeling). The minority of loss (27%) was from an increase in P+M (neointimal hyperplasia). (From Mintz G, Popma J, Pichard A, et al. Arterial remodeling after coronary angioplasty: a serial intravascular ultrasound study. *Circulation* 1996;94:35–43, with permission.)

Early Thrombus

Serial angioscopy performed in patients after elective balloon angioplasty has shown that most lesions (more than 80%) have an identifiable thrombus within the first hour (19,20). Activated platelets within the thrombus secrete a host of substances from their alpha-granules that lead to vasoconstriction, chemotaxis, mitogenesis, and activation of neighboring platelets (21,22). The released growth factors and chemokines include platelet-derived growth factor (PDGF), transforming growth factor-b (TGF-b), basic fibroblast growth factor (bFGF), epidermal growth factor (EGF), and interleukin-1 (23,24 and 25). These factors are believed to be responsible for the neointimal growth after angioplasty by stimulating the migration and proliferation of smooth muscle cells (25). Thrombus contributes to restenosis directly by lumen occupation and vasoconstriction and indirectly by mediating the growth of fibromuscular tissue, or neointima.

Neointimal Hyperplasia

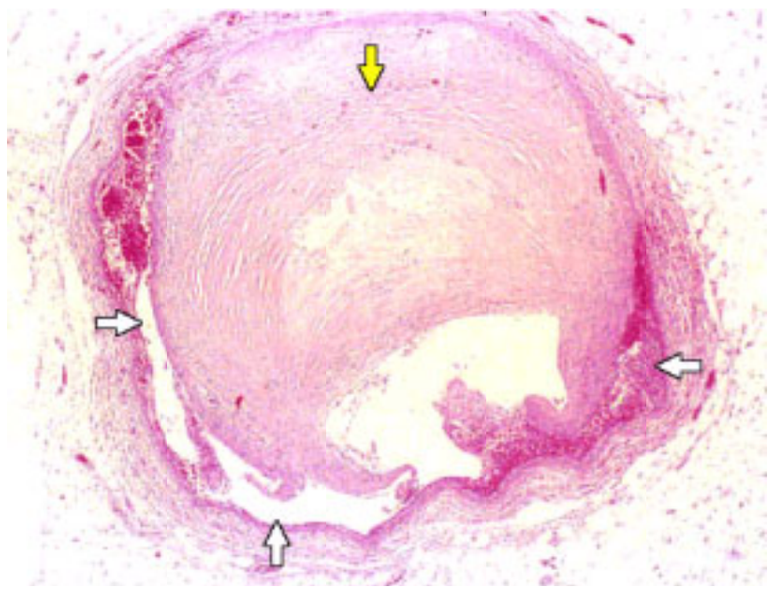
Simply stated, neointima is the new intimal tissue that develops as part of the reparative or wound healing process after vascular injury, and all angioplasty sites have some degree of neointimal formation at follow-up. These platelet-released mitogens activate surface receptors on resting medial smooth muscle cells and induce protooncogenes that stimulate the smooth muscle cells to replicate. In humans, approximately 48 hours after arterial injury, smooth muscle cells can be seen proliferating and migrating to the injured area (7,26,27). This process of replication of smooth muscle cells in the media and subsequent migration to the intima occurs during the first week after angioplasty. The final wave of neointimal growth occurs over the ensuing weeks to months as the smooth muscle cells in the intima continue to replicate and produce extracellular matrix.



Restenotic lesion. Residual tear in atherosclerotic plaque (*yellow arrows*) and large amount of neointimal proliferation 76 days after balloon angioplasty.

Restenotic Lesion

The mechanisms of restenosis—recoil, remodeling, thrombus formation, and neointimal proliferation—are dynamically interrelated (Fig. 83.3) and provide a “natural history” of the restenotic lesion. This process differs from that of *de novo* lesion formation and leads to substantial differences in lesion histology and rate of stenosis formation. *De novo* atherosclerotic lesions have a range of histologic presentations from young or “juvenile” plaques, which are often soft, lipid-laden, and covered by a relatively thin fibrous cap, to “senile,” or older, plaques, which contain more calcium and fibrous tissue in addition to the lipid component. Primary atherosclerotic lesions usually develop over years to decades, whereas restenotic lesions develop over weeks to months. Pathophysiologically, restenotic lesions (in addition to containing residual components of the original lesion) usually contain evidence of vessel wall injury, thrombus, and neointima during their development. Nobuyoshi et al. (28) studied the histopathology of 34 lesions from 20 patients who died within 2 weeks to 2 years after angioplasty. Even with this wide age range in restenotic lesions, remarkable consistency was seen in the histology. Eighty-eight percent of lesions showed intimal, medial, and adventitial tears, whereas neointimal proliferation was observed in 82%. Thrombus formation was seen most commonly among lesions treated within the prior month and was observed in 23% of all lesions studied. Neointimal proliferation was consistently present among lesions after 10 days.



Linear, circumferential dissection 2 days after balloon angioplasty of a restenotic lesion. Note the extensive neointimal proliferation (*yellow arrow*) and dissection (*white arrows*).

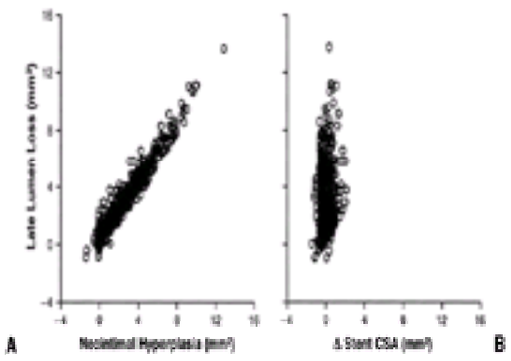
Garratt and colleagues (29) compared the histology of directional atherectomy specimens from 31 primary lesions and 30 restenotic coronary arterial lesions. Age of the restenotic lesions was 1 week to 74 months; mean age was 9 months. Among the primary lesions, 83% of the intimal tissue retrieved contained dense fibrosis and necrotic debris, and 17% of the tissue contained loose fibroproliferative (hyperplastic) tissue. In contrast, among the restenotic lesions, 55% of the intimal tissue was dense fibrosis and necrosis and 45% was hyperplastic. Likewise, foam cells were present in 32% of primary lesions but in only 3% of restenotic lesions. These two key differences—more appreciable fibromuscular hyperplasia and fewer foam cells among restenotic lesions—typify the natural history differences of restenotic lesions compared to their primary lesion predecessors. No difference in subintimal histology was seen between primary and restenotic lesions.

These histologic studies and observations have been mainly limited to restenotic lesions in native coronary arteries after balloon angioplasty, although similar findings have been reported for lesions treated by atherectomy and lesions in saphenous vein grafts (29). The contribution of the individual mechanisms of restenosis after intracoronary stent placement and the resultant histology are somewhat different from those after balloon angioplasty. The majority of lumen loss after balloon angioplasty is from remodeling, with an important but lesser component of neointimal proliferation. The converse is true of lumen loss among stented lesions that undergo restenosis. In-stent restenotic lesions have a marked hyperplastic neointimal response and very little remodeling. Hoffman et al. (30) studied 115 lesions treated with stents by serial intravascular ultrasonography and showed that late lumen loss at follow-up was strongly correlated with neointimal hyperplasia and only weakly correlated with change in stent cross-sectional area (*e*Fig. 83.3.2). Moreover, stents affected the proximal and distal segments of the arteries adjacent to the stent for at least 5 to 10 mm. Remodeling appeared progressively to increase, whereas tissue growth progressively decreased at axial distances further from the stent edge. Animal studies (31,32) and clinical investigations (30,33,34) have shown that intimal hyperplasia covers the entire stent, is exaggerated compared to that seen in lesions treated with balloon angioplasty, and results in a greater late loss. The pattern or distribution of restenotic tissue within stents is also significantly different. Volumetric intravascular ultrasonographic studies by Dussaillant et al. (35) have shown that the pattern of in-stent restenosis is more commonly focal (77% of cases), with greatest tissue growth being in the midstent articulation site, at the stent margin, or in the stent body in 45%, 30%, and 25% of cases, respectively. A more aggressive neointimal pattern within stents in which diffuse and dramatic tissue growth occurs is also well described. This growth pattern, although less common, is important because it has been associated with a high frequency of recurrent restenosis when treated by balloon angioplasty (36).



***e*FIGURE 83.3.2** When 715 segments in a total of 115 stents were analyzed by intravascular ultrasonography, the late lumen loss was found to be strongly correlated with neointimal hyperplasia **(A)** and only weakly correlated with change in the stent cross-sectional area (CSA) **(B)**. (From Hoffman R, Mintz G, Dussaillant G, et al. Patterns and mechanisms of in-stent restenosis: a serial intravascular ultrasound study. *Circulation* 1996;94:1247–1254, with permission.)

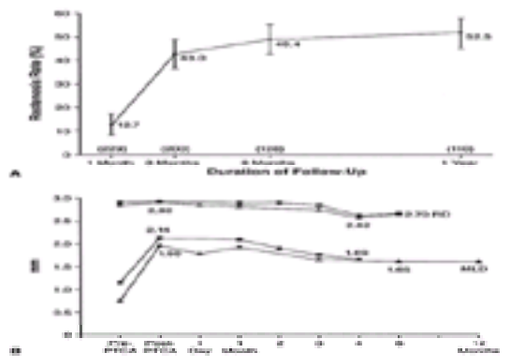
Presentation of Restenosis

The interrelated mechanisms of restenosis can translate into an anatomically or physiologically important stenosis recurrence. Depending on the predominant mechanism and its severity, as well as on characteristics of the index lesion, the timing and presentation of symptoms may vary. Restenosis can be categorized or defined angiographically or clinically, or it may be silent (asymptomatic).

Video 83.5 Anomalous origin of the left circumflex coronary artery from the right sinus with in-stent restenosis 7 months post procedure. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Timing

Three events may occur after angioplasty that can produce symptom recurrence referable to the treated lesion. The first, elastic recoil, occurs within minutes to hours after PTCA but usually does not cause symptoms. The second, abrupt vessel closure, occurs minutes to days after angioplasty in several percent of patients and produces recurrent angina or acute infarction. Finally, over the weeks to months after PTCA, restenosis due to neointimal growth and remodeling may occur. To study the time course of restenosis, Nobuyoshi and colleagues performed sequential angiography in 229 patients at 24 hours, 1 month, 3 months, 6 months, and 1 year after balloon angioplasty (10). An appreciable loss (more than 0.5 mm) in lumen diameter was detected in 15% of patients at 24 hours, consistent with lesion recoil or thrombus formation. In approximately one-half of these patients, the loss proceeded to restenosis. In the interval from 1 day to 1 month, most lesions remained unchanged or regressed, with a mean improvement in lumen diameter. During this same period, few patients (12%) were classified as having restenosis. The actuarial patient rate of restenosis increased markedly (from 12% to 43%) between 1 and 3 months, and increased only modestly thereafter (*e*Fig. 83.3.3A). This and other studies using serial angiography (*e*Fig. 83.3.3B) (37) make it evident that the majority of restenosis occurs within the first 3 months after balloon angioplasty and that restenosis after 3 to 6 months is rare (10,38,39). The time course for restenosis after intracoronary stent implantation is later by 1 to 3 months. Regardless, most patients who are free of restenosis at 6 to 8 months will have continued success for the index lesion.

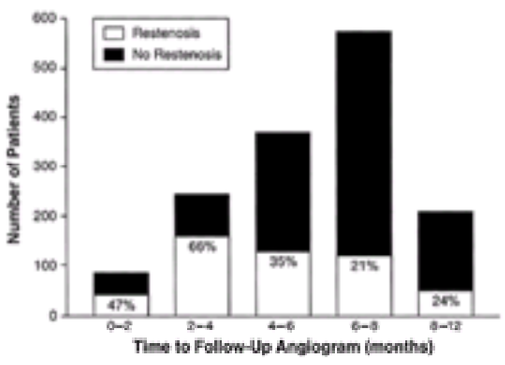


***e*FIGURE 83.3.3** By serial angiographic follow-up, restenosis after successful angioplasty can be seen to occur with highest frequency in the first 3 months in this cohort of 229 patients **(A)**. Likewise, the time-related loss in minimal lumen diameter (MLD) seen in two separate serial angiographic studies is shown to occur over this same period **(B)**. From this, the majority of restenosis can be seen to occur within the first 3 months after angioplasty. PTCA, percutaneous transluminal coronary angioplasty; RD, residual diameter. (From Nobuyoshi M, Kimura T, Nosaka H, et al. Restenosis after successful percutaneous transluminal coronary angioplasty: serial angiographic follow-up of 229 patients. *J Am Coll Cardiol* 1988;12:616–623; and from Serruys PW, Luijten HE, Beatt KJ, et al. Incidence of restenosis after successful coronary angioplasty: a time-related phenomenon. *Circulation* 1988;77:361–371, with permission.)

Symptoms

Because restenotic lesions usually develop gradually, the recurrence of symptoms or inducible ischemia also occurs gradually over weeks to months. Although soft *de novo* lesions may rupture abruptly, causing vessel occlusion, infarction, and in some cases death, fibromuscular restenotic lesions rarely present as acute infarction (2% or fewer cases) or death (1% or fewer cases) (40,41 and 42). Rather, the majority of patients with symptomatic restenosis experience the return of their typical angina or its equivalent. The safety of restenosis was seen even among angioplasty patients at high risk for ischemic events in the Evaluation of Chimeric Monoclonal 7E3 for the Prevention of Ischemic Complications (EPIC) trial (43). At 6-month follow-up, of the 549 patients who received placebo and had no clinical event during the first 30 days, only 2.0% had myocardial infarction and 1.7% died. Although these data are from patients both with and without restenosis, Weintraub et al. (44) have reported similar results among 3,363 patients followed for 6 years. In this large cohort, those with and without angiographically identified restenosis had an annual rate of death of approximately 1.0%, and the annual rate of myocardial infarction was 2.5% and 2.0% for these groups, respectively. Among all patients undergoing intracoronary stent placement, approximately 2% die between 30 days and 1 year (45,46).

When data are pooled from several early PCI studies (47,48,49,50,51,52 and 53) including nearly 3,000 patients with midterm (3- to 6-month) follow-up, two-thirds of those with angiographically identified restenosis are found to have typical angina. Patients with typical symptom recurrence within 6 months of angioplasty are more likely to have restenosis of the index lesion, whereas development of angina at later than 6 months is often due to a different stenosis. When data from an early National Heart, Lung, and Blood Institute (NHLBI) PTCA Registry report (47) were combined with those from Emory University (54) to cover a total of 1,475 patients who presented with recurrent chest pain and underwent angiography, the highest rate of symptoms deemed related to restenosis was found to occur within the first 4 months after angioplasty. After 4 months, the majority of symptomatic patients had continued success of the treated lesion (eFig. 83.3.4). Joelson et al. (55) showed that among 102 patients, symptom persistence or recurrence within the first month after angioplasty was most often due to incomplete revascularization; symptom recurrence between 1 and 6 months was due to restenosis; and symptoms after 6 months were almost always from new lesions. In topical reviews, reports are that chest pain recurs in roughly half of patients undergoing angioplasty, although the proportion with concomitant angiographically apparent restenosis ranges widely from 48% to 92% (56). Patients who present with atypical chest pain or pain different from that which they experienced before angioplasty infrequently have restenosis (47,52). In an NHLBI PTCA Registry report, Holmes et al. (47) found that 56% of patients with definite or probable angina had angiographically identified restenosis, whereas among patients without chest pain, 14% had restenosis. Overall, the positive predictive value of chest pain for restenosis is moderate.



***e*FIGURE 83.3.4** Combined data from the National Heart, Lung, and Blood Institute percutaneous transluminal coronary angioplasty registry and the Emory University registry, encompassing a total of 1,475 patients who underwent repeat angiography for chest pain, indicate that the highest rate of occurrence of symptoms deemed related to restenosis was observed within the first 4 months after revascularization. After 4 months, the majority of symptomatic patients had continued success of the treated lesion. [Adapted from Holmes DRJ, Vlietstra RE, Smith HC, et al. Restenosis after percutaneous transluminal coronary angioplasty (PTCA): a report from the PTCA Registry of the National Heart, Lung, and Blood Institute. *Am J Cardiol* 1984;53:77C–81C; and Leimgruber PP, Roubin GS, Hollman J, et al. Restenosis after successful coronary angioplasty in patients with single-vessel disease. *Circulation* 1986;73:710–717, with permission.]

Angiographically Identified Restenosis

Numerous binary definitions of angiographically determined restenosis have been proposed and used in clinical reports. Serruys et al. (57) found 12 different definitions (eTable 83.0.1) in the literature. The most commonly used definition currently is stenosis of 50% or more of lumen diameter at 6-month follow-up. Likewise, the method of assessing luminal renarrowing has also varied. Some studies have used simple visual assessment of percentage diameter stenosis to assess restenosis, whereas others have used hand-held digital calipers. Computer-assisted angiographic edge-detection systems are commonly used in contemporary research protocols. Depending on the restenosis definition, assessment method, and system used to assess the angiogram, angiographically identified restenosis rates varied from under 30% to over 50% before the stent era. Among stent studies, angiographically determined restenosis rates have ranged from under 10% to over 30%.

***e*TABLE 83.0.1** CRITERIA FOR RESTENOSIS AT FOLLOW-UP ANGIOGRAPHY USED IN THE LITERATURE

Stenosis with reduction of ³30% in lumen diameter (NHLBI 1)
Immediate post-PTCA stenosis of <50% diameter that increases to ³70% at follow-up (NHLBI 2)
Return to within 10% of pre-PTCA stenosis diameter (NHLBI 3)
Loss of at least 50% of the initial gain (NHLBI 4)
Stenosis of ³50% diameter
Stenosis of ³70% diameter
Area of stenosis of ³85%
Immediate post-PTCA stenosis of <50% diameter that increases to ³50% at follow-up
Stenosis with reduction of ³20% in diameter
Loss of ³1 mm^2 in stenosis area
Loss of ³0.50 mm in minimal lumen diameter
Loss of ³0.72 mm in minimal lumen diameter

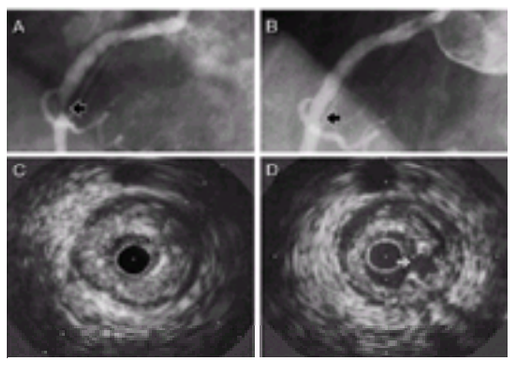
From Serruys PW, Rensing BJ, Hermans WRM, et al. Definition of restenosis after percutaneous transluminal coronary angioplasty: a quickly evolving concept. *J Interv Card* 1991;4:265–276, with

permission.

Several important problems are inherent in the angiographic evaluation of restenosis. First, visual methods of assessing stenosis severity can be inaccurate, especially in the midrange of stenosis estimates (30% to 70%). Simple visual assessments underestimate lesion severity compared to direct inspection at bypass surgery or during necropsy (58,59 and 60). Second, clinically significant intraobserver and interobserver variability is found in visual interpretation, with differences in the estimation of stenosis severity approaching 50% (61,62 and 63). Computer-assisted quantitative coronary angiography (QCA) is used in most current clinical trials because it has been demonstrated to be precise, although it does show some variability due to operator- and computer program–dependent factors. Keane et al. compared ten QCA systems from North America and Europe used in major clinical trials of restenosis. When phantom coronary artery models of known diameter were used, the accuracy of the systems varied from +26% to –1% for 0.5-mm lumen diameters and from –11% to –29% for lumen diameters of 3.0 mm. Therefore, many systems showed a slight overestimation of very small diameters, and all systems consistently underestimated all other diameters tested. For models from 0.5 mm to 1.9 mm, the precision of the ten systems ranged from ±0.14 mm to ±0.24 mm. Keane et al. concluded that this marked variability among systems precludes comparison of absolute measurements from trials using different systems or performed at different centers.

The fourth important limitation to angiographic assessment of restenosis is that angiography depicts a three-dimensional structure (the coronary lumen) in two dimensions. This “luminogram” may misrepresent the true lesion geometry (64) so that important reductions in lumen cross-sectional area may be unappreciated by angiography (*e*Fig. 83.3.5). Many studies report the averaged percent diameter stenosis from two orthogonal views; others have shown the importance of distinguishing this approach from that in which only the worst view is used (65). Finally, angiographic assessment of percent stenosis requires a disease-free reference segment with which the minimal lumen diameter (MLD) of the diseased segment can be compared. Quite often, the reference segment is significantly diseased, so that the stenosis being quantified is underestimated. Using intracoronary ultrasonography, Escaned et al. (66) assessed the “disease-free” reference segment used by QCA and found that, on average, 50% of the total vessel area was occupied by plaque. Despite these limitations and the apparent dissociation between angiographic and clinical outcomes in interventional trials, angiography remains a standard for clinical trials of restenosis. These limitations should be kept in mind when considering individual angiographic reports of restenosis, and the pitfalls of comparing rates of angiographically determined restenosis across different trials should be recognized.



***e*FIGURE 83.3.5 A–D:** Angiographic and intravascular ultrasonographic (IVUS) images of a lesion before and after balloon angioplasty. As can be seen in **B**, a reasonable result by angiography was obtained with little residual stenosis. Inspection with IVUS, however, reveals that this angioplasty result was accomplished primarily by the creation of a single tear in the atheroma. A substantial stenosis remains, and this was not appreciated by angiography. (From Topol EJ, Nissen SE. Our preoccupation with coronary luminology: the dissociation between clinical and angiographic findings in ischemic heart disease. *Circulation* 1995;92:2333–2342, with permission.)

Beyond furnishing an estimate of percent diameter stenosis, quantitative angiography is able to provide a number of indices related to the MLD of the coronary lumen. These indices (Fig. 83.4) can be helpful in understanding the mechanics of restenosis and the effect of different technologies on restenosis. The immediate gain in MLD is simply the final postprocedural MLD obtained with percutaneous revascularization minus the preprocedural MLD. Immediate gain is usually smallest for balloon angioplasty (0.7 to 1.0 mm), intermediate for rotational atherectomy (1.0 to 1.5 mm) and directional atherectomy (1.5 to 2.0 mm), and largest for intracoronary stent placement (1.5 to 2.5 mm). The late loss is the MLD at follow-up angiography minus the final postprocedural MLD. Late loss is proportional to immediate gain, so that it is greatest after stent placement and directional atherectomy, and least after balloon angioplasty. This device “taxing” is a result of the marked reparative response of the vessel wall (i.e., aggressive neointimal proliferation) to deep injury or need for extensive reendothelialization. The net gain is the follow-up MLD minus the preprocedural MLD. Because the immediate gain is so large with intracoronary stents and the late loss is moderate, the net gain is greatest with stents (approximately 1 mm). In limited series directional atherectomy has shown a net gain similar to stent placement, although in other studies has demonstrated a net gain only slightly better than that with balloon angioplasty. Balloon angioplasty and rotational and laser atherectomy usually result in a similarly moderate net gain. Finally, an important concept is the loss index, which is the late loss divided by the immediate gain and represents a “device taxing” for restenosis. The loss index is higher for new device technologies than for balloon angioplasty but may be intermediate for stents (Fig. 83.5**,** *e*Table 83.0.2) (45,67,68,69,70,71,72,73,74,75,76 and 77). If indeed the loss index is similar for different technologies and levels of aggressiveness that achieve the largest immediate gain, the theory that obtaining the largest lumen possible will give the best long-term result might hold true. This theory, called “bigger is better,” has been advanced and is discussed in the section on Procedure-Related Factors.

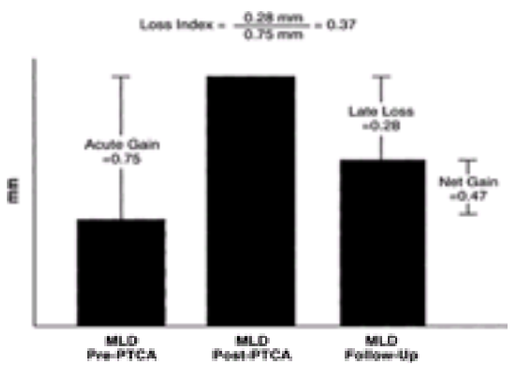


FIGURE 83.4 Indices measured and calculated during serial quantitative coronary angiography. The immediate gain is the change in minimum lumen diameter (MLD) from baseline to immediately after angioplasty. The late loss is the measured difference between the immediately postprocedure MLD and that measured at 6-month follow-up. Net gain is the difference between the follow-up MLD and the baseline MLD (immediate gain minus late loss). The loss index or “tax rate” refers to the fraction or percentage of early gain that is ultimately lost (late loss minute immediate gain). PTCA, percutaneous transluminal coronary angioplasty.

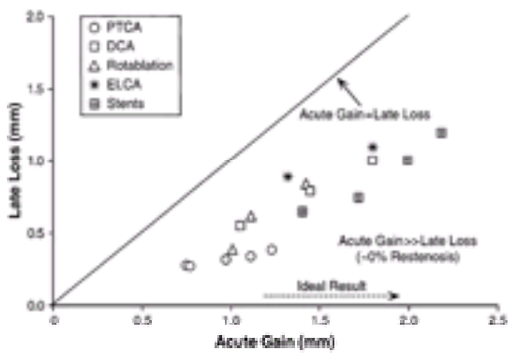

FIGURE 83.5 The loss index for angioplasty and new device technologies is represented as the relationship of late loss to immediate gain. Balloon angioplasty has the lowest loss index but produces a relatively smaller immediate gain. New technologies such as atherectomy produce a large immediate gain but have the highest loss index. Intracoronary stents also produce a large immediate gain with an intermediate loss index and, thus, a more favorable restenosis rate. The ideal revascularization procedure would produce a large immediate gain and have a low loss index. (Data are from *e*Table 83.0.2.) DCA, directional coronary atherectomy; ELCA, excimer

laser coronary angioplasty; PTCA, percutaneous transluminal coronary angioplasty.

When data are pooled from 15 clinical trials (70,71,73,78,79,80,81,82,83,84,85,86,87,88 and 89) that defined restenosis as stenosis of 50% of luminal diameter or more and included a total of over 8,000 patients (Table 83.1), the rate of angiographically determined restenosis is found to average 40% with routine balloon angioplasty. The highest reported restenosis rate in this group (53%) is from the Coronary Angioplasty Versus Excisional Atherectomy Trial (CAVEAT), in which the angiographic core laboratory reported data from the angiographic view demonstrating the severest stenosis, that is, the “worst view” method. Other angiographic trials have used the average of stenosis severity from several views, and this may artifactually lower the reported rate of angiographically identified restenosis. Also, more recent studies using more aggressive angioplasty techniques to obtain an optimally large final lumen diameter and relying on stenting in the case of important dissections report the lowest angiographically determined restenosis rates. The Balloon versus Optimal Atherectomy Trial (BOAT) (87) was conducted 3 years after CAVEAT and compared directional coronary atherectomy to PTCA using a more aggressive approach for both techniques. In the PTCA group, the final residual stenosis was 28%, compared to 36% in CAVEAT. Restenosis in the BOAT angioplasty cohort was 25% lower than that in CAVEAT (40% vs. 53%), and a substantial number of BOAT patients required intracoronary stents. Similarly, the Belgian-Netherlands Stent II (BENESTENT-II) trial (90) reported the lowest rate of angiographically determined restenosis for balloon angioplasty of any large-scale trial, nearly 35% lower than reported in the Belgian-Netherlands Stent I (BENESTENT-I) trial (21% vs. 32%) (71). This is likely attributable to more aggressive balloon dilation.

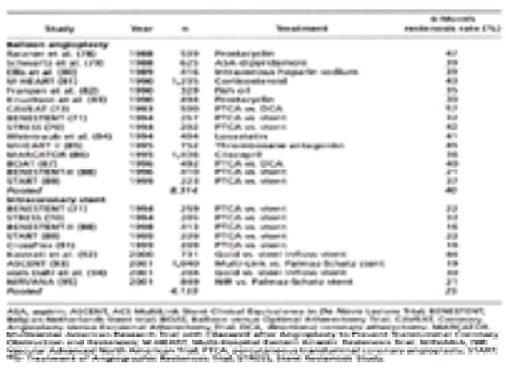

TABLE 83.1 RATES OF ANGIOGRAPHICALLY IDENTIFIED RESTENOSIS

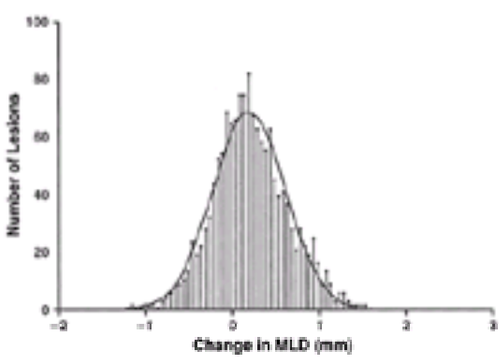
When data are pooled from many trials studying intracoronary stents (70,71,88,89,91,92,93,94 and 95) (Table 83.1), the average 6-month angiographically determined restenosis rate is 25%. These data encompass both early and more contemporary stent designs. Early stent trial data were from studies used to approve the stent design. Because of this, cases were selected and the target lesions were “ideal” for stent placement. A more recent large study reported by Kastrati and colleagues examined 2,944 consecutively treated patients divided into subgroups with simple and complex coronary lesions. Among those with simple lesions (n = 898), the rate of angiographically determined restenosis was 25%, whereas among those with complex lesions (rated B2 and C according to the classification system of the American College of Cardiology and American Heart Association; n = 2,046), the restenosis rate was 33% (45).

Clinically Apparent Restenosis

Restenosis occurs to some extent in all individuals after coronary interventions. Given that the extent of angiographic renarrowing after balloon angioplasty follows a near normal (gaussian) distribution (*e*Fig. 83.5.1) (38,68), all angiographic definitions of restenosis are arbitrary unless they are linked to physiologic or clinically relevant parameters. The clinical return of a significant coronary stenosis most often presents as recurrent angina or a positive result on a stress test. The range of reported rates for chest pain recurrence within 6 months after angioplasty is vast: 25% to 93% (40,96), with an average rate of approximately 50% from pooled data (56). When combined with results of angiographic follow-up, this clinical information becomes difficult to interpret. The proportion of patients presenting with recurrent chest pain who have restenosis demonstrable at angiography ranges from 48% to 92% (56). The average positive predictive value of symptoms alone, therefore, is approximately 60%.



***e*FIGURE 83.5.1** Histogram of the individual changes in minimal lumen diameter (MLD) from the immediately postprocedure angiogram to that at 6-month follow-up for 1,375 lesions. Lesions that progressed to complete occlusion were not included. A positive value corresponds to a decrease in MLD or lumen loss. The curve superimposed on the distribution represents the theoretical gaussian distribution. (From van der Giessen et al. Clinical and angiographic definitions of restenosis: recommendations for clinical trials. In: Schwartz R, ed. *Coronary restenosis*. Boston: Blackwell Scientific Publications, 1993:169–191, with permission.)

Because symptoms are a weak end point or marker of restenosis, “clinical” restenosis could be defined as a clinically serious cardiac event likely related to restenosis. This would include myocardial infarction, cardiac-related death, or revascularization of the target vessel by repeat percutaneous intervention or bypass surgery. Broader definitions of clinical restenosis include a positive stress test result in the territory of the target vessel. Most contemporary clinical PCI trials use a composite end point including target vessel revascularization, myocardial infarction, and death. For example, in the placebo group in the EPIC trial, the late (1- to 6-month) rate of repeat revascularization (18.4%), when hierarchically combined with the rates for myocardial infarction (2.4%) and death (1.8%), produced a composite clinical event rate of approximately 20%. This rate increased to 35% when early postangioplasty events (1 month or less), which are likely related to poor initial outcome rather than restenosis, were included. This same composite rate from immediately postprocedure to 6-month follow-up for the placebo cohort in the Evaluation of PTCA to Improve Long-term Outcomes by c7E3 Glycoprotein Receptor Blockade (EPILOG) trial (97) was 26%. This one-fourth reduction in overall clinically apparent restenosis between the EPIC and EPILOG trials is reflected by an 18% lower target vessel revascularization in EPILOG (Fig. 83.6) and likely indicates a more aggressive revascularization strategy because 14% of the placebo group required intracoronary stents to be placed. More recently, the Evaluation of Platelet IIb/IIIa Inhibitor for Stenting Trial (EPISTENT) reported an approximately 10% rate of target vessel revascularization among patients receiving an intracoronary stent (i.e., roughly half of the patients in the EPIC trial). This reemphasizes the continued change in rates of clinically apparent restenosis in contemporary practice with more aggressive percutaneous revascularization strategies. Thus, given the different ways of estimating clinical restenosis, reported rates in some studies may be as low as 10% if only target vessel revascularization is considered, 30% if all ischemic and revascularization events are considered, or over 50% if any chest pain recurrence is included.

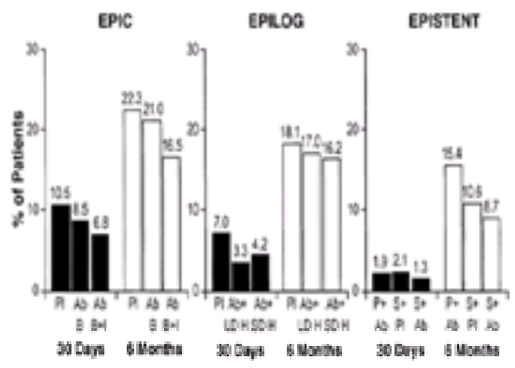


FIGURE 83.6 Target vessel revascularizations (urgent and nonurgent) performed by 30 days and by 6 months in the Evaluation of Chimeric Monoclonal 7E3 for the Prevention of Ischemic Complications (EPIC) trial, the Evaluation of PTCA to Improve Long-term Outcomes by c7E3 Glycoprotein Receptor Blockade (EPILOG) trial, and the Evaluation of Platelet IIb/IIIa Inhibitor for Stenting Trial (EPISTENT). The EPILOG trial, which involved many of the same investigators as the EPIC trial, showed a reduced occurrence in target vessel revascularization compared with the latter. This may be due to evolution of a more aggressive angioplasty technique with bail-out stenting when needed. Likewise, a further reduction in target vessel revascularization was seen in EPISTENT with routine use of intracoronary stents. Ab, abciximab; B, bolus; B+I, bolus plus infusion; LD H, low-dose heparin; P, percutaneous transluminal coronary angioplasty; Pl, placebo; S, stent; SD H, standard-dose heparin.

Silent Restenosis

Asymptomatic or “silent” restenosis can be considered to occur in 10% to 15% of angioplasty patients given that, among all PTCA patients, approximately 40% have angiographically identified restenosis whereas 25% to 30% have symptoms and angiographically apparent restenosis. Specific studies of asymptomatic restenosis are limited; nevertheless, when silent restenosis is defined as stenosis of 50% lumen diameter or more at 6-month angiography and the absence of angina, the rates in individual reports range from 2% to 16% of all angioplasty patients (eTable 83.1.1) (47,48,49,50,51,52 and 53). In these trials of medium-term follow-up, 12% of all patients had silent restenosis, whereas 35% of those with restenosis were asymptomatic. One-third to one-half of asymptomatic patients with restenosis at 6 months develop symptoms in subsequent months (49).

[a]Number of successful PTCA procedures.

The reasons for lack of symptoms despite restenosis may be related to the angiographic definition of restenosis (stenosis of 50% diameter or greater). Some patients probably do not develop ischemia until the lesion is more advanced (stenosis of 70% diameter or more), and several studies have shown that those with asymptomatic restenosis have less severe cases (49,50). Alternatively, vessels that supply nonviable myocardium, along with those previously completely occluded or collateral vessels, may not develop ischemia (49,51). Patients with diabetes may also be more likely to have a silent stenosis recurrence.

NONINVASIVE METHODS FOR CLINICAL EVALUATION OF RESTENOSIS

Because the presence of symptoms is an unreliable marker for restenosis after angioplasty, results of noninvasive cardiac stress tests have been studied by a number of investigators. The attractions of noninvasive tests over repeat angiography include a more favorable procedural cost, time requirement, and risk. When reviewing trials assessing restenosis, one should remember that, to study the accuracy of noninvasive testing, a high percentage of follow-up angiograms are needed to avoid selection bias. In addition, as newer noninvasive modalities have been developed over the past decade that have improved sensitivity and specificity for detecting myocardial ischemia, the angioplasty cases being undertaken have become more complex and often involve multivessel disease, so that the possibility arises of incomplete revascularization or multiple potential sites of restenosis. Early in the evolution of coronary angioplasty, many patients were followed by routine treadmill testing. This test was soon coupled with nuclear scintigraphy, stress echocardiography, or positron emission tomography (PET).

Exercise Treadmill Electrocardiography

Myocardial stress testing with exercise electrocardiography is widely available and has moderate sensitivity for detecting myocardial ischemia. Testing in the early postangioplasty setting can be performed relatively safely within days of the PTCA procedure (98,99), although most clinicians have focused on a 4- to 6-month postprocedure interval because this is when restenosis typically becomes manifest and predictive accuracy is higher. Other factors affecting the usefulness of exercise electrocardiography include the presence of multivessel disease, history of previous myocardial infarction or baseline electrocardiographic abnormalities, and reliability of the preprocedural exercise treadmill testing (ETT). Pooled data from 14 study reports (52,98,100,101,102,103,104,105 and 106) in which restenosis was evaluated using ETT in a total of 2,103 patients indicate that the positive predictive value and negative predictive value of ETT are 55% and 73%, respectively (*e*Table 83.1.2). Although 74% of these patients had only single-vessel disease, the accuracy of ETT was mediocre and virtually the same as reported for symptom status alone. Several studies at Duke University have examined the value of postangioplasty exercise stress testing in detecting restenosis. Bengtson et al. (52) reported the results for 200 patients who had successful elective angioplasty followed by ETT and follow-up angiography approximately 6 months after PTCA without intervening cardiac events. Among clinical and ETT-related variables, only three were independent predictors of angiographically identified restenosis: recurrent angina, exercise-induced angina, and a positive result on the exercise test. In short, the positive predictive value of ETT is moderate, and the negative predictive value is higher in studies in which a greater percentage of patients have single-vessel coronary artery disease or the test is performed later than 1 month after angioplasty.

Nuclear Scintigraphic Evaluation

Adding nuclear scintigraphy to myocardial stress testing yields higher predictive values than for electrocardiography alone, and this is the case in assessment of restenosis. Radionuclide modalities used in evaluating restenosis include exercise radionuclide ventriculography, planar thallium-201 (Th-201) myocardial perfusion imaging, single-photon emission computed tomography (SPECT), and technetium-99 (Tc-99) and rubidium (Rb) PET scanning. Radionuclide ventriculography (sometimes referred to as radionuclide angiography) compares ventricular function at rest and during exercise, whereas Th-201, Tc-99, and Rb scintigraphy are used to assess regional myocardial perfusion. Although the literature contains reports of many studies evaluating the use of radionuclide scintigraphy in detecting restenosis, many are retrospective or are biased due to a low rate of angiographic follow-up.

Several small but well-designed series provide important insight. For example, DePuey and colleagues (107) studied 41 patients using radionuclide ventriculography before, 4 days after, and 4 to 12 months after coronary angioplasty. All patients underwent angiography at late follow-up and were categorized according to degree of angiographically determined restenosis: less than 20%; more than 20% but less than 50%, and 50% or more. Abnormal results of radionuclide ventriculography, defined as less than a 5% increase in ejection fraction with exercise or an exercise-induced wall motion abnormality, were found in 27% of patients with less than 20% restenosis but in 88% of patients with 50% restenosis or more. Patients with 20% to 50% restenosis had an intermediate response. From this study, the negative predictive value of radionuclide angiography in detecting restenosis of 50% or more was higher than in most electrocardiographic studies (94% vs. 74%), but the positive predictive value remained moderate (54%).

The positive predictive value of exercise Th-201 imaging is, on average, higher than that of exercise electrocardiography or radionuclide ventriculography but is still moderate (100,104,107,108,109,110,111,112,113,114 and 115) (*e*Table 83.1.3). This moderate predictive ability again may reflect the diffuse nature of coronary atherosclerosis with significant disease in small vessels or at untreated sites, which produce a false-positive result for restenosis. In addition, exercise thallium scanning abnormalities seen in patients before angioplasty frequently persist in the early days after angioplasty and are possibly attributable to depressed coronary flow reserve. Manyari et al. (116) performed sequential thallium perfusion studies in 43 patients before and at approximately 9 days, 3 months, and 6 months after successful angioplasty. Only patients with single-vessel coronary artery disease, without prior myocardial infarction, and without restenosis at 6- to 9-month follow-up angiography were included. Although symptoms and exercise treadmill results improved immediately and remained normal after PTCA, 28% of patients had persistently abnormal thallium perfusion scans 4 to 18 days after angioplasty. The perfusion defects in the distribution of the treated stenosis progressively improved from baseline in studies at 4 to 18 days, and from results at 4 to 18 days in studies at 3 months. As with exercise electrocardiographic evaluations, planar perfusion scans performed very early after PTCA may have limited usefulness, and the best course is usually to postpone assessment for restenosis to at least 1 month after angioplasty. In summary, for combined data from 12 nuclear studies assessing restenosis in approximately 700 patients, the positive and negative predictive values are 70% and 89%, respectively (*e*Table 83.1.3). The highest accuracy is for SPECT imaging (positive predictive value of 82% and negative predictive value of 92%), and this modality is therefore recommended.

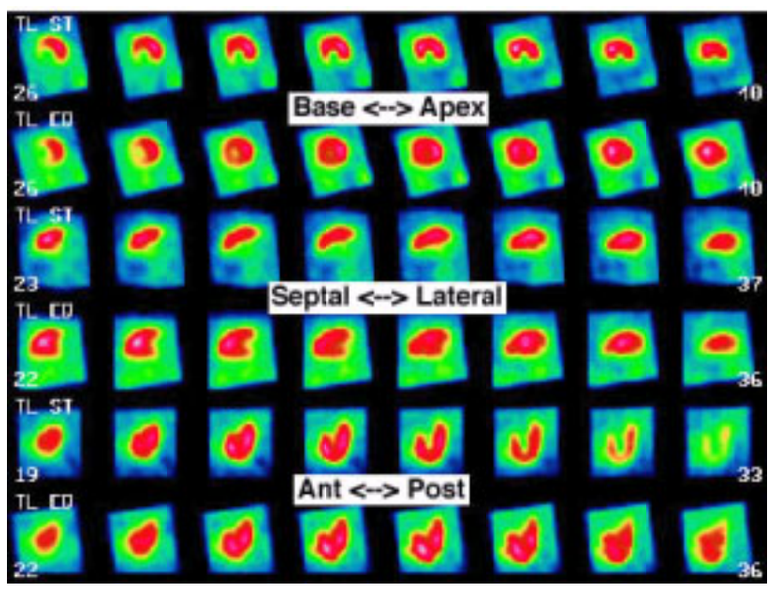
[c]Studied symptomatic patients only.

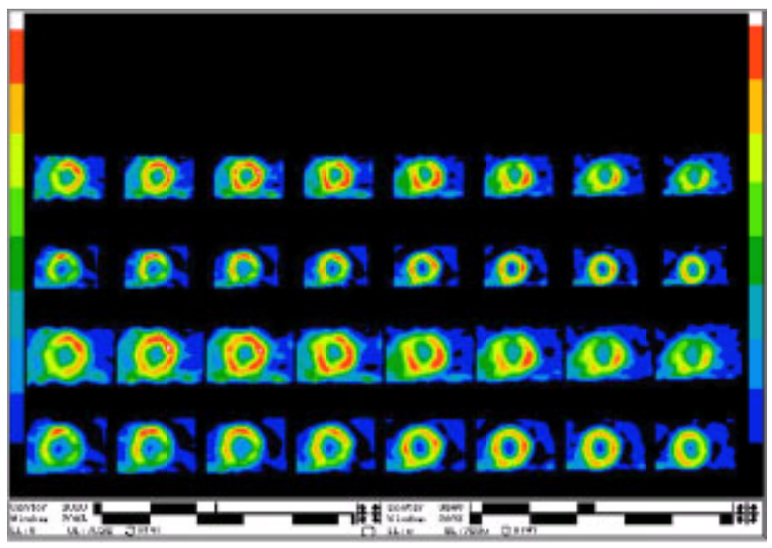
A careful prospective study of noninvasive assessment of restenosis was performed by Wijns and colleagues (100) and encompassed 89 patients who had undergone successful primary PTCA. All patients underwent exercise electrocardiography and thallium scintigraphy at 4 weeks and repeat catheterization within 6 months after angioplasty. Angiographically identified restenosis occurred in 35% of patients. The predictive accuracy of thallium perfusion scintigraphy for restenosis was 74%, compared to 50% for exercise electrocardiography alone. The authors demonstrated the insignificant contribution of electrocardiography compared with Th-201 imaging in this series. SPECT thallium imaging more effectively localizes the coronary vascular territory of ischemia than planar imaging techniques and may be advantageous in patients with known multivessel coronary artery disease or incomplete revascularization after PTCA. To study this, Hecht and colleagues (110) performed SPECT Th-201 imaging in 116 patients before performing repeat cardiac catheterization for possible restenosis. Among these patients, a similar number had had single-vessel angioplasty and multivessel angioplasty, and 77% achieved complete revascularization. Whereas exercise electrocardiography alone had a predictive accuracy of 52%, SPECT Th-201 imaging accurately identified restenosis in 86% of sites. Results were similar for patients with partial and complete revascularization. In addition, 81% of diseased nondilated vessels were correctly identified by tomographic thallium imaging.

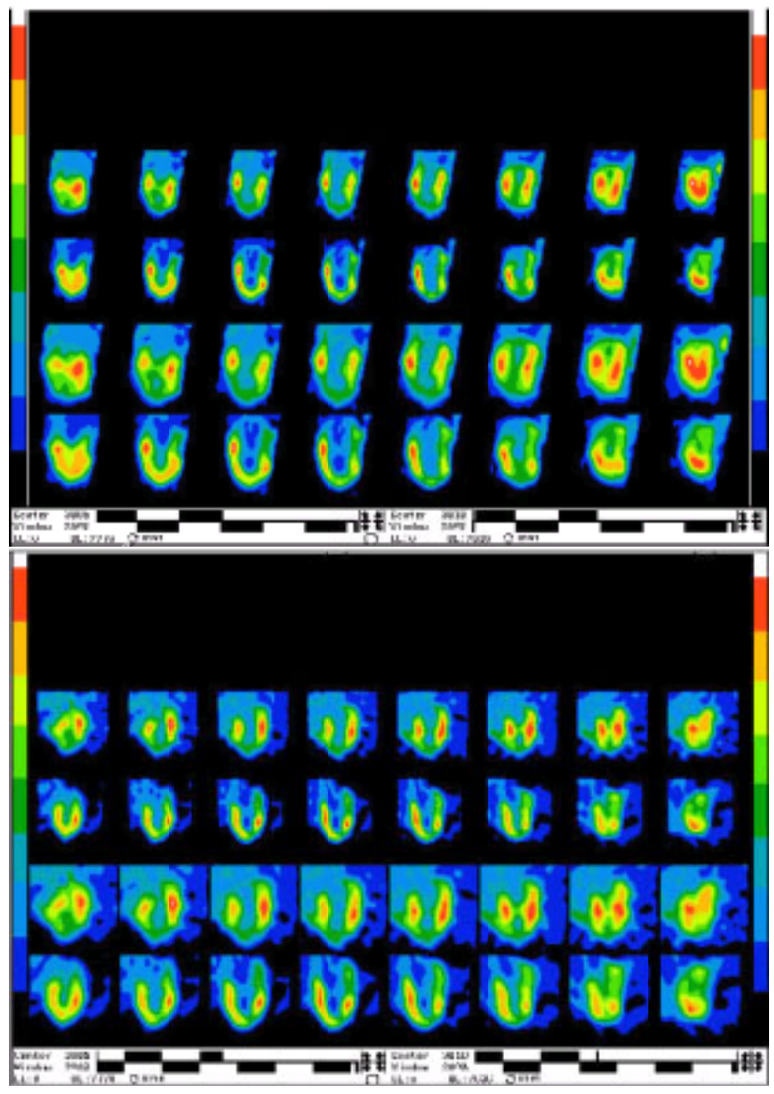


Thallium-201 single-photon emission computed tomography stress and equilibrium images. Transverse, sagittal, and coronal plane images demonstrating inferior and posterior wall ischemia in a patient with a severe proximal stenosis in a dominant right coronary artery.

Additional Noninvasive Methods

Several additional nuclear and nonnuclear imaging modalities, such as PET, isonitrile imaging, and stress echocardiography, have been studied more recently to determine their predictive ability for restenosis. Each of these modalities provides unique information or benefit. For example, by using different isotopes, PET studies can quantitate regional myocardial metabolism as well as perfusion, whereas isonitrile imaging or stress echocardiography can provide assessment of myocardial perfusion and wall motion. Several studies of exercise or pharmacologic stress echocardiography have been completed (106,112,113,114 and 115). Using supine bicycle stress echocardiography to detect restenosis in 80 patients with 129 treated sites, Hecht et al. (113) reported a sensitivity and specificity of 87% and 95%, respectively, for this test. This high sensitivity may be due, in part, to the high rate of restenosis (56%) and incomplete revascularization (32%) among patients in the study group. Overall, the positive predictive value and negative predictive value for stress echocardiography in over 500 patients are 84% and 76%, respectively (*e*Table 83.1.3).





Resting rubidium-82 with fluorinated deoxyglucose viability positron emission tomographic scanning in a 63-year-old patient in the transverse (*first image*), sagittal (*second image*), and coronal (*third image*) plane images demonstrating hibernating myocardium involving the mid and distal anterior, mid and distal anteroseptal, and distal septal segments. Matched perfusion and metabolic defects are seen involving the apical and inferoapical segments. The right anterior oblique left ventriculogram (*first video*) also shows the presence of hibernating myocardium, due to occlusion of a "wrap around" left anterior descending coronary artery. The mid and distal anterior, apical, and inferior apical walls are akinetic. The anteroposterior cranially angulated angiogram (*second video*) demonstrates subtotal occlusion of a large "wrap around" left anterior descending coronary artery in the same patient with a dominant left coronary artery.

In summary, the predictive accuracy of symptom occurrence for restenosis is, at best, moderate and is not significantly improved by the use of exercise electrocardiography. The addition of imaging by nuclear scintigraphy or echocardiography increases both the positive and negative predictive value of testing to approximately 80%. SPECT imaging with thallium or technetium-99m sestamibi have respectably high accuracy, and more recent data show stress echocardiography to be similarly accurate. These are the leading choices for noninvasive assessment of restenosis. Testing is most reliable between 1 and 5 months after revascularization.

CLINICAL PROFILE

Although no favorable variable has been identified that assures freedom from restenosis, and none has been identified that makes restenosis inevitable, several factors clearly influence the likelihood of restenosis. A large number of clinical, anatomic, and procedural variables have been associated with restenosis in various studies. Many of these observations, however, were from retrospective or small prospective studies, so some findings have been inconsistent. Large pharmacologic or device trials with high rates of angiographic follow-up have been most helpful. Importantly, many factors that were shown to be associated with restenosis after balloon angioplasty are no longer predictive of restenosis in the stent era. Table 83.2 lists factors reported to be associated with restenosis. Factors that have been independent predictors in multivariable modeling or consistently associated in many balloon angioplasty studies are printed in italics, as are similar factors for stent procedures. Factors associated with stenosis recurrence can be categorized as related to the patient, to the lesion, or to the procedure.

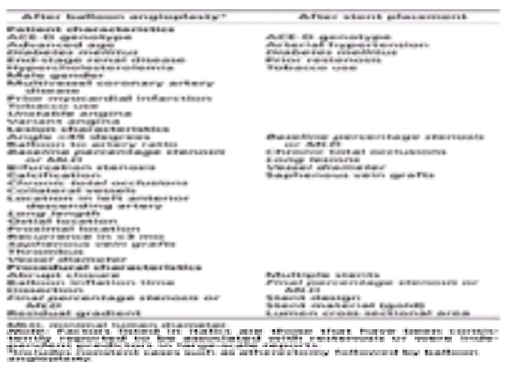

TABLE 83.2 CHARACTERISTICS ASSOCIATED WITH RESTENOSIS

Patient-Related Factors

Patient characteristics (e.g., age, race, gender, etc.) obviously have the same effect for all coronary lesions within the given individual. Weintraub et al. (117) showed that the leading predictor of restenosis for a particular lesion among patients undergoing multisite angioplasty was the occurrence of restenosis at the other treated sites. The list of patient-related variables considered in predictive models of restenosis is extensive and includes demographic characteristics, medications, concomitant medical diseases, serologic markers, and genetic polymorphisms. Large-scale clinical trials of restenosis have not revealed any consistent age-, race-, or gender-related patterns. At this time, only two patient-related risk factors have certain effects on restenosis: diabetes mellitus and unstable angina pectoris.

Demographics

Age and gender are believed not to affect restenosis, although patients of advanced age and female patients are occasionally reported to have less favorable clinical outcomes. Male gender was associated with restenosis in several older angioplasty studies (47,54), but the angioplasty equipment used in these early studies is now believed to have been undersized for the larger coronary arteries of men and thus would have left a greater residual stenosis than in female patients. More recent data have not found a gender effect in lesion recurrence. For example, among the 510 patients in the Multi-Hospital Eastern Atlantic Restenosis Trial (M-HEART) study group, restenosis was angiographically present in 39% of men and 42% of women (118). Similarly, an association between cigarette smoking and restenosis has been variably reported, but again, more recent data (56,118,119) from larger studies with greater angiographic follow-up have failed to demonstrate an association. In large-scale series of intracoronary stenting, no demographic characteristics other than the presence of diabetes mellitus has been associated with restenosis.

Diabetes Mellitus

Just as diabetes is a strong risk factor for atherosclerotic heart disease, with insulin dependency producing a higher risk, so too is diabetes an important risk factor for restenosis. This association was found first in early NHLBI PTCA Registry data (47), and a series of subsequent reports (120,121 and 122) demonstrated the relative risk of restenosis among patients with diabetes to be approximately 1.3 compared with that of patients without diabetes. Although the exact degree of risk for patient groups with type I and type II diabetes is uncertain, several studies have shown insulin-dependent diabetes to be associated more often with restenosis (123,124). Other investigations have examined this association with restenosis by studying glycosylated hemoglobin levels, insulin levels, or microalbuminuria. Regardless, the mechanisms leading to restenosis among diabetic patients are multiple (125,126,127,128,129,130,131,132,133,134,135,136,137,138,139,140,141,142,143 and 144) (Table 83.3) and vary in effect between those with type I and type II diabetes and among patients with type II diabetes depending on insulin use (145,146). High glucose concentrations and the presence of advanced glycosylation end products inhibit endothelial cell function in several ways, including by decreasing production of endothelium-derived relaxing factor and prostacyclin, and by retarding cellular replication during reendothelialization (Table 83.3). Because the process of endothelial cell regeneration at the site of vessel wall injury is slowed, the triggers of intimal hyperplasia linger, which may explain the greater neoproliferative response of diabetic patients (124,147). In an animal model of restenosis, Van Belle et al. demonstrated a reduction of in-stent intimal formation and restenosis by accelerating endothelialization with local delivery of vascular endothelial growth factor (148).

Endothelial dysfunction
↓ Endothelium-derived relaxing factor (EDRF) (131,144)
↓ Prostacyclin (133,138)
↓ Endothelial cell replication (134,140)
↑ Endothelin-1 production (126,135)
↑ Platelet-derived growth factor (PDGF) (128)
Heightened platelet activity
↑ Number of activated platelets (137)
↑ Platelet adhesiveness (141)
↑ Platelet aggregability (140)
↑ Thromboxane A_2 synthesis (139,140)
↑ PDGF (140)
↑ Fibrinogen levels (132)
Increased growth factors
↓ EDRF (125,136)
↑ PDGF (142)
↑ Insulin-like growth factor-1 (129,130)
↑ Endothelin-1 (125)
↑ Fibroblast growth factor (127)
↑ Transforming growth factor-β (143)

↑, increasing; ↓, decreasing.

TABLE 83.3 POSSIBLE MECHANISMS BY WHICH DIABETES AFFECTS RESTENOSIS

Platelets are known to exist more frequently in an activated state in diabetic patients despite clinical absence of vascular inflammation or injury (137). Similarly, in patients with diabetes, platelets have been shown to be more adhesive and aggregable when stimulated. These and other hypercoagulable features of diabetic patients (Table 83.3) likely contribute to the restenosis process. Finally, the endothelial and platelet abnormalities of diabetic patients allow growth factor promotion. The normally functioning endothelium and platelets serve to inhibit or suppress medial smooth muscle cell growth, and derangements in these systems enhance expression of mitogens such as PDGF, TGF-b, and bFGF (Table 83.3). Because of these multiple mechanisms leading to restenosis, the contemporary approach to treating patients with diabetes is aggressive.

The NHLBI presented a national health alert based on the findings of the Bypass Angioplasty Revascularization Investigation (BARI) study (149) showing patients with diabetes to have a worse 5-year survival rate after multivessel angioplasty than after bypass surgery (66% vs. 81%), perhaps in part due to late or silent restenosis. On the other hand, the survival curves for diabetic patients treated by angioplasty or bypass surgery in BARI separate slowly over a several-year period, so that restenosis is unlikely to be a primary explanation for the survival difference. A survival difference between diabetic patients undergoing percutaneous revascularization and those undergoing surgical revascularization has not been reported by any other prospective clinical trial (150) nor was this observed in the BARI registry of approximately 2,000 patients. A multicenter database encompassing nearly 16,000 patients undergoing a first revascularization also showed patients with diabetes to have a worse outcome after angioplasty than after bypass surgery, but on multivariable analysis of survival, no interaction of revascularization type and diabetes was present (151). Beyond balloon angioplasty, studies of directional, rotational, and laser atherectomy have shown diabetic patients to experience restenosis more often than nondiabetic patients.

The use of intracoronary stents has not ameliorated the effect of diabetes on restenosis. Combined data from four separate reports including nearly 3,300 patients (123,152,153 and 154) showed that angiographically identified restenosis occurred in 35% of diabetic patients and 23% of nondiabetic patients when contemporary stenting methods were used. Patients with diabetes were also more likely to undergo target vessel revascularization by 6-month follow-up than were nondiabetic patients (22% vs. 15%). Kastrati et al. reported diabetes to be a leading independent risk for restenosis in multivariable modeling based on data from over 4,500 consecutive patients. Diabetes was associated with an increase in rate of angiographically apparent stenosis from 31% to 35% and an odds ratio of 1.21 (155). Similarly, after directional atherectomy, diabetic patients in CAVEAT-I had greater late loss and restenosis than nondiabetic patients (156). That patients with diabetes have greater late loss after angioplasty, atherectomy, and stenting reemphasizes the biologic effects of diabetes. Using serial intravascular ultrasonography, Kornowski et al. (157) showed that the late loss after angioplasty among diabetic patients was due to exaggerated intimal hyperplasia. Interestingly, in EPISTENT, the combination of intracoronary stent placement and platelet glycoprotein IIb/IIIa inhibition did lead to clinically and angiographically determined restenosis rates that were low and similar among patients with and without diabetes (158). The rate of target vessel revascularization at 6 months was 8.1% and 8.8% for patients with and without diabetes, respectively (Fig. 83.7). Aside from this report, most data support the concept that, even with aggressive revascularization strategies, diabetic patients have restenosis and recurrent ischemic events more often than nondiabetic patients.

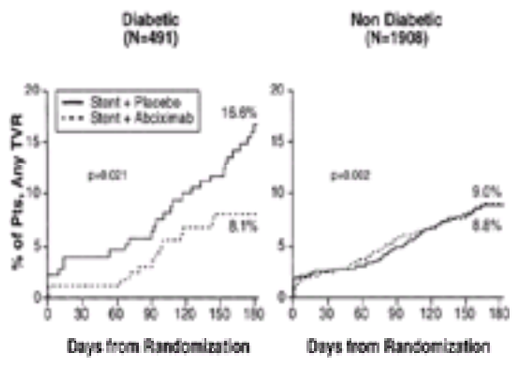

FIGURE 83.7 Kaplan-Meier distribution curves for the likelihood of restenosis among diabetic and nondiabetic patients in the Evaluation of Platelet IIb/IIIa Inhibitor for Stenting Trial (EPISTENT). As seen in previous stent trials, diabetic patients had a higher rate of target vessel revascularization (TVR) than did nondiabetic patients. In contrast, diabetic patients receiving abciximab during intracoronary stent placement had a low 6-month rate of target vessel revascularization similar to that of nondiabetic patients.

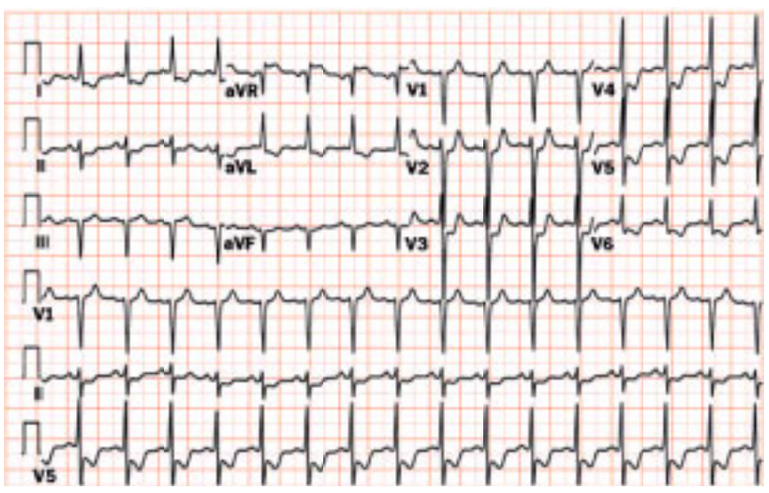
Unstable Angina

Like diabetes, unstable angina has been consistently associated with restenosis, especially when unstable angina is defined as pain at rest or accompanied by ischemic changes in the electrocardiogram. Because unstable angina defined in this way is often associated with thrombus-containing coronary lesions, the view that restenosis occurs acutely from clot propagation and chronically from clot transformation is plausible. Over the hours to days after angioplasty in the setting of a ruptured plaque, thrombus may propagate and organize to cause a substantial loss in lumen diameter. Thrombin present within the clot facilitates the release and heightened activity of several mitogens, including PDGF and bFGF, thereby promoting cellular proliferation and clot transformation into a neointimal thickening. The contents of the underlying plaque in unstable angina may also directly promote restenosis. Moreno and colleagues (159) studied 50 atherectomy specimens from patients with unstable angina. By careful immunocytochemical study of the tissue removed, they were able to demonstrate that lesions with subsequent restenosis had twice as large an area of macrophage-rich tissue within the plaque. In the lesions studied, the number of macrophages present was the only independent predictor for restenosis by logistic regression analysis. Macrophages are known to be increased in plaques from patients with unstable angina (160), and they release cytokines, metalloproteinases, and growth factors that may lead to neointimal growth and constrictive scarring of the adventitia.



Subendocardial ischemia. Anterolateral ST-segment depression is consistent with diffuse subendocardial ischemia versus non–Q-wave myocardial infarction.

Unstable angina vs. non–Q-wave myocardial infarction. ST-segment depression in leads V_2 through V_5 supports acute ischemic syndrome.

Clinically, several trials have reported an increased occurrence of restenosis among patients with new-onset angina (less than 2 months) (47,54), accelerating angina (161), or rest angina (162). The degree of symptom instability appears to be directly proportional to the subsequent event rate. Taken together, these and other balloon angioplasty trials (163) suggest that the relative risk of restenosis in those with unstable angina is 1.2 to 1.4 times higher than in patients with no or stable angina. Among patients receiving an intracoronary stent, unstable angina has not been consistently associated with restenosis.

Lipoprotein Levels

Several small studies reported an association between restenosis and the levels of various lipoproteins, including triglycerides (164), total cholesterol (119), low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol (164), and lipoprotein(a) [Lp(a)] (165,166 and 167). For each of these lipoproteins, however, a corresponding study has been carried out showing no association with restenosis (168,169). The reasons for this disparity include small sample sizes, nonnormal distributions of the levels of some lipoproteins, and changing levels of lipoproteins associated with acute coronary syndromes, hospitalization, and cardioactive medications. Moreover, dynamic changes in atherosclerotic plaque progression and regression cannot be angiographically separated from restenosis. Pooled data from the Coronary Artery Restenosis Prevention on Repeated Thromboxane-Antagonism (CARPORT) (170), Multicenter European Research Trial with Cilazapril after Angioplasty to Prevent Transluminal Coronary Obstruction and Restenosis (MERCATOR) (69), Multicenter American Research Trial with Cilazapril after Angioplasty to Prevent Transluminal Coronary Obstruction and Restenosis (MARCATOR) (86), and Post-Angioplasty Restenosis Ketanserin (171) studies reported no association—either by categoric or continuous variable approaches—between serum total cholesterol or cholesterol subfractions and angiographically identified restenosis (172). Furthermore, studies targeting the reduction of lipoproteins, in particular LDL cholesterol, have shown no reduction in restenosis (84).

Lp(a) has been specifically studied in the setting of restenosis because the Lp(a) gene is among the most polymorphic genes in the human genome, and plasma levels of Lp(a) are wide ranging in the population. Desmarais et al. (166) studied 200 consecutively treated patients undergoing balloon angioplasty for whom lipoprotein fractions, including Lp(a), were simultaneously measured. Patients were evaluated 4 to 6 months after angioplasty by treadmill testing or coronary angiography when clinically indicated. Patients with clinically identified restenosis had significantly greater Lp(a) concentrations than those without restenosis. The odds ratio for clinically apparent restenosis was substantially higher for each increasing quintile concentration of Lp(a). The investigators did not genotype these patients nor did they perform consistent quantitative angiographic follow-up. Yamamoto et al. (173) and Miyata et al. (174) separately found Lp(a) to be associated with angiographically determined restenosis in small studies of Japanese patients. Lp(a) levels of 30 mg per dL or higher predicted a greater than twofold increase in restenosis. Because Lp(a) is strongly associated with the development of coronary artery disease, investigators who have not found an association between Lp(a) and restenosis have suggested that recurrent clinical ischemia is due to disease progression or new disease formation, rather than restenosis of the target lesion (175). Levels of Lp(a), as well as of HDL, LDL, and total cholesterol, were systematically studied in 671 consecutively treated patients at stent implantation and angiographic follow-up by Wehinger et al.

(176). No correlation was found between late loss or restenosis and the level of any lipoprotein. In short, although lipoproteins are clearly related to *de novo* atherosclerotic lesion progression and regression, an effect of lipoproteins on the process of restenosis is not substantiated except possibly for Lp(a).

Genetics of Restenosis

Coronary artery disease and stenosis recurrence after PTCA are likely complex processes involving multiple genes as well as interactions with many nongenetic factors. Considering balloon angioplasty cases, Berger and colleagues performed a retrospective analysis of 144 treated lesions in 113 patients and found the rate of restenosis to be 35% among patients with a history of restenosis at a different coronary site and 27% among patients without such a history (177). This observed difference did not reach statistical significance in this report but has reached significance in several others (117,178), and these findings suggest that a history of restenosis at one site increases the likelihood of restenosis at future sites. Some data also suggest that patients undergoing multivessel PTCA have a patient-specific risk of restenosis that is separate from lesion-related factors (117). Considering this concept in the stent era, Kastrati and colleagues analyzed a series of 3,370 consecutively treated patients, more than 80% of whom had follow-up angiography at 6 months. Using a multivariate model for restenosis, they found that 12% of the predictive value for restenosis was patient specific. The remaining factors were lesion related (54%) or procedure related (34%) (179). Obviously, genetic determinants of restenosis could explain some of the patient-related factors. Indeed, examining the distribution of angiographically determined stenosis diameter 6 months after stent placement, Schömig et al. (180) showed the frequency distribution curves to be bimodal, which suggests two different populations with different propensities for restenosis (Fig. 83.8).

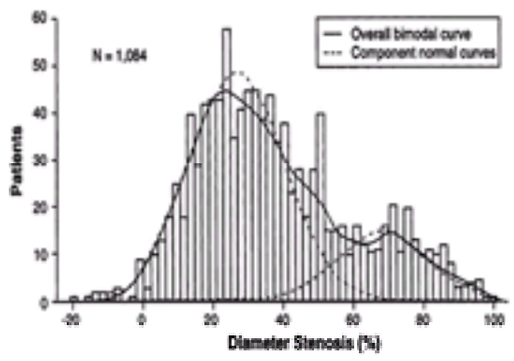


FIGURE 83.8 Distribution of percentage diameter of stenosis at follow-up angiography for 1,084 patients receiving an intracoronary stent. The overall curve appears bimodal, which suggests the existence of two separate populations or components of the normal curve. These two populations appear to have divergent propensities for restenosis, which implies a genetic or populational basis for restenosis. (From Kastrati A, Dirschinger J, Schömig A. Genetic risk factors and restenosis after percutaneous coronary interventions. *Herz* 2000;25:34–46.)

Several genomic studies have assessed the relationship between restenosis and a particular gene, locus, or combination of genes, including the angiotensin-converting enzyme (ACE) gene, HLA-C locus Cw1, apolipoprotein E (apoE) genes (181), and platelet glycoprotein IIb/IIIa polymorphisms. Experimental studies support the hypothesis that the renin-angiotensin system plays a role in the pathogenesis of restenosis (182), and ACE inhibitors have been shown to prevent neointimal thickening after angioplasty in animal models. In humans, the presence of the ACE deletion (ACE-D) allele is associated with higher tissue and plasma levels of ACE and has been identified as a potential risk factor for myocardial infarction (183). In 1993 Ohishi et al. (184) reported presence of this ACE deletion to be a potent genetic risk factor for coronary restenosis. In this relatively small study of patients undergoing emergency angioplasty for acute myocardial infarction, the investigators found a greater likelihood of angiographically identified restenosis among those with the ACE-D allele. Subsequent studies have not been consistent. Hamon et al. (185) studied 118 consecutively treated patients with single-vessel coronary artery disease after successful angioplasty. In this quantitative study, the ACE gene polymorphism had no influence or association with angiographically apparent restenosis. A similar negative finding was reported by Samani et al. (186) for 233 patients in the Subcutaneous Heparin Angioplasty Restenosis Prevention study.

Table 83.4 summarizes studies assessing the ACE polymorphism as it relates to angiographically determined restenosis (184,185,186,187,188,189,190 and 191). When data were pooled for 640 patients after balloon angioplasty, the odds ratio for restenosis for patients with the deletion genotype was 1.3 relative to patients with the insertion genotype. When this relationship was assessed among patients after coronary stenting, the odds ratio was 1.2 (95% confidence interval, 0.9 to 1.5). Important, however, is the wide variability in odds ratios among studies. This is likely due to the small sample size in most studies. As can be seen, the larger studies found the smaller odds ratios, and their results suggest no or minimal effect of ACE genotype. Addressing this issue, Koch et al. (190) prospectively studied 1,850 consecutively treated patients undergoing stent implantation. The ACE-DD genotype was not associated with angiographically apparent restenosis at 6 months (odds ratio of 0.9), nor did this genotype influence 1-year clinical outcome. In summary, the likely contribution of the ACE-deletion genotype alone to restenosis is minor.

TABLE 83.4 ACE-DD POLYMORPHISM AND RESTENOSIS

The reason for these inconsistent reports may be the multifactorial nature of restenosis, small sample sizes, or reporting bias. Although atherosclerotic coronary artery disease is believed to be a complex polygenic process, data considering restenosis as a polygenic process are limited. van Bockxmeer et al. (187) examined the combined influence of ACE and apoE genotypes on restenosis. Two hundred seven patients were systematically studied with angiographic follow-up. The distribution of the ACE genotypes did not predict restenosis, whereas the $apoEe_4$ genotype was more frequent among those with restenosis. More importantly, among those who had the combination of ACE-D and $apoEe_4$, the likelihood of restenosis was increased by 16-fold. In addition, multiple linear regression comparing the degree of lumen loss at follow-up angiography as a continuous variable revealed a significant independent effect of the ACE and apoE genotypes. These data suggest that, although the ACE genotype alone may not influence restenosis, important interactions may occur with other genes, such as the apoE gene. Understandably, advanced technologies are needed to step beyond this candidate gene approach and perform genomic studies of restenosis on a larger scale.

As genetic polymorphisms newly suspected to affect restenosis are studied, a wide variability in the predicted importance of these genes (or lack thereof) will be observed. For example, several studies have considered the association between platelet $a_{IIb}b_3$ (PI^A) polymorphism and restenosis after percutaneous coronary intervention. This particular polymorphism is associated with the gene encoding the platelet glycoprotein IIb/IIIa receptor and has been variably reported to affect the development of precocious atherosclerosis, myocardial infarction, and restenosis. As with the ACE polymorphism, not until large-scale evaluations are performed can the certainty and degree of effect for particular genes be determined.

Lesion-Related Factors

*De Novo**versus Restenotic Lesions***

The question of whether a prior restenosis portends a higher likelihood of restenosis at the same site has been the subject of great interest. Several studies have shown that the likelihood of restenosis after balloon angioplasty of a restenotic lesion (i.e., a second PTCA of the same site) is similar to that after angioplasty of a *de*

novo lesion (192,193,194 and 195). Comparing separate reports of restenosis after first and subsequent interventional procedures is difficult because the percentage of patients undergoing follow-up angiography has been low. In general, the reported rate of angiographically identified restenosis for lesions treated a second and third time by balloon angioplasty is approximately 40% (155,194,196,197,198,199,200,201,202,203,204,205,206 and 207) (eTable 83.4.1), which is similar to rates cited for *de novo* lesion balloon angioplasty in past years (Table 83.1). Bauters and colleagues, in a series of reports on a limited number of balloon angioplasty patients (196,197,208), showed that the rate of restenosis was similar after a first, second, and third angioplasty among patients within the same institution. The occurrence of restenosis does increase substantially in patients who undergo a fourth PTCA procedure or who undergo a second or third angioplasty less than 3 months after the previous procedure (197). Several studies using multivariate models to predict restenosis among those undergoing repeat angioplasty have shown time to retreatment of 3 months or less to be the strongest predictor (197,200,201). Intracoronary stents are now routinely used to treat restenotic lesions, and favorable results have been reported (155,205). Several studies comparing *de novo* versus restenotic lesions have shown 6-month target vessel revascularization and restenosis rates to be higher when stents are placed in restenotic lesions (155,209,210 and 211), increasing from approximately 30% to 36%.

Vessel

In general, saphenous vein grafts have a substantially higher rate of restenosis than native coronary arteries after balloon angioplasty and somewhat higher rates after stent placement. In the M-HEART study of 510 patients with angiographic follow-up, the highest restenosis rate (68%) was found for saphenous vein graft lesions (212). Within saphenous vein grafts, stenoses tend to recur more commonly for lesions at the proximal anastomosis or in the shaft of the conduit, although data remain limited (213,214). More recent data on saphenous vein graft intervention suggest that the predictors of restenosis are more similar to those for native coronary vessels (i.e., vessel size, residual MLD, lesion ulceration) than previously considered (215). In a randomized trial in which 220 patients with vein graft stenoses were treated with either balloon angioplasty or stent placement, the 6-month restenosis rates were 46% for the group undergoing angioplasty and 37% for the group given stents (216). For native coronary arteries, the highest rate of restenosis after balloon angioplasty has been for the left anterior descending artery (LAD). M-HEART investigators reported restenosis in 45% of LAD lesions (Fig. 83.9), compared with 31% and 32% for lesions of the left circumflex artery and right coronary artery, respectively. Considering 3,736 lesions from several large-scale trials, Foley et al. (217) found only location in the LAD to independently predict a greater loss and smaller MLD at follow-up. Similarly, Weintraub and colleagues (218) showed LAD location to be among the highest independent predictors of restenosis among 11,337 patients. The mechanism of increased restenosis after balloon angioplasty of the LAD is uncertain. Speculations include the possibility that the LAD may be undertreated because it is usually the largest coronary segment on which intervention is performed, and it has more recoil because of its course along the muscular interventricular septum.

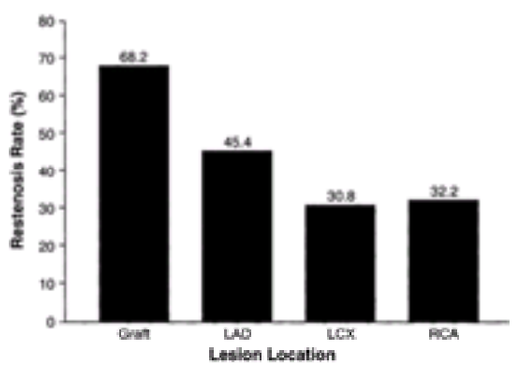

FIGURE 83.9 The vessel treated was found to be an independent predictor for restenosis for 598 treated sites in the Multi-Hospital Eastern Atlantic Restenosis Trial (chi-square *p* value for vessel = .003). The height of each column represents the restenosis rate for each group of segregated lesions. Graft, saphenous vein graft conduit; LAD, left anterior descending artery; LCX, left circumflex artery; RCA, right coronary artery. (Adapted from Hirshfeld JWJ, Schwartz JS, Jugo R, et al. Restenosis after coronary angioplasty: a multivariate statistical model to relate lesion and procedure variables to restenosis. *J Am Coll Cardiol* 1991;18:647–656, with permission.)

Placement of intracoronary stents likely minimizes the effect of the LAD predisposition toward restenosis, because in the Stent Restenosis Study (STRESS) the restenosis rate for stented LAD lesions was similar to that for the other coronary arteries (70). Phillips et al. (219) suggested that LAD location lowered restenosis for patients receiving an intracoronary stent, which is a plausible tenet because larger vessel size is associated with lower restenosis rates. Two separate and sizable reports have since shown that LAD location is not a predictor of restenosis with intracoronary stent placement. The pooled data from BENESTENT-I, BENESTENT-II, and Multicenter Ultrasound Stenting in Coronaries (MUSIC) studies gathered by Serruys et al. (220) showed vessel size and residual diameter of stenosis alone to be the best predictors of restenosis, whereas Schömig and colleagues (155) found no independent predictive value from LAD lesion location.

Vessel Location or Site

Within the LAD, the likelihood of restenosis after balloon angioplasty increases as the stenosis approaches the ostium and is highest for sites within 5 mm or less of the ostium (221). Boehrer et al. (222) showed that ostial LAD and proximal LAD stenoses have a similarly high rate of restenosis after directional atherectomy or balloon angioplasty, whereas other reports have shown that proximal lesions have a higher rate of restenosis than those in distal segments (54,86,223). Aorto-ostial lesions (right coronary artery, left main coronary artery, saphenous vein graft) should be considered separately from non–aorto-ostial or branch vessel stenoses, because several studies have shown that aorto-ostial lesions have a higher occurrence of complications and restenosis (224,225). That aorto-ostial lesions are more likely to undergo restenosis is probably due to elastic recoil of the aorta around the vessel ostia as well as the simultaneous presence of rigid fibrotic plaque. Similarly, bifurcation lesions and stenoses within bends have occasionally been reported to show higher restenosis rates, likely owing to the often diffuse and complex development of plaque involving a bend or ostium of a branch vessel (225). Because lesions in branch vessel ostia, bifurcations, and angled segments of arteries are generally considered to portend increased risk and worse outcome, they may be underrepresented in prospective and retrospective studies. Their independent effect on restenosis has been variably reported (218,226). Likewise, the prospective stent data are limited because most clinical trials exclude patients with ostial and bifurcation target lesions.

Vessel Size

Several large-scale studies have reported an inverse relationship between vessel size and restenosis. Separating reference vessel diameters into quartiles, the M-HEART investigators found the restenosis rate to decrease from 44% to 36% after balloon angioplasty when vessel size was greater than 2.9 mm (Fig. 83.10). Likewise, vessel diameter was one of the few variables found independently to predict restenosis in MARCATOR (86). Foley and colleagues pooled data from several large pharmacologic trials of restenosis to assess the influence of vessel size on restenosis using quantitative coronary angiography (217). Lesions from over 3,000 patients were systematically studied and, by multiple linear regression analysis, increasing coronary vessel size was noted independently to predict decreasing late lumen loss and increasing MLD. The investigators concluded that the maxim “Bigger is better” (referring to a larger postprocedural lumen) should be modified to “Bigger vessels have a better outcome.” In the large registry report from Emory University (218), the odds ratio for restenosis was 0.86 per 1-mm increase in vessel size.

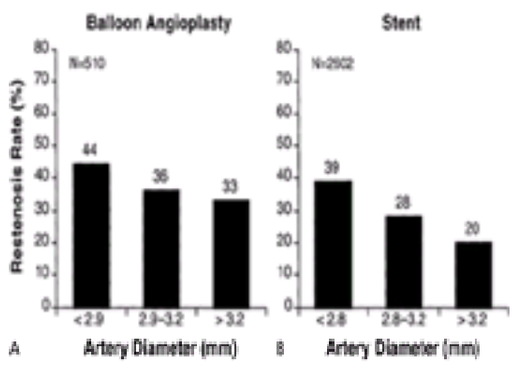

FIGURE 83.10 A: Separating reference vessel diameters into quartiles, Multi-Hospital Eastern Atlantic Restenosis Trial investigators found the restenosis rate to decrease from 44% to 36% when vessel size was larger than 2.9 mm by angiography. This inverse relationship of vessel size to restenosis has also been observed in other large-scale nonstent studies. **B:** Elezi and colleagues reported a similar pattern of restenosis in relation to vessel size among 2,602 stent patients. Vessel size is a leading predictor of restenosis regardless of method used. The benefit of stent placement over balloon angioplasty with regard to restenosis is likely lost for vessel diameters below 2.8 mm. (Adapted from Hirshfeld JWJ, Schwartz JS, Jugo R, et al. Restenosis after coronary angioplasty: a multivariate statistical model to relate lesion and procedure variables to restenosis. *J Am Coll Cardiol* 1991;18:647–656; and from Elezi S, Kastrati A, Neumann F-J, et al. Vessel size and long-term outcome after coronary stent placement. *Circulation* 1998;98:1875–1880, with permission.)

Considering the effect of vessel size on restenosis after coronary artery stenting, Kastrati and colleagues (155) have shown this to be the strongest predictor (Fig. 83.10 and Fig. 83.11) in a series of 4,510 consecutively treated patients. Vessel size accounted for 34% of all predictive value, and the risk of restenosis for a vessel of 2.7 mm was 79% higher than for a vessel of 3.4 mm. In a separate report from this group, in which 2,602 patients were systematically studied with quantitative coronary angiography and long-term follow-up, similar results were found. Vessel size was divided into terciles (less than 2.8 mm, 2.8 to 3.2 mm, and larger than 3.2 mm), and vessel size was highly significantly linked with angiographically apparent restenosis (39%, 28%, and 20% for the terciles, respectively) (p <.001) (Fig. 83.10). Interestingly, for each size tercile, the late lumen loss was similar (1.1 mm), and two associated covariates affected restenosis: namely, diabetes and lesion complexity (227). As mentioned earlier, the pooled BENESTENT-MUSIC data sets (220) systematically showed vessel size and postprocedural diameter stenosis to be the best predictors of restenosis.

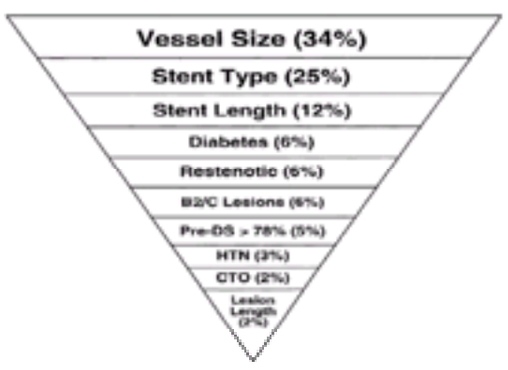

FIGURE 83.11 Pyramid of predictive factors affecting restenosis among 4,510 consecutively treated patients undergoing coronary stent placement. Percentages represent the amount of the restenosis in the model that was accounted for by the individual predictive factors. Vessel diameter and stent length accounted for nearly half of all predictive value for restenosis. CTO, chronic total occlusion; DS, diameter stenosis; HTN, hypertension. (Data from Kastrati A, Mehilli J, Dirschlinger J, et al. Restenosis after coronary stent placement of various stent types. *Am J Cardiol* 2001;87:34–39.)

Preprocedural Percent Diameter Stenosis

The preprocedural and postprocedural lesion severity or MLD has been shown to be a leading and independent predictor of stenosis recurrence in nearly every large-scale clinical study of restenosis, regardless of the revascularization device used. For example, in the CARPORT study (68), in which quantitative coronary angiography was performed on over 600 lesions before and 6 months after successful balloon angioplasty, the preprocedural MLD was directly correlated with the late loss in lumen diameter at follow-up. Specifically, as the preprocedural MLD decreased by 40%, the late loss in lumen diameter increased by nearly 70%. A similar association was also noted by the M-HEART investigators (212), who reported an increased rate of restenosis from 25% to 40% as pre-PTCA stenosis severity surpassed 73% (Fig. 83.12). Likewise, among patients receiving an intracoronary stent, preprocedural stenosis greater than 78% lumen diameter has been shown to be an independent predictor of angiographically identified restenosis (Fig. 83.11) (155). The complex interrelationship between preprocedural MLD, lumen gain, late loss, and follow-up MLD was also studied by Foley et al. (217) using the combined quantitative coronary angiography data set from several trials. In brief, the investigators showed, using mathematical models, that although smaller MLDs were associated with greater initial gain, this gain was associated with proportionally more late loss, so that larger preprocedural MLD was directly correlated with a more favorable long-term result.

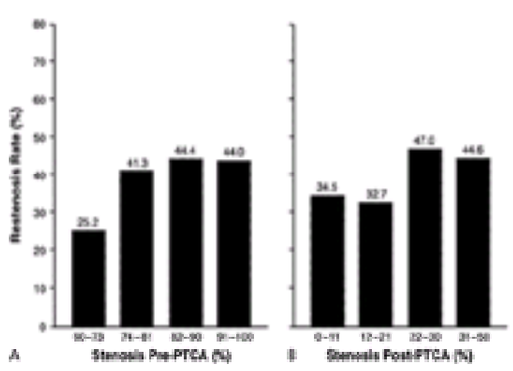

FIGURE 83.12 Relation of preprocedural **(A)** and postprocedural **(B)** stenosis severity on restenosis for 598 treated sites. In both panels, the height of each column represents the restenosis rate for each group of segregated lesions. Preprocedural stenosis severity was observed to be strongly associated with restenosis (p = .004), with higher restenosis rates for lesions with greater than 73% lumen diameter narrowing. Similarly, the postprocedural stenosis severity was independently associated with restenosis (p = .022), with a higher incidence of restenosis for lesions with a residual narrowing of more than 21%. PTCA, percutaneous transluminal coronary angioplasty. (Adapted from Hirshfeld JWJ, Schwartz JS, Jugo R, et al. Restenosis after coronary angioplasty: a multivariate statistical model to relate lesion and

procedure variables to restenosis. *J Am Coll Cardiol* 1991;18:647–656, with permission.)

Lesion Length

Long lesion length has been associated with an increased rate of restenosis in several large, prospective clinical trials (161,212,228). Bourassa et al. (161), categorizing lesions in a binary fashion, reported an increase in restenosis rate from 38% to 52% for lesions greater than 10 mm long. Others have divided lesion lengths into percentiles and have reported increased restenosis for lengths longer than 4.6 mm (212) to 6.8 mm (228). Long lesions, in addition to representing greater atherosclerotic burden at the treatment site and requiring a more extensive revascularization, are associated with diffuse coronary artery disease in general. Although it is not easily quantitated, more diffuse disease such as seen in diabetic patients and those with chronic renal insufficiency has a greater restenosis potential. Intracoronary stents placed in long lesions have also been associated with an increased occurrence of restenosis. Kastrati et al. (155) reported rates of restenosis to increase from 32% to 36% for lesions longer than 10 mm. Hamasaki et al. (229) reported an increase from 20% to 31% for lesions 15 mm or longer. Yokoi et al. (230) studied several different types of stents placed in lesions longer than 20 mm and reported restenosis rates of 35% to 56%.

Degree of Occlusion

PTCA of chronically occluded coronary arteries has been estimated to comprise 10% of the total number of coronary interventions (231). The initial success rate of PTCA is lower and the incidence of restenosis is higher in cases of chronic occlusion, especially for vessels occluded 3 months or more (232). Combined data from several studies show that the recurrence of angina pectoris within months of successful balloon angioplasty of chronic occlusions is roughly 40% (233,234,235,236 and 237), whereas the rate of angiographically identified restenosis is over 60% (232,235,236,237,238,239 and 240). In the MARCATOR study, 139 patients were followed after successful angioplasty of a total occlusion and compared with 1,295 patients treated for a subtotal stenosis. The rate of angiographically demonstrated restenosis was not dissimilar in the two groups (49% in the chronic occlusion group and 42% in the subtotal stenosis group; $p = .119$), although complete vessel occlusion at follow-up was present in 19% and 7%, respectively ($p > .001$) (241). On the basis of these findings, intracoronary stent placement after successful balloon angioplasty has been advocated. The first randomized study of balloon angioplasty versus intracoronary stent placement, the Stenting in Chronic Coronary Occlusions trial, enrolled 119 patients. Restenosis occurred in 74% of the balloon angioplasty group, but in only 32% of the stent group ($p < .001$). Reocclusion was also lower in the stent group (12%) than in the balloon angioplasty group (26%). Several studies have since reported restenosis rates for stented chronic occlusions ranging from 19% to 52% depending on the rate of angiographic follow-up (238,239,242,243). In nearly every study, the rate of reocclusion and restenosis has been more favorable with stenting than with balloon angioplasty alone, yet these rates remain higher than among patients without preprocedural complete occlusions (244). Schömig and colleagues reported the rate of restenosis after coronary stent placement to increase from 33% to 48% when a chronic total occlusion was present (155). The reason for the higher predilection for restenosis among treated complete occlusions is uncertain, but these lesions may contain the highest plaque burden (i.e., the smallest possible MLD) and many have recently contained an active thrombus.

Procedure-Related Factors

Postprocedural or Residual Diameter of Stenosis

As does the severity of preprocedural stenosis, the extent of residual stenosis after successful PTCA strongly predicts restenosis. In the M-HEART study (212), the percentage of stenosis immediately after PTCA was separated into quartiles, and lesions with residual stenosis of more than 21% had a significantly higher restenosis rate than did those with a post-PTCA stenosis of 21% or less (Fig. 83.12). Similar results of reduced restenosis in the setting of least residual stenosis were reported by Bourassa et al. (161), who found that postangioplasty stenosis of 30% or more of luminal diameter was associated with a restenosis rate of 40%, compared to 28% for segments with residual stenosis of less than 30%. These studies, along with statistical models of restenosis (39), have given rise to the concept of maximizing immediate gain (i.e., the gain in lumen diameter from baseline to immediately after PTCA), or the “bigger is better” concept. Kuntz et al. (39) compared models of restenosis after balloon angioplasty, stenting, and directional atherectomy. They concluded that the loss index (late loss divided by immediate gain) was the same for all device strategies and that therefore the immediate result (procedural stenosis) was what determined the late outcome. Challenging this view, Foley and others have studied large databases of quantitative angiographic results and demonstrated different device “taxing,” with more favorable angiographic profiles found for dilating devices (balloons and stents) than for debulking procedures (atherectomy). Their findings suggest that restenosis is not only influenced strongly by vessel size and lumen gain, but also by the technique used to achieve the larger lumen (Fig. 83.5). Aside from measures obtained by quantitative angiography, perhaps the best predictor of angiographically identifiable restenosis is the percent postprocedural cross-sectional narrowing as assessed by intravascular ultrasonography (IVUS) (245). In examining numerous clinical, angiographic, and IVUS variables for 360 coronary artery lesions, Mintz et al. found IVUS cross-sectional narrowing to be the most consistent single predictor of restenosis (245,246) (Fig. 83.13). Clinically, the angiographically determined parameters of vessel size and the final percentage diameter of stenosis are primarily used to predict the likelihood of restenosis.

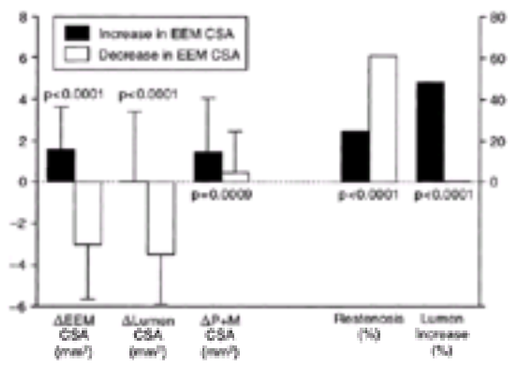

FIGURE 83.13 When numerous clinical, angiographic, and intravascular ultrasonographic variables were considered, cross-sectional narrowing as measured by ultrasonography was found to be the most consistent single predictor of restenosis. During serial study, 22% of lesions showed an increase in overall vessel size (increased external elastic membrane, or EEM, area), whereas the remainder showed a decrease. Lesions with an increased EEM had lower rates of angiographically identified restenosis than those with a decreased EEM (26% vs. 62%). D, change; CSA, cross-sectional area; P+M, plaque plus media. (From Mintz G, Popma J, Pichard A, et al. Intravascular ultrasound predictors of restenosis after percutaneous transcatheter coronary revascularization. *J Am Coll Cardiol* 1996;27:1678–1687, with permission.)

PRINCIPLES OF MANAGEMENT

When the epidemiology of restenosis is pulled together, a framework for monitoring the patient after successful angioplasty can be established. One might begin by considering the patient-, lesion-, and procedure-related factors associated with the angioplasty. Factors consistently identified as risks for restenosis after balloon angioplasty include the presence of diabetes mellitus, the presence of unstable angina, lesion location in saphenous vein grafts, lesion location in the ostium of the major epicardial arteries, long (diffuse) lesions, small vessel size, and greater severity of preprocedural and postprocedural stenosis. In the stent era, the factors consistently associated with increased rates of restenosis include the presence of diabetes, small vessel size, and larger residual diameter of stenosis (Table 83.2). Because the process of restenosis is complete within 3 to 6 months after angioplasty, clinical follow-up should take place during this interval. Depending on the patient’s initial symptoms, extent of myocardium at risk, and associated comorbidities, a tailored level of treatment aggressiveness can be established. For example, a patient initially presenting with predictable exertional angina and a small area of myocardium at risk might be followed for symptoms alone if the underlying ventricular function and overall health are good. In contrast, patients with atypical or unpredictable ischemia, a large area of myocardium at risk, or important comorbidities such as depressed ventricular function should routinely undergo stress cardiac imaging in the early months after angioplasty. Many interventional cardiologists perform cardiac stress testing for all asymptomatic patients even though most patients with restenosis have recurrent angina and not infarction. Given the poor predictive value of symptom status alone and the invasive nature of repeat angiography, this is not unreasonable. In choosing a cardiac stress test, simultaneous imaging with nuclear scintigraphy or echocardiography is worthwhile as demonstrated in *e*Table 83.1.3. If the baseline stress test results were positive and accurately located the ischemic territory, repeat testing with that particular imaging modality is logical. The positive predictive value of imaging cardiac stress testing averages approximately 80%, and this has been considered acceptable for most patients. When stress testing is believed to be unreliable and the amount of myocardium at risk is large (e.g., with ostial lesions in LAD or left-dominant left circumflex artery systems), angiography should be performed to be certain restenosis has not occurred. The need for routine or serial angiography in clinical practice is infrequent.

For patients who develop restenosis, several treatment options are available, including repeat percutaneous revascularization, which has a similar short-term and long-term success rate as with *de novo* lesions (eTable 83.4.1). Intracoronary stent placement is a prudent option for lesions not previously treated with a stent, provided the anatomy is suitable. Most patients with single-vessel restenosis undergo a second angioplasty, whereas patients with restenosis in multiple vessels may undergo percutaneous or surgical revascularization. When all patients initially treated by PTCA for multivessel disease are considered, slightly more of those with restenosis undergo a repeat angioplasty than undergo coronary artery bypass grafting. In the BARI study, nearly 70% of the cohort randomly assigned to undergo PTCA avoided surgery at 5-year follow-up (149).

Restenosis within stents is an increasing occurrence owing to the dramatic increase in stent use. In-stent restenosis usually is a diffuse proliferation of neointima (30,35), and the optimal interventional treatment is uncertain. Balloon angioplasty, perfusion balloon angioplasty, atherectomy (rotational and laser), and stent-within-stent approaches have all been tried. For focal restenotic lesions, the rate of second restenosis is 30% to 40%, whereas for diffuse restenotic lesions it is roughly 70% (36). The mainstay of current treatment is balloon angioplasty with or without intracoronary brachytherapy (local radiation). This is reviewed in the section In-Stent Restenosis.

As with most medical treatments, the best strategy for restenosis is prevention. Numerous basic scientific and clinical investigations using a wide variety of therapeutic agents (247,248 and 249) have been conducted in search of an inhibitor of restenosis. By using animal models for preclinical testing on targets of restenosis, the biology of restenosis has been advanced, although the clinical impact remains limited.

CLINICAL PREVENTION TRIALS: PHARMACOLOGIC

Many different therapeutic agents have been tested in an attempt to find a treatment that can inhibit the development of restenosis (247,248 and 249). Although thousands of patients have been enrolled in over 50 clinical trials over the past 20 years, no large-scale study has produced a pharmacologic therapy to suppress restenosis. Many animal studies targeting factors from thrombin to thromboxane, microtubules to calcium channels, and prostacyclin to platelets (i.e., factors associated with thrombus formation and cellular proliferation) have engendered hope of producing a meaningful reduction in restenosis, but these findings have been discounted by negative results from human studies, as displayed in Table 83.5 (27,79,81,83,84,86,170,250,251,252,253,254,255,256,257,258,259,260,261,262,263,264,265,266,267,268 and 269). Given the mechanisms of restenosis, most studies have specifically targeted a factor associated with thrombus formation, vascular remodeling, or neointimal growth. An important point to be remembered when reviewing these many trials is that restenosis after balloon angioplasty is primarily a result of vessel wall remodeling as opposed to neointimal formation, and that in balloon angioplasty trials many of these agents were used in an attempt to influence neointimal proliferation.

TABLE 83.5 ANIMAL STUDIES AND CLINICAL TRIALS OF AGENTS TO PREVENT RESTENOSIS

Strategies Targeting Thrombus Formation

Antiplatelet Agents

Because platelet functions (adhesion, aggregation, and release of vasoactive, mitogenic, and chemoattractant factors) are central to thrombus formation and the vascular response to injury, they are logical targets to limit restenosis. Virtually all percutaneous revascularization procedures are performed in the setting of antiplatelet therapy to prevent acute ischemic complications, although none of these therapies has shown a clear effect on angiographically identified restenosis. Aspirin, dipyridamole, thienopyridines, thromboxane antagonists, and prostacyclin analogs each has shown some promise in animal models of restenosis, although none has produced clinical benefit (Table 83.6). The most potent antiplatelet therapy, that using glycoprotein IIb/IIIa antagonists, has been studied in animal models and in several large-scale clinical trials. Animal models of restenosis demonstrated a reduction in neointimal development through blocking of either the platelet glycoprotein IIb/IIIa ($a_{IIb}b_3$) or vitronectin receptor (a_vb_3) (270,271). Matsuno et al. (270) postulated that this effect was due both to an early event such as inhibited secretion of PDGF and to a late event, possibly the interference of the smooth muscle cell a_vb_3 receptor.

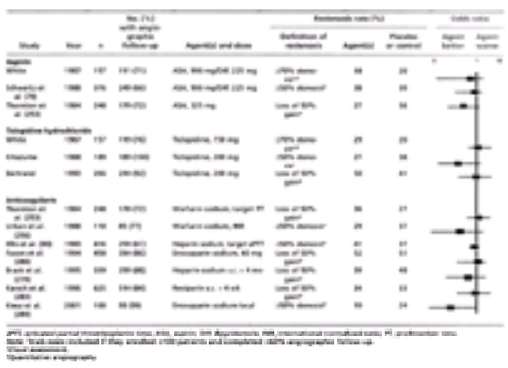

TABLE 83.6 CLINICAL TRIALS EVALUATING THE USE OF ANTITHROMBOTIC AGENTS TO LIMIT ANGIOGRAPHICALLY IDENTIFIED RESTENOSIS

By using a glycoprotein IIb/IIIa inhibitor, chimeric 7E3 Fab, and blocking the final common pathway for platelet aggregation, the EPIC (272) investigators showed the incidence of acute ischemic complications during high-risk angioplasty to be substantially reduced. At 6-month follow-up, clinically apparent restenosis was also reduced (43), but this was primarily due to a reduction in myocardial infarction. Since then, several trials have completed 6-month follow-up on patients randomly assigned to receive platelet IIb/IIIa antagonists or placebo. The Integrilin to Manage Platelet Aggregation and Coronary Thrombosis II trial, Randomized Efficacy Study of Tirofiban for Clinical Outcomes and Restenosis, EPILOG study, and Chimeric 7E3 Antiplatelet in Unstable Angina Refractory to Standard Treatment trial studied eptifibatide (Integrilin), tirofiban hydrochloride, and abciximab. Pooling of results for these 12,305 patients showed no significant reduction in target vessel revascularization at 6-month follow-up for patients given active treatment versus those receiving placebo (18.6% vs. 20.2%) (43,273,274 and 275), and no difference was seen in quantitative angiographic or neointimal tissue volume (276). The only potential exception may be for diabetic patients who received an intracoronary stent and were given abciximab, as observed in the Evaluation of Platelet IIb/IIIa Inhibitor for Stenting Trial (158) (Fig. 83.7), although this result is not confirmed in other studies.

Anticoagulants

In addition to containing activated platelets, a thrombus at the site of injury can act as a bioabsorbable matrix and also serve as a reservoir of active thrombin. Therapy with warfarin sodium, a broad-spectrum anticoagulant, did not reduce restenosis in an early angiographic study (256) but did reduce target vessel revascularization in a more recent trial of 1,058 patients (277). More specific inhibitors, such as the antithrombins heparin sodium, low-molecular-weight heparin, hirudin, and bivalirudin, have also been studied. Beyond being an anticoagulant, heparin inhibits smooth muscle cell proliferation and migration. Several small randomized trials of heparin

versus placebo unfortunately showed no salutary effect on restenosis (80,278) after nonstent procedures. Long-term heparin administration (twice-daily subcutaneous injections for 4 months) also did not favorably affect angiographic or clinical outcome (279). Low-molecular-weight (fractionated) heparin has a longer half-life than unfractionated heparin, is a more potent factor X_a inhibitor, and has been studied in several balloon angioplasty trials (280,281 and 282). Restenosis was not reduced in any of these trials, even when therapy extended for weeks postprocedure (283). More recently, a small study (n = 100) was performed using some contemporary practices: implantation of intracoronary stents, local drug delivery versus systemic administration, and therapy with low-molecular-weight heparin versus unfractionated heparin. This study, the Polish-American Local Lovenox NIR Assessment study (284), randomly assigned patients to receive locally delivered enoxaparin sodium or systemic unfractionated heparin for stent placement. At 6-month follow-up, restenosis was found in 10% of the group receiving enoxaparin versus 24% of the group given systemic heparin. Late lumen loss and target vessel revascularization were also improved by local enoxaparin delivery.

Finally, more potent antithrombins that do not require antithrombin as a cofactor (hirudin, bivalirudin, and argatroban) have been studied. The trial Hirudin in a European Trial versus Heparin in the Prevention of Restenosis after PTCA randomly assigned 1,141 patients to receive heparin during the PTCA procedure and in 24-hour infusion, hirudin during the procedure and in 24-hour infusion, or hirudin during the procedure, in 24-hour infusion, and in 3 days of subcutaneous therapy (285). Early ischemic events were reduced by the use of hirudin, but no difference in late outcome related to restenosis was observed. Similarly, the Hirulog Angioplasty Study (286) randomly assigned 4,098 patients undergoing angioplasty to receive either Hirulog (bivalirudin) or heparin. At 6 months the rate of repeat revascularization was similar for the two groups (22.9% and 23.9%). These data reveal no reduction in restenosis with anticoagulant therapies even when administered for days to weeks after angioplasty.

Vasodilators

Thromboxane Antagonists

Because the vasomotor effects of aspirin are mixed with concomitant inhibition of thromboxane and prostacyclin, specific inhibitors of thromboxane and analogs of prostacyclin have been tested for restenosis prevention after balloon angioplasty. The CARPORT trial randomly assigned 697 angioplasty patients to receive the thromboxane A_2 antagonist vapiprost or a placebo, although all patients also received aspirin. At 6-month follow-up angiography, no difference was observed in restenosis in the two groups. Similar results were found in the Glaxo Restenosis and Symptom Project (287) and M-HEART-II (85) studies using vapiprost and sulotroban, respectively. Together, these three large trials enrolled over 2,400 patients and showed no impact on restenosis (*e*Table 83.6.1).

[b]Visual assessment.

Prostacyclin

Prostacyclin is produced by healthy endothelium and causes vasodilation and platelet inhibition, effects opposite those of thromboxane. Prostacyclin supplementation or use of prostacyclin analogs (prostanoids) has been tried in several small studies to reduce postangioplasty neointimal formation. The largest of these trials randomly assigned 311 patients to receive ciprostene or placebo and showed an overall clinical benefit: a reduction in the composite of death, infarction, and revascularization at 6-month follow-up (263). This trial did not conduct systematic angiographic follow-up, however, and those that have done so have shown no reduction in restenosis (83,288). A large-scale trial with angiographic follow-up is needed to clarify the role of prostanoids in preventing angiographically and clinically demonstrated restenosis.

Serotonin Receptor Antagonists

Serotonin, 5-hydroxytryptamine, is able to induce vasoconstriction in the setting of abnormal endothelium and is an agonist for platelet aggregation. In addition, serotonin promotes smooth muscle cell migration and proliferation and the synthesis of extracellular matrix (289,290). Therefore, use of ketanserin, a serotonin antagonist, is a potential therapeutic approach to limit restenosis. In the Postangioplasty Restenosis Ketanserin trial, 658 angioplasty patients were randomly assigned to receive ketanserin or placebo, and 592 patients had quantitative coronary angiography at 6 months (171). No difference in angiographically identified restenosis or clinical events was observed between patients receiving ketanserin and those given placebo (*e*Table 83.6.1).

Calcium Channel Antagonists

Calcium channel antagonists have been studied in restenosis because of their potent coronary vasodilatory effects and the known role of recoil and vasoconstriction in restenosis (291,292). Although use of calcium channel antagonists is beneficial in vasoactive coronary artery disease, several small trials failed to demonstrate a

benefit for restenosis prophylaxis (265,293,294). Interestingly, one study (264) and a metaanalysis of several trials (295) showed a borderline reduction in restenosis (odds ratio of 0.5 to 0.9; p <.05) (*e*Table 83.6.1). The use of calcium channel antagonists for restenosis prevention has not been adopted because peer-reviewed data are limited, and some agents have been associated with an increased risk of ischemic events after myocardial infarction.

Angiotensin-Converting Enzyme Inhibitors

The antihypertensive and putative antiproliferative effects of ACE inhibitors are provided by blockade of angiotensin II production. Angiotensin II is a potent vasoconstrictor, and genes that encode the mitogens PDGF, TGF-b, and thrombospondin may be induced by angiotensin II (266,296). Thus, with regard to restenosis, ACE inhibitors could be categorically considered as vasodilators or antiproliferative agents. Two parallel studies, MERCATOR in Europe and MARCATOR in the United States, have shown no reduction in the incidence of restenosis after treatment with cilazapril (69). In addition, no differences were seen in clinical outcomes, including death, nonfatal myocardial infarction, coronary revascularization, and recurrence of angina, between treatment and placebo groups. Fosinopril sodium was also studied in the setting of PTCA and had no impact on restenosis (297) (*e*Table 83.6.1). Animal studies showing a restenosis benefit with ACE inhibitors used substantially higher dosages; comparable dosages in humans have been considered unacceptable because of the possibility of systemic hypotension (266,296).

Antiproliferative Agents

Immunosuppressant and Antiinflammatory Agents

The antiproliferative agents are the current hopes for reducing restenosis in the contemporary stent era. Previously tested in patients undergoing balloon angioplasty, several immunosuppressive and antimitogenic agents showed encouraging results in animal studies without demonstrating success in human trials. Corticosteroids were among the first classes of agents studied because of their known clinical effects on suppression of inflammatory response to injury and reduction in the production of smooth muscle mitogens. Specifically, corticosteroids suppress monocyte-lymphocyte interaction and lymphocyte proliferation, perhaps by decreasing platelet and macrophage-derived growth factor expression (298,299). Pepine et al. (81) performed the largest corticosteroid-angioplasty study, randomly assigning 915 patients to receive 1 g methylprednisolone or placebo the day before angioplasty. Six-month angiographic follow-up in 71% of those with successful angioplasty showed a nearly identical per-lesion restenosis rate for steroid-treated patients (40%) and placebo-treated patients (39%). Colchicine, which acts by binding to tubulin and disrupting spindle formation during cell division and inhibiting collagen formation (300,301), produced a dose-dependent reduction in neointimal formation in animal models. In clinical trials in which colchicine was used in tolerable doses alone (268,302,303), however, it was ineffective in preventing restenosis.

Finally, tranilast is an antiinflammatory agent that suppresses macrophages and fibroblasts, inhibits smooth muscle cell migration induced by PDGF, inhibits collagen synthesis in vascular smooth muscle cells, and is used to prevent keloid formation. Tranilast was initially tested in the Tranilast Restenosis Following Angioplasty Trial. Two hundred fifty-five patients were randomly assigned to receive 600 mg of tranilast, 300 mg of tranilast, or placebo for 3 months. The rate of angiographically determined restenosis for these groups at 3 months was 18%, 39%, and 39%, respectively (304). The largest clinical trial ever performed in interventional cardiology—the Prevention of Restenosis with Tranilast and Its Outcomes trial—tested the use of tranilast among 11,500 PCI patients. Tranilast was administered (300 or 450 mg twice daily) for 1 or 3 months after stent or nonstent procedures to treat *de novo* or restenotic lesions. The primary end point was the 9-month composite of death, myocardial infarction, or ischemia-driven target vessel revascularization. A 2,000-patient angiographic substudy was also performed (305).

Growth Factor Inhibitors

Trapidil

As listed in Table 83.3, several growth factors, including PDGF, bFGF, insulin-like growth factor-1, TGF-b, and EGF have been implicated in the hyperproliferative response after vascular injury. In addition to nonspecific immunosuppressant and antiinflammatory agents, specific antagonists to these growth factors have been studied in prevention of restenosis. Trapidil is a PDGF inhibitor that significantly reduces neointimal formation in animal models of restenosis (306). A small randomized clinical trial of trapidil showed a significant reduction in restenosis (from 42% to 19%) at 6 months (307). This finding was substantiated by the Studio Trapidil versus Aspirin nella Restenosi Coronarica trial (308), a multicenter, double-blind, randomized study of trapidil versus aspirin involving 305 patients. The occurrence of angiographically identified restenosis was reduced by 40% (*e*Table 83.6.1). Another study randomly assigned 97 stent patients to receive ticlopidine hydrochloride plus aspirin or ticlopidine plus trapidil (309). At 6 months, no difference was seen in angiographically determined restenosis (approximately 29% for all groups). These small studies are encouraging and indicate that further investigation is warranted.

Angiopeptin

The most widely studied growth hormone antagonist in restenosis prophylaxis is angiopeptin, a synthetic analog of somatostatin. Angiopeptin acts on the pituitary gland to reduce growth hormone secretion and may limit release of insulin-like growth factor-1 (310). In animal models of vascular injury, administration of angiopeptin before or during angioplasty reduced neointimal growth (258,311,312). Clinical results, however, have been inconsistent (259,313,314). Two trials, one using low-dose angiopeptin and the other high-dose angiopeptin, included nearly 1,400 patients and performed angiographic follow-up but showed no reduction in restenosis (259,314). Questions remain as to whether a more prolonged dosing of angiopeptin is needed to affect neointimal growth. A small placebo-controlled study in which angiopeptin was administered for hours after PTCA demonstrated angiographically determined and clinically determined restenosis rates that were 70% lower and 26% lower, respectively, with angiopeptin treatment. These discrepant findings indicate the need for further study before large-scale efforts are repeated.

Cilostazol

Acting as an antiplatelet agent by increasing levels of cyclic adenosine monophosphate, cilostazol is also an antiproliferative agent that inhibits smooth muscle cell growth by blocking synthesis of DNA. Sekiya and colleagues (315) randomly assigned 126 stent patients to receive placebo, probucol, cilostazol, or the combination of probucol and cilostazol. Drug treatment began 5 days before coronary intervention and continued until 6-month angiographic follow-up. At follow-up, restenosis was found in 32% of patients receiving the placebo, 17% of those given probucol, 13% of those getting cilostazol, and 10% of those receiving both probucol and cilostazol. Among 211 balloon angioplasty patients randomly assigned to receive either 3 months of cilostazol (200 mg per day) or a control regimen, the rate of angiographically identified restenosis at 3 months was lowered from 40% to 18% by cilostazol (316). In two more recent studies, 409 patients and 130 patients undergoing stent implantation were randomly assigned to receive either aspirin plus ticlopidine or aspirin plus cilostazol. The larger of the trials, by Park et al. (317), showed no reduction in restenosis at 6-month follow-up angiography among patients receiving cilostazol compared with those given ticlopidine (restenosis rates of 27% vs. 23%, respectively), although the smaller trial, conducted by Kozuma and colleagues (318), reported a halving of angiographically identified restenosis and target vessel revascularization rates at late follow-up among patients receiving cilostazol. Together, these trials included nearly 900 patients and showed a substantial (40%) reduction in relative risk of angiographically determined restenosis with cilostazol (32% vs. 19%).

Paclitaxel

Paclitaxel (Taxol) is a microtubule-stabilizing drug that reduces cellular functions such as migration and proliferation, which makes it a potent cytotoxic antitumor agent. Animal models of restenosis have shown delivery of paclitaxel via local catheters to be associated with reduced neointimal proliferation and increased vessel size (319). Because paclitaxel is a potent agent, local delivery is key. Linking the molecule in a polymer fashion to a stent, stent sleeve, or biodegradable stent is an option being tested (320,321). Preliminary reports of a small number of early clinical cases have reported zero restenosis rates. Although the results seem overly promising, several larger-scale clinical trials are already under way in Europe, Asia, and North America.

Rapamycin

Sirolimus (Rapamune) is a macrocyclic lactone with antibiotic, immunosuppressive, and antiproliferative actions. It is approved for use as prophylaxis for renal transplant rejection. Biologically it induces cell-cycle arrest and affects proliferation and migration of smooth muscle cells. It has been shown in animal models of restenosis to substantially reduce neointimal thickening after vascular injury (322). Sousa and colleagues (323) reported quantitative angiographic and three-dimensional intravascular ultrasonographic data on 30 patients who received sirolimus-coated stents. At 4-month follow-up, the in-stent late loss was negligible (approximately 0.1 mm) and the diameter of stenosis was virtually unchanged (approximately 5%). These remarkable results have prompted several moderate-sized (400-patient) studies in Europe and the United States, including the Rapamycin-Eluding versus Plain Polymer Stents trial and the Sirolimus-coated BX Velocity Balloon-Expandable Stent trial.

Antisense Oligonucleotides

Activation of growth factor receptors prompts gene expression in the nucleus, which leads to cytoplasmic synthesis of specific proteins. These proteins, in turn, direct the cell replication and matrix production of neointimal growth. The failure of individual antiproliferative agents to limit restenosis in clinical trials may also be related to

the existence of many different growth factors. Thus, by targeting gene expression, the final common pathway leading to cellular growth and replication, gene therapy may be particularly advantageous (324). The use of antisense agents is an approach that blocks gene expression via specific complementary DNA sequences to small segments of the messenger ribonucleic acid (mRNA). Several antisense oligonucleotides directed at protooncogenes such as c-myb and c-myc, proliferating-cell nuclear antigen, and cell-cycle regulatory genes, such as cdc2 kinase and cdk2 kinase, reduced neointimal hyperplasia in a balloon injury in the rat carotid artery model (325). Several problems still exist with antisense therapies, including agent tability, low cellular uptake, and target specificity. The development of local drug delivery systems and the efficacy of carrier systems will likely govern the future success of antisense therapies in preventing restenosis. When the intracoronary route was used, administration of c-myc antisense was shown to be safe in 16 patients undergoing percutaneous transluminal coronary revascularization (PTCR) (326).

Hypolipidemic Agents and Antioxidants

Fish Oils

Omega-3 polyunsaturated fatty acids reduce serum levels of triglycerides and very low-density lipoproteins and are associated with lower rates of atherosclerotic heart disease. In addition, because these fish oils have vasodilatory effects, show anti–platelet-aggregatory effects, alter smooth muscle cell proliferation and monocyte function (327,328 and 329), and inhibit PDGF expression from endothelial cells (330), they have been studied for restenosis prophylaxis (*e*Table 83.6.2). Five of nine studies (260,330,331,332 and 333) evaluating omega-3 fatty acids reported a beneficial effect, and a metaanalysis suggested a significant influence in reducing restenosis, with an odds ratio of 0.5 to 0.8 (56). Unfortunately, each of these studies was limited not only by small size but also by differences in dosing and definitions of restenosis. In contrast, the Fish Oil Restenosis Trial, a large multicenter study in the United States encompassing 503 patients, showed no reduction in restenosis with fish oils (334), and a large Canadian trial of fish oil and enoxaparin (2 × 2 factorial design) known as the Enoxaparin and Maxepa for the Prevention of Angioplasty Restenosis trial had negative results (281).

[c]Visual assessment.

Hydroxymethylglutaryl–Coenzyme A Reductase Inhibitors

Hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors were reported to have a direct antiproliferative effect on endothelial and smooth muscle cells in addition to lowering lipid levels (335). In a small open-label trial (262), lovastatin reduced the restenosis rate from 45% to 15%. The unblinded method and low angiographic restudy rate, however, reduce the value of such a study. A subsequent larger multicenter, double-blind, placebo-controlled, randomized trial (84) showed that restenosis was not decreased in patients who received lovastatin, despite a greater than 40% reduction in the levels of LDL cholesterol (*e*Table 83.6.2). In addition, no significant difference in clinical outcomes was observed. Even with combination therapies or apheresis, no consistent reduction in restenosis rate has been seen despite dramatic reductions in levels of LDL cholesterol and Lp(a). Fluvastatin sodium, which reportedly has the greatest suppressant effect on neointimal growth, was studied in the large Fluvastatin Angioplasty Restenosis trial (n = 1,054) (336). Despite markedly lowering LDL cholesterol levels, fluvastatin did not lower restenosis compared with placebo (restenosis rates of 28% vs. 31%, respectively; $p = .42$). No reports of prospective large-scale trials are available that assess the use of cholesterol-lowering agents among stent-treated patients, although a retrospective analysis suggests a potential benefit (337).

Antioxidants and Combination Therapies

Antioxidants have been suggested to be useful in the prevention and treatment of several medical conditions because of their ability to remove free radicals. By preventing oxidation of LDL, reducing platelet aggregation, and modulating prostaglandin and leukotriene synthesis, antioxidants may also be efficacious in limiting restenosis (338). Probucol, ascorbic acid, and alpha-tocopherol have been shown to reduce intimal hyperplasia in various animal models (339,340). Early clinical trials of probucol combined with other therapies found no reduction in restenosis, whereas two studies that administered probucol alone for months after angioplasty have shown an overall 40% reduction in angiographically identified restenosis (341,342) (*e*Table 83.6.2). These more recent and encouraging results deserve further investigation.

CLINICAL TRIALS: TECHNOLOGIES

Atherectomy

As mentioned previously, the leading predictor of angiographically determined restenosis is the postprocedural or residual stenosis diameter. Most new technologies in interventional cardiology, such as the atherectomy devices, have targeted debulking of coronary artery lesions to produce the largest postprocedural lumen possible. Each new technology brings the hope of reducing restenosis or treating specific lesion subsets better than can balloon angioplasty. The directional coronary atherectomy (DCA) catheter allows shaving and extraction of atheroma and enables the production of a larger lumen and net gain. Data from the DCA registry and from two large multicenter trials, CAVEAT (73) and the Canadian Coronary Atherectomy Trial (74), demonstrated this; however, in combination, these studies report similar restenosis rates for DCA and balloon angioplasty. The BOAT study compared balloon angioplasty to "optimal" DCA. In BOAT, atherectomy produced larger immediate and net gain, and the rate of angiographically identified restenosis at the specific enrolling centers able to perform optimal atherectomy (15% mean residual stenosis) was lower for DCA (32%) than for balloon angioplasty alone (40%) (87). This occurred without an increase in "major" adverse events, although patients undergoing DCA were nearly three times more likely to have a significant periprocedural rise in levels of myocardial muscle creatine kinase isoenzyme. Target vessel revascularization rates at 6-month and 1-year follow-up were similar for the groups undergoing PTCA and optimal DCA.

Excimer laser and rotational atherectomy have been assessed in the Excimer Laser Rotational Atherectomy Balloon Angioplasty Complications study (77), the Study to Determine Rotablator and Transluminal Angioplasty Strategy, the Amsterdam Rotterdam (AMRO) trial (343), and the Comparison of Balloon Angioplasty versus

Rotational Atherectomy in Complex Coronary Lesions study (67). Compared with balloon angioplasty, these atherectomy devices used to debulk the lesion before balloon dilation have yielded higher procedural success rates and greater immediate gain. No significant outcome differences have been found during clinical or angiographic follow-up, however, with restenosis rates approximating 50% in all treatment groups in each trial. Like DCA, these debulking devices facilitate balloon angioplasty but cause a greater late lumen loss, or device taxing, which implies that remodeling and neointimal proliferation are not favorably reduced.

Intracoronary Stents

Stent Placement Compared with Balloon Angioplasty

The increasingly popular intracoronary stents address restenosis from the perspective of plaque persistence, recoil, and remodeling (Fig. 83.3) by compressing the plaque and scaffolding the vessel lumen to safely maximize diameter. Early stent registry data indicated that restenosis rates were similar to those with balloon angioplasty unless the lesion treated was “ideal,” in other words, was a short, *de novo* lesion in a vessel 3 mm or more in diameter. With this in mind, two randomized trials of stent implantation versus stand-alone balloon angioplasty in *de novo* native coronary artery lesions were undertaken: the BENESTENT trial (71,344,345) and the STRESS trial (344,346). The BENESTENT investigators reported a restenosis rate of 22% in the stent group and 32% in the balloon angioplasty group. A decreased incidence of cardiac events—mainly repeat percutaneous coronary revascularization—was noted for the stent group at 6-month follow-up. The STRESS trial (70) also demonstrated an absolute 10% lower occurrence of restenosis among subjects receiving a Palmaz-Schatz coronary stent than among those undergoing balloon angioplasty (32% and 42%, respectively). Similarly, at 8-month follow-up, the STRESS stent group had a better event-free survival and had undergone fewer revascularization procedures. Comparison of angiographically determined restenosis rates in past balloon angioplasty trials and in more recent stent trials confirms this 10% to 15% lower rate of restenosis after stent implantation (Table 83.1).

Since completion of the BENESTENT and STRESS trials, many other stent-versus-angioplasty trials have been performed (Table 83.1) to assess the effect of contemporary stenting techniques (high-pressure deployment, IVUS, reduced anticoagulation), characteristics of patient and clinical subgroups (presence of diabetes or acute myocardial infarction), features of specific lesions (restenotic lesions, chronic occlusions, long lesions), and new stent designs. Although restenosis rates have been somewhat lowered with more aggressive balloon angioplasty, intracoronary stenting has proven superior in nearly every study. In BENESTENT-II, for example, in which aggressive balloon angioplasty was tested against placement of heparin-coated stents with high-pressure delivery, the restenosis rate after angioplasty was only 31%, but the rate was an impressively low 16% in the stent group. Other studies using different stents or more contemporary practices than in STRESS-I and BENESTENT-I confirm this impressively low restenosis rate (347).

Important points to be remembered regarding restenosis in the current stent era include the exception in which stent placement has not been proven superior to balloon angioplasty—in small vessels. Several studies showed comparable rates of restenosis for balloon angioplasty and stent placement when vessel size was 2.8 mm or less (155). For small vessels, the rate of restenosis approximates 40% regardless of treatment assignment. In addition, the rates of restenosis initially published for nearly all stent designs were for ideal lesions, and large-scale observational studies have reported higher overall rates than in those trials used to gain U.S. Food and Drug Administration approval of particular stent designs. In summary, target vessel revascularization rates in contemporary stent practice can approximate the single digits (i.e., less than 10%). When angiographically determined restenosis is considered, the rates increase to 20% to 25%, and when the nonideal end of the spectrum is included, this rate may double.

In-Stent Restenosis

With the exponential increase in stent use over the past few years and the increased rate of percutaneous revascularization overall, in-stent restenosis has become a new epidemic in medicine. Angiographically identified restenosis (stenosis of 50% or more lumen diameter) occurs in one of four stent patients, and repeat revascularization of the target lesion is needed in roughly 10% of patients receiving an intracoronary stent. Because stents stimulate more neointimal proliferation than other interventional methods (balloon angioplasty and atherectomy), antiproliferation strategies are the main therapeutic consideration. Results of the conventional mechanical treatment of in-stent restenosis using balloon angioplasty, cutting balloon angioplasty, repeat stenting, or atherectomy have been disappointing, with recurrent rates of restenosis averaging 30% to 50% for focal disease and approximately 70% for diffuse in-stent restenosis (348,349,350 and 351). Current treatment options include gamma and beta radiation, and antiproliferative drugs are being studied.

Vascular Brachytherapy for In-Stent Restenosis

Gamma and beta radiotherapy have been studied for the treatment of in-stent restenosis over the past several years. Radiation is emitted during the spontaneous decay of the nuclei of certain elements. This radiation can be gamma radiation (electromagnetic energy carried by photons, which may penetrate more than 10 mm of human tissue) or beta particles (electrons carrying a wide range of energy levels and traveling 2 to 3 mm in human tissue). By affecting DNA in the actively dividing cells in the vascular media and intima, brachytherapy inhibits smooth muscle proliferation and neointima formation. Isotopes studied for clinical brachytherapy include iridium-192 (Ir-192, gamma emitter), phosphorus-32 (P-32, beta emitter), strontium-90 (Sr-90, beta emitter), yttrium-90 (Y-90, beta emitter), and rhenium-188 (Re-188, beta emitter). Three types of radiation delivery systems have been tested: balloon-filled catheters, radioactive stents, and catheter-based delivery of radioactive seeds. Only the last one has been examined in randomized clinical trials and approved by U.S. Food and Drug Administration.

Gamma Radiation

Several randomized clinical trials have reported the efficacy of Ir-192 gamma radiation in preventing restenosis in patients with in-stent restenosis (352,353,354 and 355) (Fig. 83.14). Teirstein and colleagues have reported the 1-year and 3-year results of the Scripps Coronary Radiation to Inhibit Proliferation Post-Stenting trial, which randomly assigned 55 patients with restenosis (both in-stent restenosis and post-PTCA restenosis) to receive gamma radiation or placebo after undergoing a successful angioplasty procedure. Late luminal loss was significantly lower in the Ir-192–treated group than in the placebo group (1.85 ± 0.89 mm vs. 2.43 ± 0.78 mm, p = .02) in the first year of follow-up, and adverse ischemic events remained lower at 3 years (352) (Table 83.7). In the GAMMA-1 trial (353) Ir-192 was administered after a successful PTCA and was associated with less target lesion revascularization (24% vs. 42%; p <.01) (Fig. 83.14) and less binary angiographically determined restenosis (32% vs. 55%; p = .01) than was delivery of a placebo. In the Gamma Washington Radiation for In-Stent Restenosis Trial (WRIST), patients who were assigned to receive ^{192}Ir also had less target lesion revascularization (23% vs. 63%; p <.001) (Fig. 83.14) and less angiographically identified restenosis (19% vs. 58%; p = .001) than did those in the placebo group at 6 months. For long lesions (mean stent length 70 mm), the Long WRIST study reported a 50% reduction of target lesion revascularization (p = .001) (Fig. 83.14). A significant reduction in the composite of death, myocardial infarction, and target vessel revascularization was noted in each study at 6-month to 1-year follow-up (352,353,354 and 355) (Table 83.7).

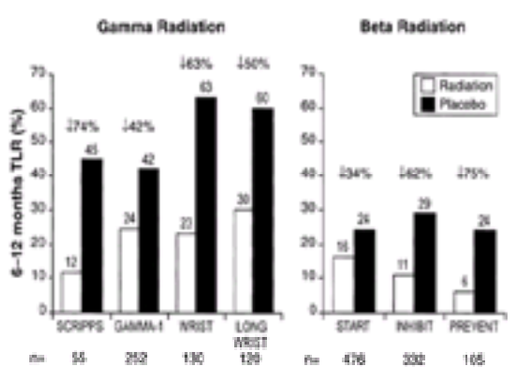

FIGURE 83.14 Rates of target lesion revascularization (TLR) after intracoronary brachytherapy for in-stent restenosis. Compared with results after placebo administration, target vessel revascularization was relatively reduced by 43% to 74% after gamma radiation therapy and by 34% to 63% after beta radiation at 6 to 12 months of follow-up. TABLE 83.7 CLINICAL TRIALS OF INTRACORONARY RADIATION FOR TREATMENT OF IN-STENT RESTENOSIS

Beta Radiation

Initially studied as an adjunctive treatment to prevent restenosis in *de novo* lesions in native coronary arteries, beta radiation has been demonstrated to effectively lower recurrent stenosis after PCI for in-stent stenosis (356,357 and 358). The Beta WRIST (359), a registry of Y-90 beta radiation in treating in-stent restenosis, first reported the safety of Y-90 administration. At 6 months, target lesion revascularization was 26%, which compared favorably with the previous results of the placebo cohort in Gamma WRIST. The Sr-90 Treatment of Angiographic Restenosis Trial (358), in which 476 patients were randomly assigned to undergo either Sr-90 brachytherapy or a placebo procedure for in-stent restenosis, demonstrated a marked reduction in favor of the group receiving beta radiation in both clinically determined restenosis (Sr-90 24% vs. placebo 34%; risk reduction, 34%; $p = .008$) and angiographically determined restenosis (Sr-90 14% vs. placebo 42%; $p < .001$) at 8 months (356,358,359) (Table 83.7; Fig. 83.14). The Intimal Hyperplasia Inhibition with Beta In-Stent Trial is a moderately sized (332-patient) multicenter, randomized, placebo-controlled trial that has preliminarily observed a 63% reduction in target vessel revascularization (11% for the radiation group vs. 29% for the placebo group) at 8 months through treatment with a P-32 beta radiation source (Table 83.7; Fig. 83.14).

Parallel to the development of catheter-based brachytherapy, stent-based brachytherapy using a beta-emitting P-32 radiation source has been investigated (360,361). Advantages of this technique include the fact that it does not require the presence of radiation oncologists, additional shielding in the catheterization laboratory, or particular additional equipment. Although in-stent restenosis is essentially eliminated, stent-edge hyperplasia due to the stimulating effect of low-dose radiation (geographic miss) and balloon injury is a major limitation of this technique.

Late Restenosis and Late Thrombosis

Although intracoronary radiotherapy has been proven to attenuate restenosis overall, its effects are not always consistent or curative. At the extremes of outcomes are patients who have divergent late effects of either thrombosis (perhaps due to inadequate reendothelialization) or restenosis (possibly from paradoxical neointimal stimulation of adjacent vessel segment), although such occurrences are infrequent. In the Scripps Coronary Radiation to Inhibit Proliferation Post-Stenting trial, late luminal loss was observed in some patients between the 6-month and 3-year follow-up. This suggests that a time course–modified restenosis model may be needed when considering brachytherapy. Although not reported in any of the trials mentioned earlier, mitotic changes (carcinoma) or aneurysmal changes in coronary arteries are potential late sequelae, and observing such potential events may require many years of follow-up. More important concern about the safety of radiation was raised when late thrombosis and myocardial infarction occurred months after radiotherapy. After intracoronary radiation, endothelial repair is delayed due to the same inhibiting effect of radiation in attenuating tissue proliferation. Late thrombosis is thought to be due either to delayed reendothelialization of stents or to late positive arterial remodeling that causes separation of the stent from the arterial wall. The reduction in the composite primary end points with radiation therapy in these clinical trials is driven mainly by the reduction in target vessel revascularization. For example, in GAMMA-1 (353) a trend was seen in the ^{192}Ir arm toward increased death (3.1% vs. 0.8% for the placebo arm; $p = .17$) and increased myocardial infarction (4.6% vs. 2.5% in the placebo arm; $p = .09$) at 9 months. When data for the brachytherapy trials are combined, late thrombosis is found to occur in 9.1% of the radiation-treated group versus 1.2% of the placebo group ($p < .0001$). By multivariate logistic regression analysis, new stent implantation and long lesions were found to be the major predictors of late thrombosis. Current recommendations, therefore, include either the avoidance of new stent placement or long-term therapy with thienopyridine. The GAMMA-V and Plavix WRIST registries are intended to study the efficacy of a 6-month course of clopidogrel bisulfate and aspirin for prevention of subacute thrombosis after Ir-192 radiotherapy (362). In beta radiation trials, prolonged clopidogrel and aspirin therapy (3 to 6 months) was associated with low (less than 2%) incidence of late thrombosis (357,358).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Despite extensive basic scientific and clinical research, the epidemiology, prophylactic measures, and treatment of restenosis after angioplasty are still surrounded by controversy. For example, for many years the working hypothesis of restenosis pathophysiology focused on neointimal hyperplasia. Thus, pharmacologic and mechanical therapies targeted thrombus formation, intimal dissection, and smooth muscle cell proliferation in keeping with this hyperplastic paradigm. Subsequent histologic investigations in animal models (363) and serial intravascular ultrasonographic data from clinical studies (18), however, suggested that the majority of lumen loss after balloon angioplasty was due to negative arterial remodeling or vessel contracture, not neointimal growth. These new findings may explain why some final lumen diameters have been reported to increase in the months after angioplasty, whereas in other cases lumen diameters remain the same or restenosis develops (Fig. 83.2) (38). They would also explain why early pharmacologic therapies did not improve restenosis after balloon angioplasty. Hence, reevaluation of those therapies that limited neointimal growth but were not successful in halting the remodeling-induced restenosis of balloon angioplasty is reasonable. Used in association with intracoronary stents, these agents may prove to be particularly useful. Agents for which results currently appear hopeful include probucol, cilostazol, paclitaxel, and rapamycin.

Although the effect of remodeling was being elucidated in the balloon angioplasty population, intracoronary stent placement increased in frequency to become the leading procedure, and in-stent restenosis is almost entirely due to neointimal hyperplasia. This has necessarily led to reevaluation of the epidemiology of restenosis. Regarding predictors of restenosis, most of the previously described anatomic and demographic risk factors still apply to contemporary balloon angioplasty procedures. On the other hand, data on intracoronary stents show that these well-entrenched restenosis predictors have decreased in importance (Table 83.2). For example, unstable angina, chronic total occlusion, vessel treated, and lesion length—all strong predictors of restenosis after balloon angioplasty—have little or no predictive value for restenosis after stent placement.

The rapid replacement of balloon angioplasty by intracoronary stent placement has also introduced several other important controversies. First, despite several focused studies comparing balloon angioplasty to stent placement, much of the rush to use stents in the interventional laboratory has not been evidence based. For example, although few controlled data are available, stents are being placed in gradually smaller vessels, in longer lesions, and in lesions already containing a restenotic stent. Although these practices may be the treatment of choice in the future, current practice remains ahead of prospectively collected evidence and technology. Several studies are continuing to elucidate when a “stent-like” result obtained with balloon angioplasty or other techniques alone provides a restenosis rate similar to that achieved with stent placement.

A second area of current interest created by the rapid flux of stent use includes both the prophylaxis and treatment of in-stent restenosis. Despite the relatively low rate of restenosis within stents, the actual number of patients with in-stent restenosis now exceeds the number with nonstent restenosis. For the prophylaxis of in-stent restenosis, radiation therapy and use of platelet glycoprotein IIb/IIIa inhibitors continue to be studied. Because diabetic patients account for approximately 20% of all patients undergoing intervention, the suggestion that abciximab may reduce target vessel revascularization among diabetic patients needs to be further explored. The 6-month data from the Do Tirofiban and ReoPro Give Similar Efficacy Outcome Trial (364) and Enhanced Suppresion of the Platelet IIb/IIIa Receptor with Integrilin Therapy (365) trials may give additional insight. Administration of gamma and beta radiation has proven successful in attenuating recurrent in-stent restenosis. Data must accumulate before the factors that predict benefit from radiation therapy can be understood (366). Likewise, one hopes that the several unattractive features of radiation delivery and safety will be improved. Although controversies do abound, the future will undoubtedly continue to supply new pharmacologic and mechanical therapies targeting restenosis. Given the complex and interrelated mechanisms of restenosis, a combination of therapies will most likely provide the optimal preventive strategy.

THE FUTURE

With new information regarding the mechanisms of restenosis and the application of strategies to limit recurrence of stenosis, the future for interventional cardiology is bright. The spectrum of patients and coronary anatomy that can be successfully treated with percutaneous revascularization will continue to broaden. At the same time, the occurrence of restenosis should be further reduced as novel techniques and agents, such as intracoronary stents incorporating radiation or antiproliferative agents, are applied.

OVERVIEW

The important issues in the postbypass patient who has recurrent angina or ischemia are providing relief of symptoms and ischemia with the least morbidity and cost and doing it in a manner that provides durable benefit. It takes considerable judgment to make the best decision in these patients because there are frequently many options, most of which have substantial baggage (complications and short-term benefit).

HISTORICAL PERSPECTIVE

Advent and Maturation of Surgical Revascularization

As was later true of percutaneous transluminal coronary angioplasty (PTCA) (1,2 and 3), surgical coronary revascularization began more than 30 years ago with attempts to revascularize a single coronary artery. The result of these efforts was a dramatic change in cardiologic practice as surgical techniques adequate to palliate multivessel obstructive disease evolved. Within a decade, the growth of coronary bypass surgery was exponential (Fig. 84.1). Hundreds of thousands of patients were operated on annually, creating a large population of several million postbypass patients in the United States alone. Owing to the progressive nature of the atherosclerotic process and the limited durability of venous conduits and in spite of widespread use of arterial grafts and antiplatelet agents, recurrent ischemia after surgical revascularization is a problem all cardiologists face with increasing frequency. Recurrence of angina in the first year alone was reported in 24% of patients in the Coronary Artery Surgery Study (4), and by the fifth postoperative year, almost one-half of the broad spectrum of postoperative patients have recurrent symptoms (4,5 and 6).

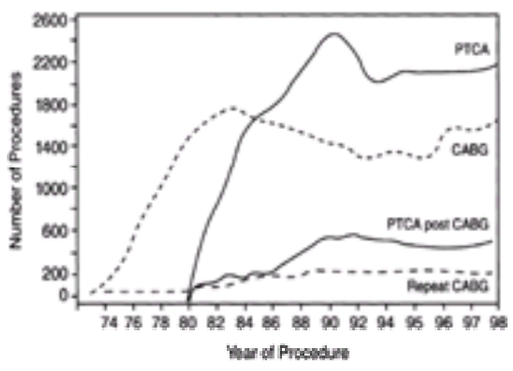

FIGURE 84.1 Coronary artery revascularization procedures at Emory University Hospitals from 1973 to 1998. CABG, coronary artery bypass grafting; PTCA, percutaneous transluminal coronary angioplasty.

Recurrent angina sufficient to require reoperation occurred in 12% to 15% of patients within one decade of a first coronary operation at Emory University and at The Cleveland Clinic, and by the twelfth to fifteenth year, 30% required reoperation (7,8). Reoperative coronary surgery when compared with initial operation proved to be more costly, two to three times more likely to lead to in-hospital death or myocardial infarction (MI), and less effective in achieving angina relief (7,9,10 and 11). Among 2,030 patients who underwent reoperation at Emory University, in-hospital mortality was 7.0% (4.6% younger than 60 years, 8.2% aged 60 to 69, 10.0% 70 years or older). Five- and 10-year survival was 76% and 55%, respectively (10). Reported outcome data confined to patients who underwent reoperation in the 1990s confirmed the high operative mortality noted previously (7.4%) and reported a higher rate of Q-wave infarction, a longer length of stay, and higher costs than initial operations (11). The increase in complications and reduced efficacy of reoperative coronary surgery are probably related to the more extensive disease present, the requirement to use second-line venous conduits in many cases, and the technically more difficult and operator-dependent nature of reoperative heart surgery.

Percutaneous Intervention Postbypass

Percutaneous catheter revascularization in patients who had prior coronary bypass surgery (Fig. 84.2) was first described by Gruentzig, who treated eight patients, six successfully, among the first 50 patients he reported. Seven of the eight postbypass patients had angioplasty of saphenous vein graft (SVG) lesions, and three of five treated successfully had recurrences, leading Gruentzig to make the following insightful comments based on such limited observations: "The different kind of disease may explain the high incidence of recurrence in graft stenosis. Further experience will show whether we should eliminate this lesion from consideration" (12).

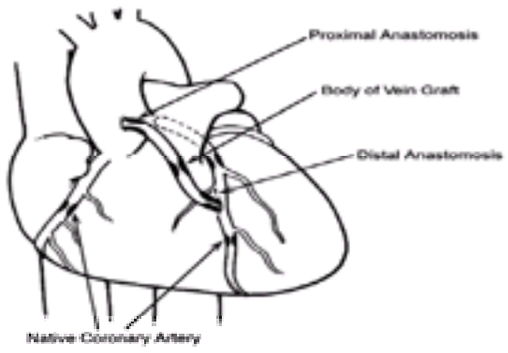

FIGURE 84.2 Targets for percutaneous coronary intervention include saphenous vein grafts and native coronary artery sites in unbypassed and bypassed vessels. In addition, internal mammary artery, radial, subclavian, innominate, and gastroepiploic artery grafts are potential targets. (Adapted from Douglas JS Jr, Gruentzig AR, King SB III, et al. Percutaneous transluminal coronary angioplasty in patients with prior coronary bypass surgery. *J Am Coll Cardiol* 1983;2:745–754, with permission.)

Among the first 1,116 patients treated with coronary angioplasty in the National Heart, Lung, and Blood Institute PTCA Registry, 62 patients had had previous bypass surgery. The in-hospital mortality in these patients, 8.1%, was significantly higher than in patients without prior surgery, 0.7%, causing concern about the safety of the procedure in this group of patients (13). The early experience at Emory University was reassuring, however; 116 patients were treated with no procedural death, three emergency operations, and one Q-wave MI (Fig. 84.2). One late death occurred during an 8.3-month mean follow-up. Gruentzig's observation of higher restenosis rates for SVGs was reaffirmed for mid- and proximal graft sites, but an acceptable restenosis rate for distal anastomosis lesions of 18% (4 of 22) was first reported (Fig. 84.3) as well as the initial report of attempted internal mammary artery (IMA) graft angioplasty (14). In subsequent experience with more than 34,000 coronary angioplasty procedures at Emory University, a history of prior bypass surgery was not associated with increased risk of death or Q-wave MI and was negatively correlated with need for in-hospital coronary artery bypass graft (CABG) surgery (15).

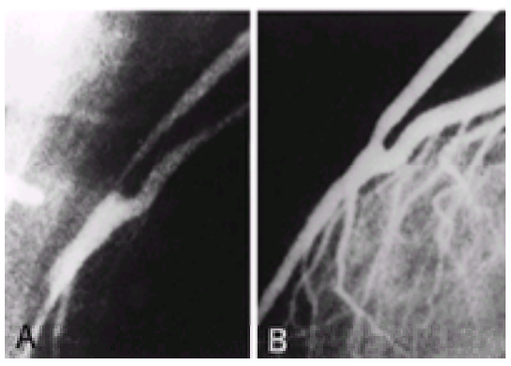

FIGURE 84.3 A 57-year-old man underwent saphenous vein bypass grafting to the distal left anterior descending (LAD) artery in July 1981; coronary arteriography a few months later **(A)** revealed high-grade stenosis at the junction of the saphenous vein graft to the LAD artery (left lateral view). Percutaneous transluminal coronary angioplasty was successful (residual stenosis, 13%), and recatheterization 9 months later showed a widely patent anastomosis **(B)**. The patient subsequently remained completely asymptomatic, and at last follow-up 19 years later (July 2000), he had a negative stress thallium scan result. (From Douglas JS Jr, Gruentzig AR, King SB III, et al. Percutaneous transluminal coronary angioplasty in patients with prior coronary bypass surgery. *J Am Coll Cardiol* 1983;2:745–754, with permission.)

Percutaneous coronary intervention (PCI) became a less invasive revascularization alternative for many symptomatic postbypass patients (Fig. 84.1), including an increasing number who, because of contraindications (pulmonary and renal failure, old age, malignancy), were not candidates for reoperative coronary artery surgery. Patients with patent arterial grafts that would be jeopardized by reoperation, patients with relatively small amounts of ischemic, symptom-producing myocardium, and patients with no available venous or arterial conduits for grafts underwent percutaneous revascularization at an acceptable risk. At many centers, patients with prior bypass surgery account for up to 25% of the PCI procedures performed (Fig. 84.1).

In 4,174 postbypass patients who underwent coronary revascularization at Emory University, 2,613 (63%) underwent PTCA, and 1,561 (37%) underwent CABG, with 1.2% and 6.8% (p <.0001) in-hospital mortality, respectively, and with in-hospital costs of $8,500 ± $7,300 for PTCA compared with $24,200 ± $17,000 ($p$ <.0001) for CABG (16). The initial cost advantages of PTCA over CABG may, however, be moderated by the current increasing use of multiple devices, especially stents, in postbypass patients, a group of patients in whom coronary interventional strategies have the broadest application and by subsequent reinterventions. It is the goal of this chapter to focus on the cause and treatment, emphasizing percutaneous revascularization strategies, of recurrent angina after bypass surgery.

ANATOMIC CONSIDERATIONS

Among the anatomic factors influencing revascularization decisions (Table 84.1), the status of the left anterior descending coronary artery (LAD) and its graft is paramount. Placement of an IMA, a conduit immune to atherosclerosis, as a graft to the LAD has been shown to enhance survival and reduce ischemic events 10 to as long as 20 years later (17,18 and 19). In a patient with a patent IMA graft to the LAD, reoperative surgery to treat non-LAD ischemia has been reported to offer no survival benefit (20,21), may jeopardize the arterial graft, and, in our experience and others, more frequently leads to percutaneous intervention. Multivessel involvement, small number of patent grafts, severe vein graft disease (especially if to LAD), and a damaged left ventricle are factors more likely to lead to reoperative surgery (22,23).

Often leads to percutaneous transluminal coronary angioplasty	Often leads to coronary artery bypass grafting
Patent arterial graft (especially left anterior descending coronary artery)	Diseased saphenous vein graft to left anterior descending
≤2 patent grafts	Bulky saphenous vein graft atheroma
1–3 culprit lesions	>3 culprit lesions
Difficult surgical access	Multiple saphenous vein graft lesions
Mediastinal scarring secondary to radiation, infection, or pericarditis	Available arterial conduits
Prior muscle transfer closure of unhealed sternotomy	Ejection fraction 25% to 35%
Posterior lateral target vessel	
Inadequate conduits	
Near normal left ventricle	
Future cardiac surgery anticipated	
In situ prosthetic valve	
Mild to moderate aortic or mitral valve disease	

P>**TABLE 84.1** ANATOMIC FACTORS INFLUENCING REVASCULARIZATION DECISIONS IN POSTBYPASS PATIENTS

PATHOPHYSIOLOGY: BASIS FOR RECURRENT ISCHEMIA

Incomplete Revascularization

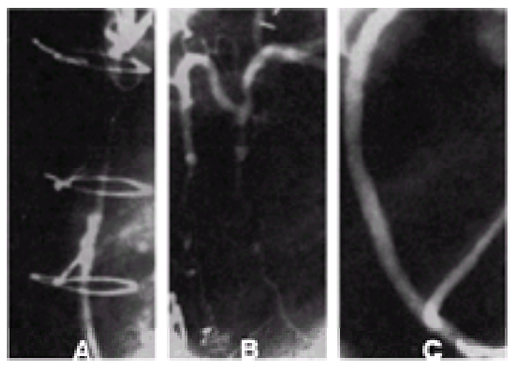
In many patients, complete surgical revascularization was not achieved due to the presence of distal coronary disease, whereas less common causes include the following: an inadequate amount of venous or arterial conduit, inadequate conduit lumen due to small vessel size (IMA especially) or injury, intramyocardial location of target coronary vessel, placement of grafts to the wrong coronary artery or to a coronary vein, creating an arterial venous fistula (24), use of an IMA in the presence of significant stenosis of the subclavian or innominate arteries (25,26), or coronary steal phenomenon attributed to large arterial graft side branches (27), a cause that has been questioned (28). Intentional incomplete surgical revascularization is an increasingly frequent phenomenon in patients selected for "beating heart" operations because of the technical difficulty of bypassing posteriorly located coronary arteries. In some patients, this strategy has resulted in subsequent percutaneous revascularization because of inadequate relief of symptoms. In others, incomplete surgical revascularization has been dealt with up front with adjunctive percutaneous

revascularization during the same hospitalization, the so-called hybrid approach. In addition to less complete revascularization with beating heart surgery, there is some evidence that less precise anastomoses may compromise graft patency, especially in the surgical learning curve (see Venous Graft Attrition and Arterial Graft Compromise, later in this chapter).

Loss of Revascularization Benefit

Venous Graft Attrition

In patients with recurrent ischemia and infarction after bypass surgery, stenosis, occlusion, or both stenosis and occlusion of SVGs is the most common cause of venous graft attrition (6,21,29,30,31,32,33,34,35,36,37,38,39 and 40). Thrombotic occlusion related to surgical technical problems or slow graft flow secondary to a small or compromised distal coronary arterial bed results in closure of 10% to 15% of SVGs within the first month (29,30 and 31), and even with aspirin therapy, 7% of vein grafts were shown to be occluded by 9 days, with up to 17% of patients having a closed graft at that time (29). Subsequently 15% to 20% of vein grafts occlude by 1 year, 1% to 2% per year from years 1 to 6, and 4% per year from 6 to 10 years after surgery (eFig. 84.3.1) (29,30 and 31,41). After 10 years, a minority of vein grafts were free of significant occlusion disease (32,45).



***e*FIGURE 84.3.1** A 66-year-old man with unstable angina and two prior bypass operations, the first to the right coronary artery 15 years ago and the last to the right and left anterior descending arteries 10 years ago, was found to have a long stenosis of the saphenous vein graft to the right coronary artery **(A)**. The left internal mammary artery graft to the left anterior descending was patent. Recanalization of the old right coronary artery occlusion **(B)** was successful using a stiff hydrophilic-coated guidewire and conventional balloon angioplasty followed by placement of 3.5-mm stents **(C)**. The patient was treated for right coronary artery in-stent restenosis 2 years later, and at 5 years the patient was asymptomatic and fully active.

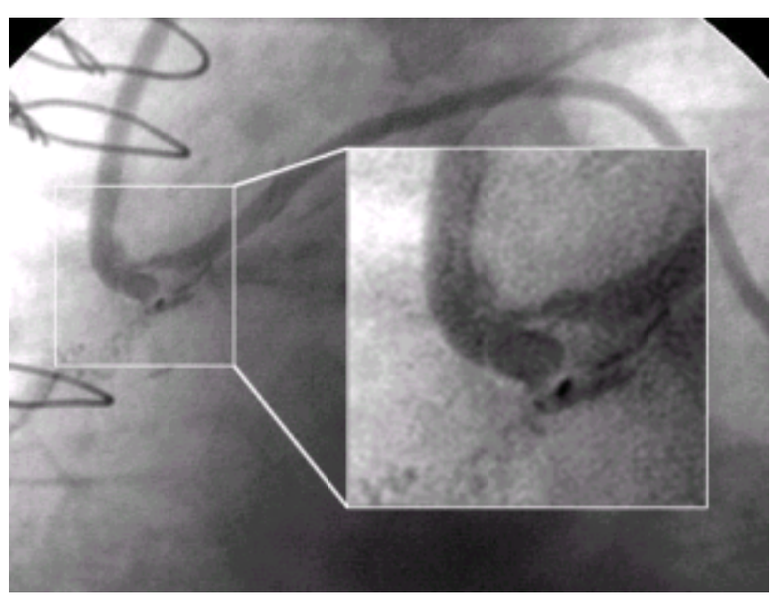
The morphologic changes occurring in arterialized saphenous veins that lead to stenosis and occlusion have been described in detail (42,43 and 44). Diffuse intimal thickening universally present in vein grafts in place longer than 1 month infrequently causes high-grade focal narrowing but may account for the following: perianastomotic lesions, stenoses where vein branches have been ligated and clipped, and diffuse narrowing throughout a graft (43,45). Use of beating heart surgical techniques has resulted in more frequent anastomotic problems, probably related to learning curve issues and the currently evolving technology that is used to assist the surgeon by stabilizing the heart. Beginning approximately 3 years after surgery, atherosclerotic vein graft lesions become increasingly frequent. Vein graft atheroma contain foam cells, cholesterol clefts, blood elements, and necrotic debris with less fibrous tissue and calcification than is present in native coronary arteries (44,46). Atheroma in older vein grafts are frequently larger, softer, and more friable than native coronary lesions and are more likely to lack a fibrous cap and have associated thrombus (47,48,49 and 50), all features with ominous prognostic implications for subsequent cardiac events and for atheroembolic complications of percutaneous intervention. Information from surgical and angioplasty series are concordant, indicating that even mild stenoses of vein grafts are associated with significant risk of recurrent ischemic events (stenosis 41% to 50%, recurrent ischemic events 45%; stenosis 31% to 40%, recurrent ischemic events 18%; stenosis less than or equal to 30%, recurrent ischemic events 2%) (21,51). Extrinsic focal compression of SVGs by mediastinal scar is infrequently recognized by development of stenosis at a fixed graft flexion point, and high balloon pressure is frequently required to dilate such stenoses.

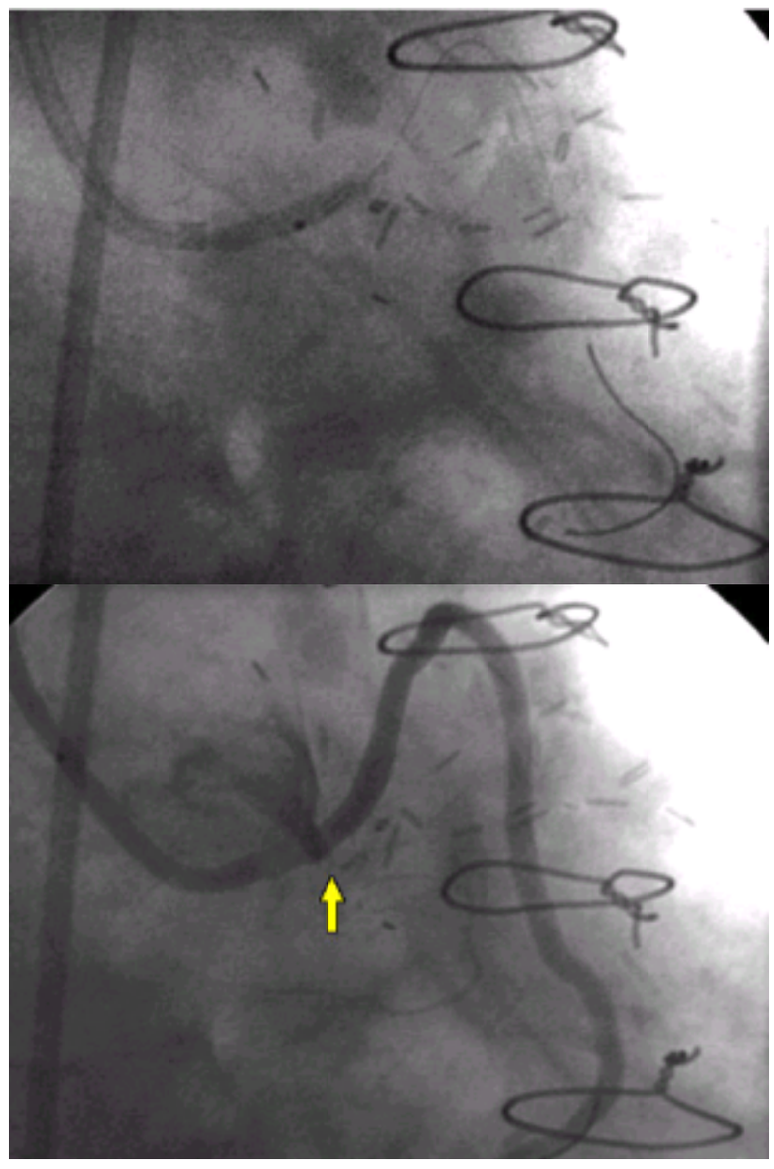
Native Coronary Artery Progression

Worsening of native coronary artery disease after bypass surgery has been reported in approximately 5% of patients annually (52,53 and 54). Frequency of disease progression at native vessel sites at 5 years was reported as follows: proximal to graft insertion (70%), unbypassed artery (15%), and distal to graft insertion (0%) (55). Loop and colleagues noted that progression of disease distal to grafts was uncommon and that at 2 years progression of disease proximal to grafts was more common for SVG than for IMA grafts (67% vs. 39%) (18). Progression of native coronary disease proximal to grafts has implications for coronary intervention when graft disease or occlusion occurs and is an important cause of ischemia due to poor perfusion of side branches (such as diagonal coronary arteries).

Arterial Graft Compromise

Although numerous publications attest to the excellent long-term patency of arterial grafts, several hundred patients have been reported who required IMA, radial artery, or subclavian artery intervention (25,26 and 27,56,57,58,59,60,61 and 62). In most instances IMA interventions were needed for anastomotic lesions, but proximal and midgraft sites have been treated (see Arterial Graft Intervention). The technical difficulty of performing an anastomosis in beating heart surgery probably accounts for more anastomotic problems after this type of surgery.



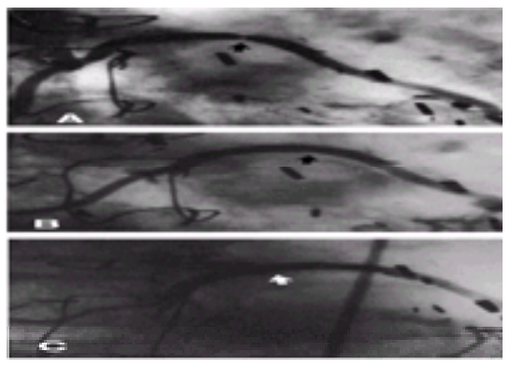


Palmaz-Schatz coronary stent placement in the ostium of a free right internal mammary artery graft to an obtuse marginal branch of the left circumflex (A). The stent is positioned so that the proximal 1 to 2 mm of the stent protrudes into the ascending aorta to guarantee coverage of the ostium (B). The postintervention result is shown in C.

CLINICAL PROFILE

Early Postoperative Ischemia (within the First Year)

Recurrent ischemia presenting as unstable angina or MI within a few hours or days of surgery is usually due to venous graft thrombosis, but coronary arteriography may reveal a compromised proximal or distal anastomosis, narrowing in the midportion of a graft due to graft torsion, IMA spasm, incomplete revascularization, or other surgical technical problems (injured IMA, and so forth), and in 25% of patients, the cause of ischemia is not apparent (61,62 and 63). Occlusion of an important graft may produce cardiogenic shock (64). Recurrent angina between 1 month and 1 year postoperation is most often due to perianastomotic stenosis (Fig. 84.3), graft occlusion, or mid-SVG stenoses due to fibrous intimal hyperplasia (eFig. 84.3.2) and only rarely due to progression of native coronary artery disease. Recurrence of angina at approximately 3 months postoperatively is highly suggestive of a distal graft anastomosis lesion and should, in most cases, lead to coronary arteriography.

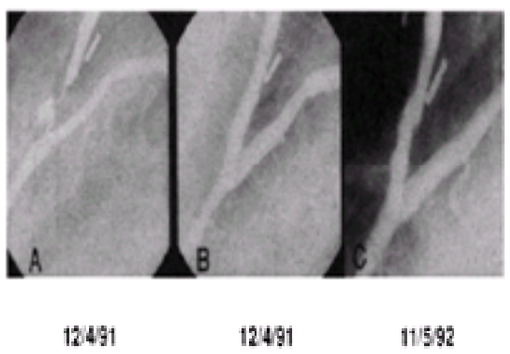


***e*FIGURE 84.3.2** A 74-year-old man developed unstable angina within 5 months of bypass surgery (left internal mammary artery to left anterior descending and saphenous vein graft to obtuse marginal). The right coronary artery was occluded and not grafted. Balloon angioplasty of a stenosis of the midportion of the vein graft to the circumflex was twice followed by restenosis within 6 weeks. Because of severe recurrent angina, a focal stenosis of 88% **(A)** (*arrow*) was dilated and stented with a 3.5-mm Palmaz-Schatz stent in July 1991 with an excellent initial result **(B)** (*arrow*). Protocol-driven recatheterization 7 months later revealed a widely patent stent site **(C)** (*arrow*). The patient has remained completely asymptomatic and fully active for over 5 years (last follow-up, July 1996).

Late Postoperative Ischemia (Greater Than 1 Year)

When ischemia develops more than 1 year following bypass surgery, culprit lesions are commonly present in graft conduits and in native coronary arteries. In 95 postbypass patients with unstable angina or non–Q-wave infarction, culprit lesions were identified in 51 vein grafts, 17 ungrafted coronary arteries, and 9 grafted arteries; in 18 patients a culprit lesion could not be determined. One-half of the vein grafts and 25% of unbypassed coronary arteries were totally occluded (33).

Approximately 3% of postbypass patients experienced acute MI annually (65), and mortality related to reperfusion strategies was relatively high, presumably due to the presence of multivessel disease and prior MI (34,35 and 36). In two-thirds of patients with evolving infarction, the culprit lesion was in a vein graft (*e*Fig. 84.3.3) (34,35 and 36,49), and this may have contributed to the low reperfusion rate of 25% reported by some (37) but not all investigators (39) with intravenous thrombolytic therapy.



***e*FIGURE 84.3.3** A 74-year-old man presented in December 1991 with unrelenting chest pain, left bundle branch block, and hypotension. There was a history of bypass surgery (1981) and prior percutaneous transluminal coronary angioplasty to the circumflex coronary artery, a saphenous vein graft to the left anterior descending coronary artery (LAD), and an occluded right coronary artery. Coronary angiography revealed a complex stenosis of the saphenous vein graft to the LAD (**A**, left lateral view). Balloon angioplasty and deployment of a 3.5-mm stent yielded an excellent angiographic result **(B)**. Follow-up angiography 1 year later revealed only mild narrowing **(C)**. At last follow-up 6 years later, the patient was asymptomatic and had had no cardiac events. Younger patients with such complex saphenous vein graft lesions of left anterior descending grafts are commonly referred for reoperation in our hospital. (From Douglas JS Jr. Percutaneous strategies for the management of angina pectoris after bypass surgery. In: Ventrovec GW, Carabello BA, eds. *Invasive cardiology: current diagnostic and therapeutic issues*. Armonk, NY: Futura Publishing, 1996:489, with permission.)

PRINCIPLES OF MANAGEMENT

Preventive Measures

Patients who have had coronary bypass surgery are at substantial risk for subsequent cardiac events related in large part to progressive arteriosclerosis. Recurrence of angina, angiographic progressions of vein graft atheroma, and pathologic changes at autopsy have been correlated with increased serum lipids and smoking, and lipid lowering has been shown to be beneficial (4,9,41,48,66,67 and 68). Given the increased effectiveness of current strategies for lipid lowering and smoking cessation, and reduced cardiac events that accrue, an aggressive approach to risk factor modification is mandatory in all postbypass patients. An aggressive lipid-lowering strategy resulted in a 30% reduction in revascularization (p = .0006) and a 24% reduction in a composite clinical end point (p = .001) during 7.5 years of follow-up in the post-CABG trial (67,68). The place of more aggressive antiplatelet therapy in the post-CABG patient is not clear, but more recently reported mortality benefits with clopidogrel are provocative and suggest that the use of this or other adjunctive agents may become routine in the future (69).

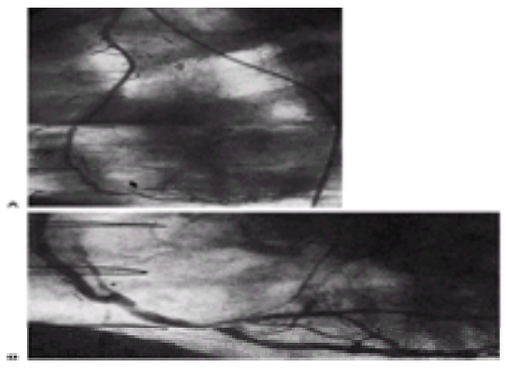
Treatment of Ischemia in the Postoperative Patient

Patients with recurrent symptoms or signs of ischemia after bypass surgery constitute an extremely heterogeneous group (Fig. 84.2). Treatment strategies must be based on a careful analysis of multiple factors (many angiographically based) including anatomic factors (Table 84.1), the likelihood of a successful percutaneous intervention, risk of complications, probability of long-term symptomatic benefit, and resource consumption compared with other viable options (7,14,70,71,72,73,74 and 75). Patient preferences must be considered since reinterventions are common with percutaneous intervention in postbypass patients, occurring in approximately 50% of patients at 5 years (72). In the postbypass patient, the ability to effect ischemia relief percutaneously is influenced by the time that has lapsed since surgery, the type of conduit (SVG vs. native vessel vs. IMA graft), and location of the stenotic segment.

Native Coronary Intervention

Technical Strategy

Although SVG attrition is the most common cause of ischemia postbypass, native vessel intervention frequently offers the most durable percutaneous revascularization and should be considered whenever possible. Approaches to native vessel sites in the postbypass patient present unique challenges including treatment of very old, calcified stenoses including left main coronary disease, recanalization of old total occlusions (eFig. 83.3.1), and treatment of native vessel sites via grafts. Treatment of native coronary sites via IMA grafts or SVGs may require even better guide catheter support and longer balloon catheters (or shorter guide catheters) than are necessary for graft angioplasty (eFig. 84.3.4), especially if catheters must be passed retrograde into native vessel sites proximal to graft insertion (see Saphenous Vein Graft Intervention and Arterial Graft Intervention). Retrograde passage to proximal coronary artery sites may require special guidewire strategies and high-performance catheters to traverse the sharp angles involved (73).



***e*FIGURE 84.3.4** A 57-year-old man developed disabling angina 7 years following bypass surgery. Cardiac catheterization revealed normal left ventricular function, a patent left internal mammary artery to the left anterior descending, and a patent right internal mammary artery to the right coronary artery, but severe stenosis of the continuation of the right coronary beyond the posterior descending **(A)**. Black arrow indicates site of lesion. Angioplasty was successful **(B)** from the femoral approach using a 145-cm balloon catheter. Four and a half years postangioplasty, the patient developed mild angina, and recatheterization showed no significant changes, with only mild narrowing at the percutaneous transluminal coronary angioplasty site, and medical therapy was advised.

Results of Native Coronary Intervention

The procedural outcome of angioplasty for native coronary intervention after CABG was reported for the first 372 such patients treated at Emory in 1987 (74). Most were men (81%), and 78% had multivessel disease. Angiographic success was achieved in 91%, and in-hospital complications were infrequent: mortality, 0.3%; Q-wave MI, 2%; non–Q-wave infarction, 4%; bypass surgery, 6%. At Mid-America Heart Institute, 1,543 postbypass patients underwent angioplasty of native coronary arteries; 21% were older than 70 years, 47% had unstable angina, and 74% had triple-vessel disease. Angiographic success was 94%, in-hospital mortality 0.8%, Q-wave MI 1.5%, and emergency bypass surgery 1.0% (75). At Emory University between 1980 and 1995, 2,246 postbypass patients underwent coronary intervention of native arteries with favorable outcome: procedural success 89%, in-hospital mortality 1%, Q-wave MI 1%, non–Q-wave infarction 4% (creatine kinase greater than three times normal), and emergency or elective surgery 2.8%. Although the definitions of outcomes were slightly different in these series, the overall procedural results were favorable, with a trend toward less need for in-hospital bypass surgery for failed percutaneous intervention. These outcomes were largely that of conventional balloon angioplasty. The Mayo Clinic experience with 937 post-CABG patients treated between 1995 and 1998 reflected a dramatic increase in stent use to 76% of patients and a reduction in use of atherectomy and laser strategies. Patients who underwent interventions in native vessels were younger, more likely female, had less severe coronary disease (70), and had a more favorable long-term outlook than those who underwent venous bypass graft intervention (71).

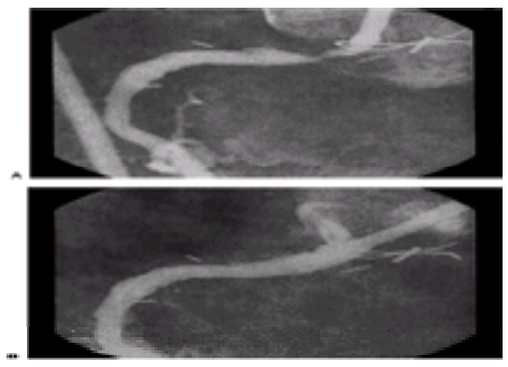
Saphenous Vein Graft Intervention

Technical Strategy

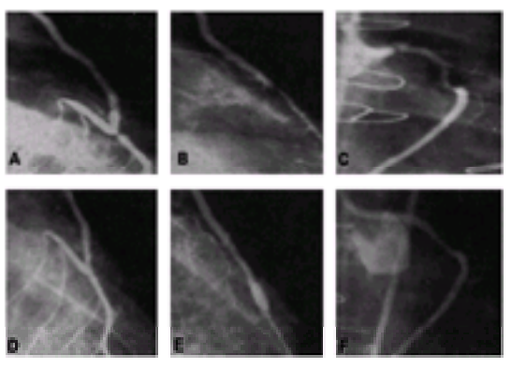
Guide catheters for SVG interventions are selected to achieve coaxial alignment and excellent backup support. For grafts arising from the outer curve of the aorta (usually to the right coronary), the multipurpose shape is best; for grafts arising anteriorly (LAD and diagonal), many shapes are adequate (right Judkins, left venous bypass, hockey stick), but for grafts arising in the inner curve (to the circumflex), guide catheter selection is critical, and the hockey stick and Amplatz left shapes are used most often. Side-hole guide catheters are sometimes used to avoid flow interruption with catheter engagement (i.e., with small grafts and ostial lesions).

Video 84.1 The angiographic characteristics of a lesion are important to characterize the risk associated with treating the lesion percutaneously. Left anterior oblique angiogram showing eccentric ulcerated lesion in a saphenous vein graft to the posterolateral branch of the left circumflex coronary artery. (Courtesy of Dr. Debabrata Mukherjee.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Balloon angioplasty is performed frequently at Emory University for focal lesions at the distal anastomosis occurring within a year of surgery. Almost all other SVG interventions include stent implantation with a balloon to graft diameter ratio of unity. Slight oversizing of the stent is usually safe when dealing with restenotic lesions. Inflation pressures exceeding 15 atm are used only to achieve complete stent expansion due to data from the Stent Versus Angioplasty in Saphenous Vein Graft (SAVED) trial, suggesting higher pressure had a deleterious effect on 6-month angiographic outcome in vein grafts (76). Although based only on clinical experience, many operators use a slightly longer stent than might be selected for a native vessel lesion (due to longitudinal extrusion of the plaque material) and prefer to use a high scaffolding stent placed without predilation to trap as much atheroma as possible. Directional atherectomy is not currently used for mid-SVG lesions due to increased complications and lack of long-term benefit (see Results of Saphenous Vein Graft Intervention, later in this chapter). Aortoostial vein graft lesions (*e*Fig. 84.3.5) are most often treated with placement of stents (77,78,79 and 80). Debulking before stenting aortoostial lesions is probably unnecessary based on results of observational studies (79). Nondilatable aortoostial or distal anastomotic lesions have been successfully treated with rotational or directional atherectomy (80) (*e*Fig. 84.3.6). Techniques to achieve protection from distal embolization of graft atheroma are currently evolving and will become an integral part of vein graft intervention (see Results of Saphenous Vein Graft Intervention, later in this chapter, and Chapter 81). Whether filters, covered stents, or occlusion-aspiration techniques are used depends on the location of the lesion and the availability of appropriate distal protection devices currently undergoing evaluation.

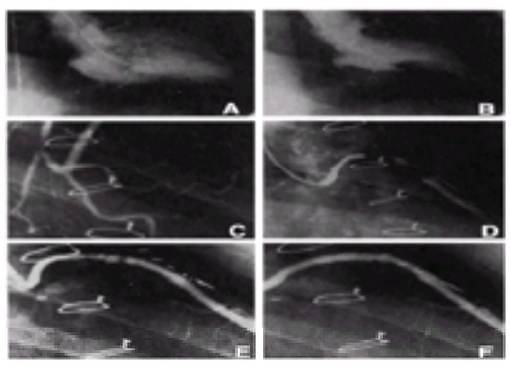


***e*FIGURE 84.3.5** Right anterior oblique view of a severe aortoostial stenosis of the saphenous vein graft to the right coronary artery in a 77-year-old woman with disabling angina that was refractory to medical therapy 4 years after coronary artery bypass grafting **(A)**. A vein graft to the left anterior descending was patent. Directional coronary atherectomy of the stenosis was successful using a JR 4.0 inferiorly directed guide catheter and 7-G AtheroCath without predilating **(B)**. The patient developed restenosis 3 months later with recurrence of unstable angina. Directional coronary atherectomy was repeated with a similar angiographic result, and 7 years postatherectomy, the saphenous vein graft to the right coronary artery was widely patent. Unfortunately, restenosis is relatively common at this site with directional coronary atherectomy, stents, and laser angioplasty. Most patients are currently treated with stent implantation without debulking procedures.



***e*FIGURE 84.3.6** A 53-year-old non–insulin-dependent diabetic secretary developed unstable angina and was found to have severe left main coronary disease with a dominant circumflex artery and underwent bypass surgery [left internal mammary artery to left anterior descending, saphenous vein graft to posterior lateral obtuse marginal (PLOM), saphenous vein graft to anterior lateral obtuse marginal (ALOM)] in September 1995. Angina recurred in February 1996, and a stenosis of the saphenous vein graft to ALOM was dilated successfully. In June 1996, unstable angina recurred, and cardiac catheterization revealed left ventricular hypokinesis with an ejection fraction of 30%, 80% stenosis of the left anterior descending artery just beyond insertion of the left internal mammary artery graft **(A)**, severe stenosis at the junction of the saphenous vein graft with ALOM **(B)**, closed saphenous vein graft to PLOM, severe stenosis of the ostium of the left main coronary, and moderately severe proximal circumflex stenosis **(C)**. The left anterior descending artery was successfully dilated **(D)**. The stenosis at the junction of the saphenous vein graft with ALOM failed to respond to 26-atm inflation of a 2.5-mm balloon catheter, and this site was successfully treated with rotational atherectomy (1.5- and 1.75-mm burrs) followed by a 2.5-mm balloon inflation with excellent result **(E)**. The left main coronary artery was dilated and stented with a Palmaz-Schatz 3.0-by 7-mm stent that was postdilated to 15 atm, and the proximal circumflex was dilated with a 3.0-mm balloon **(F)**. Intravascular ultrasound revealed excellent stent and proximal circumflex results. The patient was asymptomatic and working full-time at last follow-up 5 years later.

SVG lesions with associated thrombus are considered to be high-risk lesions and are treated with percutaneous intervention only if there are no better alternatives. Most such lesions are treated with mechanical thrombectomy followed by stenting (*e*Fig. 84.3.7) or by pretreatment with heparin and a IIb/IIIa platelet receptor inhibitor for a few days before intervention (81,82,83 and 84). Infusions of a thrombolytic agent into the graft have been carried out before intervention to reduce thrombus (85,86 and 87), and thrombolytic agents or IIb/IIIa inhibitors have been delivered locally (88,89 and 90). Ultrasound thrombolysis is an interesting strategy currently being evaluated (91,92). Completely occluded SVGs are rarely recanalized unless there are both recent occlusion and ongoing ischemia.



***e*FIGURE 84.3.7** A 61-year-old woman with a history of bypass surgery 9 years earlier was hospitalized with prolonged chest pain and anterior T-wave changes. A thallium scan revealed a large anterior septal perfusion abnormality with almost complete redistribution (large ischemic defect, small scar?). Left ventricular angiography showed minimal anterior hypokinesis and a normal ejection fraction **(A,B)**. A saphenous vein graft to the circumflex was patent **(C)**. The right coronary artery and proximal left anterior descending (LAD) were occluded. The saphenous vein graft to the LAD had no effective flow, and a large thrombus was present. There was no antegrade or collateral flow to the distal LAD. Intragraft urokinase was given, and after 3 days of heparin, there was no change in the LAD graft **(D)**. Transluminal extraction catheter atherectomy followed by a 12-hour infusion of abciximab (ReoPro) removed much of the thrombus **(E)** and restored flow into a large distal LAD that appeared suitable for bypass surgery, but there were no donor veins, both internal mammary arteries were inadequate by angiography, and the gastroepiploic artery was unavailable due to previous gastric surgery. Two 4-mm Palmaz-Schatz stents were deployed in the vein graft with excellent angiographic

results **(F)**.

In the presence of thrombus or bulky vein graft lesions, there is an increased incidence of slow or no reflow and MI due to distal embolization and microvascular spasm (50,93,94), and calcium channel blocking agents have been helpful in prevention and relief of this phenomenon (verapamil or diltiazem, 100-µg doses intracoronary to a total of 900 µg) (94,95); adenosine and nitroprusside have also been used in this setting (96,97).

The place of glycoprotein IIb/IIIa inhibitors in SVG PCI has not been clearly established (see below). Because the use of these agents is intuitively appealing in SVG PCI, many PCI operators administer them even though the limited published data do not support their use (98).

Results of Saphenous Vein Graft Intervention

A number of reports have described the results of balloon angioplasty in SVG disease (eTable 84.1.1) (14,99,100,101,102,103,104,105,106,107,108,109,110,111,112,113,114,115,116,117 and 118), indicating that in selected patients success rates of approximately 90% were achieved with mortality of approximately 1%, Q-wave MI of less than 2%, and in-hospital CABG in approximately 2% of patients. Many of these patients had relatively favorable anatomy with focal lesions free of obvious thrombus. Non–Q-wave MI, the most frequent complication, occurred in 78 (13%) of 599 patients at Emory University (105). The length of time since surgery was an important predictor of restenosis (less than 6 months, 32%; 6 months to 1 year, 43%; 1 to 5 years, 61%; and 64% for those older than 5 years, $p < .02$) as was the location of the lesion (proximal anastomosis, 68%; midgraft, 61%; distal anastomosis, 45%; $p < .06$). The lowest restenosis rate, 22%, was noted for lesions that occurred at the distal anastomosis within 1 year of surgery, and these patients had excellent event-free survival (Fig. 84.3).

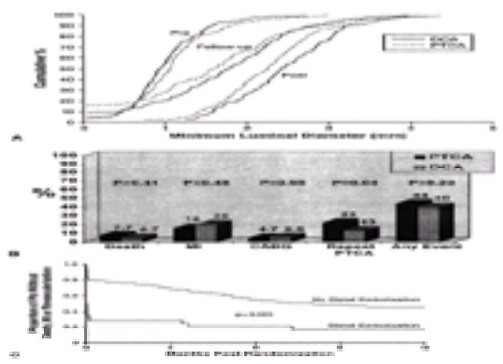
[a]A total of 19 patients (5%) had acute myocardial infarction.

Directional atherectomy, the first nonballoon procedure approved by the U.S. Food and Drug Administration, was used in SVGs with the hope that debulking would reduce complications and restenosis. A multicenter, randomized comparison of directional atherectomy and balloon angioplasty in SVGs [Coronary Angioplasty Versus Excisional Atherectomy Trial (CAVEAT II)] was performed in 305 patients, 86% with midvein lesions (111). The results paralleled CAVEAT I: higher angiographic success with atherectomy, a trend toward more non–Q-wave MIs with atherectomy (16.0% vs. 9.6%), and similar restenosis at 6 months (45.6% for atherectomy and 50.5% for angioplasty, $p = .491$) (eFig. 84.3.8). There was a trend toward more target lesion revascularization at 6 months with angioplasty (22% and 13% for atherectomy, $p = .04$) (eFig. 84.3.8B). There was, however, no difference in the frequency of experiencing any cardiac event at 6 months. Angiographic evidence of distal embolization noted twice as frequently with atherectomy (13.5% vs. 5.1%) was a predictor of adverse events in-hospital and at 12 months (112) (eFig. 84.3.8C). An increased awareness of the importance of non–Q-wave infarction combined with an absent restenosis benefit and increased cost led to decreased use of this approach for midvein lesions. Performance of directional atherectomy for treatment of aortoostial SVG lesions (eFig. 84.3.5) has been reported only in relatively small observation series with angiographic success in 94.0%, major complications in 5.9%, and repeat target lesion revascularization in 42.0% at 12 months (compared with 33% with stenting, $p = .05$) (113). Results from Emory suggest similar high subsequent cardiac event rates of approximately 50% at 1 year with balloons, directional atherectomy, and stents at proximal and midvein sites (114).



***e*FIGURE 84.3.8 A:** Graph showing preprocedure, postprocedure, and follow-up minimal luminal diameter by treatment group in the Coronary Angioplasty Versus Excisional Atherectomy Trial II (CAVEAT II), a randomized comparison of directional coronary atherectomy (DCA) and balloon angioplasty (percutaneous transluminal coronary angioplasty, PTCA) in saphenous vein graft intervention. At follow-up angiography, there was no significant difference in the minimum lumen diameter achieved by directional coronary atherectomy and PTCA. **B:** Major cardiac events at 6 months in CAVEAT II. MI, myocardial infarction. (**A** and **B** from Holmes DR, Topol EJ, Califf RM, et al. A multicenter, randomized trial of coronary angioplasty versus directional atherectomy of patients with saphenous vein graft lesions. *Circulation* 1995;91:1966–1974, with permission.) **C:** Kaplan-Meier plots of freedom from the composite end point of death, myocardial infarction, repeat intervention, or coronary artery bypass grafting for patients with or without distal embolization in CAVEAT II. (From Lefkovits J, Holmes DR, Califf RM, et al. Predictors and sequelae of distal embolization during saphenous vein graft interventional from the CAVEAT-II trial. *Circulation* 1995;92:734–740, with permission.)

Excimer laser angioplasty has been applied to treatment of SVG lesions with 495 patients reported in a multicenter registry (115). At least one in-hospital complication occurred in 6.1%: death (1.0%), bypass surgery (0.6%), and Q-wave (2.4%) or non–Q-wave (2.2%) MI. The use of a saline flush technique aimed at bloodless laser ablation for prestent debulking of high-risk vein graft lesions yielded favorable results (100% procedural success, 8.7% non–Q-wave MI, 0% no reflow, and 0% major ischemic complications in 81 patients) (116,117). However, the lack of definitive data supporting incremental benefit relative to the increased cost and complexity of laser technology has resulted in little use of lasers in SVG PCI in most centers.

Stenting of SVGs, which has become the dominant percutaneous strategy, was carried out for more than a decade, initially with mixed results. The first vein graft

implantations were with the Wallstent (Schneider, Zurich, Switzerland) (119), and subsequent reports (Table 84.2) indicated a 99% to 100% deployment success rate, a 4% to 10% rate of early thrombosis, and restenosis in 34% to 47% (125,126,127,128,129 and 130). In follow-up of 62 patients with 93 stents (90% were Wallstents) out to 5.9 years (median, 2.5 years), there was a high cardiac event rate: 8% died, 23% had MI, 20% underwent bypass surgery, and 23% underwent angioplasty. The estimated 5-year survival and event-free survival rates were 83% ± 5% and 30% ± 7% (127). Of potential importance is the fact that optimal Wallstent expansion with high-pressure balloons was not routinely used in the reported patients.

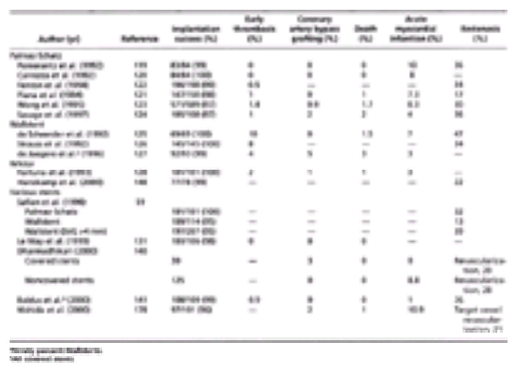


TABLE 84.2 RESULTS OF STENTING OF AORTOCORONARY SAPHENOUS VEIN GRAFTS (SVG): SELECTED REPORTS OF GREATER THAN OR EQUAL TO 50 PATIENTS

The largest experience in vein graft stenting has been with the Palmaz-Schatz stent (Johnson & Johnson Interventional Systems) (Table 84.2). Deployment success rates were high, and in-hospital complications were low, including a lower rate of stent thrombosis than was observed in native coronary artery use at that time. Six-month restenosis rates in the Multicenter U.S. Palmaz-Schatz Registry were a surprisingly low 18% for *de novo* lesions and 46% for restenotic lesions. The 12-month actuarial event-free survival was 76% (123). When used in the treatment of aortoostial vein graft disease in 29 patients, stents proved effective with 100% deployment success, and at 11 months, 24 (82%) were free of death, MI, and repeat revascularization (131). In a report of 20 patients who underwent stenting of aortoostial lesions, seven (35%) restenosed (132).

The first randomized multicenter comparison of the use of balloon angioplasty and stents in SVGs (the SAVED trial) was carried out with the Palmaz-Schatz coronary stent in 215 patients with focal *de novo* stenosis (124). Patients were excluded who had MI within 7 days, thrombus, ejection fraction less than 25%, and contraindications to coumadin anticoagulation. Graft age (mean, 10 years), lesion characteristics, and patient characteristics in the balloon (n = 107) and stent (n = 108) groups were similar except for an increased incidence of diabetes in the balloon group (36% vs. 23%, p = .03). In the stent group, 105 (97%) had successful stent deployment, two patients were treated with balloon angioplasty alone, and one with bypass surgery. In the balloon group, 96 patients (90%) were treated with balloons, seven (7%) received bailout stenting, two had bypass surgery, and two were treated medically. Procedural technical success (less than 50% stenosis with assigned therapy) was therefore higher with stenting (95% vs. 75%, p <.001). In-hospital complications of death, Q-wave MI, bypass surgery, and abrupt closure were similar, but there was a trend toward more non–Q-wave infarctions in the balloon group (7% vs. 2%, p = .10), and more stent patients required transfusions (10% vs. 1%, p = .003). At 6 months, restenosis occurred in 36% of stent patients versus 47% of balloon patients (p = .11) (Fig. 84.4A), and the minimal luminal diameter of stent patients was significantly larger (1.75 vs. 1.47 mm, p = .05) (Fig. 84.4B) as was the net gain in lumen diameter (0.87 vs. 0.52 mm, p = .015). Cumulative cardiac events (death, Q-wave MI, non–Q-wave infarction, CABG, and repeat PTCA) were significantly less frequent in stent patients (26% vs. 38%, p = .05) (Fig. 84.4C). A number of single-center and multicenter observational reports of stenting in SVGs have been reported (Table 84.2).

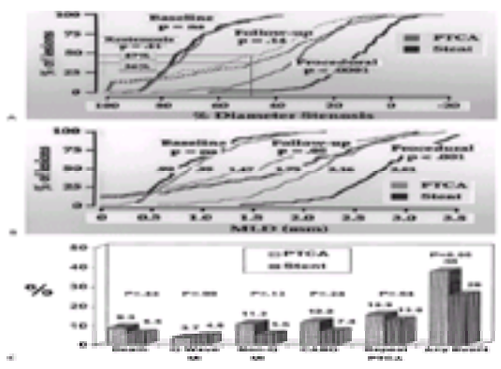

FIGURE 84.4 A: Cumulative frequency of percent diameter stenosis determined by quantitative coronary angiography before, immediately after, and at 6 months after stent or balloon angioplasty in the Stent Versus Angioplasty in Saphenous Vein Graft (SAVED) trial. **B:** Cumulative frequency of minimal luminal diameter (MLD) before, immediately after, and 6 months after stenting or balloon angioplasty in the SAVED trial. **C:** Major cardiac events experienced by patients 6 months after randomization to balloon angioplasty or stent in the SAVED trial. CABG, coronary artery bypass grafting; MI, myocardial infarction; ns, not significant; PTCA, percutaneous transluminal coronary angioplasty.

In one of the most recent publications, 106 consecutive patients who underwent SVG stenting at the Ottawa Heart Institute were reported; in-hospital success was 98%, and before discharge, no patient died, required bypass surgery, or had repeat PCI of the same graft (131). With complete follow-up at a median of 18 months, only 44% experienced event-free survival emphasizing the high late event rate after SVG stent implantation (15% died, 17% had MI, 20% had repeat CABG, and 37% had repeat PCI). Factors that have been reported to have the strongest predictive value for late adverse events after SVG stenting include unstable angina, diabetes, previous PTCA, and number of stents (132).

Several other studies of contemporary SVG stenting indicated that even with mostly single-lesion, single-stent procedures, the incidence of clinically important myocardial necrosis (creatine kinase greater than three times normal) was approximately 20%. In the Reduced Anticoagulation Vein Graft Study, 22% of patients had Q-wave or non–Q-wave MI (133), and in more than 400 patients treated in two high-volume centers from 1995 to 1997, 17% had creatine kinase MB greater than three times normal, and among these patients the 30-day mortality was 14% (134). As the lesion complexity, length, and plaque volume increased, so did the rate of myonecrosis and procedure risks (93). Procedural MI also affected long-term outcomes. In a study of 1,056 consecutive SVG PCI procedures, procedural creatine kinase MB elevation was the strongest independent predictor of late mortality (135). A heightened appreciation of the importance of atheroembolic MI in SVG PCI dovetailed with the development of strategies for distal protection generating enormous interest in its potential for improving outcomes of SVG PCI (136). Webb and colleagues, using the PercuSurge system (distal occlusion balloon and aspiration, Medtronic-AVE, Santa Rosa, CA) in 45 patients, reported aspiration of atherosclerotic debris in more than 80% of patients and an MI rate of less than 4% (137). Carlino et al. used this device in 15 patients with degenerated SVGs with no evidence of atheroembolic infarction (138). In a randomized trial comparing SVG PCI outcomes with and without PercuSurge (SAFER trial) in 551 patients, in-hospital major adverse cardiac events were reduced by 50% (17.3% to 8.8%, p <.001) with distal protection (139). Q-wave MI was reduced from 2.2% to 1.1%, and non–Q-wave MI from 14.4% to 7.3%. It seems likely that some form of distal protection will be used in many, perhaps all, SVG PCI procedures in the future. Other strategies currently being evaluated include the use of filters to catch atherosclerotic debris liberated during PCI procedures and using covered stents to trap debris, excluding it from the circulation. Both of these strategies avoid the need to routinely occlude blood flow in the SVG for several minutes. Randomized trials are currently testing these approaches. Observational reports of the use of a polytetrafluoroethylene (PTFE)-covered stent in SVG PCI by Colombo and colleagues suggested that both immediate and long-term outcomes were better than with conventional stents or balloon angioplasty (140) (Fig. 84.5). In a multicenter study Baldus et al. reported 6-month outcomes from 109 consecutive patients who received PTFE-covered stents for *de novo* stenoses in SVG, noting periprocedural increase in creatine kinase MB in 5%, angiographic evidence of in-stent restenosis in 8%, vessel occlusion in 9%, and an 8% mortality (141). In five consecutive patients who received a PTFE-covered stent in one SVG and a conventional stent in another SVG, Baldus et al. reported that four of five conventional stents developed restenosis, but all five covered stents remained patent, with only a 9% decrease in lumen diameter at 5 months (142). A variety of filter devices also appear promising for “distal protection” in SVG procedures (136,143,144). In an initial experience with a porous membrane filter (80- to 100-µm holes) mounted in a 0.014 PTCA wire and supported by a nitinol basket, it was possible to successfully deploy the filter in 23 of 24 patients, and no in-hospital death, MI, or CABG occurred; one patient experienced a small creatine kinase elevation, and visible debris was removed in more than 80% of patients (144) (eFig. 84.5.1).

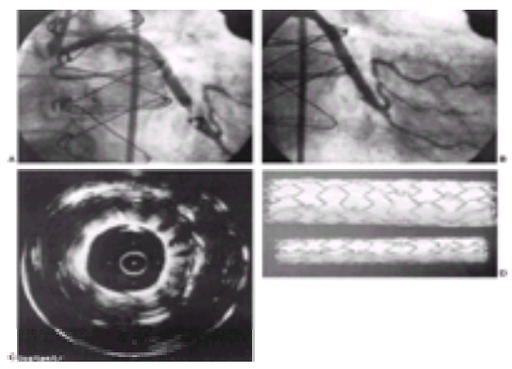

FIGURE 84.5 Severely diseased saphenous vein graft with large filling defect consistent with thrombus **(A)** successfully treated **(B)** with a 4.0-by 16.0-mm Jostent coronary stent graft (Jomed, Rangendingen, Germany), a polytetrafluoroethylene-covered stent. ***e*FIGURE 84.5.1 A:** Investigational filter device for embolic protection (Angioguard, Cordis-Johnson & Johnson, Miami, FL). **B:** Filter with trapped atherosclerotic debris.

The large amount of atheroembolic debris filtered or aspirated during SVG stent procedures (137,139,144) provides insight into the failure of IIb/IIIa platelet receptor inhibitors to reduce periprocedural ischemic events during SVG PCI. Ellis et al. found degenerated SVG to be the only lesion type not to benefit from abciximab when data from the Evaluation of c7E3 for the Prevention of Ischemic Complications (EPIC) trial and the Evaluation of PTCA to Improve Long-Term Outcome with Abciximab GPIIb/IIIa Receptor Blockade (EPILOG) trial were pooled (145). Similarly when data from five trials [EPIC, EPILOG, Evaluation of Platelet IIb/IIIa Inhibitor for Stenting (EPISTENT), Integrelin to Minimize Platelet Aggregation and Coronary Thrombosis in Stenting II (IMPACT II), and Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT)] totaling 627 patients with SVG PCI and the Cleveland Clinic registry of 278 patients with SVG PCI were analyzed, there was no benefit from IIb/IIIa inhibitors or stents with respect to 30-day outcome, and a trend was present toward increased MI with stenting (p = .09) (146,147). The lack of any acute benefit with SVG stent deployment is consistent with the SAVED trial (124) and the VENESTENT Study (148), each of which randomized patients to balloon angioplasty or stent implantation and demonstrated an improved major adverse cardiac event-free survival at 6 months, but no early difference in major adverse cardiac events.

The transluminal extraction catheter (Interventional Technologies, San Diego, CA) and the rheolytic thrombectomy catheter (Angiojet; Possis Medical, Inc., Minneapolis, MN) have been used for the treatment of thrombus-associated lesions in SVGs (81,82,83 and 84,116) (*e*Fig. 84.3.7). Although both devices were shown to be relatively effective in clearing thrombus from the treatment site as judged by angioscopy (83,149), distal embolization remained a problem, occurring in 15% with transluminal extraction catheters, associated with a 36% mortality (150), and resulting in non–Q wave in 27% with the Angiojet (151,152).

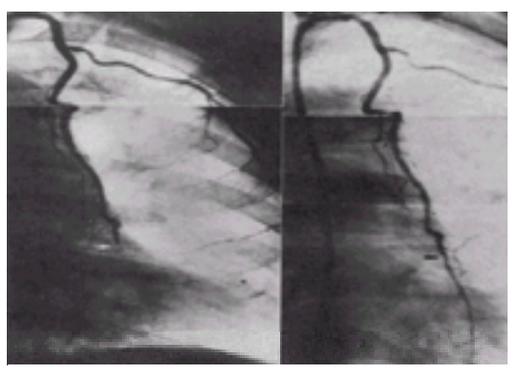
Recanalizing totally occluded SVGs not in the setting of acute MI has tempted interventional cardiologists for years in spite of low long-term patency and significant procedural complications (91,92,153,154,155,156,157,158,159,160,161 and 162). In a multicenter trial of 107 patients with total vein graft occlusion who received an intragraft infusion of thrombolytic agent for a mean of 25 hours, 74 (69%) achieved initial patency. Adverse acute events included MI (22.0%), emergency CABG (4.0%), stroke (3.0%), transfusion (19.0%), and death (6.5%) (161). Of 40 patients who underwent recatheterization at 6 months, 16 had a patent graft. In a single-center report of 77 consecutive patients with intervention to occluded vein graft, angiographic success was achieved in 71%, 5% died, and 8% underwent bypass surgery within 30 days (162). Three-year survival, event-free survival, and freedom from severe angina were not different in patients with angiographic success and failure. Whether new strategies of mechanical thrombectomy or ultrasound thrombolysis will alter the risk-benefit relationship in these difficult patients remains unclear.

On a brighter note, intravascular radiation for the prevention of recurrence of restenosis yielded promising results in the Washington Radiation for In-Stent Restenosis Trial for Saphenous Vein Grafts. This was a double-blind, randomized trial in 120 patients with diffuse in-stent restenosis (less than 47 mm in length) in SVGs, which compared iridium-192 versus placebo. Of the first 78 patients who completed 6-month angiographic evaluation, 48 (62%) had restenosis, 14 (29%) from the radiation arm and 34 (71%) from the placebo group (163). It is, therefore, anticipated that the final results of Washington Radiation for In-Stent Restenosis Trial for Saphenous Vein Grafts will demonstrate effectiveness of intravascular radiation in this setting.

Arterial Graft Intervention

Technical Strategy

Although arterial grafts are resistant to arteriosclerosis, percutaneous intervention has been used to relieve ischemia, most often in the IMA via a femoral approach using 6- to 8-Fr guide catheters. A radial or brachial approach may be necessary if guide catheter support is poor and if severe graft tortuosity or a difficult distal lesion is present. A novel catheter shape for a right brachial approach to IMA angioplasty has been reported (164). In patients with severe stenosis or occlusion of the subclavian or innominate arteries, dilation, stenting, or both have been performed before bypass surgery to permit use of the mammary artery and after surgery to relieve ischemia in patients with a patent IMA graft or to treat a dissection complicating IMA angioplasty (165,166,167,168,169 and 170). Conventional balloon angioplasty is used for most IMA lesions, and an over-the-wire system is favored for tortuous grafts, or if a total occlusion must be recanalized (*e*Fig. 84.5.2), or if retrograde passage into the native coronary artery is necessary. Hydrophilic steerable guidewires are also helpful in the presence of severe graft tortuosity. Prophylactic nitroglycerin is usually given before intervention. Balloon-mounted stents have been used to treat dissections in both mammary arteries (171,172). Use of a low-osmolar contrast agent is recommended; a blinded study reported that there was less discomfort with ioxaglate, a low-osmolar ionic dimer, than with iopamidol, a nonionic monomer (173). Care must be taken to ensure that there is sufficient catheter length to reach distal sites through tortuous mammary grafts. Extra long (145 cm) balloon catheters or short (80 cm) guide catheters can provide the additional length required, or the guide catheter can be shortened and capped by a flared, short sheath one size smaller (174). Intervention to relieve stenosed radial artery and gastroepiploic artery grafts has also been required (175).



***e*FIGURE 84.5.2** A 52-year-old man developed recurrent angina 5 months after coronary bypass surgery. Coronary arteriography revealed occlusion of the left internal mammary artery graft 1 to 2 cm proximal to insertion into the left anterior descending coronary artery (*left*). The graft was recanalized by balloon angioplasty (*right*) after using an intermediate wire to punch across the resistant total occlusion. At last follow-up 5 years after bypass surgery, the patient was totally asymptomatic and the left internal mammary artery was widely patent.

Results of Arterial Graft Intervention

Procedural success in IMA graft intervention was approximately 90% and highly dependent on the presence of excessive graft tortuosity and lesion location (Table 84.3). The most common complication was dissection, which occurred in 3.5%, rarely resulting in infarction or bypass surgery. In a published report of 68 consecutive patients, angiographic follow-up at a mean interval of 8 months was available in 78% of successful procedures. Restenosis occurred in 15% (6 of 40) of distal anastomotic sites and 43% (3 of 7) in the midportion of the graft (176). At a mean follow-up of 14 months, 76% of patients had class I or II angina, and event-free survival was 86%. The favorable results at the distal anastomosis parallel those of vein graft lesions at that site (176,177,178 and 179). Gruberg et al. reported outcomes in 174 consecutive patients, 63% with anastomotic lesions treated predominantly with balloon angioplasty (116 of 128, 91%), whereas ostial lesions were treated more frequently with stents (11 of 16, 69%) (61). Procedural success was 97% and 1-year target lesion revascularization was 7.4%. Long-term results of radial and gastroepiploic artery graft intervention have not been reported.

TABLE 84.3 RESULTS OF INTERNAL MAMMARY ARTERY GRAFT PERCUTANEOUS CORONARY INTERVENTION: SELECTED SERIES

CONTROVERSIES AND PERSONAL PERSPECTIVES

Value of Saphenous Vein Graft Intervention

After successful SVG intervention, there is a high cardiac event rate for most patient subgroups. Distal anastomotic lesions are an exception. The restenotic process in vein grafts does not plateau as it does in native coronary arteries, and mild to moderate nontarget vein graft lesions are associated with recurrent ischemic events in approximately one-third of patients (51). Even with careful selection of patients, emphasizing focal disease and absence of thrombus as was the case in the SAVED trial, the 6-month major cardiac event rate was 26% for SVG stenting, and restenosis occurred in almost 40% of patients (124). At Emory, 5-year event-free survival for vein graft intervention was 31% (105), and survival was less favorable than that with native coronary intervention (Fig. 84.6). If one moves from these relatively ideal candidates to the treatment of diffuse vein graft disease, recent total occlusions, or even to chronic occlusions, the prospects for long-term patency and clinical stability diminish, while the acute risk of thromboembolic MI and bleeding and costs escalate. Although continued study is needed to develop methods to prolong the functional life of degenerating venous grafts, day-to-day application of percutaneous strategies to these difficult problems must be done with caution.

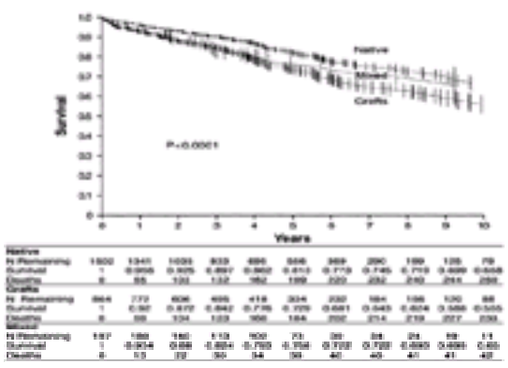

FIGURE 84.6 Ten-year survival of postbypass patients who underwent percutaneous coronary intervention of a native coronary artery (native), saphenous vein grafts (grafts), or both (mixed) at Emory University Hospitals (Kaplan-Meier method).

Repeat Interventions

Andreas Gruentzig envisioned coronary angioplasty as a strategy that could be used over the years to prevent patients from moving from low-risk categories (nil or single-vessel disease) to high-risk coronary disease. In the postbypass patient, percutaneous intervention is more often performed in an attempt to control symptoms and preserve quality of life. If the patient can be palliated safely by repeat interventions, even for periods as short as a year, this may be reasonable (179,180). However, thoughtful cost-conscious consideration of risks and benefits and of resource consumption must take place.

THE FUTURE

In the next decade, there will be an increasing number of postbypass patients who have begun to have recurrent angina requiring hospitalization. Because of the enormous cost, morbidity, and impracticality of surgical revascularization, it will be important to palliate these patients by percutaneous means as much as possible. We expect improved technology (especially better, coated, and covered stents) to help, but a major problem is the inadequacy of strategies to treat old, degenerated SVGs. Perhaps with the development of reliable methods of distal protection, techniques to renew (pave?) old grafts and prevent restenosis will evolve.

OVERVIEW

Recent technical advances have enabled intraluminal evaluation of the coronary arteries using ultrasonographic imaging, Doppler probes, small pressure sensors, and angioscopy. Data from miniaturized intravascular devices are increasingly used to supplement angiographic data. The rationale for these new imaging devices is based on multiple studies showing limited accuracy and reproducibility of coronary arteriography in determining the morphologic changes and associated physiologic disturbances in the coronary arteries. Intracoronary ultrasonography enables visualization of the full 360-degree circumference of the vessel wall with high spatial resolution.

Normal ultrasonographic morphology of coronary arteries consists of an echogenic intimal leading edge, a sonolucent media, and an echogenic adventitia, although not all of the normal arteries show all three layers. Atherosclerotic lesions consist of lipid-laden plaques of low echogenicity, more echogenic fibrous lesions, and calcified plaques that produce acoustic shadowing. Angiography and ultrasonography are frequently discrepant in the assessment of atheroma eccentricity. Angiography also exhibits poor sensitivity in detection of coronary calcification. Important artifacts in ultrasonographic images include nonuniform rotational distortion and the ring-down phenomenon. Patients with "normal coronary arteries" frequently have abnormal ultrasonographic findings. False-negative angiograms often result from coronary remodeling and diffuse disease. In cases of ambiguous angiographic stenosis, ultrasonography often permits lesion quantification. Ultrasonography is useful for measuring intimal proliferation in cardiac transplant recipients. After angioplasty, studies usually reveal plaque fissuring or dissection. Ultrasonography and angiography correlate poorly in assessing residual stenosis after interventions. Ultrasonography has refined the understanding of restenosis, suggesting, although not proving, the relative importance of "negative remodeling" and neointimal proliferation. Intravascular ultrasonography (IVUS) has been used to guide directional atherectomy and rotational ablation. IVUS has significantly influenced the development of coronary stenting.

Coronary angioscopy uses visible light conducted through fiberoptic filaments to directly visualize the luminal surface. Thrombus is frequently seen in unstable syndromes. The technique is cumbersome as it requires temporary interruption of blood flow imaging and is limited to proximal straight segments of the coronary arteries. A miniaturized Doppler-equipped guidewire has made assessment of coronary blood flow feasible during catheterization. Doppler flow measurements are used to confirm or exclude the functional severity of angiographically identified intermediate stenoses and to assess the results of percutaneous interventions.

Normal flow reserve as measured by Doppler devices is typically greater than 3:1 with large individual variability. Hemodynamically significant stenosis reduces flow reserve below 1.8:1, increases the proportion of flow during systole, and increases the ratio of proximal to distal flow velocity. Microvascular disease and transplant vasculopathy can also reduce flow reserve. False-positive findings are common, particularly in patients with increased basal flow, for example, those with ventricular hypertrophy.

Measurement of fractional coronary flow reserve is a new method for determining the functional significance of coronary stenosis. Using very small sensors, intracoronary pressures are measured during maximal pharmacologic vasodilatation to calculate the ratio of flow in a stenotic vessel and flow in the same vessel if no stenosis were present. Careful systematic studies demonstrated the reproducibility and reliability of this method in a wide range of clinical settings.

All of the new intracoronary imaging modalities are contributing to clinical practice and research. Several of these methods, especially ultrasonographic imaging and fractional flow reserve measurement, are likely to have a larger role in the catheterization laboratory in the future.

INTRODUCTION

Since its introduction by Sones in 1958, contrast angiography has served as the predominant imaging technique used to guide therapy for coronary artery disease. Technical advances in the last decade in ultrasonographic imaging, Doppler flow devices, small pressure sensors, and associated microelectronics have enabled development of miniaturized catheter systems capable of real-time intraluminal interrogation of the coronary arteries (1,2,3,4,5,6,7,8,9 and 10). Each of the new intravascular modalities offers certain unique capabilities that expand the diagnostic armamentarium. The incremental value of IVUS originates principally from two key features: its tomographic perspective and the ability to directly image coronary atheromas (2). Although angiography depicts the cross-sectional coronary anatomy as a planar silhouette of the lumen, ultrasonography directly images the atheroma within the vessel wall, allowing measurement of atheroma size, distribution, and, to some extent, composition. The principal value of angioscopy is derived from its ability to directly visualize the surface anatomy of the arterial wall, particularly the presence or absence of thrombus (8). The guidewire-size Doppler flow wires and miniaturized pressure-sensing devices provide useful data regarding coronary blood flow and the hemodynamic effects of stenosis (9,10).

New coronary imaging devices are rapidly altering conventional paradigms in the diagnosis and treatment of coronary artery disease. Despite the independent and incremental value of these new imaging modalities, however, intracoronary application usually requires fluoroscopy and angiographic road mapping. Accordingly, these new techniques should be considered supplemental and complementary to angiography and not an alternative to conventional radiographic methods. This chapter reviews the status of each of the technologies and defines its role in assisting percutaneous coronary revascularization. The implications of these findings for understanding the pathogenesis and optimal management of coronary pathophysiology are discussed.

INTRACORONARY ULTRASONOGRAPHY

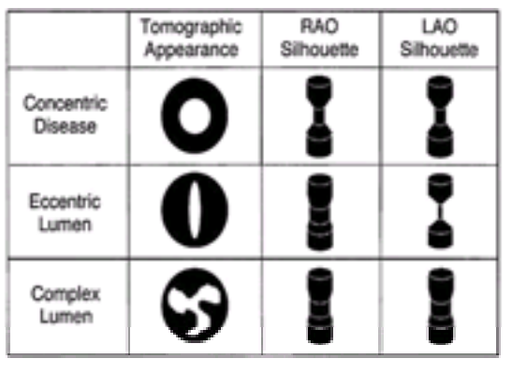
Rationale and Technique

Limitations of Angiography

The well-established limitations of angiography represent an important component of the rationale for intraluminal coronary imaging (11,12,13,14,15,16 and 17). Visual interpretation of angiograms exhibits clinically significant intra- and interobserver variability (15,16). Importantly, comparisons of angiographic information to postmortem histology have documented major discrepancies between the apparent angiographically determined severity of lesions and results of postmortem histologic examination (11,12,13 and 14). Nearly all necropsy studies demonstrate that angiography significantly underestimates the extent of atherosclerosis. Location of the lesion, lumen irregularity, angle of the x-ray beam, diffuse nature of the disease, tortuosity, and overlapping vasculature all contribute to this discrepancy.

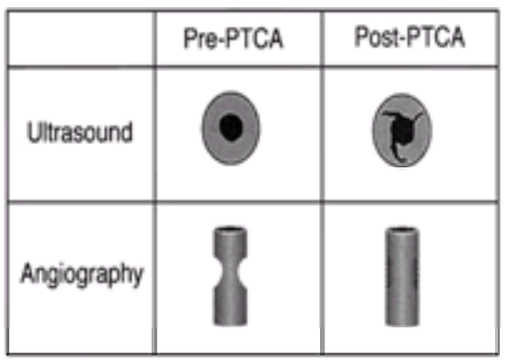
Angiography provides no direct information on the hemodynamic effects of coronary stenosis. This limitation is particularly important in evaluating angiographically identified intermediate lesions in the range of 40% to 75% diameter stenosis. Making a clinical decision between a recommendation for medical therapy versus a recommendation for percutaneous or surgical revascularization is particularly difficult. Using functional testing, investigators have demonstrated a striking discordance between angiographically determined lesion severity and measurements of the physiologic effects of the stenosis (17). Accordingly, most patients with ischemic disease require one or more functional tests, in addition to angiography, to enable appropriate clinical decision making.

Several inherent properties explain the limitations of coronary angiography. Angiography is a two-dimensional imaging modality, depicting the complex coronary cross-sectional anatomy as a planar silhouette of the contrast-filled lumen. Both necropsy and IVUS studies, however, demonstrate that coronary lesions are often highly complex, exhibiting markedly distorted or eccentric luminal shapes (6,18,19). Accordingly, any arbitrary angle of view may misrepresent the true extent of luminal narrowing (*e*Fig. 85.0.1). Although orthogonal angiograms should accurately reflect the severity of many complex lesions, optimal imaging angles are frequently unobtainable because the vessel may be obscured by side branches, disease at a bifurcation, or foreshortening.



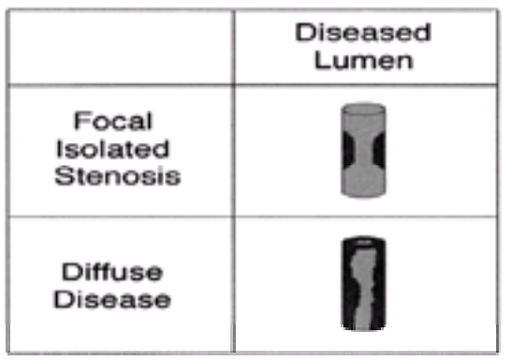
***e*FIGURE 85.0.1** Theoretical differences between intravascular ultrasonography and angiography. **Top:** For a concentric coronary narrowing, the right anterior oblique (RAO) and left anterior oblique (LAO) angiograms accurately depict the severity of the obstruction. **Middle:** If the lumen is eccentric, angiography will show major differences between the RAO and LAO silhouettes. **Bottom:** If the lumen exhibits a complex shape, no angle of view may adequately reflect the severity of the narrowing.

Percutaneous coronary interventions increase the complexity and irregularity of lumen shape, further impairing the ability of a luminal silhouette to accurately depict coronary anatomy (6,20,21,22 and 23). After balloon angioplasty, the angiographic appearance of a dissected postintervention vessel often consists of an enlarged, frequently hazy lumen (22) (*e*Fig. 85.0.2).



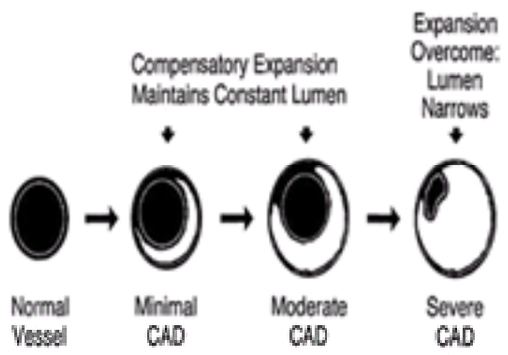
***e*FIGURE 85.0.2** Schematic representation of angiography and ultrasonography before and after balloon angioplasty (PTCA). **Bottom:** The angiogram may show an enlarged, although hazy, silhouette. **Top:** Ultrasonography will frequently show a lesser degree of luminal enlargement with multiple cracks or dissections in the atheroma that are opacified by iodinated contrast, which produces the appearance of an enlarged silhouette.

The method most commonly used to assess the severity of angiographic lesions uses visual or computer measurements to determine the percent diameter of the stenosis. This approach compares the luminal diameter within the lesion to the caliber of an adjacent, “normal” reference segment. Necropsy examinations have demonstrated that coronary atherosclerosis is often diffuse, involving long segments of the diseased vessel. Therefore, in many patients, no truly normal reference segment exists, which precludes accurate calculation of the percent diameter reduction. In the presence of diffuse vessel involvement, determination of percent diameter stenosis predictably underestimates true disease severity (18,19,22). In the most dramatic circumstances, diffuse, concentric, and symmetrical coronary disease can affect the entire length of the vessel, which results in an angiographic appearance of a small artery with minimal luminal irregularities (*e*Fig. 85.0.3).



***e*FIGURE 85.0.3** Underestimation of stenosis severity due to diffuse disease. **Top:** Measurement of percent stenosis assumes that a narrowing consists of a focal isolated stenosis. **Bottom:** In many clinical settings, however, the coronary obstruction consists of a focal stenosis superimposed on a diffusely diseased vessel. In such cases, percent stenosis will predictably underestimate disease severity.

Accurate assessment of the severity of coronary disease by angiography is further confounded by the phenomenon of coronary arterial remodeling, first described by Glagov et al. (24). This process consists of outward displacement of the external vessel wall in segments with atherosclerosis (eFig. 85.0.4). In the early stages of coronary disease, this adventitial enlargement prevents the atheroma from encroaching on the lumen and thereby conceals the presence of a lesion on angiography. Although such lesions do not restrict blood flow, observational studies demonstrate that minimal, nonobstructive angiographically identified lesions represent an important substrate for acute coronary syndromes (25,26).



***e*FIGURE 85.0.4** Coronary remodeling (compensatory enlargement). As originally proposed by Glagov et al. (24), coronary artery disease (CAD) in its earliest stages results in compensatory enlargement of the adventitia, which opposes luminal encroachment. In the later stages of coronary disease, the luminal encroachment overcomes the luminal expansion, which results in an angiographic stenosis.

Advantages of Ultrasonography

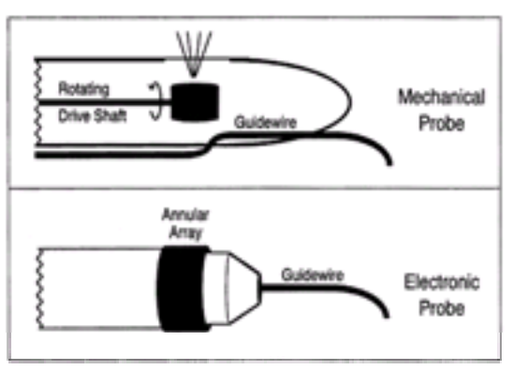
Several characteristics inherent in IVUS imaging have potential value in the precise quantitation of atherosclerotic coronary artery disease. The tomographic orientation of ultrasonography enables visualization of the full 360-degree circumference of the vessel wall, rather than a two-dimensional projection of the lumen, which allows accurate assessment of the plaques residing in the vessel wall. Measurement of lumen area uses direct planimetry performed on a cross-sectional image, which, unlike angiography, is not dependent on the projection angle. In angiographic stenosis sizing, careful calibration of the analysis system is required to correct for radiographic magnification. Ultrasonographic devices, however, rely on an electronic distance scale, internally generated and overlaid on the image. Because the velocity of sound within soft tissues is nearly constant, ultrasonographic measurements are inherently accurate and require no special calibration methods.

Ultrasonographic Catheters

The equipment required to perform intracoronary ultrasonography consists of two major components, a catheter incorporating a miniaturized transducer (20 to 50 MHz) and a console containing the electronics necessary to reconstruct the image. In the currently available ultrasonographic systems, axial and lateral resolution approach 80 to 100 µm and 250 µm, respectively. Two different transducer systems are in use. Mechanical systems use a rotating transducer. Electronic systems use a multielement solid-state nonmoving transducer.

Because the transducer is placed in close proximity to the vessel wall, high ultrasonic frequencies are used for intravascular imaging, typically, centered at 20 to 50 MHz for coronary imaging. The use of high frequencies provides excellent theoretical resolution because the ultrasound wavelength, which determines the theoretical maximum resolution, is inversely proportional to the frequency. Spatial resolution of an ultrasonographic image is expressed in two directions: axial resolution (parallel to the sound beam) and lateral resolution (perpendicular to the beam). At 30 MHz, the wavelength is approximately 50 µm (0.05 mm), which permits axial resolution to approach 80 to 100 µm. Determinants of lateral resolution are more complicated and depend on imaging depth and beam shape determined by not only wavelength but also by aperture. Typically, lateral resolution for a 30-MHz device averages approximately 250 µm at the typical distance of 2 to 4 mm most prevalent in coronary imaging. Although higher frequency catheters may be desirable for better resolution, significant trade-offs may exist in moving beyond the current 25- to 40-MHz frequency range. For example, although high-frequency probes enable better axial and lateral resolution, penetration is likely to be impaired in comparison to that of more conventional devices. In addition, greater backscatter from blood cells at high frequencies may interfere with discrimination of the interface between lumen and vessel wall. As the demand for catheter miniaturization becomes more intense, however, use of a shorter wavelength becomes more important in preserving near-field image quality. Use of a center frequency of 40 to 50 MHz, for example, would allow discrimination of small fatty deposits or zones of fibrous tissue separated by as little as three to four times the size of a red blood cell.

Initial efforts to develop miniaturized transducers for intraluminal examination were begun some three decades ago by Bom et al. (1). Practical applications, however, required major improvements in the physical properties of imaging catheters. Reductions in catheter sizes and improvements in image quality resulted in the reintroduction of modern coronary ultrasonographic devices in 1989 (2). Two dissimilar technical designs for transducers have emerged: mechanically rotated devices and multielement electronic arrays (eFig. 85.0.5).



***e*FIGURE 85.0.5** Two types of intravascular ultrasonography catheter designs. **Top:** Mechanical devices use a drive shaft that rotates a single transducer element located near the catheter tip. A short monorail allows positioning of the device over a guidewire. **Bottom:** Electronic probes use an annular array of transducer elements near the catheter tip. The absence of a mechanical drive shaft allows a traditional over-the-wire approach.

Mechanical probes use a drive cable running the length of the catheter that rotates a single piezoelectric transducer element mounted near the distal catheter tip. For most mechanical ultrasonographic systems, a rotation rate of 1,800 rpm is used, which corresponds to 30 full revolutions per second, yielding 30 images per second.

In the electronic systems, an annular array of multiple piezoelectric transducer elements (currently up to 64) is activated sequentially to generate a tomographic image. The electronic signals are processed and multiplexed by several ultraminiaturized integrated circuits near the catheter tip. Accordingly, only two flexible conductive wires are required within the catheter shaft, which yields a flexible catheter with a central lumen, which can accommodate a guidewire. For image generation, this device uses a reconstruction algorithm known as a “synthetic aperture array,” which has different operational principles from the “phased-array” devices used in conventional ultrasonography. In a synthetic aperture approach, radial scan lines are reconstructed from data derived from multiple transducer elements, using a smaller number of elements for pixels near the catheter surface and a larger number for pixels in the far field. This approach yields a variable aperture, which provides a consistent focus and more uniform image quality throughout the near and far fields.

Early devices available for IVUS were relatively large, ranging from 4.3 Fr to 5.5 Fr (1.43 to 1.67 mm), which limited examination to proximal and occasionally midvessel segments. Currently available ultrasonographic catheters for intracoronary applications have an outer diameter at the tip of approximately 3 Fr (0.96 to 1.17 mm).

The smaller ultrasonographic catheters (3 Fr) can be delivered through a large-lumen 6-Fr guide catheter and are suitable for examination of the most stenotic lesions

before intervention, even if they are located distally within the coronary artery. The mechanical ultrasonographic catheters for coronary arteries use a distal sheath (telescopic shaft) system, which allows the safe and free movement of the ultrasonic transducer mounted on a central cable. The ultrasonographic catheter is advanced over a guidewire using a short monorail segment (15 mm in length) located at the tip of the sheath beyond the most distal point that the transducer can be advanced. Thus, the tip of the ultrasonographic catheter should be placed 2 cm beyond the most distal site that needs to be imaged by ultrasonography. Once the operator places the ultrasonographic catheter in the coronary artery, the transducer can be advanced or retracted within the sheath to interrogate the vessel freely. Mechanical catheters should be flushed with saline carefully; otherwise, even microbubbles of air trapped near the transducer can markedly degrade the image quality. The catheters using the electronic solid-state systems have no moving parts. They are designed as over-the-wire as well as monorail catheters. In these systems the ring-down artifact around the transducer is minimized by subtraction before catheter insertion into the coronary artery.

Regardless of the design of the catheter delivery device, most systems contain an integrated videotape recording system for archival storage of imaging studies on super-VHS tape. Digital image-recording technology has now been introduced to IVUS imaging, and the most recent commercially available systems permit digital recording of up to 60 seconds of an ultrasonographic pullback. Newer systems can display the acquired “cine loop” at variable playback rates, provide digital freeze frames, and permit writing of the sequence to a recordable CD-ROM disk. They also allow on-line reconstruction of the individual tomographic images into longitudinal two- or three-dimensional images.

Examination Technique

Standard interventional techniques for intracoronary catheter delivery are used for intraluminal ultrasonographic examination. Intravenous heparin sodium and intracoronary nitroglycerin are routinely administered before imaging. Most practitioners use a 6- or 7-Fr guiding catheter and a steerable 0.014-in. angioplasty guidewire. A stable guiding catheter position with good support is desirable, because current ultrasonographic catheters have less trackability and a larger profile than modern balloon angioplasty catheters. After placing the catheter into the distal coronary artery, the operator carefully retracts the imaging core or the catheter to examine the vessel in real time, recording images on videotape for subsequent quantitative or qualitative analysis.

Settings of the ultrasonographic system should be carefully adjusted before imaging, using the controls on the machine. Time gain compensation controls are for optimization of the signal amplitude at different depths. Overuse of these adjustments may result in loss of real information from near field or far field. Gradations of gray are adjusted using compression and adjustment controls. These adjustments are not found in solid-state systems.

Most operators use a motorized pullback device to withdraw the catheter at a constant speed (between 0.25 and 1.00 mm per second, most frequently 0.5 mm per second). Pullback at a constant speed allows the registration of the location of a given cross section along the vessel (27). Side branches, visualized with both angiography and ultrasonography, and extraarterial structures such as veins and pericardial shadows are useful as landmarks to facilitate interpretation and comparison of sequential examinations. Automatic pullback is also useful in measuring the length of a given arterial segment. Length measurement is a prerequisite for volumetric analysis. The advantages provided by automatic pullback are particularly useful in serial ultrasonographic studies.

A number of combination devices incorporating both an imaging and a therapeutic device have been developed. An angioplasty balloon with an ultrasonic transducer, a transducer combined with a directional atherectomy device, and a combined ultrasonographic and brachytherapy catheter could provide on-line guidance during revascularization procedures (28,29 and 30).

Safety of Coronary Ultrasonography

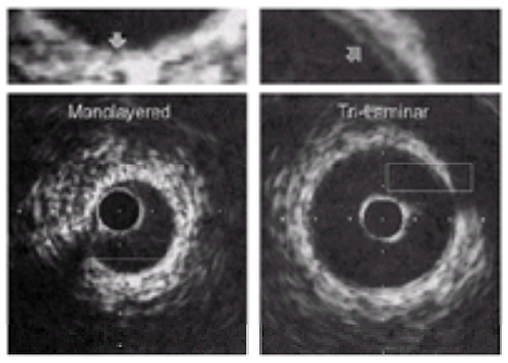
IVUS has been performed safely in a wide variety of clinical situations with few serious untoward effects. In interventional practice, coronary ultrasonography has been performed safely after most types of revascularization procedures, including balloon angioplasty, directional coronary atherectomy (DCA), rotational ablation, and stent deployment. Focal coronary spasm is the most frequent complication of ultrasonographic imaging but is usually transient and responds rapidly to intracoronary administration of nitroglycerin (100 to 300 g). Multicenter registries indicate that complications other than spasm occur in less than 1% of patients (31,32). Additional care is required when imaging small distal vessels or tight stenosis, because the imaging transducer can partially or totally occlude the blood vessel and lead to ischemia.

Although the safety of intracoronary ultrasonography is well documented, any device placed subselectively in the coronary arteries carries the potential risk of vessel injury. Isolated incidents of a new or worsening coronary dissection after ultrasonographic examination have been reported. Because of the inherent risk, many centers that use IVUS during diagnostic catheterization limit credentialing for intraluminal examination to personnel with interventional training. This safety measure ensures that the necessary personnel and equipment are immediately available in the unlikely event of an intimal disruption.

Image Interpretation

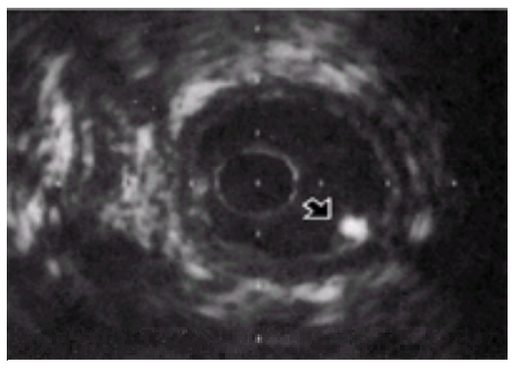
Standards for applications, image interpretation, measurement, and nomenclature have been published by the European Society of Cardiology, American College of Cardiology, and the American Heart Association (33,34).

Ultrasonographic studies performed either *in vivo* or using excised, pressure-distended vessels have characterized the appearance of normal and abnormal coronary artery wall by IVUS (6,35,36,37,38,39,40 and 41). Important determinants of the vessel wall appearance include both the normal arterial structure and the inherent properties of ultrasound. An abrupt change in acoustic impedance between adjacent tissue layers is the most important factor responsible for the ultrasonographic appearance of the vessel wall. The leading edge of the intima (at the interface between the blood-filled lumen and the endothelium) and the outer border of the media (at the junction of media and external elastic membrane) are two particularly strong acoustic interfaces. As a result, both boundaries are typically well visualized by ultrasonography in human coronaries and are described as trilaminar (trilayer) in appearance except in younger individuals in whom intima is too thin to be detected by ultrasonography (eFig. 85.0.6).



***e*FIGURE 85.0.6** Normal coronary wall morphology by intravascular ultrasonography. **Left:** A monolayered arterial structure is evident (*arrow*). **Right:** A trilaminar structure is observed (*arrow*). In both examples, the inset at the top of the panel shows a magnified portion of the image that is indicated by the white rectangle.

The two classical interfaces are not well visualized in all normal subjects (37). Theoretically, at 30 MHz, the maximal axial resolution for IVUS devices is approximately 80 µm, although actual clinical performance is usually less, typically 100 to 150 µm. The normal intima is thin and consists principally of a superficial layer of endothelial cells and connective tissue, which results in a relatively small impedance difference between blood and intima. Accordingly, in young subjects, ultrasonographic imaging frequently cannot distinguish the intima from deeper wall layers, which results in a single rather than trilayer appearance. In older subjects, progressive intimal thickening or the development of pathologic intimal changes results in an ultrasonographic pattern consisting of two distinct echogenic layers sandwiching a sonolucent intermediate layer (three-layered appearance; eFig. 85.0.7). A clear delineation of the inner border of the media (internal elastic membrane) is frequently difficult or impossible, so that only two layers are normally distinguished with ultrasonography. The inner layer, often described as *intima* or *intimal plaque*, should be more correctly described as *intima-media complex*. Whether the artery is trilaminar or monolayered, the deepest layers representing the adventitia and periadventitial tissues exhibit a characteristic “onionskin” pattern. The outer border of the vessel is usually indistinct, primarily because no acoustic differences exist between the adventitia and other encasing tissues. Accordingly, total wall thickness cannot be measured using ultrasonography, except in vessels with a distinct outer border such as aorto-coronary saphenous vein grafts.

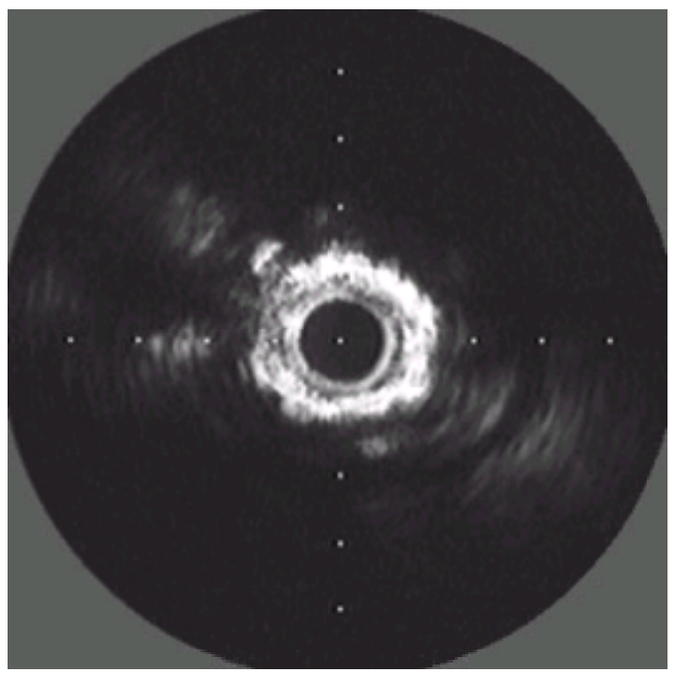


***e*FIGURE 85.0.7** Minimal circumferential intimal thickening. In this example, the intima is slightly thickened, but no luminal encroachment is seen. The bright circular object indicated by the arrow is a 0.014-in. guidewire.

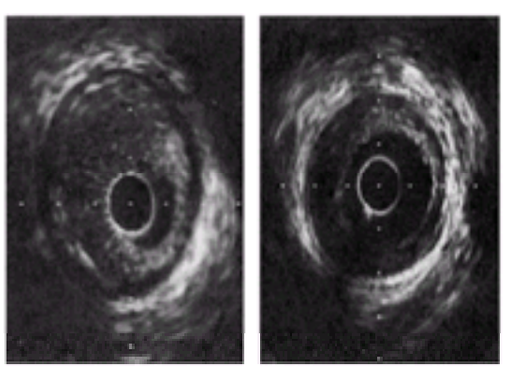
The blood within the vessel lumen exhibits a characteristic pattern of echogenicity in IVUS examinations. At frequencies greater than 25 MHz, the lumen is characterized by subtle, finely textured, specular echoes that move in a characteristic swirling pattern during blood flow. The echogenicity within the lumen arises from reflection of acoustic energy by circulating blood elements, although the precise origin of this effect remains uncertain. In many clinical situations, the presence of blood "speckle" can assist image interpretation by confirming the communication between dissection planes and the lumen. The pattern of blood speckle is dependent on the velocity of flow, exhibiting increased intensity and a coarser texture when flow is reduced. This latter property can represent a confounding variable in some examinations because the increased echogenicity of blood may interfere with delineation of the blood tissue interface.

Classification of Atheromas

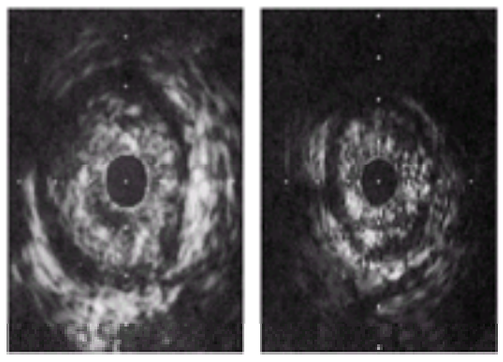
The subtle changes observed by histology early in the development of coronary atherosclerosis, such as fatty streaks, are not visible using currently available 30-MHz ultrasonographic devices. Vessels with classical atherosclerosis exhibit a diversity of abnormal features that reflect the severity, composition, and distribution of the atheromas (6,23,34,35,36,37,38,39,40,41 and 42) (*e*Fig. 85.0.8, *e*Fig. 85.0.9, and *e*Fig. 85.0.10). Sites with limited disease often exhibit generalized or focal thickening of the intimal leading edge, whereas advanced lesions appear as large echogenic protrusions encroaching on the lumen. Three basic types of lesions are distinguished: (a) highly cellular fibromuscular lesions or lesions with diffuse lipid infiltration, which have a low echogenicity (*e*Fig. 85.0.8); (b) dense fibrous lesions, which produce bright echo reflections (*e*Fig. 85.0.9); and (c) calcified lesions, which produce intensely bright reflections with acoustic shadowing (*e*Fig. 85.0.10).



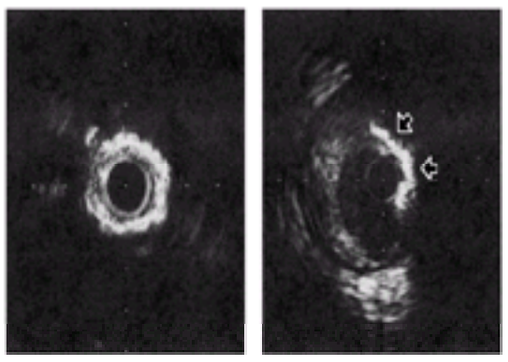
Severe coronary calcification. In this example, there is dense shadowing due to 360 degrees of lesional calcification.



***e*FIGURE 85.0.8** Soft, lipid-laden coronary atheromas. In both panels, the atherosclerotic plaque is relatively sonolucent, which indicates a high lipid content.



***e*FIGURE 85.0.9** Fibrotic coronary atheromas. In both panels, the atheroma approaches the egocentricity of the adventitia, which indicates a high content of fibrous tissue.

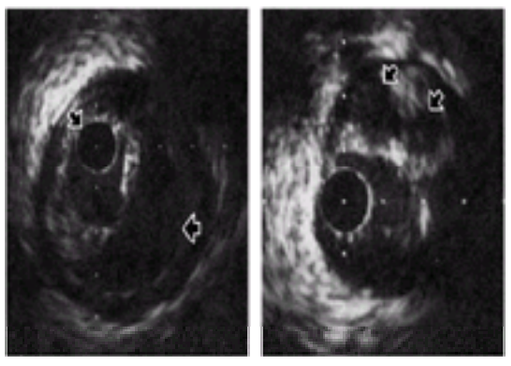


***e*FIGURE 85.0.10** Calcified coronary atheromas. **Left:** Calcification extends throughout the 360-degree circumference of the vessel ("napkin-ring" calcification). **Right:** A more focal area of calcification is shown (*gray arrows*).

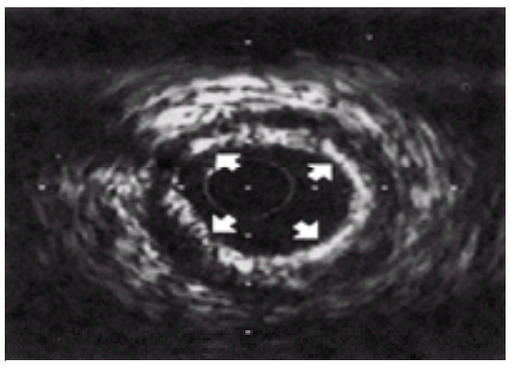
No standardized method exists for analysis of atheroma composition. Most classification schemes differentiate atheromas into one of three categories (soft, fibrous, or calcified) according to plaque echogenicity. The echogenicity of the atheroma is dependent not only on the acoustic properties of tissue, however, but also on the acquisition settings (gain, compression, etc.) of the ultrasonographic system. Accordingly, most classification methods compare the echo intensity of the plaque to that of the surrounding adventitia to correct for differences in ultrasonographic technique. When this approach is used, atheromas are termed "soft" if they are less echogenic than the adventitia and "fibrous" or "hard" if echodensity is similar to that of the adventitia. Most plaques are mixed, however, with elements of lipid, fibrosis with or without calcification, and necrosis.

Calcified atheromas exhibit a characteristic morphology by IVUS. Calcium attenuates transmission of high-frequency ultrasound and thereby obscures deeper layers of the vessel wall, a phenomenon known as *acoustic shadowing*. Obstruction of ultrasound transmission, not merely a high degree of echogenicity, is a requisite for identification of calcium. Except for detection of multiple scattered microcalcifications, ultrasonography can be considered highly specific and sensitive for the detection of calcified plaque. Because of the importance of calcium for the selection of coronary interventional devices, most interpretation schemes further classify calcified atheromas (43,44 and 45). Additional descriptors indicate whether deposits are single or multiple, the circumferential extent of calcium expressed in degrees of arc, and the length in millimeters. Most approaches also determine the depth of the calcification, described as "superficial" or "deep" depending on whether tissue is found between the calcium deposit and lumen.

The appearance of unstable or degenerating atheromas by ultrasonography remains incompletely characterized (46,47) (eFig. 85.0.11). Some plaques contain a zone of reduced echogenicity within the central core of the atheroma. Current methods cannot distinguish whether these represent areas of lipid deposition or necrotic degeneration, both of which can appear as zones of low density. Often, an echolucent zone within the atheroma is covered by a distinct "cap" of greater echogenicity, which presumably represents the classical fibrous cap described by histology (eFig. 85.0.12). Spontaneous plaque rupture associated with unstable coronary syndromes is sometimes evident in ultrasonographic examination of the culprit lesions (hours to days after the event) (48). These lesions often show single or multiple channels within the plaque that communicate with the lumen. The ultrasonographic appearance of angiographic "pseudoaneurysms" typically consists of crevices within the atherosclerotic plaque, most likely due to emptying of the lipid-rich necrotic plaque core. In a serial study, ultrasonographic characteristics of vulnerable plaques that subsequently ruptured included presence of an echolucent core and a relatively thin echogenic cap (49).



***e*FIGURE 85.0.11** Features of unstable coronary lesions. **Left:** The ultrasonographic catheter is located within the "true" lumen (*top arrow*). The bottom arrow points to a secondary flow channel within the body of the atheroma, which has been recanalized. **Right:** The arrows point to a secondary flow channel within the body of the atheroma in a patient recovering from an episode of unstable angina.



***e*FIGURE 85.0.12** Thickened fibrous cap. An atheroma of low echogenicity is covered by a more echogenic fibrous cap (*arrows*).

The presence of mobile intraluminal masses suggests the presence of thrombi, but at 30 MHz, organizing thrombus appears visually indistinguishable from other types of plaques. In several small observational studies, the IVUS appearance of a coronary thrombus was defined as low echogenic material within the lumen demonstrating slight synchronic pulsation. This entity has significantly different acoustic impedance at the interface between the thrombus and the more echogenic plaque (50,51). Analysis of the unprocessed radiofrequency signals is a promising technique in differentiating the intracoronary thrombus from the atherosclerotic plaque (52,53).

Despite extensive research regarding assessment of plaque morphology by IVUS, some caution is warranted in interpretation of images. Although contemporary devices produce remarkably detailed views of the vessel wall, interpretation must rely on simple visual inspection of acoustic reflections to determine plaque composition. In echogenicity and texture, different histologic features may exhibit comparable acoustic properties and therefore appear quite similar by IVUS. Furthermore, the pictures displayed on the monitor are the result of multiple processing steps in the scanner that influence the ultrasonographic texture of the plaque in a variety of ways.

IVUS can delineate the thickness and echogenicity of vessel wall structures but does not provide actual histology. Validated methods do not yet exist for objective or automated classification of atheromatous lesions. One must also emphasize that classification of the plaque morphology uses common terms that are not precise indicators of the mechanical characteristics of the atheroma. For example, the definitions of "soft" and "fibrous" are potentially misleading, because some plaques classified as "soft" may not necessarily be mechanically soft and show a high resistance to dilatation (54).

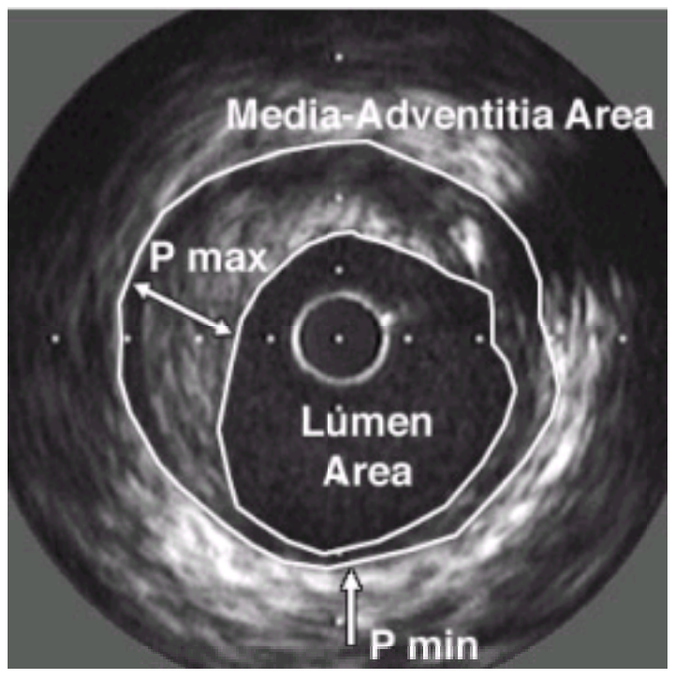
Despite these limitations, the general classification of coronary plaques into the categories of soft, fibrous, or calcified has significant clinical implications. Initial experience suggests that the three different categories often respond differently to interventional devices (55,56). For example, very dense fibrotic or calcified plaques often resist removal with DCA devices (57,58). The presence of heavily calcified or fibrotic plaques can prevent full expansion of stents. Armed with this information, the

interventionalist may choose an alternative revascularization technique, such as rotational atherectomy, for such lesions. Further refinement of interventional strategies based on ultrasonographic lesion morphology is likely and may permit improved results or reduction in complications.

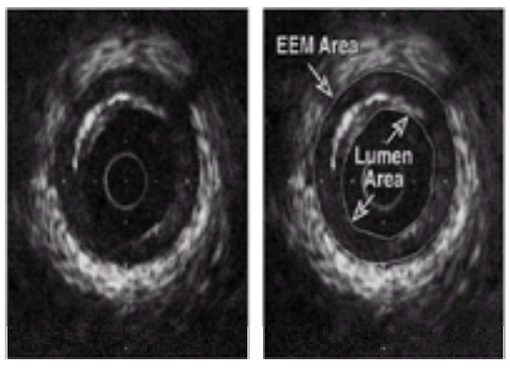
Ultrasonographic Measurements

Lumen Area

The lumen cross-sectional area (CSA) is determined by tracing the circumference of the leading edge of the blood-intima interface (*e*Fig. 85.0.13). Maximum and minimum lumen diameters are measured over a line crossing the center of the lumen. Lumen area stenosis is analogous to percent diameter stenosis on the angiogram and is calculated using the following formula: (reference lumen CSA – minimum lumen CSA)/reference lumen CSA.



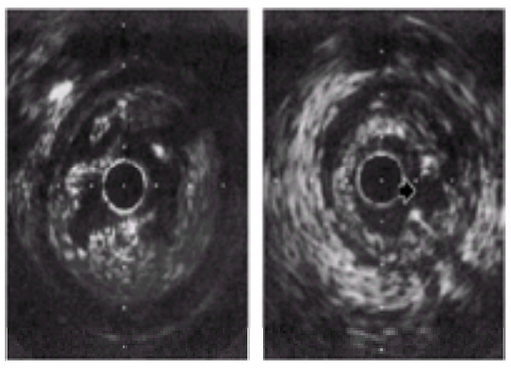
Method of intravascular ultrasonography measurement. Plaque area is the area between the external elastic membrane border and the lumen. Minimum and maximum plaque thicknesses are often reported in the literature (P max and P min).



***e*FIGURE 85.0.13** Intravascular ultrasonographic measurements of the areas of the lumen and external elastic membrane (EEM). The area of the atheroma is the EEM area minus the lumen area. In both cases, planimetry is performed on the leading edge of the structure to be measured.

Because of the speckled nature of ultrasonographic images, individual frames of the video recording may not contain a continuous intimal leading edge. Accordingly, review of the videotape with the vessel in motion may assist in accurate edge detection by allowing the moving display of images to fill in discontinuous portions of the vessel circumference. This process is also facilitated by differentiating the dynamic speckle pattern characteristic of flowing blood from the more static pattern of adjacent tissue. The injection of contrast dye or saline into the vessel temporarily clears the echogenic blood signals and may facilitate border delineation.

After coronary interventions, particularly balloon angioplasty, the shape of the lumen may be extremely complex, exhibiting plaque fissures or deep wall dissections (18,20,21 and 22,43) (*e*Fig. 85.0.14). These extraluminal channels contribute little to blood flow capacity, which raises the question of whether such structures should be included in tracing the luminal contour. A commonly applied solution to this conundrum distinguishes the true lumen area (in general, the lumen in which the ultrasonographic catheter is positioned) from the "dissection area," which is separated from the true lumen by a dissection flap.



***e*FIGURE 85.0.14** Complex dissections after balloon angioplasty. **Left:** A complex stellate-like lumen is evident. **Right:** A single curvilinear split in the plaque is apparent (*arrow*).

Relative location of the lumen in the vessel cross section is expressed by lumen eccentricity: (maximum lumen diameter – minimum lumen diameter)/maximum lumen diameter. This calculation yields an index of 1.0 if the lumen is perfectly round, with values less than unity indicating increasing luminal eccentricity.

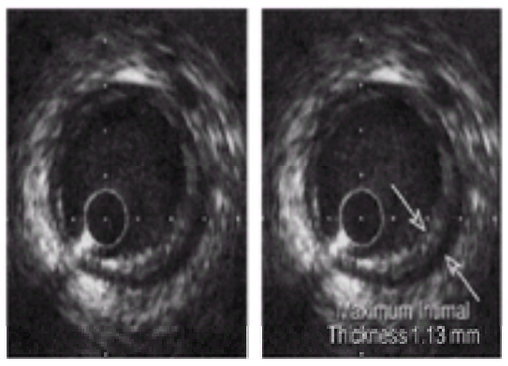
External Elastic Membrane Area

The total cross-sectional area of the vessel is defined as the area enclosed by the interface between the media and adventitia—the leading edge of the external elastic membrane (EEM). The terms *total vessel area*, *EEM area*, and *external elastic lamina area* are used interchangeably.

As previously discussed, measurement of the area within the external elastic lamina does not allow calculation of true plaque or intimal area because the *internal* elastic membrane is not well delineated with ultrasonography. Calcium-induced acoustic shadowing can obscure a large portion of the vessel wall, which requires interpolation of missing portions of the vessel circumference. Coronary stent implantation compresses the plaque, media, and surrounding adventitia and, together with the variable degree of acoustic shadowing produced by stent struts, may also give rise to difficulties in quantitating the EEM area.

Atheroma Area and Thickness

In addition to cross-sectional area measurements, most laboratories also routinely measure atheroma area and thickness (eFig. 85.0.15). All atheroma measurements include the media thickness and area. Thus, the terms *atheroma area* and *plaque plus media area* are used. Maximal atheroma thickness is defined as the longest distance between the intimal and adventitial leading edges, whereas the minimum thickness is the shortest distance between these two interfaces. The difference between maximum and minimum atheroma thickness represents a useful measure of plaque eccentricity, usually expressed by the following calculation: (maximum plaque plus media thickness – minimum plaque plus media thickness)/maximum plaque plus media thickness.



***e*FIGURE 85.0.15** Measurement of maximal intimal thickness. In this example, the distance from the leading edge of the intima to the external elastic membrane reaches a maximum valve of 1.13 mm (*arrows*).

Plaque area or plaque plus media (or atheroma) is calculated by the following formula: EEM CSA – lumen CSA.

The circumferential extent of disease is also commonly classified by determining whether abnormal intimal thickening involves the entire circumference of the vessel. Longitudinal extent of atherosclerosis can be expressed in millimeters if automatic pullback is used or reported using the qualitative terms *diffuse* and *focal*.

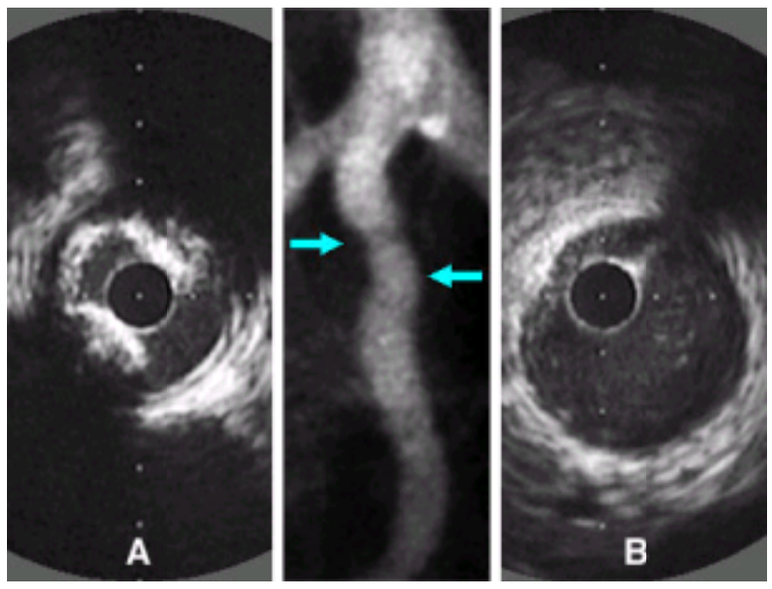
Percent Vessel Area Stenosis

The calculated value of percent vessel area stenosis is different than lumen area stenosis because it represents the atheroma or plaque burden and cannot be measured with angiography. This parameter has been referred to as *percent vessel area stenosis*, *plaque area stenosis*, or simply *percent stenosis*. This measurement, however, is not equivalent to angiographically determined percent stenosis, which represents an expression of luminal narrowing at the stenosis relative to the reference segment. The percentage of the vessel area occupied by atheroma is calculated using the following formula: [(EEM CSA – lumen area)/EEM CSA] × 100.

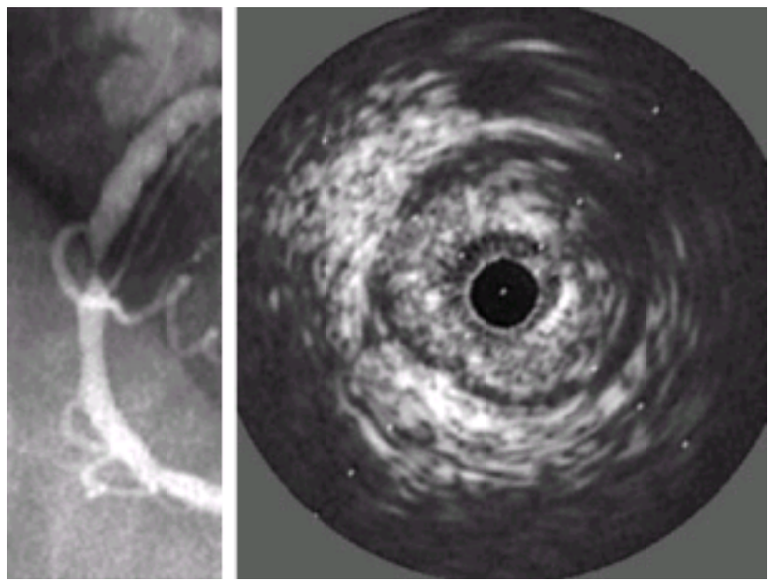
Discrepancies with Angiography

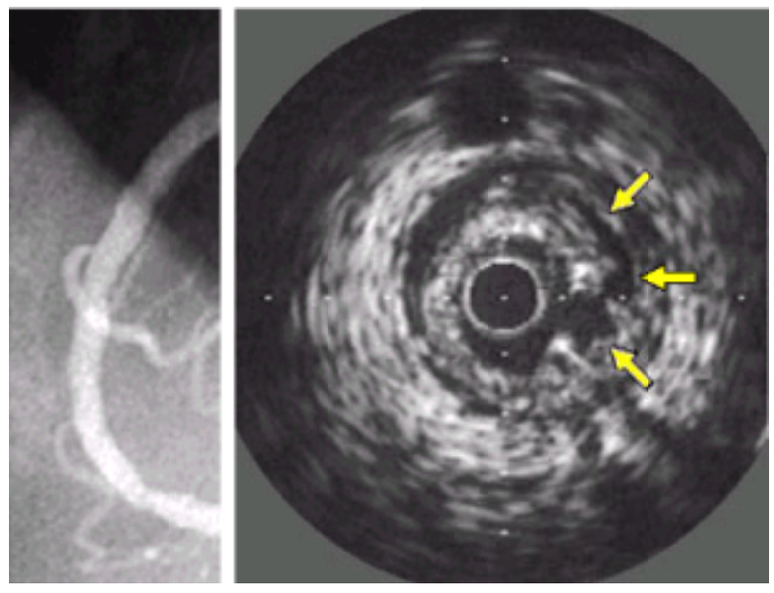
Percent Stenosis

The percent vessel area stenosis determined by ultrasonography is greater than the percent diameter stenosis evident by angiography (22). This phenomenon is a consequence of two major factors: (a) the diffuse nature of coronary atherosclerosis, which frequently affects the angiographically normal “reference” vessel (eFig. 85.0.16); and (b) the presence of adaptive enlargement of the vessel, which opposes luminal encroachment and thereby keeps the lumen constant during the early phases of atherosclerosis (24) (eFig. 85.0.17).

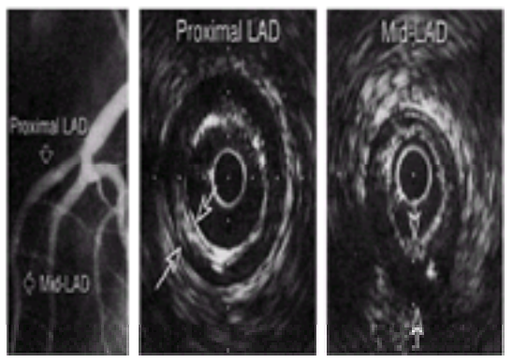


Limitations of angiography. Haziness in angiogram (*top arrow*) corresponds to lesional calcium (A). In comparison, a site just distal to the lesion (*bottom arrow*, B) remains within normal limits.

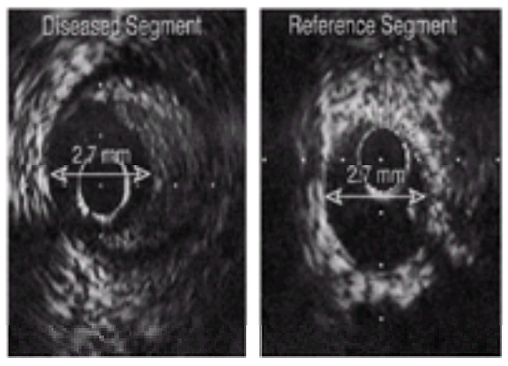




Limitation of angiography. In this example, A shows a preinterventional view of a tight distal right coronary artery stenosis. Due to intimal tears and irregular lumen shape after an angioplasty, it may be difficult to assess the lumen gain by angiography. In B, what appears to be a good result on angiogram is actually less favorable with intimal dissection evident on intravascular ultrasound examination.



***e*FIGURE 85.0.16** Diffuse disease resulting in false-negative angiography. **Left:** Two sites, one in the proximal left anterior descending artery (LAD) and another in the mid-LAD, are indicated by arrows. **Middle:** Ultrasonography at the proximal LAD site shows extensive atherosclerosis with increased intimal thickness (*arrows*). **Right:** A mid-LAD site with a similar degree of atherosclerosis is illustrated. Intimal thickness is significantly increased at both sites, which leads to false-negative angiography (*arrows*).

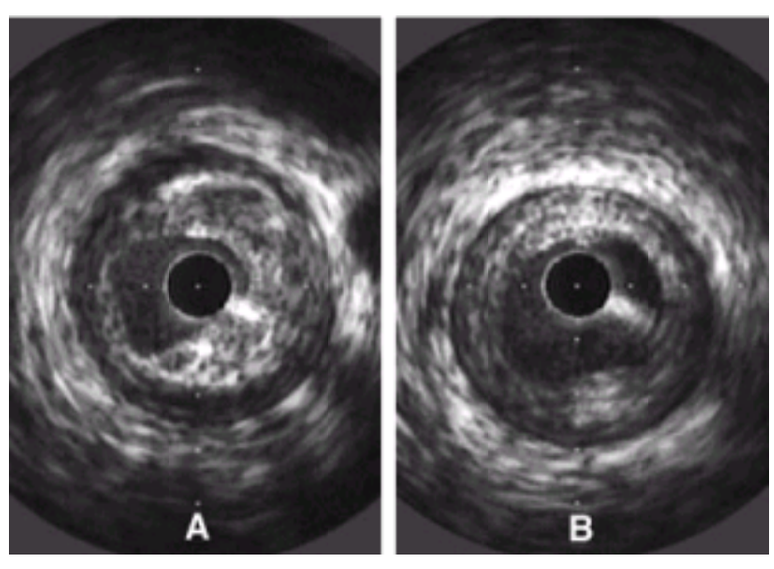


***e*FIGURE 85.0.17** Coronary remodeling. **Left:** In the diseased segment, the lumen is 2.7 mm and round, with lumen size maintained by outward displacement of the adventitia overlying a large atherosclerotic plaque. **Right:** Lumen size is nearly identical, although no atheroma is present. Because lumen size is identical in the diseased and reference segments, the angiogram is normal.

As previously discussed, angiography, a planar technique, has major limitations in measuring the size of vessels with complex luminal geometry. Accordingly, studies comparing angiographic and ultrasonographic assessment of luminal narrowing show close correlation for arteries with a nearly circular cross section and progressively lower correlation with increasing luminal eccentricity (5,6,22).

Atheroma Distribution

A second frequent area of discrepancy concerns the eccentricity of the atheromas. In patients with coronary disease, the circumferential distribution of the atheroma varies from symmetric, circumferential plaques to highly eccentric lesions in which the entire atheroma is located on only one side of the artery. The majority of plaques is eccentric by IVUS, with a maximum atheroma thickness more than twice the minimum plaque thickness. Comparative studies have demonstrated a poor correlation between the apparent plaque distribution by angiography and the actual circumferential pattern revealed by ultrasonographic examination. In 267 of 651 lesions (41%) deemed concentric by angiography, ultrasonography revealed a ratio between maximum and minimum plaque thickness greater than or equal to 3.0 (59). Conversely, only 126 of 795 plaques deemed eccentric by angiography (15%) had a segment of completely normal vessel wall. Such studies demonstrate the inaccuracy inherent in determining plaque distribution from projected two-dimensional silhouettes of the lumen (angiography). This observation has important implications for guidance of coronary interventions, particularly techniques for selective plaque removal such as DCA.

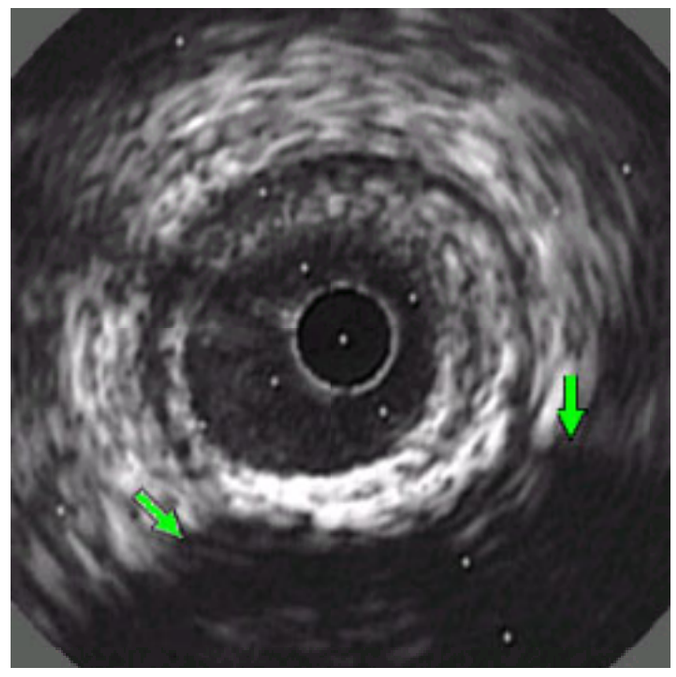


Atheroma distribution patterns. Eccentric plaque has a significant difference between the maximum and minimum plaque thickness (A). A concentric

lesion shows similar plaque thickness throughout the entire circumference of the vessel (B).

Atheroma Calcification

Extensive atheroma calcification represents an important sequela of coronary atherosclerosis, generally associated with disease of long duration. The traditional approach to identifying calcification uses cinefluoroscopy to visualize moving opacities in proximity to the vessel silhouette. This approach is limited by many factors, including the moderate spatial and contrast resolution of fluoroscopy and the confounding effects produced by the overlap of other calcium-containing structures. Studies comparing ultrasonography and angiography demonstrate poor sensitivity for angiography in detection of coronary calcification. Among 1,155 coronary lesions, Mintz et al. detected calcium in 73% of the lesions by ultrasonography and in only 38% by angiography (44). In interventional target lesions, Tuzcu et al. reported that angiography identified less than half (45%) of cases in which calcification was detected by ultrasonography (45). Even in the presence of more extensive calcification, the sensitivity of angiography remains poor, with angiography correctly identifying only 52% of lesions with calcium subtending more than 90 degrees of vessel circumference and only 63% of lesions with more than 180 degrees of involvement.



Lesional calcification. The arrows identify the calcified portion of the vessel circumference, which impedes transmission of the 30-MHz ultrasound signal, a phenomenon known as acoustic shadowing.

Although the sensitivity of angiography in detecting calcification is low, the specificity remains high. In 183 patients examined before coronary interventions, the presence of calcium identified by angiography at the target stenosis was almost invariably associated with greater than 90 degrees of arc of calcium (45). Visualization of calcium by fluoroscopy at a site remote from the target stenosis is also associated with target lesion calcification. Ultrasonographically detected calcification was evident in 35% of lesions with remote angiographic calcification. Conversely, when calcium was not present by fluoroscopy anywhere in the coronary arterial tree, the likelihood of severe target lesion calcification was low.

Arterial Remodeling

The phenomenon of coronary remodeling, originally described by Glagov from necropsy examinations, represents another important mechanism underlying false-negative angiography (24,60,61). It is also an important factor that confounds the angiographic estimation of the true size of the coronary artery, which is crucial to the technique and result of percutaneous coronary revascularization. IVUS with its tomographic perspective contributed substantially to the understanding of the remodeling phenomenon. The findings of Glagov et al. were validated *in vivo* by intracoronary ultrasonographic imaging (eFig. 85.0.17). In some of the IVUS studies and most histologic investigations, the presence and extent of remodeling are inferred from the comparison of plaque and EEM area in groups of lesions of differing severity (60). Positive remodeling is defined by a positive correlation between plaque and EEM area. In this type of analysis, remodeling can be described for a large group of lesions but not for individual lesion sites.

To assess the extent and direction of remodeling in individual lesions, one must compare vessel size at the lesion site to vessel size at an adjacent reference site. Positive and negative remodeling are defined as larger or smaller EEM area at the lesion site than at an adjacent reference site. Angiographically “normal” reference segments frequently contain mild to moderate atherosclerosis and remodeling, however. If serial ultrasonographic images are available, the changes in plaque and EEM areas can be assessed over time, which eliminates the confounding variable of reference segment remodeling.

Changes in the vessel wall in response to atherosclerosis are not always in the form of outward expansion but can manifest as a shrinkage. The phenomenon of negative remodeling was demonstrated in peripheral as well as coronary atherosclerosis (62,63). At diseased sites, the artery may actually shrink in size and contribute to, instead of compensate for, the degree of luminal stenosis.

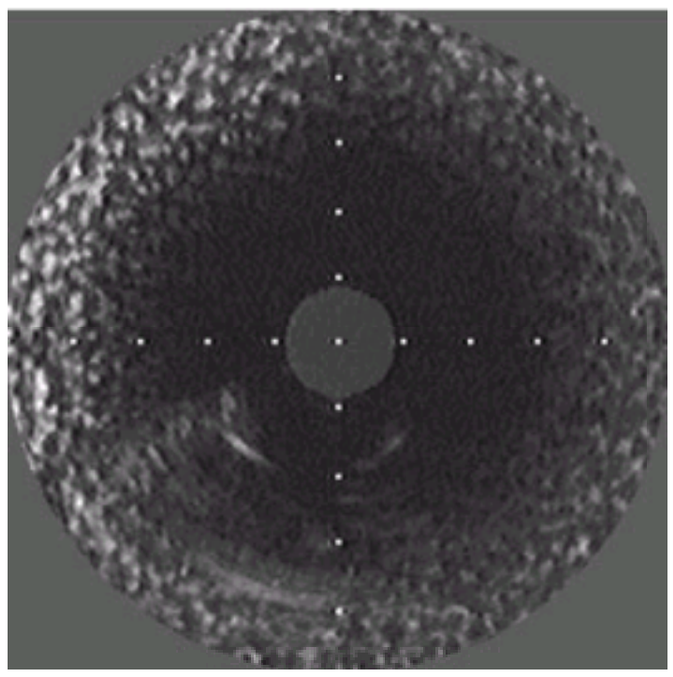
Intriguing IVUS and histopathologic studies provided new insights into arterial remodeling by shedding new light on the relationship between remodeling and the clinical presentation of coronary artery disease. In one study, positive remodeling was more prevalent in patients who presented with unstable angina (51% vs. 18%; $p = .002$), and negative remodeling was more prevalent in patients with stable angina (58% vs. 33%; $p = .002$) (64). A similar relationship between the direction of remodeling and clinical presentation was also shown in the setting of myocardial infarction (65). In a combined IVUS-angioscopy study, unstable lesions were more commonly characterized by positive than by negative remodeling (58% vs. 17%). Also, angioscopically complex lesions more often had positive than negative remodeling (57% vs. 14%) (66). These studies support the hypothesis that plaque vulnerability and positive remodeling have some common pathophysiologic mechanisms.

The pathophysiologic mechanisms underlying plaque vulnerability and remodeling are not well known. However, inflammation may represent a common link. An IVUS and histologic study of the human femoral arteries showed an association between histologic markers associated with plaque inflammation and positive arterial remodeling (67). Comparative analysis of the preatherectomy ultrasonographic images and histology of the plaque tissue obtained by DCA demonstrated an association between intense matrix metalloprotein staining and positive remodeling, which suggests that degradation of the extracellular matrix plays a role in arterial remodeling (68).

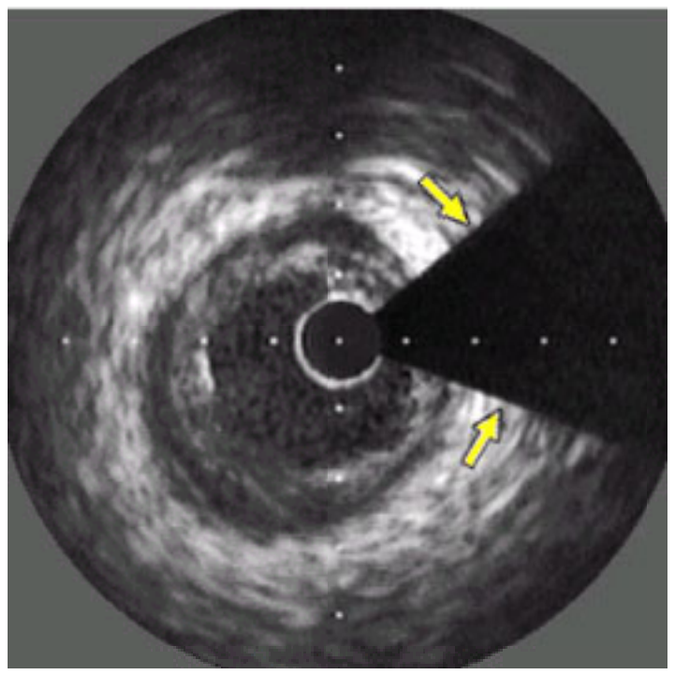
Changes in the geometry of the vessel and tissue changes leading to the geometric alteration probably affect the response of the vascular segment to balloon angioplasty. Immediate and long-term outcomes of various percutaneous coronary interventions have been correlated with direction and extent of remodeling (69,70,71 and 72).

Limitations and Artifacts

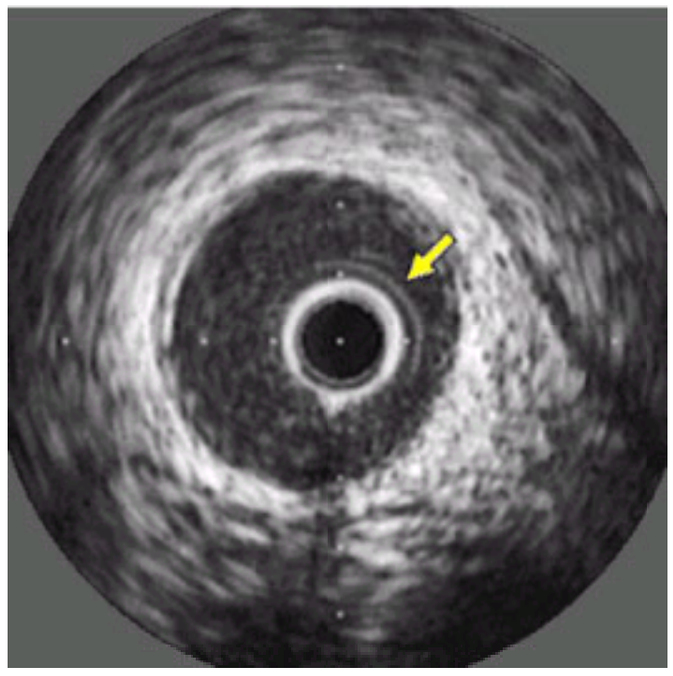
Important artifacts are often present in images generated by contemporary IVUS devices. These artifacts can have wide-ranging consequences and may adversely affect image quality, increase interpretation difficulty, or reduce the accuracy of quantitative measurements (73). Imaging of small coronary arteries or preinterventional assessment of target lesions with severe stenosis requires imaging close to the transducer surface. *Ring-down artifact*, however, a defect that appears in virtually all medical ultrasonographic devices, impairs the ability to image structures adjacent to the transducer surface (eFig. 85.0.18). The size of the catheter itself can be the cause of artifact by disrupting the severely stenotic plaque. Geometric distortion, which influences area and diameter measurements, is the result of noncoaxial alignment of the ultrasonographic catheter.



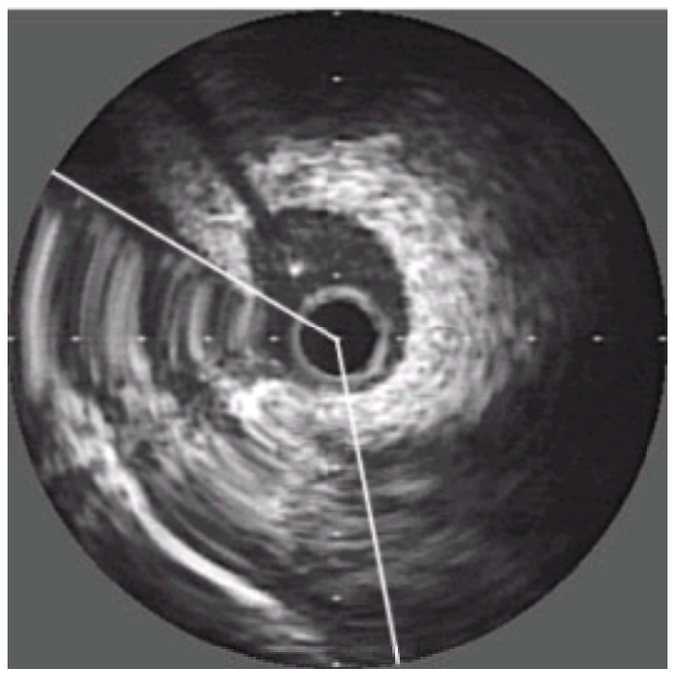
Appearance of an imaging artifact. Air within the catheter surrounds the transducer, resulting in absence of an interpretable image.



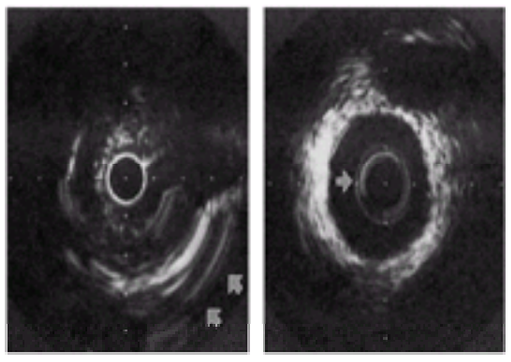
Imaging artifacts. An incomplete connection between the catheter and patient interface results in missing image information from a portion of the vessel circumference.



Imaging artifacts. "Ring-down" artifact consists of high amplitude echo signals in the near field (*arrow*).



Intravascular ultrasound artifacts. Nonuniform rotational distortion (NURD) results from variability in rotational velocity in mechanical intravascular ultrasound catheters (zone between lines).



***e*FIGURE 85.0.18** Two types of intravascular ultrasonographic imaging artifacts. **Left:** The ultrasonographic image exhibits nonuniform rotational distortion, which can be recognized by a circumferential "stretching" of the image (*arrows*). **Right:** A large "near-field" artifact (ring-down) is evident (*arrow*).

Ring-down artifacts are produced by acoustic oscillations in the piezoelectric transducer material, which results in high-amplitude ultrasonic signals that preclude near-field imaging. Inability to image structures immediately adjacent to the transducer results in an acoustic catheter size that is slightly larger than its physical size. Current designs use carefully chosen transducer materials, ultrasound-absorbent backings, specialized coatings, and electronic filtering to suppress ring-down artifacts. In the electronic array design, the transducers are surface mounted, and ring-down must be reduced by digital subtraction.

The physical size of ultrasonographic catheters (currently approximately 1.0 mm) constitutes an important limitation in certain clinical applications. Although the operator may be able to reach many critical stenoses with a 1-mm device, lesional morphology and quantitative measurements are distorted by the distending effect of the catheter. Reductions in transducer size are feasible, but finite physical limitations exist to further transducer miniaturization. A smaller transducer reduces the "aperture" of the device, which limits available acoustic power, significantly reduces lateral resolution, and impairs the signal-to-noise ratio. The resolution limits at small apertures may be partially compensated by using higher frequency transducers (40 to 50 MHz).

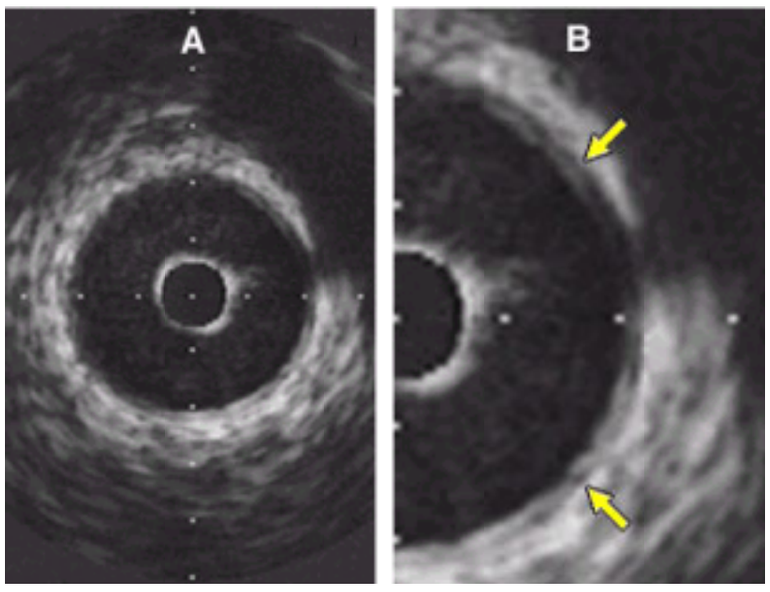
Geometric distortion can result from imaging in an oblique plane (not perpendicular to the long axis of the vessel). Noncoaxial alignment of the transducer within the artery results in an elliptical rather than circular cross-sectional imaging plane (74). This phenomenon can represent a significant confounding variable in the application of IVUS for quantitative plaque and lumen measurements. During data acquisition, the operator often can recognize a nonorthogonal catheter position and manipulate the device to a more coaxial position. The maximum extent of obliquity is influenced by the relative sizes of imaging catheter and lumen. Accordingly, this artifact can be more troublesome when larger vessels such as the aorta or the peripheral vasculature are imaged.

A very important artifact, known as *nonuniform rotational distortion* (NURD), is present in all mechanical IVUS systems (*e*Fig. 85.0.18). This artifact arises from uneven mechanical drag on the catheter drive shaft during the various portions of its rotational cycle, which results in cyclical oscillations in rotational speed. Nonuniform speed variation, when severe, produces visible distortion of the ultrasonographic image. During the portion of the rotational cycle when velocity is high, the image exhibits circumferential "stretching" with "compression" of the contralateral vessel wall (*e*Fig. 85.0.18). NURD is most evident when the drive shaft is deformed into a small radius of curvature either by external manipulation or vessel tortuosity. One preventable cause of NURD is excessive tightening of the hemostasis valve at the hub of the guiding catheter. Improvements in the mechanical precision of ultrasonographic devices have reduced the impact of this artifact, but it remains a troublesome problem during some examinations.

Diagnostic Clinical Applications

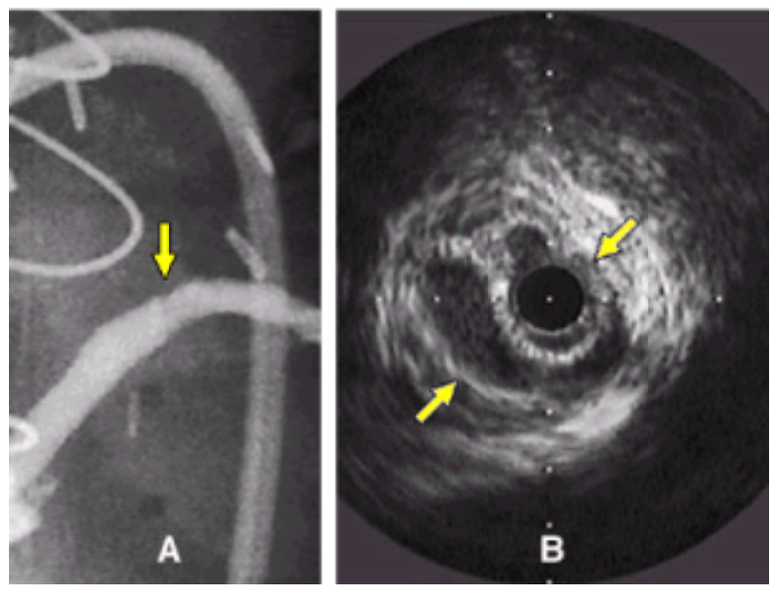
Angiographically Normal Coronary Arteries

Normal angiograms are obtained in 10% to 15% of patients undergoing coronary angiography for suspected coronary artery disease. In these patients with clinical symptoms of coronary disease, IVUS commonly detects atherosclerosis at angiographically normal sites (6,75,76,77 and 78). Erbel et al. observed atherosclerotic abnormalities in 21 of 44 patients (48%) with suspected coronary artery disease and a normal coronary angiogram (75). Combining ultrasonography with methods for functional assessment (measurement of coronary flow reserve and endothelium-mediated vasodilator response) reduced the proportion of completely normal results to only 36%. Other studies demonstrate that, if any luminal irregularity is present by angiography, ultrasonography usually demonstrates disease at nearly all other examined sites (6). The prevalence of disease at angiographically normal sites confirms the finding, previously reported from necropsy studies, that coronary disease is more extensive than apparent by angiography (19).



Normal coronary wall morphology by intravascular ultrasound. A trilaminar appearance is apparent with distinct layers representing the intima, media, and adventitia (B, *arrows*).

IVUS studies have revealed several important mechanisms by which angiography may underestimate the presence, extent, or severity of atherosclerosis. Angiography compares the interrogated site to an adjacent uninvolved segment to detect a focal stenosis. The diseased vessel may be reduced in caliber along its entire length, however, containing no truly normal segment for comparison (*e*Fig. 85.0.16). Accordingly, the angiographer could erroneously conclude that the vessel is simply "small in caliber." The ability to obtain optimal radiographic projections is limited in some patients. For example, at certain angles, overlapping structures such as adjacent vessels can obscure some segments of the coronary artery. Mechanical radiograph positioners have finite limits in the available projection angles. Accordingly, an eccentric lesion may not be visualized adequately by angiography.



Limitation of angiography: A minor angiographic luminal irregularity is present at the distal end of a stent (A, *arrow*) in a saphenous vein graft. Intravascular ultrasonography (B) shows a dissection with two flow channels. The arrow at 2 o'clock shows the true lumen containing the imaging catheter, and the arrow at 7 o'clock indicates the false lumen.

As previously discussed, compensatory enlargement (remodeling) of the vessel wall overlying the plaque preserves lumen diameter, which results in an angiographic diameter similar to that of adjacent, uninvolved coronary segments (eFig. 85.0.17). Finally, vessel foreshortening can conceal short "napkin-ring" lesions (usually less than 1 to 2 mm in length) from angiographic detection, which results in false-negative angiography.

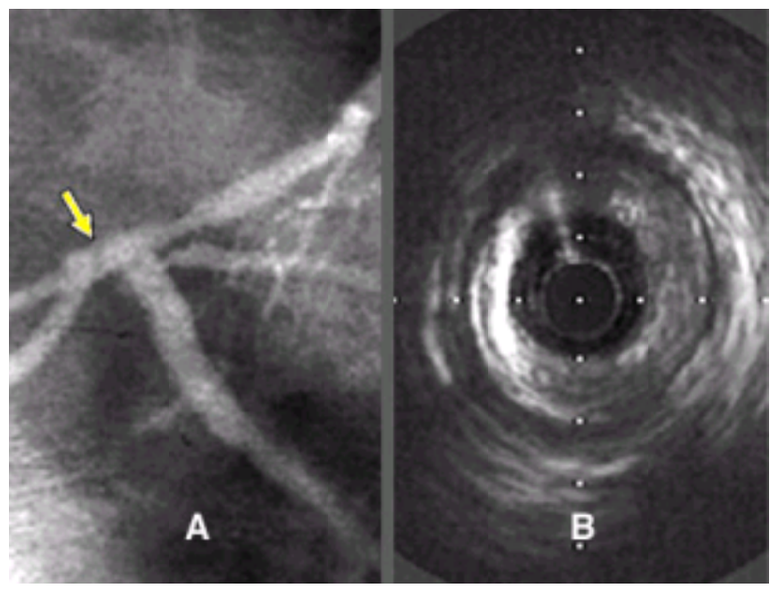
Intermediate Stenosis

Angiographers commonly encounter lesions that elude accurate characterization despite thorough examination using multiple radiographic projections. Difficult lesions include ostial lesions, bifurcation lesions, and moderate stenoses (angiographic severity ranging from 40% to 75%) in patients whose symptomatic status is difficult to evaluate. Occasionally, insufficient quality of the angiogram results from extreme obesity, emphysema, or chest deformities. For ambiguous lesions, ultrasonography provides a tomographic perspective, independent of the radiographic projection that often permits lesion quantification. In reports from two centers, intracoronary ultrasonography changed the management strategy in more than 20% of cases in which examinations were performed immediately before coronary intervention (treatment of angiographically insignificant lesions after imaging or vice versa) (55,56). In both studies, however, the selection of patients for ultrasonographic examination may have resulted in an overestimation of the true impact of ultrasonographic imaging on clinical decision making. Furthermore, the retrospective nature of these studies limits the applicability of their results to routine clinical practice.

No consensus exists regarding the criteria that would allow the application of ultrasonographic measurements to the functional assessment of the coronary blood flow and clinical decision making. The lesion lumen area and ultrasonographically derived stenosis indices such as luminal area showed sensitivities and specificities ranging between 80% and 90% when myocardial perfusion imaging is used as the gold standard (79).

The role of IVUS in clinical decision making has been assessed in two single-center retrospective clinical studies. In one of the studies, intervention was deferred in 300 patients based on ultrasonographic information. At 1-year follow-up, the rate of adverse events (death, myocardial infarction, or target lesion revascularization) was low, particularly in patients with a minimum lumen area greater than 4.0 mm (80). In another study that used IVUS and fractional flow reserve measurements, a minimum lumen area of greater than 3 mm^2 was recommended as the threshold for deferring intervention in native coronary artery obstructions other than left main coronary artery (81).

Angiographic quantification of the severity of left main coronary artery obstruction represents a particularly vexing clinical problem (13). Because the left main artery is short, no normal segment may exist that can be used as a reference. Furthermore, contrast in the aortic cusp often obscures the ostium, which requires the operator to engage the vessel with the angiographic catheter and "reflux" dye to visualize the proximal vessel. The angle between the catheter and the left main coronary artery and the take-off angle of this vessel may give the false impression of severe ostial stenosis. Sometimes, streaming of contrast material from the injection vortex may also result in pseudostenosis. Furthermore, overlapping vessels at bifurcation or trifurcation often conceal the distal left main coronary artery. Accordingly, IVUS is commonly used to quantify left main coronary artery obstruction when angiographic interpretation is uncertain (82). No consensus yet exists regarding the cutoff at which the left main obstruction is considered to require surgical treatment. Although stenosis of greater than 50% of the vessel area is proposed as a cutoff for consideration for revascularization, no data exist to support such a critical measure (83,84).

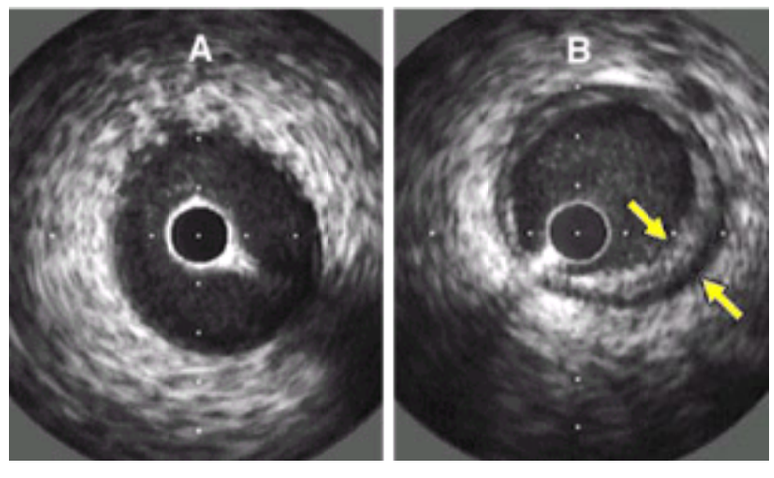


Limitation of angiography. The concentric plaque in the left main trunk (A) was not clearly defined by angiography because of the diffuse nature of the disease. Intravascular ultrasound examination demonstrates a major area reduction by concentric plaque (B).

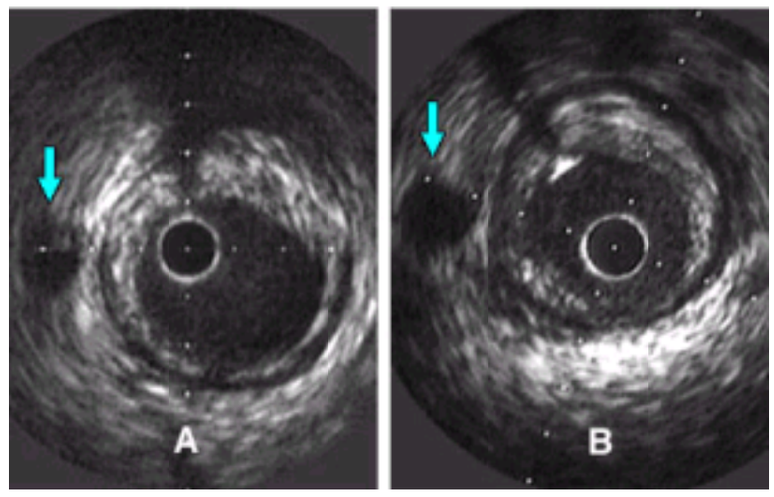
Morphologic information provided by IVUS is valuable in decision making in the catheterization laboratory, particularly at angiographically poorly defined sites such as ostia, bifurcations, and tortuous segments. Ultrasonography, however, unlike physiologic measurements such as Doppler coronary flow reserve and fractional flow, does not give physiologic information. Thus, a physiologic rather than a morphologic method should be used as the first choice in the assessment of borderline lesions (angiographically determined severity ranging from 40% to 75%).

Cardiac Allograft Vasculopathy

Accelerated coronary vasculopathy is the leading cause of mortality in cardiac transplant recipients beyond the first year after transplantation (85). Because cardiac allografts are functionally denervated, major clinical events such as myocardial infarction, congestive heart failure, and sudden death may occur without prodromal angina. Although most transplant centers perform coronary arteriograms annually for screening, these surveillance studies often fail to detect atherosclerosis before a clinical event (77,86). Intracoronary ultrasonography is an accurate and reproducible method. It provided valuable insights to the understanding of transplant coronary artery disease and demonstrated that the incidence of transplant coronary disease is much higher than previous angiographic studies had documented (77,87,88 and 89).



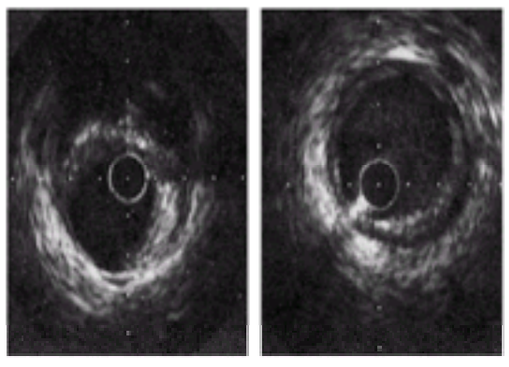
Serial intravascular ultrasound study in a cardiac transplant patient. The baseline intravascular ultrasound study (A), 1 month after transplantation, shows a normal left anterior descending artery. After 1 year (B), there is obvious thickening of intima with a concentric distribution pattern.



Serial intravascular ultrasound study in transplant recipient. The baseline study (A, 2 months after cardiac transplant), shows an eccentric plaque in the left anterior descending artery. One year later (B), the same site is identified with the help of anatomic and angiographic landmarks (a branch vessel, *arrow*). This permits repeated imaging of the same site, which reveals no change over 1 year.

Studies performed in patients soon after transplantation have helped define the normal appearance of young healthy arteries but have also shown that advanced atherosclerotic changes can be present in apparently normal donor hearts (77,87). Several studies, however, showed that preexisting donor disease detected by IVUS did not accelerate the progression of transplant vasculopathy within the first few years after cardiac transplantation (90,91). Serial studies starting a few weeks after transplantation led to differentiation of allograft vasculopathy from donor-transmitted atherosclerosis, which would be impossible in cross-sectional studies done one or more years after transplantation (91,92 and 93).

In contrast to the histologic paradigm of transplant coronary artery disease, large ultrasonographic studies have demonstrated a heterogeneous distribution of coronary lesions (92,93) (eFig. 85.0.19). In early allograft vasculopathy, focal and eccentric lesions were common in the proximal segments. Fibrous intimal proliferation occurs mostly during the first 2 years after transplantation, whereas calcification of plaques occurs to a significant extent only later in the process. Detection of early vasculopathic changes has significant clinical implications. Development of intimal thickness is an independent predictor of overall and cardiac survival and of freedom from retransplantation (94,95).



***e*FIGURE 85.0.19** Concentric and eccentric patterns of disease in a transplant recipient. **Left:** The atheroma involves approximately 270 degrees of the circumference of the artery with sparing of the opposite wall. This pattern is typical of disease grafted from the donor heart. **Right:** A more circumferential pattern is evident, consistent with acquired immune-mediated transplant vasculopathy.

Studies have shown a correlation of multiple immunologic and metabolic recipient factors as well as donor characteristics with intimal thickness, a finding which suggests a multifactorial etiology for transplant vasculopathy. Lipid values, particularly marked change in levels of low-density lipoprotein cholesterol, were shown to play a role in the development of severe vasculopathy (96). A small randomized study that used serial ultrasonographic imaging demonstrated reduction in the progression of transplant coronary disease with pravastatin sodium therapy (97). Introduction of IVUS imaging to the follow-up of posttransplant patients improved the understanding of transplant coronary disease and led to the development of new treatment strategies.

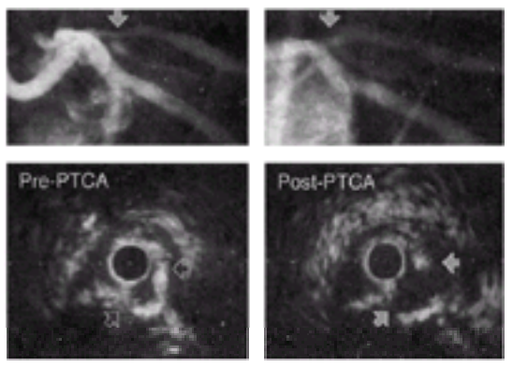
Interventional Clinical Applications

Preintervention Device Selection

The small diameter of contemporary ultrasonographic imaging catheters permits interrogation of most coronary lesions before mechanical intervention. Occasionally, severe calcific stenosis precludes passage of the imaging catheter, so that the operator must dilate before ultrasonographic examination. Intracoronary imaging offers several potential advantages for selection of the most appropriate treatment modality for a particular lesion. However, prospective randomized studies examining the utility of ultrasonographically directed revascularization strategies are essentially nonexistent. In the absence of controlled trials, interventional operators commonly use a variety of morphologic features to assist in selection of the optimal interventional approach. These include the extent of calcification, the degree of lesional eccentricity, and the amount of vessel remodeling. Despite the absence of strong data, useful observations regarding application of specific devices have emerged from initial research. These observations offer useful insights into the mechanisms of benefit and risk for many interventional approaches.

Balloon Angioplasty

Postmortem examination of the coronary arteries in patients who expired within a few days after balloon angioplasty reveal plaque fracturing or dissection as the most common mechanism of successful balloon dilatation (18,20). Ultrasonographic studies performed both *in vitro* and *in vivo* have confirmed that plaque fissuring or dissection is the most common mechanism of luminal enlargement after conventional balloon angioplasty (21,23,98,99) (eFig. 85.0.20). The diagnosis of dissection requires the visualization of blood flow in a newly created lumen or behind an intraluminal “flap.” In some cases, injection of saline or iodinated contrast through the guiding catheter can be helpful to opacify structures and aids in confirming the diagnosis. The severity of wall disruptions can be defined by measuring the circumferential extent, length, and maximal depth of the dissection.

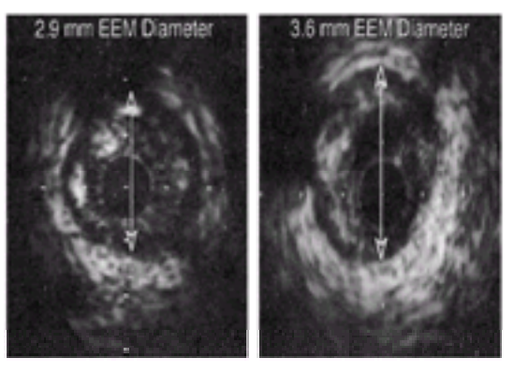


***e*FIGURE 85.0.20** Angiographic and intravascular ultrasonographic images before and after balloon angioplasty. **Top left:** An angiographic narrowing is indicated by the gray arrow. **Top right:** After balloon angioplasty, this narrowing appears improved (*gray arrow*). **Bottom left:** A dense fibrocalcific lesion is shown before intervention (*arrows*). **Bottom right:** After percutaneous transluminal coronary angioplasty (PTCA), the ultrasonographic image shows two areas of plaque fracture with extensive dissection (*arrows*).

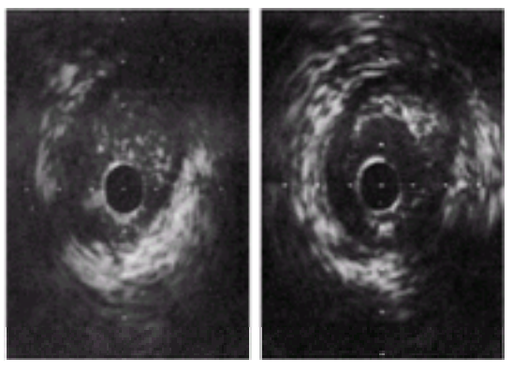
Although dissection is the most common finding, ultrasonography often reveals alternative mechanisms of luminal enlargement after balloon angioplasty that cannot be appreciated by angiography (98,99,100 and 101). For example, systematic comparison of pre- and postangioplasty ultrasonographic measurements shows that "stretching" of the external elastic lamina occurs in many patients (*e*Fig. 85.0.21). In other patients, an apparent reduction of the atheroma area ("compression") is evident, although studies using automatic pullback devices have shown that "compression" actually represents longitudinal redistribution of plaque in the vessel (101) (*e*Fig. 5.0.22).

VIDEO

Video 85.1 Coronary dissection by intravascular ultrasound. A tissue flap is seen protruding in the lumen of the vessel after high-pressure postdilatation of a Palmaz-Schatz stent in the adjacent segment. Angiographically, this flap was visualized as an area of 'peri-stent' haziness. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

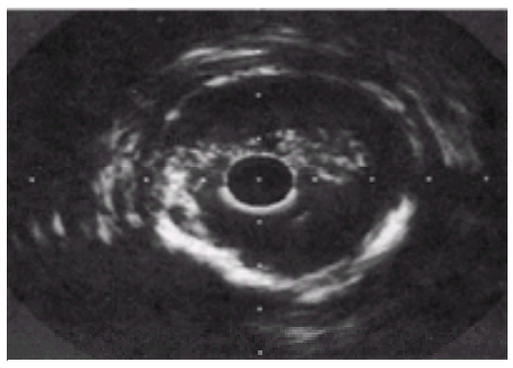


***e*FIGURE 85.0.21** Luminal enlargement by stretching of the vessel during percutaneous transluminal coronary angioplasty. **Left:** The external elastic membrane (EEM) diameter is 2.9 mm before balloon angioplasty and increases to 3.6 mm after the intervention. Thus, lumen gain is almost exclusively secondary to stretching.



***e*FIGURE 85.0.22** Luminal enlargement by plaque redistribution. **Left:** Ultrasonographic image before intervention shows a sonolucent, eccentric, bulky atheroma. **Right:** After intervention, the lumen is enlarged, and the plaque area appears to be reduced. Serial sections demonstrate that the plaque has actually been redistributed within the vessel.

Preinterventional assessment of lesions offers the potential to modify the dilatation strategy through selection of the length and size of the balloon. For example, ultrasonography may reveal a more diffuse atherosclerotic involvement than that expected from angiography, which suggests the use of a longer balloon. Ultrasonographically guided balloon sizing considers measurements not only of the lumen diameter but also of the total vessel diameter (EEM diameter). In the multicenter Clinical Outcomes with Ultrasound Trial (CLOUT) study, investigators addressed the question of how ultrasonographic information could be used in the guidance of balloon angioplasty. IVUS was performed after a satisfactory angiographic result was obtained by standard intervention. A weighted average of the lumen and EEM diameters obtained by ultrasonography was used for balloon size selection. Following this strategy led to selection of larger balloons for 73% of the patients. This ultrasonographically guided strategy led to further increase in minimal luminal diameter from 1.95 to 2.21 mm and in lumen area from 3.2 to 4.4 mm^2 (102). In contrast to previous angiographic studies, which have shown that a balloon to artery ratio greater than 1.1 leads to more severe dissections, procedures with a balloon to artery ratio of 1.3 in the CLOUT study did not result in excess dissections (103). These data suggest that with discriminate ultrasonographically guided balloon upsizing, the results of balloon angioplasty can be improved. Nonrandomized studies from two centers provide further support for ultrasonographically guided balloon sizing. Aggressive balloon sizing (based on the media to media dimension determined by ultrasonography) led to stent-like procedural results and complication and target vessel revascularization rates (104,105 and 106). Most operators experienced in IVUS believe that the presence, depth, and circumferential extent of calcification have predictive value in estimating the risk of complications after balloon angioplasty (43). Dissections frequently occur at the junction between soft tissue and calcium due to the different stress modulus of these two plaque components (*e*Fig. 85.0.23). Contrary to these observations, in a series of 197 patients who underwent ultrasonographic imaging before and after angioplasty, lesion morphology was not a predictor of severe coronary dissections (107). Whether knowledge of coronary calcification can be used in planning interventional procedures to reduce dissections has not yet been adequately tested in clinical trials.



***e*FIGURE 85.0.23** Large dissection after intervention. A large peninsula of plaque nearly bisects this vessel after coronary intervention. Because such lesions are surrounded by contrast, they may be inapparent on angiography.

The most important information obtained by IVUS concerns assessment of the procedural results. After angioplasty, ultrasonography can detect the circumferential and longitudinal extent of dissection. Several studies report a poor correlation between ultrasonography and angiography in assessing residual stenosis after angioplasty (108,109). Measurements of luminal cross-sectional area after angioplasty are generally smaller by ultrasonography than by angiography. These differences likely represent enhancement of the apparent angiographic diameter of the vessel produced by extraluminal contrast within cracks or splits in the intima or media, or both, of the vessel. Because balloon dilatation distorts the vessel lumen and wall, the reported differences between angiographic and ultrasonographic measurements probably reflect the differences between silhouette and tomographic imaging of complex eccentric lumen shapes after angioplasty.

Two factors influence the tendency of angiographic imaging to yield overly optimistic results after balloon angioplasty. Because of the frequent presence of unrecognized atherosclerosis at the reference site, angiography tends to underestimate the diameter of the normal reference vessel. At the lesion site, angiography tends to overestimate the actual gain in luminal diameter, because contrast material penetrates into complex cracks and fissures produced by the intervention, which gives the appearance of a more enlarged lumen. To calculate a postprocedure percent diameter stenosis, the diameter at the target site (an overestimate) is divided by the reference diameter (an underestimate), which results in a more favorable impression of the actual gain in luminal dimensions. Accordingly, when quantitative angiography reports a residual diameter of stenosis of 10% to 15%, ultrasonography not uncommonly reports that 60% to 80% of the vessel is still occupied by atheroma (percent vessel area stenosis).

Intravascular Ultrasonography and Restenosis

IVUS provides a unique perspective to better understand the mechanisms and characteristics of restenosis, which continues to be the Achilles' heel of percutaneous coronary intervention. Angiographic parameters, including quantitative angiographic measurements, are limited predictors of the long-term results after balloon angioplasty (110). Preliminary ultrasonographic studies have shown conflicting data concerning the factors predictive of restenosis after balloon angioplasty (111,112). A more complete understanding of restenosis has evolved from serial ultrasonographic measurements of plaque and lumen areas at follow-up studies after balloon angioplasty and DCA (113,114).

IVUS provided valuable insight about the mechanism and characteristics of the restenosis phenomenon. In the Post Intra-Coronary Treatment Ultrasound Restenosis Evaluation study, ultrasonography was used to assess lesion composition, mechanism of luminal enlargement, and quantitative measurements of the lumen and plaque after final balloon inflation (111). In this small prospective trial enrolling 200 patients, clinical and angiographic results could not be predicted by ultrasonographic findings. However, lack of blinding of interventional operators and the relatively small patient population were important limitations of this study.

A single-center observational study demonstrated that the residual cross-sectional area stenosis measured by ultrasonography was an independent predictor of restenosis (114). Plotting of the residual cross-sectional area stenosis versus the probability of restenosis at 6 months demonstrated a curvilinear relationship, with restenosis occurring in more than 50% of the lesions showing more than 70% residual area stenosis immediately after intervention.

The Guidance by Ultrasound Imaging for Decision Endpoints II trial was a multicenter study assessing the factors predictive of restenosis after balloon angioplasty and DCA based on a final ultrasonographic examination (112). The analysis, performed without discriminating between balloon angioplasty and DCA, demonstrated that two ultrasonographic parameters were predictive of long-term recurrence of symptoms: residual plaque burden and luminal cross-sectional area after intervention. The results of these studies suggest that ultrasonography may be useful whenever angiography shows diffuse haziness or intraluminal defects in the treated segment, suggestive of the presence of suboptimal results associated with a high risk of persistence or recurrence of symptoms.

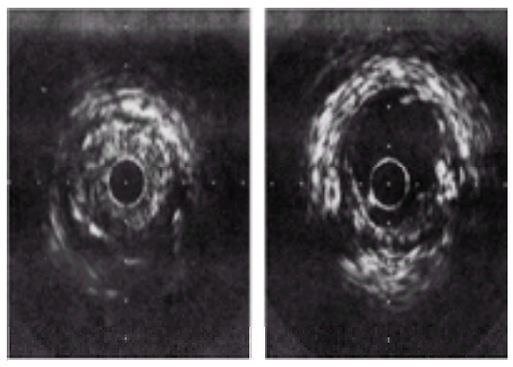
Until recently, neointimal proliferation was thought to be the predominant mechanism of restenosis after angioplasty and atherectomy. Studies of the peripheral arteries using IVUS imaging demonstrated that negative remodeling, or localized shrinkage of the vessel wall, was the primary mechanism of restenosis (62,115). Observations in patients who underwent repeat percutaneous coronary angiography supported this concept. In follow-up ultrasonographic examinations, a decrease in EEM area and an increase in plaque area were observed at the site of intervention. Decrease in EEM area caused 70% of lumen loss, whereas neointimal proliferation contributed to only 23% of the loss after percutaneous transluminal coronary angioplasty (PTCA). Late loss was correlated more strongly with the change in EEM area than with the change in plaque area (63). In a unique systematic serial study, 57 patients were examined by IVUS before and immediately after balloon angioplasty or atherectomy, and again after 24 hours, 1 month, and 6 months (114). The lumen area continued to enlarge during the first month after the intervention but decreased significantly at 6 months. The changes in EEM area or vessel area corresponded to those in the lumen area, with EEM area increasing in the first month and decreasing at 6 months. Plaque area, on the other hand, steadily increased from the immediately postintervention image to the 6-month follow-up image. The changes in lumen area correlated strongly with the changes in EEM area (r = .72, p = .0001). Correlation of the change in the plaque area with lumen loss was less impressive (r = .34, p = .0008). The findings of these studies indicated a complex remodeling response after nonstent percutaneous coronary interventions. Bidirectional changes of the vessel (EEM) area and intimal hyperplasia contributed to the late lumen loss.

Unlike restenosis after angioplasty or atherectomy, restenosis after stenting is primarily due to neointimal proliferation. In a serial ultrasonographic study, late lumen loss correlated strongly with the degree of in-stent neointimal growth (r = 0.98) (116,117). In another serial ultrasonographic study, the area within the stent did not change over time, which indicates that stented segments are not affected by recoil or negative remodeling over time (116). Resistance to constricting forces combined with the greater initial lumen expansion accomplished with stenting results in a lower net restenosis rate than occurs with angioplasty or atherectomy. The severity of intimal proliferation correlated with the preinterventional plaque burden (118). Although positive remodeling was associated with in-stent intimal hyperplasia, other studies demonstrated no such correlation (71,119). New insights into the mechanism of restenosis provided by IVUS explain the lower restenosis rate observed in randomized multicenter studies comparing balloon angioplasty and stent implantation (120,121). Other phenomena observed by ultrasonography may also play a role in determining the outcome after coronary interventions. The relatively poor correlation between angiographic and ultrasonic dimensions after angioplasty raises a provocative issue.

Response to various percutaneous interventions and development of restenosis have been correlated with remodeling. The response of the coronary segment to balloon dilatation appears to be linked to the direction of remodeling. The absolute lumen gain achieved with balloon angioplasty did not differ significantly for lesions with positive and negative remodeling, but differences were seen in the mechanism of lumen gain. Stretch of the EEM area was significantly larger in the group with wall shrinkage than in the group with compensatory enlargement. Subsequent lumen loss secondary to elastic recoil was not significantly different for the two groups (69). The direction of remodeling also affects outcome after percutaneous interventions. Target vessel revascularization after nonstent interventions was more frequently observed in lesions with positive remodeling (70). This effect of positive remodeling on target lesion remodeling was not observed in one report of stented segments (71). Conflicting reports have been published regarding the relationship between extent of remodeling and neointimal proliferation after coronary stenting (72).

Guidance of Directional Atherectomy

Although vessel stretch contributes to lumen enlargement, in DCA plaque removal is the primary aim of luminal enlargement (57,58) (*e*Fig. 85.0.24). Ultrasonographic studies, however, revealed that despite a successful angiographic result after atherectomy, 40% to 60% or more of the cross-sectional vessel area at the target site was still occupied by atheroma (122,123). Pre-DCA ultrasonography provides information about location, eccentricity, and calcium content of the plaques. Repeated ultrasonographic examinations during the procedure allow the operator safely to maximize plaque removal. However, only limited data are available suggesting that ultrasonographically guided DCA leads to stent-like results with comparable long-term outcome.



***e*FIGURE 85.0.24** Intravascular ultrasonographic images taken before and after directional coronary atherectomy. **Left:** A bulky plaque is illustrated. **Right:** Greater than 70% of the atheroma has been removed using a directional coronary atherectomy device.

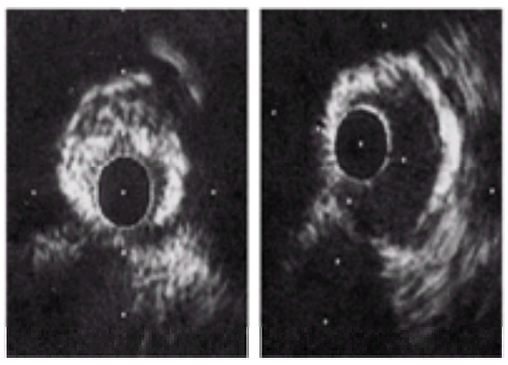
Angiographically guided DCA was not proven superior to conventional balloon angioplasty in two large prospective trials conducted in the early 1990s (124,125). Studies of “optimal” atherectomy showed superiority of DCA in achieving larger lumens (122). Ultrasonography can define plaque location and circumferential distribution, potentially improve preprocedural planning, and aid intraprocedural decision making, which results in maximal plaque removal (59). Preinterventional ultrasonographic imaging is the most sensitive method for detecting, localizing, and quantifying calcium deposits (44,45). Subendothelial plaque calcium has been shown to be an important factor that limits tissue retrieval and increases the incidence of procedural complications (57,59). Efficacy of new titanium cutters in ablating calcium has been anecdotally reported, but controlled studies are not yet available. Preinterventional ultrasonographic information also helps the operator target the cutter to the plaque using anatomical landmarks and side branches. Studies demonstrate that the use of ultrasonography during atherectomy results in a more aggressive strategy and leads to greater plaque removal and a larger final lumen diameter (126). The results of the Optimal Atherectomy Restenosis Study registry support the hypothesis of an improved immediate result (angiographically determined residual diameter of stenosis of 8 11%) and a high initial procedural success with aggressive ultrasonographically guided atherectomy (122). Despite these stent-like immediate results, however, a relatively large residual plaque area (mean of 58%) was still observed by ultrasonography after atherectomy. Some investigators have proposed that a larger lumen after atherectomy would in turn result in a lower restenosis rate. In the Adjunctive Balloon Angioplasty After Coronary A therectomy Study, which compared DCA alone to DCA plus PTCA, ultrasonographic guidance allowed operators to perform very aggressive atherectomy with residual plaque occupying 46% of the vessel area with stand-alone DCA (127). Similarly, in the Stent versus Directional Coronary Atherectomy Randomized Trial, operators used serial ultrasonographic imaging and achieved a residual plaque burden of 52%. In this randomized study, restenosis was significantly lower in the group receiving aggressive IVUS-guided atherectomy (16%) than in those undergoing stenting (33%) (128).

Despite the promising results from preliminary studies of a novel device that combines an ultrasonographic transducer with an atherectomy catheter, no commercially available devices enable the operator to visualize the plaque located directly in the path of the atherectomy cutter (29).

Guidance of Rotational Ablation

Rotational ablation is effective in the treatment of heavily calcified coronary arteries. IVUS is helpful in detecting and quantifying the extent of calcification. It is also useful in the assessment of outcome and in determining type and size of other interventional devices that need to be used.

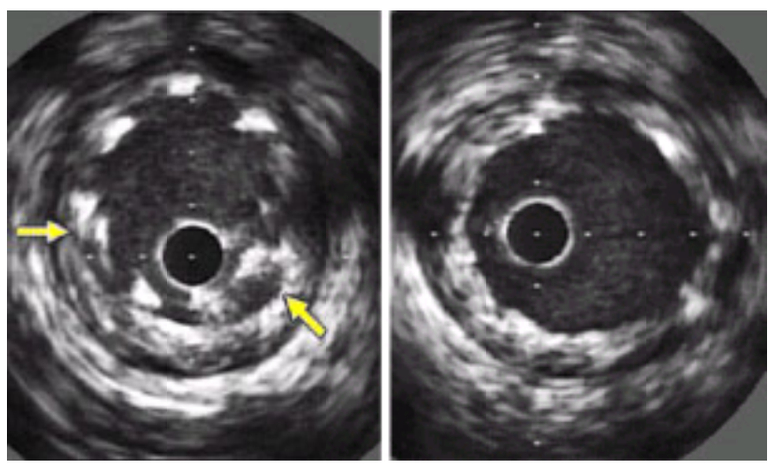
Rotational ablation uses a high-speed diamond-coated burr to debulk atheromas within coronary stenosis. Angiographically and ultrasonographically guided studies have demonstrated the efficacy of this approach at removing calcium from stenotic vessels (129,130 and 131). As noted previously, however, a poor correlation exists between ultrasonography and fluoroscopy in assessment of the presence and extent of calcification. Angiography cannot distinguish subendothelial from deep calcium. Accordingly, the demonstration of heavy vessel calcification by ultrasonography permits the operator to use rotational ablation in settings in which it may be particularly efficacious (eFig. 85.0.25). Precise guidelines for ultrasonographically directed rotational ablation have not been defined. In centers performing preinterventional IVUS, rotational ablation is commonly used if the arc of superficial calcium exceeds 180 degrees in multiple cross sections along the stenotic segment. Vessels revascularized using rotational ablation frequently have diffuse disease, and the “normal” dimension can be difficult to determine angiographically. Ultrasonography can be performed to size the vessel and determine the largest burr that can be safely used. The residual lumen after rotablation is usually round or ellipsoid, and the resulting lumen may have a 15% to 20% greater area than the largest burr used, presumably due to lateral movement of the burr during the procedure. Rotational atherectomy is also effective in treating “soft” plaques such as the hyperplastic response within stents observed in diffuse restenotic lesions (130).



***e*FIGURE 85.0.25** Intravascular ultrasonographic images taken before and after rotational ablation. **Left:** A heavily calcified lesion is illustrated. **Right:** The lumen is enlarged by removal of calcium using the Rotablator. The dark oval structure at 6 to 7 o’clock is a diagonal side branch of this left anterior descending coronary artery.

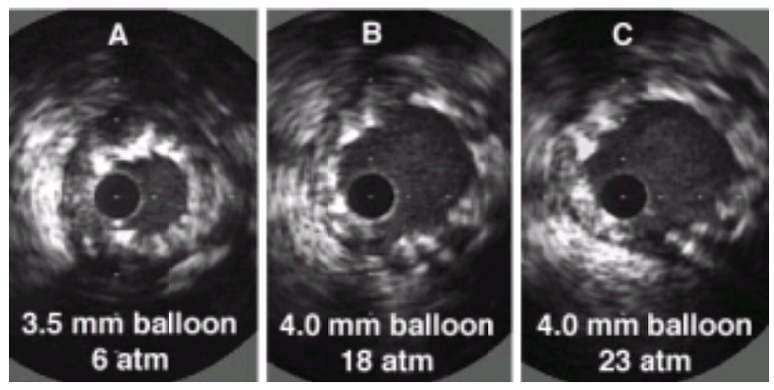
Coronary Stent Deployment

IVUS has significantly influenced the application of stenting in the treatment of coronary disease (132,133,134 and 135). The studies leading to U.S. Food and Drug Administration approval of the articulated slotted-tube stents were performed using conventional balloon pressures of 6 to 10 atm (120,121). To prevent subacute stent thrombosis, patients received aggressive anticoagulation therapy during and immediately after the procedure using both antiplatelet and antithrombotic agents. Although these preapproval studies demonstrated a reduction in the restenosis rate compared to balloon angioplasty, a high prevalence of hemorrhagic complications, longer hospital stays, and sometimes fatal subacute stent thrombosis were important obstacles to widespread acceptance of stent implantation in the treatment of coronary artery disease.

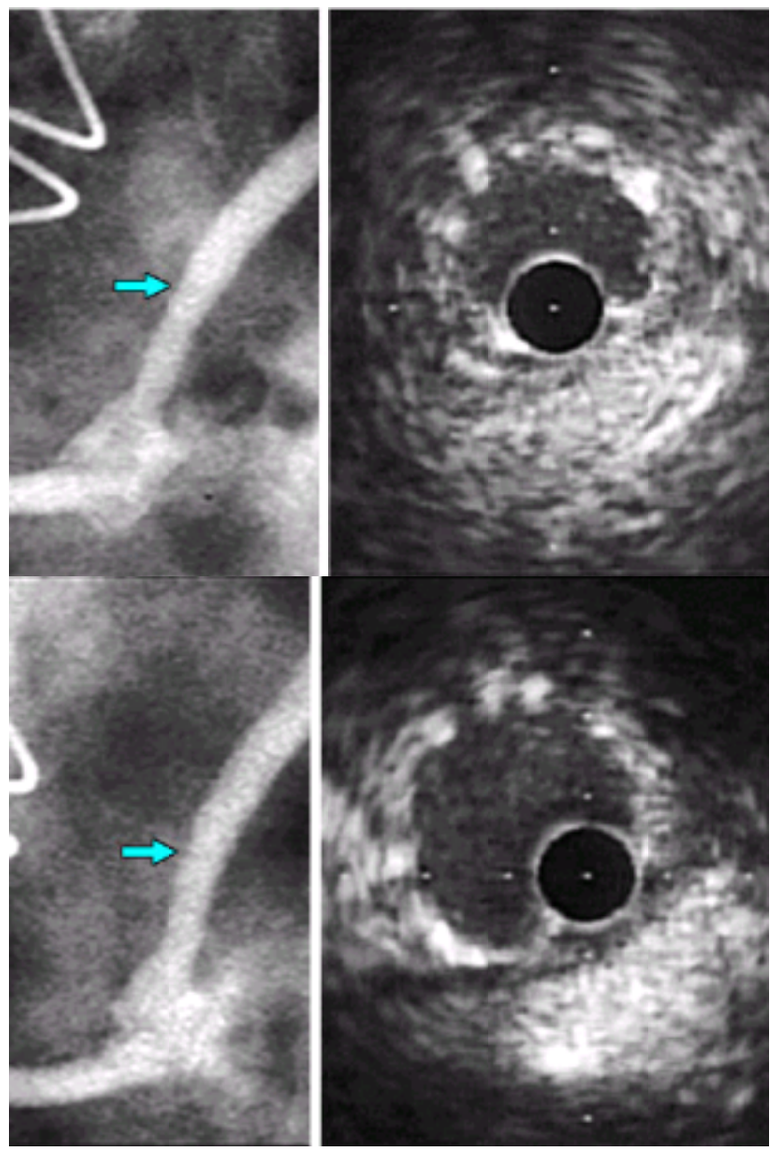


Intravascular ultrasound assessment of stent deployment. In the left panel, incomplete stent expansion is evident, which is improved after further balloon

dilatation.

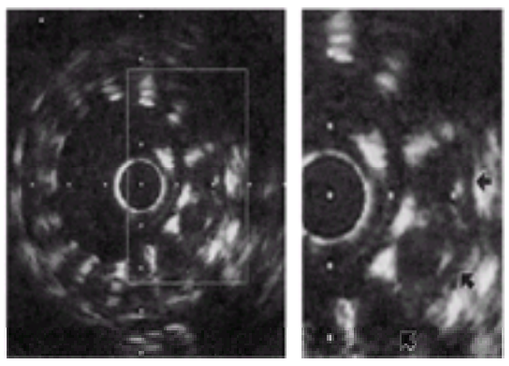


Intravascular ultrasound in stent deployment. These images show the effect of both increased balloon size and pressure on the size of the in-stent lumen.



Role of intravascular ultrasound in optimizing stent deployment. Although the angiogram shows minimal residual stenosis (A), the intravascular ultrasound lumen size is small (<5 mm^2). After further dilatation (B), the lumen area increased to >7 mm^2.

IVUS studies in the early 1990s demonstrated that the standard technique of stent deployment used in the pivotal randomized Stent Restenosis Study and Belgian-Netherlands Stent trial often resulted in failure of stent expansion or presence of unopposed struts or both (132,133). In all these studies inadequate expansion or strut apposition was observed in the majority of patients despite the excellent results shown on angiography. Because stents are porous structures, angiographic contrast can flow outside of a partially deployed stent and result in the angiographic appearance of full deployment, despite the presence of incomplete apposition (*e*Fig. 85.0.26). A pioneering IVUS study detailing the experience of Colombo et al. significantly altered the understanding of the optimal technique for stent deployment and prevention of subacute thrombosis (134). This large but nonrandomized study used routine IVUS imaging after angiographically guided stent placement and revealed an average ultrasonographically derived 51% residual lumen area stenosis. The authors frequently observed an absence of complete stent contact with the vessel wall (incomplete apposition) after angiographically guided low-pressure deployment. When apposition was incomplete, operators performed additional balloon inflations at higher pressures (typically 18 to 20 atm) or used a larger balloon (or both), which resulted in a larger in-stent lumen area. Interestingly, the final angiographic percent stenosis was negative (–7.0%). Using ultrasonography to guide deployment, this study reported a subacute thrombosis rate of only 0.3% when patients were given aspirin and ticlopidine hydrochloride but not warfarin sodium. It is now widely accepted that high-pressure deployment of the stents dramatically reduces the incidence of subacute thrombosis and obviates the need for immediate and long-term administration of antithrombotic agents.



***e*FIGURE 85.0.26 Left:** Incomplete apposition of a Palmaz-Schatz stent. **Right:** Enlargement of the area contained within the white rectangle. A false channel deep to the stent struts is evident (*black arrows*).

In the era of high-pressure stent deployment, the number of cases in which further interventions are triggered by ultrasonographic findings is certainly lower than initially reported. On the other hand, some observers have advocated routine high-pressure deployment without ultrasonographic imaging to achieve excellent procedural results and low subacute thrombosis rates (135). In the French registry, a subacute thrombosis rate of 1.6% in 1,156 patients is compelling evidence that high-pressure dilatation, supported by effective antiplatelet therapy (aspirin, ticlopidine), can achieve a substantial decrease in subacute stent thrombosis without ultrasonographic guidance (135). Despite the application of high-pressure balloon dilatation, however, ultrasonography frequently leads to further refinements of the result, most importantly an increase in the in-stent lumen area and decrease in residual stenosis at stent edges (136).

The additional lumen gain achieved with these further ultrasonographically driven interventions should be considered potentially useful, not only to eliminate subacute thrombosis but also to reduce stent restenosis. In the Milan experience, despite the high incidence of restenotic lesions, long lesions, small vessels with diffuse

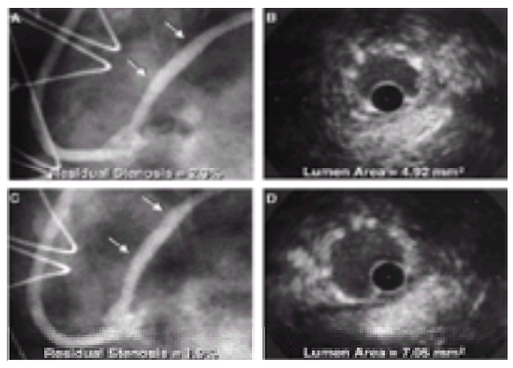
disease, and total occlusions, the overall angiographic restenosis rate was 21% and repeated interventions were required in 13% of patients (134).

Restenosis after stent implantation is strongly related to the in-stent lumen area. Achieving the largest lumen area in the stented segment within the confines of the vessel size is probably the most important antirestenosis strategy. Even after the routine use of high-pressure postdilatation, additional ultrasonographically guided inflations increase immediate lumen gain. The resultant larger lumen area may help to reduce restenosis rates. In a case-control study, patients who had optimum stent expansion according to predefined ultrasonographic criteria had an angiographically determined restenosis rate of 13.0% compared with 28.3% for those with suboptimal expansion (137). In another nonrandomized trial (Can Routine Ultrasound Influence Stent Expansion study) investigators assigned eight centers to perform ultrasonographic guidance and ten centers to perform angiographic guidance (138). In-stent lumen area was 0.9 mm larger in the ultrasonographically guided group and target vessel revascularization was reduced by 38%, from 14.9% to 8.9%.

Three multicenter randomized trials tested the hypothesis that increased in-stent lumen areas resulting from ultrasonographic guidance actually translate to lower target vessel revascularization rates. In the Optimal Coronary UltraSound trial, 550 patients were randomly assigned to procedures using either ultrasonographic or angiographic guidance. No significant difference was seen in restenosis rates for the two groups (139). The differences in stent dimensions between the IVUS and angiographically guided groups were smaller than in other trials, however. A smaller randomized trial (Restenosis after IVUS-Guided Stenting) enrolled 155 patients. An absolute reduction in target vessel revascularization rate of 6.3% was seen, but this difference did not reach statistical significance, mainly due to small sample size (140). In a larger randomized trial (Angiography versus IVUS-Directed Stent Deployment), 759 patients were randomly assigned to undergo procedures with either IVUS or angiographic guidance (141). Overall, a trend was seen toward improved 12-month target lesion revascularization rates in all groups in which IVUS guidance was used, but this trend did not achieve statistical significance (8% vs. 12%). A statistically significant difference in favor of IVUS guidance was seen in vessels with a reference diameter of less than 3.25 mm, in more severe lesions, and, in particular, in saphenous vein grafts.

Despite the improved understanding of stent deployment using IVUS, no consensus exists regarding the optimal procedural end points for ultrasonographically guided stenting. The goal of complete apposition of the stent struts to the wall is generally accepted. The criterion for optimal expansion is controversial, however. In their initial experience, Colombo et al. aimed to achieve 60% or more of the average reference lumen area, but later revised their target to 100% or more of the distal reference vessel area (134). The criteria developed in the pilot Milan experience have been revised and tested in the multicenter trial Multicenter Ultrasound Guided Stent Implantation in the Coronaries (142). Using optimal expansion criteria of 100% or more of the distal and 80% or more (for large vessels) or 90% or more of the average proximal and distal reference lumen areas, and a lumen symmetry index greater than 0.7, investigators achieved a subacute thrombosis rate of only 0.6% and restenosis rate of less than 10% in this trial. Other criteria based on the comparison of the smallest in-stent area to the areas of proximal or distal reference segments or to their average have been proposed. Interestingly, these procedural end points are not easy to achieve in most cases (134,137,141,142 and 143). In the Optimal Stent Implantation Trial investigators serially dilated each stent at 12, 15, and 18 atm and evaluated the result at each pressure level by quantitative angiography and IVUS. Ultrasonographic imaging documented gradual and marked increase in stent expansion with higher pressures, but these changes often were not apparent by angiography. In this study, end points of more than 90% of the average reference or more than 100% of the smaller reference were not achieved in half of the patients at an inflation pressure of 15 atm. At a pressure of 18 atm, these end points were attained in only 60% of patients (144). In the preliminary results of the Angiography versus Intravascular Ultrasound–Directed Stent Placement trial, the target end point of 90% or more of the distal reference was not achieved in two-thirds of the patients, and 27% of the patients required further intervention because of inadequate dilatation (141).

The predictive value of the stent-to-reference area ratio as an end point for stenting has been studied. In a study of 165 patients receiving one or two Palmaz-Schatz stents, the target vessel revascularization rate was 11% after 8 months (136). This adverse clinical outcome was best predicted by the value of the in-stent lumen area achieved at the end of the procedure (odds ratio, 1.4; 95% confidence interval, 1.1 to 1.9) and not by the ratio of stent to reference lumen area (odds ratio, 1.1; 95% confidence interval, 0.85 to 1.60). Revascularization procedures were required in more than 30% of patients with a minimum in-stent lumen area of less than 5 mm^2 but in only 3% of cases with a minimum area exceeding 9 mm^2. In other studies with larger cohorts of patients the conclusions were similar: Incidence of restenosis was inversely related to the absolute minimum in-stent lumen area (145,146). Most of the studies indicate that the end points of a predefined stent-to-reference area ratio are difficult to achieve and correlate weakly with stent thrombosis and restenosis rates. In-stent restenosis is mainly due to the extent of the neointimal proliferation, which can be measured accurately only by IVUS (147). The degree of intimal hyperplasia during the 9 months after stent implantation is independent of the final stent lumen size (148). Accordingly, in a given lesion restenosis occurs when immediate lumen gain is inadequate to accommodate the neointimal proliferation. Therefore, higher restenosis rates are common in smaller vessels and inadequately expanded stents. Although larger absolute in-stent lumen area is correlated with lower target vessel revascularization rates, the extent of stent expansion is limited by the size of the coronary artery. When the size of the vessel is taken into account, the incremental predictive value of ultrasonographic criteria diminishes (136). Nevertheless, the experience of the last decade demonstrated that IVUS is helpful in optimizing the assessment of the true vessel size and maximizing stent expansion safely (eFig. 85.0.27).

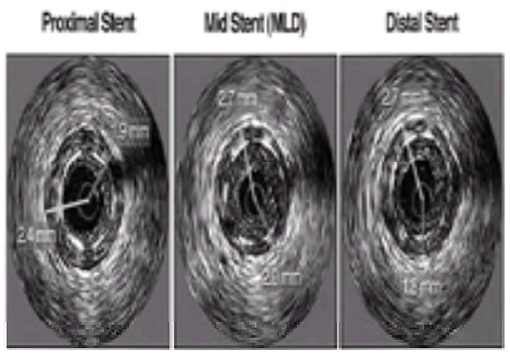


***e*FIGURE 85.0.27** Angiographic findings after stent placement can sometimes be deceiving. **A:** After stent placement, angiography shows excellent results with no residual stenosis of the stented segment (*arrows*). **B:** On interrogation by intravascular ultrasonography (IVUS), however, the stent is seen to be underexpanded with a suboptimal lumen area. **C:** When the stent was postdilated with a noncompliant balloon, the angiographic appearance did not change. **D:** On IVUS imaging, however, the lumen area is significantly increased.

In addition assessing final lumen area, stent expansion, symmetry, and strut apposition, IVUS is useful in evaluating the morphologic changes in the vessel wall at the edges of the stented segment, such as tissue prolapse, dissections, and so on. Some of these poststent morphologies partially obstruct the lumen and may increase the risk of stent thrombosis (134). Axial redistribution of plaque from the lesion into the reference segments contributes to lumen enlargement after stenting (149). To see a step down or areas of haziness at the edges of the stents is not uncommon. In a study of 201 stent patients, 31 segments of peristent angiographic haziness were detected. Of those, ultrasonographic imaging revealed an occult, moderately severe obstructive lesion in 15, a peristent wall injury in 14, and mild intimal thickening in the remaining two segments (150). The extent of neointimal hyperplasia at the stent margins has been linked to preexisting reference segment disease (151) (eFig. 85.0.17). Peristent wall injury and dissections are frequently seen by ultrasonographic imaging after high-pressure inflations. The natural history of the ultrasonographically detected edge tears, which are angiographically silent, appears to be benign, and they do not require further intervention (152).

Analysis of Brachytherapy Results

Intracoronary radiation is a promising therapy to decrease restenosis after percutaneous coronary interventions. Animal studies showing inhibition of neointimal formation were followed by randomized clinical trials demonstrating the reduction of restenosis by treating restenotic lesions with intracoronary brachytherapy (153,154). IVUS has been critical in understanding the effects of brachytherapy on the vascular wall. IVUS analysis of patients treated for in-stent restenosis corroborated angiographic data showing that intravascular brachytherapy is associated with a reduction in late lumen loss mainly through reduced neointimal hyperplasia (155). Serial ultrasonographic studies demonstrated that radiation treatment led to larger lumen areas after balloon angioplasty of *de novo* lesions (156). This gain was mainly due to vessel enlargement rather than plaque reduction. IVUS was pivotal in understanding the impact of radiation on neointimal growth and vessel size in different lesions (157). Ultrasonography has been helpful in documenting potential adverse effects of brachytherapy, particularly edge restenosis after radioactive stent implantation (158). Delivered dose homogeneity is an important issue when treating coronary segments with variable degrees of curvature, tapering, remodeling, and plaque extent, particularly with the application of beta radiation, which shows a rapid dose fall-off (eFig. 85.0.28). The difficulty in achieving adequate doses when treating long restenotic segments may explain the persistence of high rates of recurrences in these lesions (159). Dose-volume histograms obtained by ultrasonography have been implemented as a tool for dosimetry. Accordingly, a study involving 18 patients showed a wide range of dose distribution in the irradiated coronary segments and, in general, a lower than prescribed dose to the adventitia (160). Serial IVUS has also been used to study a phenomenon that has led to the withdrawal of radioactive stents due to a prominent reduction in lumen area at the stent edges, mainly due to intimal hyperplasia (161,162).

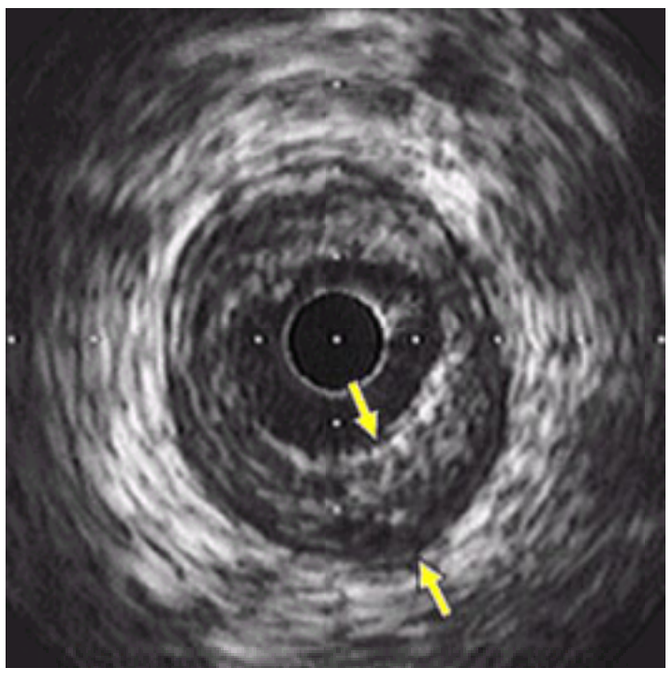


***e*FIGURE 85.0.28** An example of dose calculations for iridium-192 coronary brachytherapy based on intravascular ultrasonography. A survey of the treated segment is performed. At a minimum, the proximal, middle, and distal portions are measured. The example shows the minimum three images needed for prescription. The minimum radius from the center of the catheter to the external elastic lamina (EEL) (*blue lines*) and the maximum radius from the center of the catheter to the EEL (*gold lines*) are measured. The absolute maximum and minimum radii (2.7 mm and 1.8 mm, respectively, in this example) across the entire segment are noted. A prescription is calculated so that the dose at the maximum distance (radius) is 8 Gy, whereas that at the minimum does not exceed 30 Gy. If this is not possible, the dose at the minimum distance (radius) is prescribed to be 30 Gy and that at the maximum distance is less than 8 Gy. This latter circumstance arises when the ratio of the dose rate at the shortest radius to the dose rate at the longest radius exceeds 3.75. MLD, minimal lumen diameter.

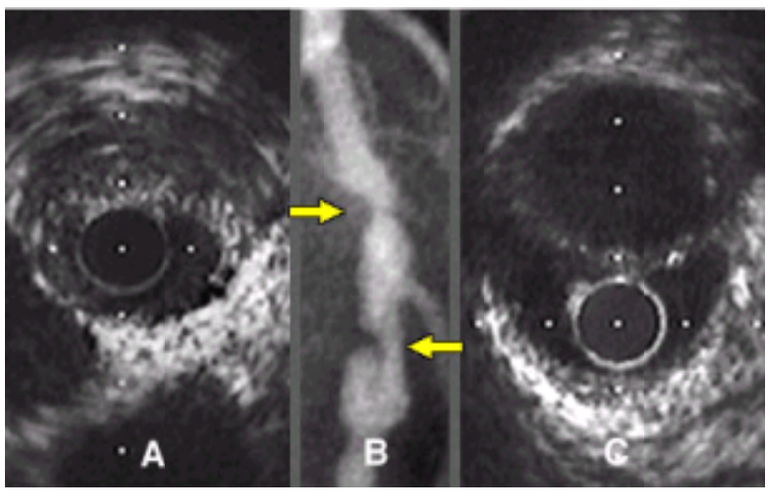
Future Directions

Tissue Characterization

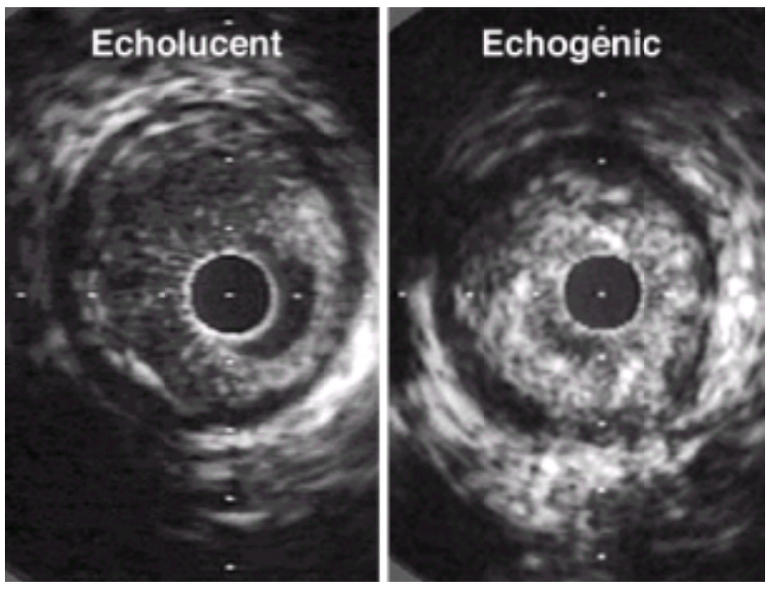
Accurate characterization of the atheroma contents *in vivo* will enhance the understanding of atherosclerosis and its complexity and heterogeneity. Conventional IVUS, although a powerful tool for tomographic imaging, is limited in delineating the plaque contents accurately. Analysis of backscattered ultrasonographic signals obtained directly from the ultrasonographic catheter before they are subjected to postprocessing has been used to perform “tissue characterization” of coronary plaques. Intrinsic characteristics of the backscattered ultrasonographic signals, including the amplitude distribution, frequency response, and power spectrum of the signal, convey specific information about tissue types (163). The use of computer-based analysis of the unprocessed radiofrequency backscatter to differentiate the histologic layers of the normal vessel wall remains investigational.



Plaque morphology. This image demonstrates a soft echolucent plaque.



Intravascular ultrasound interrogation of a complex coronary lesion. The proximal part of the lesion shows an eccentric soft plaque (A), whereas the distal end of the lesion (B) demonstrates rupture of the plaque with a double lumen.



Differences in lesion composition. Intravascular ultrasonography can characterize lesions into soft (echolucent) and fibrous (echogenic). Available evidence demonstrates that sonolucent lesions exhibit a high lipid content, whereas more echogenic lesions have greater fibrous tissue content.

In a study addressing the question of whether spectral analysis of unprocessed radiofrequency signal offers advantages over standard video densitometric analysis in identifying the morphology of coronary atherosclerotic plaques, regions of interest were imaged at 30 MHz from postmortem, pressure-perfused coronary arteries in saline baths. The analysis of the digitized radiofrequency data revealed parameters of spectral slope, *y*-axis intercept, mean power, and maximum power over a given bandwidth of 17 to 42 MHz. Lipid-rich areas, moderate and dense fibrotic tissue, and calcified deposits were differentiated (164). In an animal model of allograft rejection, conventional video images and radiofrequency signals were acquired from cross sections of the recipient and the allograft aortas. Radiofrequency attenuation measurements were more sensitive than visual or quantitative gray-scale analysis in differentiating the vessel wall changes of transplant vasculopathy (165). In another *in vitro* study, impedance as well as spectral analysis was used to differentiate lipid-rich plaques from fibrotic ones (166). In an attempt to better characterize the atheroma contents, mechanical properties of vasculature were assessed. In an *in vitro* study, IVUS elastography has been proposed as a technique capable of reflecting the mechanical properties of the vessel wall and characterizing different plaque components (167).

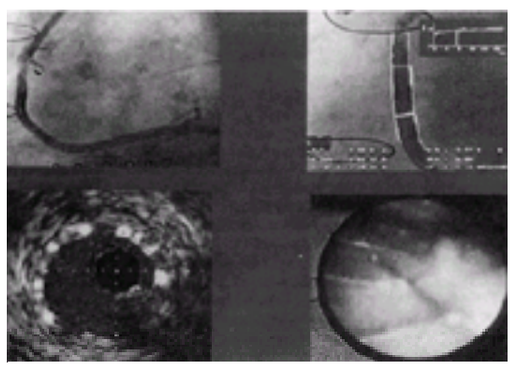
Three-Dimensional Reconstruction

Quantitative studies using IVUS require the identification of the luminal and medial-adventitial borders in image sequences. Traditional methods of border detection involve manual tracing of many IVUS images. Automated and semiautomated segmentation techniques have been developed to replace the tedious and time-consuming method of manual tracing (168). Three-dimensional reconstruction using automated pullback systems and electrocardiographic gating have been partially successful. However, tortuosity of the coronary arteries, limitations of automatic pullback and border detection, and the additional time needed prevent it from being a widely used clinical tool.

Segmenting borders manually in three-dimensional image sequences is laborious; therefore, automated or semiautomated techniques can reduce not only observer variability but also the time needed for analysis. The development of three-dimensional segmentation techniques, which take advantage of the similarity of borders between frames, is a recent development in the movement toward routine automatic quantitative analysis in catheterization laboratories (169,170). Three-dimensional reconstruction of IVUS data has been proposed as a means to facilitate understanding of the spatial relationship between the structures within different tomographic cross sections, particularly after percutaneous interventions (171). A prerequisite for most three-dimensional reconstruction techniques is the use of a motorized pullback, which allows the acquisition of successive cross sections separated by known distances. Other three-dimensional IVUS reconstruction techniques, however, track the transducer as it passes through the vessel. This procedure negates the requirement of a pullback device (168). Electrocardiographic gating was proposed to improve accuracy of volumetric assessment by registering similar points of the cardiac cycle in every image (172). Despite the promise of three-dimensional reconstruction, many unresolved problems remain. The algorithms applied for three-dimensional reconstruction do not consider the presence of curvatures of the vessel and assume that the catheter passes in a straight line through the center of consecutive cross sections. The systolic expansion of the coronary vessel and the movements of the catheter within the vessel during the cardiac cycle also generate characteristic artifacts. Despite these limitations, this technique remains the best method for volumetric plaque determination and has become the gold standard for assessment of the efficacy of interventions aimed at reducing the progression of atherosclerosis and preventing restenosis (173). Simultaneous digitization of biplane fluoroscopic tracking of the radiopaque transducer and catheter tip has the potential to overcome some of these limitations but at present is practical only for small-scale research studies (174,175 and 176). A novel technique of blood flow measurement simultaneous with IVUS imaging has been described. Color mapping of flow velocities and decorrelation of the radiofrequency signals were used for volumetric blood flow measurements (177).

CORONARY ANGIOSCOPY

Coronary angioscopy uses visible light conducted through fiberoptic filaments to obtain direct visual information of the surface characteristics and intraluminal morphology of the human coronaries *in vivo*. The images appear in full color on a television monitor, which enables detailed examination of the hue of the target lesion and associated plaques. Angioscopy allows the differentiation of platelet-rich thrombus from fibrin-rich thrombus and provides evidence of atheroma rupture, intraplaque hemorrhage, and coronary dissection. Accordingly, this diagnostic modality yields information on the pathogenesis of acute coronary syndromes not obtainable by any other technique (eFig. 85.0.29).



***e*FIGURE 85.0.29** Angiographic, ultrasonographic, and angioscopic appearance of a Palmaz-Schatz stent implanted in a saphenous vein graft. Both angioscopy and ultrasonography confirm the full apposition of the stent struts to the vessel wall.

Equipment and Technique

Development of an effective coronary angioscope is technically challenging. It should be small and flexible to steer easily and safely over a guidewire through tortuous coronary segments. A daunting challenge to device design and profile is the necessity for a multitask catheter. All angioscopes require a blood-free field for visualization of the arterial wall. The coronary lumen must be cleared of residual blood by continuous irrigation.

A variety of design iterations were used in initial animal and human investigations. One angioscope uses an occluding balloon to clear the examination field. Another type of angioscope uses a probing catheter to introduce the device. A multifiber imaging bundle and the light source provide surface images in the blood-free coronary segments.

The procedural aspects of coronary angioscopy are similar to those of other interventional techniques. After heparin administration, the operator places a conventional guidewire subselectively in the distal portion of the target coronary through a standard angioplasty-guiding catheter. The angioscope is attached to the light source, camera, and irrigation system and then advanced over the guidewire or through the probing catheter until it is just proximal to the target segment. The balloon is gently inflated to occlude the lumen while clear irrigation solution is infused distal to the balloon or through the catheter. The longitudinal axis of the vessel is examined by advancing and withdrawing the fiberoptic bundle. Because no coronary flow is permitted during examination, the operator must complete the examination quickly to minimize ischemia. Despite the inherent difficulties of maneuverability and induced ischemia, the monorail design and the moderate size of the angioscope allow the operator to obtain high-quality images with reasonable speed and safety.

Clinical Applications

Coronary angioscopy enhances the understanding of the atherosclerotic process by showing the surface characteristics of the atheroma. Angioscopy provides the opportunity to directly observe the unstable plaque, saphenous graft lesions, and different types of thrombi and lesions of the allograft vasculopathy. It has also been used in the setting of percutaneous coronary interventions.

Plaque Characterization

Coronary angioscopy was first performed during cardiac surgery and demonstrated important differences in the intraluminal appearance of stable versus unstable coronary atheromas (8). Later studies that used percutaneous angioscopy also demonstrated the high prevalence of thrombus-containing lesions in patients with unstable angina but not in those with stable angina (178). On the other hand, plaque disruption and thrombus were absent in a considerable number of patients with unstable angina who underwent imaging with angioscopy (179).

In addition to identifying the presence of thrombus, studies have documented the ability of angioscopy to differentiate grayish-white platelet-rich thrombus from red fibrin-rich thrombus, depending on the color assessment by the operator (180). This differentiation, however, is confounded by the hardware-induced chromatic

distortions and the subjectivity of human color perception. Quantitative colorimetric angioscopic analysis was proposed as a more objective and reproducible analytical tool (181).

Angioscopy can distinguish other surface features of coronary atheromas. Stable plaques are recognized by their elevated contour, smooth configuration, and yellowish-white color. In a study of 199 patients, those with predominantly yellow plaques were found to have higher levels of low-density lipoprotein cholesterol and apoprotein B lipoprotein (182). In a multivessel angioscopic study of patients with myocardial infarction, all three major epicardial coronary arteries were found to be diffusely diseased with multiple yellow, although nondisrupted, plaques (vulnerable plaques) (183). These findings suggest that acute myocardial infarction may represent the pan-coronary process of vulnerable plaque development. In an interesting study by Van Belle et al., 56 patients underwent angioscopic imaging between 24 hours and 4 weeks after myocardial infarction. Their findings suggest that healing of the infarct-related lesion requires more than 1 month and that “unstable” yellow plaques and thrombus are common within the first month after infarction (184).

Angioscopy can also identify morphologic features of degenerative saphenous vein grafts. In such vessels, angiography often reveals complex lesions with irregular borders and multiple filling defects. Necropsy studies have shown that such lesions often contain friable and sometimes frankly necrotic atheromatous material, intraluminal thrombus, or both. Angioscopic studies demonstrated that vein grafts frequently contained friable plaques even when angiography did not reveal the complexity. These studies suggest that surface morphology of the atherosclerosis of the native coronary arteries and saphenous vein grafts are similar except that a high incidence of friable plaque is seen in the latter group (185).

Observations during Coronary Interventions

Assessment of lesions before or after coronary intervention represents the most commonly reported application of coronary angioscopy. Angioscopy after balloon angioplasty demonstrates that dissections and thrombus are present in almost all cases, although angiography often shows neither luminal irregularities, tears, nor filling defects (178). In a comparative study of angiography and angioscopy, the specificity of angiography for identifying thrombus was high (100%), but the sensitivity of angiography (compared to angioscopy) was only 19.4% (186). Acute closure after angioplasty may be secondary to dissection, thrombus formation, coronary spasm, vessel wall hematoma, or elastic recoil, or combinations of these mechanisms. Several small studies have reported that, once acute closure has occurred, angioscopy can correctly identify whether thrombus or dissection is the primary mechanism of early abrupt closure (178,186,187).

Angioscopy has been used after other types of transcatheter procedures, including DCA and rotational ablation. After plaque removal by DCA, angiography often reveals an enlarged lumen with a smooth contour. Angioscopy has demonstrated, however, that the intimal surface is often very irregular with pieces of atheromatous material protruding into the lumen. Finally, angioscopy has provided information about the human endothelial response to implanted stents. Ueda et al. performed angioscopy in 14 patients immediately after stent deployment, at 8 to 45 days after the procedure, and again at 65 to 142 days (188). These investigators found that completion of neointimal coverage required approximately 3 months in the majority of patients.

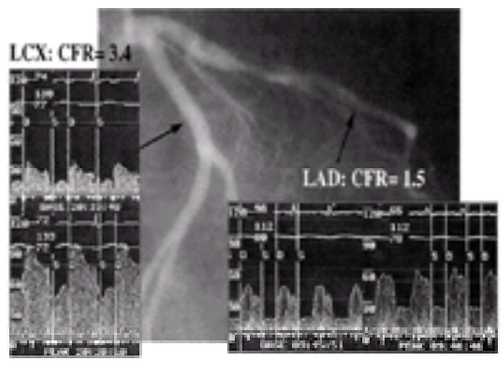
Limitations of Coronary Angioscopy

Despite recent technical advances, angioscopy is still limited to the proximal and mid-portion of relatively straight coronary arteries. Due to the present limits of size and flexibility, advancing angioscopic catheters through tortuous coronary arteries into small distal branches remains difficult. Furthermore, the development of ischemia in some patients during balloon inflation limits the time of examination. Angioscopy shows only the surface characteristics of plaques and cannot discern the underlying atheroma morphology. Accordingly, whether visualization of surface anatomy alone warrants the time, expense, and risk of angioscopy remains unproved. Lastly, the occlusion of coronary flow may produce important imaging artifacts. Angioscopy frequently observes flaps or fronds of tissue protruding into the lumen. This appearance, however, may represent an artifact produced by depressurization of the coronary by the occlusion balloon and may not reflect actual *in vivo* pathophysiology. Another important issue in the application of coronary angioscopy is interobserver variability. Interpretation of the angioscopic images may vary among observers. A study of the European Working Group on Coronary Angioscopy demonstrated that, although interobserver agreement is acceptable in the identification of red thrombus and dissection, wide interobserver variability is seen in other angioscopic diagnoses (189).

ASSESSMENT OF CORONARY CIRCULATION

The myocardium is supplied by an extensive network of vascular channels. Epicardial coronary arteries originate from the aorta as large trunks and decrease in size as they give branches. Epicardial coronary arteries do not create any significant resistance to coronary blood flow. They act as conduit vessels. The smaller arteries, arterioles, and capillaries constitute the distal vascular bed or microvasculature and act as resistance vessels. In contrast to epicardial coronary arteries, smaller arteries and arterioles change in size—dilate or constrict—in response to a variety of stimuli. This characteristic makes the microvasculature the regulator of coronary blood flow. Coronary blood flow is influenced by various structural, humoral, neural, and hemodynamic factors. In this environment of multiple interactions and continuously changing demands, coronary blood flow is kept at an adequate level in a wide range of driving pressures. Coronary vasculature maintains optimum myocardial perfusion through autoregulatory mechanisms.

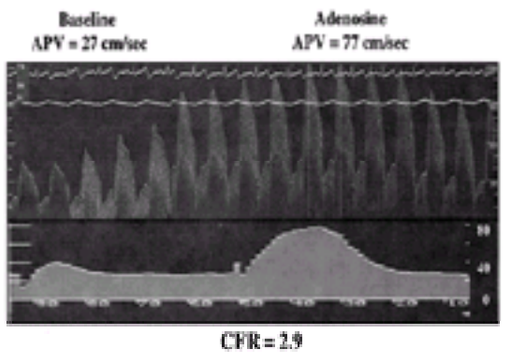
Flow patterns differ substantially within different coronary branches (eFig. 85.0.30). Under normal conditions, flow in the left coronary and its branches occurs primarily in diastole, whereas the right coronary exhibits a more homogeneous distribution with more continuous flow throughout the cardiac cycle (190). A predominant diastolic component is observed only in the most distal branches of the right coronary artery (posterolateral and descending posterior arteries) (191). Pulsatile flow is presumed secondary to the presence of a “reservoir” that is compressed during the systolic phase of the cardiac cycle and refills during the after diastole.



***e*FIGURE 85.0.30** Flow velocity measurements during baseline and hyperemia in the mid left anterior descending coronary artery (LAD) and in the proximal left circumflex artery (LCX). Note the blunt flow velocity response in the LAD, with a coronary flow reserve (CFR) of 1.5, and the normal flow increase in the left circumflex (CFR of 3.4). Relative flow reserve can also be calculated.

Coronary Flow Reserve

The principle of flow reserve was established originally by the work of Gould et al. (192). In the normal coronary artery, the distal arteriolar bed actively dilates in response to increased metabolic demands (e.g., exercise), producing a two- to sixfold increase in coronary blood flow (eFig. 85.0.31). In the presence of a hemodynamically significant epicardial coronary stenosis, vasodilatation of the microvasculature occurs in a progressive fashion to compensate for the flow limitation created by the stenosis. The vasodilatation maintains a stable level of coronary blood flow. Eventually, increasing epicardial narrowing exhausts the vasodilatory capacity of the microvasculature and leads to inducible myocardial ischemia (eFig. 85.0.30). The term *coronary flow reserve* (CFR) refers to the maximum vasodilatory capacity of the coronary vasculature in response to demand (hyperemic stimulus). This capacity is usually expressed as the ratio of maximum hyperemic blood flow to basal flow. If all measurements are obtained after maximum vasodilatation of the epicardial coronary arteries by nitroglycerin, the cross-sectional area of the epicardial vessels does not change any further. Thus, the ratio of velocities is equal to the ratio of coronary flows, and the terms *coronary flow reserve* and *coronary velocity reserve* can be used interchangeably.



***e*FIGURE 85.0.31 Top:** Progressive flow increase after injection of adenosine, 18 g, into the left main coronary artery. Note the rapid peak and the short duration of action, which make adenosine the ideal drug for repeated measurements. **Bottom:** Velocity trend, showing the stability of the basal flow velocity and the duration of the peak effect (approximately 30 seconds). APV, average peak velocity; CFR, coronary flow reserve.

The presence of a flow-limiting stenosis in a major epicardial vessel generates a pressure drop across the stenotic lesion, which is the result of viscous and turbulent resistances. In the presence of moderate or severe narrowings, the resting flow remains unchanged. Only very severe stenoses (greater than 90% diameter reduction) produce a pressure drop reduction in blood flow during normal resting conditions. Less severe stenoses (40% to 90% diameter stenosis) limit the maximum increase in blood flow in response to demand, which results in a reduction in coronary flow reserve (3,4).

Maximal Hyperemia

Maximal hyperemia can be induced by transient coronary occlusion or pharmacologic agents (193). Iodinated contrast media, which was used in the past, does not produce maximal vasodilatation. Likewise, the nitrates predominantly affect large-conductance vessels and do not consistently induce maximal flow increase. Continuous intravenous infusion of an adequate dose of dipyridamole results in maximal coronary vasodilation, but it has the disadvantage of having a relatively long duration of action. An 8- to 12-mg dose of intracoronary papaverine hydrochloride is equivalent to an intravenous infusion of dipyridamole in a dose of 0.56 to 0.84 mg per kg of body weight (194). In dogs, a high-rate infusion (600 g per minute) or a large intracoronary bolus of adenosine triphosphate (ATP) or papaverine has been shown to induce the same flow increase as a 15-second occlusion of the coronary artery (195) (eFig. 85.0.31). These results have not been confirmed using similarly large, clinically applicable doses of ATP or adenosine (100-g bolus) (196). Intracoronary adenosine or ATP does not induce significant changes in heart rate or blood pressure and does not prolong the QT interval, so that the potentially dangerous ventricular arrhythmias occasionally observed after papaverine are avoided (197). However, the time from intracoronary injection of adenosine to peak effect and the total duration of the hyperemic response is much shorter (198). A continuous intravenous infusion of 140 g per kg per minute of adenosine also induces maximal coronary vasodilatation but may produce mild hypotension, bradycardia, flushing, chest discomfort, headache, dyspnea, or atrioventricular block (199). In view of the high safety profile, absence of side effects, and ease of use, low-dose intracoronary adenosine is the most frequently used agent to induce maximal hyperemia. The intra coronary dose of adenosine is 18 to 48 g for the left coronary artery. A lower dose (12 g) should be used initially for the right coronary artery to reduce the risk of sinus node or atrioventricular node depression. If a guiding catheter with side holes must be used, only a fraction of the total dose can be delivered into the coronary artery. Intravenous adenosine administration is the best alternative in this setting, although some investigators have recommended increasing the intracoronary dose threefold (200).

DOPPLER CORONARY FLOW MEASUREMENTS

The development of small intracoronary devices incorporating a Doppler flow transducer has made *in vivo* physiologic assessment of coronary blood flow feasible during diagnostic or therapeutic catheterization. Doppler flow probes are commonly used to evaluate ambiguous lesions and to determine the success of coronary interventions at restoring normal flow reserve.

Equipment and Technique

A change in frequency occurs when a source and receiver of electromagnetic radiation or sonic energy move relative to each other, a phenomenon known as the *Doppler effect*. This change in frequency due to the relative motion between source and receiver is called the *Doppler shift*. Motion that reduces the distance between the energy source and receiver raises the frequency, whereas motion that increases the gap lowers the frequency. The magnitude of the Doppler shift is proportional to the velocity and direction of motion. Electronic processing of signals can precisely measure this effect and thereby determine the velocity at which the two objects move relative to each other. The principles of Doppler flow measurement are further described in Chapter 51.

The first probe designed to measure intracoronary flow velocity consisted of a transducer mounted on a Sones-type angiographic catheter. Subsequently, technical developments yielded probes designed for subselective intracoronary placement. The initial devices were relatively large (3 Fr) and used a transducer mounted either on the side or at the tip of the catheter. Because of size considerations, these devices could sample flow velocities only in the largest portions of the proximal coronary artery. The Millar device (Millar Instruments, Houston, TX) was the most widely used due to its flexibility and compatibility with a guidewire. It was designed to minimize the angle between the ultrasonic beam and the centerline of the intravascular flow profile, which thus allowed a close approximation of the maximal velocity.

Commercial development has led to the introduction of a miniaturized Doppler-equipped guidewire, called the JOMETRICS FloWire (JOMED). This device consists of a 0.014-in. steerable, 175-cm-long, flexible guidewire with handling characteristics similar to those of angioplasty wires and a 12-MHz piezoelectric transducer integrated into the tip. The smaller profile allows the operator to advance the device into distal coronary segments and beyond stenoses. In addition, the guidewire device accommodates over-the-wire or monorail balloon angioplasty systems and thus enables diagnostic and therapeutic procedures to be performed without exchanging the wire. The FloWire transducer uses a pulsed waveform Doppler system that samples at 5.2 mm beyond the guidewire tip. It samples a relatively large blood volume by using an ultrasonic beam that diverges at an angle of 14 degrees on either side of the centerline of flow. The sample volume is approximately 0.65 mm thick and 2.25 mm in diameter. In contrast to earlier catheter-mounted probes, the Doppler guidewire system uses fast Fourier transform signal processing (201), generating approximately 90 spectra per second. The Doppler guidewire is attached via a sterile cable to a console that displays the flow signal pattern and generates a superimposed envelope tracing that depicts the relative contributions of systolic and diastolic flow and continuously updates the measurements of peak velocity, averaged over two consecutive beats.

This system has been validated in *in vitro* and *in vivo* models by comparison with electromagnetic quantitative volumetric analysis (202). This study has shown that in vessels of less than 7.5 mm, the blood flow velocity measurements by the Doppler guidewire system had a close correlation (r^2 = 0.85 to 0.99) to measured flow volumes. The safety of using this device to obtain Doppler flow measurements has been demonstrated in a study involving 906 patients. Most of the complications (bradycardia, atrioventricular block) resolved rapidly without sequela. They were largely due to the concomitant use of adenosine (203).

Coronary Flow: Normal and Abnormal

Pulsatile Coronary Flow

The pulsatile pattern of flow is altered in the presence of a hemodynamically significant narrowing, which depresses the diastolic component. Experimental and intraoperative human studies have demonstrated the change in the diastolic flow in the presence of a significant epicardial stenosis (190,204,205). Unfortunately, the applicability of this phenomenon in clinical practice is limited because of the large variability of this index. The diastolic to systolic velocity ratio is influenced by changes in myocardial contractility, site of measurement, and artifacts. The flow patterns in other vascular structures of the heart are variable. The venous flow pattern consists mostly of a systolic component. Saphenous vein grafts and the arterial conduits behave according to the pattern of flow in the native artery to which they are anastomosed (206). Changes in cardiac function may affect the flow pattern, for example, left bundle branch block may delay left ventricular relaxation and impair early diastolic blood flow (207).

Characteristic flow patterns have been described in particular clinical settings. A predominantly negative systolic flow velocity and rapid flow velocity deceleration have been identified as a typical flow pattern in patients with slow flow or no reflow phenomena after percutaneous coronary interventions (208,209). A specific flow pattern has been described in patients with myocardial bridging. It consists of accelerated flow velocity and rapid deceleration in early diastole (fingertip phenomenon) with reduced systolic antegrade flow or retrograde flow in the proximal segment, more evident after administration of nitrates (210). The Doppler guidewire device can also identify reverse coronary flow, such as collateral flow from other vessels (211).

Proximal versus Distal Coronary Flow

The normal coronary arterial tree maintains relatively constant flow velocities despite the presence of multiple branches originating from the main coronary artery throughout its length (212). A marked difference in the flow velocities across a stenosis was thought to have hemodynamic significance. A high proximal to distal velocity ratio (greater than 1.7) has been proposed as a marker of severe flow-limiting epicardial stenoses (190). Basal and hyperemic flow velocity in “normal” arteries, however, shows large variability leading to inconsistencies in the proximal-to-distal velocity ratio (213). In clinical studies, this index was shown to have no predictive value for post-PTCA outcome.

Continuity Equation

The continuity equation that is most frequently used in the calculation of the valve areas is based on the concept that the volume of blood in the proximal vessel must reach the distal segment, so that the velocity measurements in a reference segment and across the stenosis can be used to estimate the percent area stenosis and even to calculate the absolute minimal cross-sectional area at the site of the stenosis provided the reference area is known. The following equation is used:

$$APV_L \times A_L = APV_D \times A_D$$

where *APV* = average peak velocity at the lesion (L) and distally (D)

A_L = area within the lesion

A_D = area distal to the lesion

Thus, by measuring the peak velocity both within and distal to the target lesion, the area of the lesion and the percent diameter stenosis can be calculated. The value obtained is subject to the limitations of velocity measurements and reflects the functional arterial dimension rather than the actual minimal lumen diameter. The calculated diameter reflects more the actual channel through which blood flows, rather than the anatomic dimensions. Nevertheless, this value can be useful in evaluating the functional stenosis before and after intervention, particularly in segments poorly visualized angiographically (such as bends, superimposed vessels, etc.).

The continuity equation was initially used in studies employing Millar catheters, but the size and characteristics of these transducers did not allow assessment of more severe lesions (214,215). The use of Doppler guidewire systems with high repetition frequency allows measurement of flow velocity up to 4 m per second and interrogation of severe stenoses without inducing flow impairment. Lumen area calculations based on flow velocity measurements correlate well with angiographic measurements (216). A similar method has been proposed for measurement of the residual cross-sectional narrowing after stent implantation (217). However, difficulties associated with optimal alignment of the Doppler wire with the centerline of flow in segments with severe flow disruption and recording of high-quality signals limit the applicability of this method.

Flow Reserve: Normal Range

Intracoronary papaverine was found to increase coronary blood flow velocity four- to sixfold in subjects with normal coronary arteries (218). In this study, however, a highly selected patient population was examined, and patients with myocardial hypertrophy, previous myocardial infarction, or other conditions known to increase the basal coronary flow (anemia, hyperthyroidism, etc.) were excluded. Intracoronary adenosine was used as the hyperemic agent in a large study of 490 subjects without coronary artery stenosis in the target arteries. The study population included patients with chest pain and angiographically normal arteries, patients with known coronary artery disease in whom the vessels measured were without stenoses, and cardiac transplant recipients without significant coronary disease. Coronary flow rate (CFR) was similar in the three major epicardial coronary arteries and in men and women. The lowest values were observed in the group with significant atherosclerotic involvement of other arteries (2.50 0.95) (219). Also, after coronary interventions, even with a complete elimination of the epicardial stenosis with successful stent implantation, similar values of CFR are observed (final CFR of 2.59 0.87 in 132 patients) (220). This large individual variability and the low average values measured in arteries without significant epicardial stenoses in patients with coronary artery disease are due to the presence of many other variables that affect CFR in this patient population. For example, left ventricular hypertrophy is associated with abnormal CFR due to the increased resting demands of the greater muscle mass (221). Factors to correct for basal flow velocity and age have been proposed and have been calculated from measurements performed in 141 patients with angina-like symptoms and angiographically unobstructed coronary arteries [corrected CFR for the left anterior descending artery = 2.85 × CFR × 10 × (0.48 × log basal average peak velocity) + (0.025 × age in years) – 1.16] (222). The possible usefulness of these proposed correction factors to improve the specificity of CFR has not been tested in large clinical studies. Interpretation is further complicated if abnormal myocardium is present in the territory subtended by the vessel in question, as scarred myocardium tends to have an abnormal vasodilatory response due to structural damage to the vascular bed.

Despite these limitations, various groups have demonstrated a close correlation between coronary flow reserve measured with the Doppler flow wire and thallium-201 or technetium-99m sestamibi SPECT. A cutoff value between 1.7 and 2.0 for CFR identifies more than 90% of the patients with abnormal scintigraphy (223,224,225,226,227 and 228).

In a large patient population with single-vessel disease, distal CFR was the only Doppler index predictive of the presence and severity of ST-segment depression. It correlated with minimal luminal diameter, the functionally relevant quantitative angiographic index of stenosis severity (229). To improve the diagnostic accuracy and identify false-positive flow reserve measurements (normal scintigraphy with less than 2.0 flow reserve), the determination of flow reserve in a second artery without significant stenoses has been advocated. The ratio between CFR in a normal control artery and CFR in the artery under evaluation is called *relative flow reserve* (230). Relative flow reserve of less than 0.65 was associated with reversible perfusion defects in a relatively small study (228). Although relative flow reserve is used in the evaluation of low CFR measurements, particularly after percutaneous interventions, several factors limit its routine use (231). Measurement of CFR in a second coronary artery requires additional time, intracoronary manipulation, and a suitable normal or near-normal coronary artery. Furthermore, the presence of a severe stenosis in an artery can affect flow in other arteries as well. The presence of collateral flow may increase basal velocity in the contralateral artery and lead to a falsely low CFR. CFR increases (on average by 0.8) after the dilatation of the stenotic artery that was the recipient of the collateral flow. This phenomenon is less evident but is still present (average increase of 0.3) in the absence of angiographically visible collaterals (232).

Clinical Applications

Assessment of Intermediate Lesions

In clinical practice, the lesions that pose the greatest diagnostic dilemmas fall in the intermediate range, typically a 30% to 70% diameter reduction. Gould et al. have shown in their classic work in dogs that myocardial perfusion reserve gradually becomes abnormal over this intermediate range of stenoses (192). Noninvasive assessment of intermediate coronary lesions has relied mainly on the demonstration of an abnormal response to exercise, in the form of characteristic electrocardiographic changes, nuclear scintigraphic perfusion defects, or segmental wall motion abnormalities on echocardiography. Noninvasive detection of ischemia, however, faces many confounding variables related to the ability to exercise, pretest probability of the disease, and the presence of ischemia in multiple territories. Moreover, because of a widespread trend to perform angiography and angioplasty in the same session to reduce cost and patient discomfort (233), a significant proportion of patients undergo coronary angioplasty without a preceding functional test (234).

Doppler flow measurements correlated with thallium stress test results in patients with angiographically intermediate stenosis. Accordingly, intracoronary Doppler measurements were proposed as a functional test for selection of patients requiring percutaneous revascularization without leaving the catheterization laboratory. In two studies, patients were observed after revascularization was deferred based on the Doppler flow velocity measurements. At 1-year follow-up, the target-lesion–related event rate, including the need for revascularization, was less than 10% (235,236). These findings support the concept that Doppler flow parameters can be used in selection of patients for percutaneous coronary interventions.

Chest Pain and Normal Angiography

The presence of normal or near-normal coronary arteries in patients with typical angina or evidence of ischemia during noninvasive tests is observed in 10% to 20% of the patients undergoing coronary angiography. After vasospasm or angiographically occult significant lesions (e.g., ostial or bifurcation lesions) are excluded, the cause of the symptoms or signs of ischemia remain to be investigated. Abnormal responses can be elicited at an epicardial and at a microvascular level, and the combination of morphologic and functional techniques described in this chapter (quantitative angiography, IVUS, and Doppler flow measurements) allow the calculation of flow velocity, absolute coronary flow, and flow resistance after different pharmacologic stimuli. Acetylcholine produces epicardial and microvascular vasodilatation by stimulating a normally reacting endothelium when concentrations of 10^{-8} to 10^{-6} mol per L are obtained with subselective intracoronary infusion. Paradoxical

vasoconstriction of the epicardial arteries or inadequate flow increase may reveal the presence of a significant endothelial dysfunction (237). In patients with diffuse atherosclerosis or transplant vasculopathy, the response to adenosine or nitrates can possibly be normal, but an abnormal reaction to acetylcholine can reveal impaired endothelial function in these patients (238,239). In patients with chest pain and angiographically normal arteries, microvascular disease with flow reserve impairment has been reported (240). Other studies, however, have found contradictory results, which may be explained by differences in inclusion criteria and methodology (241,242). More recent studies with Doppler flow wires indicate that the flow velocity response in this population is heterogeneous and may reflect either impairment of response to endothelium-independent vasodilators such as adenosine, or an endothelium-mediated response (243,244,245 and 246). Initial reports suggest that these results may have relevance for prognostic stratification (247) and for guidance of aggressive risk factor modification that is able to restore endothelial function and improve symptoms (248). Furthermore, with serial measurements the method can be used to study the effect of drugs on endothelium-dependent and endothelium-independent flow changes (249,250 and 251).

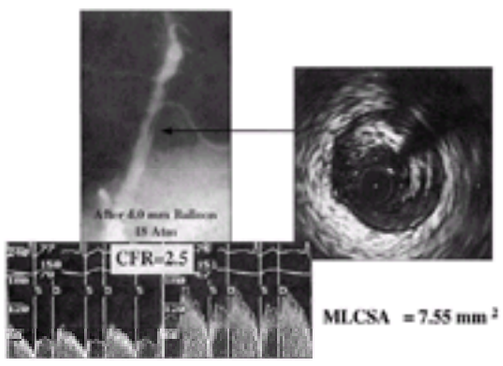
Transplant Vasculopathy

Necropsy studies describe transplant vasculopathy as a diffuse disease involving vessels smaller than 400 µm and resulting in a reduction of maximal coronary blood flow. The initial experience with Doppler catheters documented a normal flow reserve in these patients (252). More recent studies using Doppler guidewire systems suggest that the maximal hyperemia in these patients is frequently impaired. These studies also demonstrate a dissociation between degree of flow impairment and severity of the intimal thickening of the epicardial vessels as assessed with intracoronary ultrasonography (253,254).

The prognostic value of an impaired CFR after cardiac transplantation is still controversial. Wolford and Kern documented that angiographic abnormalities and elevated coefficient of variation of CFR were predictive of death, heart failure, or development of significant coronary stenoses (255). On the other hand, Spes et al. found no correlation between coronary flow measurements and ultrasonographically detected intimal thickening or abnormal stress test results (256). In the experience of this group, only left ventricular hypertrophy and donor age were correlated with higher resting flow velocity and low CFR (257).

Flow Alterations after Angioplasty

Doppler flow measurements can be used instead of noninvasive functional tests in the evaluation of angiographically intermediate lesions to save time and reduce cost by allowing intervention to proceed immediately after coronary angiography. During interventions, however, noninvasive methods of functional assessment are not applicable. Doppler flow measurements have the potential to become an indispensable functional parameter in the assessment of the results of percutaneous coronary interventions. Unfortunately, especially during coronary interventions, the use of intracoronary Doppler flow measurements is challenged by the development of major hemodynamic changes and the presence of microvascular dysfunction that may interfere with the ability of Doppler flow sensing to detect the effect of percutaneous coronary interventions on epicardial stenoses. Coronary revascularization deemed successful by angiography is usually associated with restoration of normal Doppler flow characteristics (205,258,259) (eFig. 85.0.32). On the other hand, abnormalities in CFR may persist after PTCA due to the limitations of angiography in detecting the true lumen gain after treatment (260). CFR impairment may persist even after truly successful angioplasty. The discrepancy between the adequately enlarged lumen and the depressed CFR may be due to procedure–related hemodynamic changes, microembolization, or transient or persistent changes in the distal vasculature. Later normalization of CFR in some of the lesions is probably due to these transient alterations (261).



***e*FIGURE 85.0.32** Basal and hyperemic flow velocity after percutaneous transluminal coronary angioplasty with a 4.0-mm balloon at 18 atm selected based on the media-to-media diameter measured with intracoronary ultrasonography. Note the restoration of a normal coronary flow reserve (CFR) despite the large residual dissection. Ultrasonography shows a large residual fibrous plaque and a minimal lumen cross-sectional area (MLCSA) of 7.55 mm^2.

Large studies have demonstrated that a postintervention impairment in flow reserve is more frequently associated with persistent or recurrent angina and that such patients are more likely to have a positive exercise test result at 1 month or to require target lesion revascularization by 6 months, or both (262,263). In the Doppler Endpoints Balloon Angioplasty Trial Europe (DEBATE) study, the combination of an optimal result by angiography (less than 35% diameter residual stenosis) and a CFR of greater than 2.5 was associated with a favorable clinical outcome at 6 months (16% incidence of major adverse cardiac events) (264). In the DEBATE trial the patients were also monitored for 15 minutes after the last balloon inflation: If CFR remained stable and no cyclic flow velocity variations were observed, a rare but ominous phenomenon related to recurrent platelet emboli (264,265), no abrupt closure was observed in the 24 hours after PTCA (266).

Based on these results, three randomized trials were performed to test the hypothesis that angiographic and Doppler parameters can identify postangioplasty results that have a relatively low restenosis risk similar to that observed after stent placement (267,268 and 269). In the DEBATE II study, only patients with discrete lesions in relatively large arteries (larger than 2.75 mm) were included. Patients underwent an unbalanced randomization: 97 patients were treated with elective stenting; 523 patients were categorized according to whether they fulfilled a predetermined criterion of residual stenosis of less than 35% lumen diameter and CFR of more than 2.5 and then underwent a second randomization to stenting or PTCA. The study confirmed the high risk of major adverse cardiac events in the patients undergoing PTCA who did not reach the angiographic and Doppler criteria. Overall event-free survival rate was similar in patients treated with elective and provisional stenting (86.6% and 85.6%, respectively). The separate analysis of the subgroup that achieved the optimal end points after PTCA demonstrated that stenting could further improve 1-year event-free survival (93.5% vs. 84.1%; p = .066). This difference was not statistically significant but casts doubts on the provisional stenting strategy, especially when the higher cost of this strategy after 1 year of follow-up is considered (EUR 6573 vs. EUR 5885; p = .014). The other two trials, the French Randomized Optimal Stenting Trial (FROST) and the Doppler Endpoints Stent International Investigation (DESTINI), enrolled 251 and 723 patients, respectively. These trials, which compared elective stenting and guided angioplasty strategies, differed from the DEBATE II trial in several ways. Both of these studies used a simple 1:1 randomization protocol. The CFR threshold to define success was lower (2.0 in DESTINI and 2.2 in FROST), and inclusion criteria were less restrictive. For example, in DESTINI patients with multivessel disease were included, provided that all lesions were suitable for stent implantation. Both studies showed a similar clinical outcome at 1 year. In DESTINI, the incidence of major adverse cardiac events was 17.8% in the elective stenting group and 18.9% in the guided PTCA group, and the incidence of repeat target lesion revascularization at 1 year was 14.9% in the elective stent group and 15.6% in the guided PTCA group. In FROST a follow-up angiogram was also performed, which demonstrated that the groups with provisional and elective stenting had similar minimal luminal diameters (1.90 0.79 mm vs. 1.99 0.70 mm, respectively; p = 0.39) and similar binary restenosis rates (27.1% vs. 21.4%, respectively; p = 0.37). In the DESTINI trial, possibly because of the greater complexity of the lesions treated, cost was higher and procedure duration was longer in the elective stenting arm (270).

Two reviews on provisional stenting (271,272) have stressed the fact that in these trials only a minority of the patients in a provisional stenting strategy guided by Doppler flow measurements and quantitative angiography were treated with balloons only, and that 50% to 60% of these patients required a stent after balloon angioplasty. Under these circumstances, this strategy is unlikely to lead to cost and time savings compared to elective stenting, which, with modern stents, can be performed in 30% to 60% of cases without predilation (273).

Acute Myocardial Infarction

Flow velocity measurements do not fully correlate with angiographically determined flow [as graded based on the results of the Thrombolysis in Myocardial Infarction (TIMI) trial] or frame count. In particular, a very low flow velocity is observed in the majority of patients with TIMI grade 2 flow that is not significantly different from that in patients with TIMI grade 1 flow. These findings suggest that incomplete recanalization is responsible for the limited recovery of ventricular function in these cases (274,275). Continuous monitoring of flow velocity with the Doppler guidewire device allows confirmation of flow restoration after thrombolysis and can document the persistence of antegrade flow in the hours after thrombolysis (276). An abnormal pattern of early systolic retrograde flow and prolonged diastolic flow velocity has been shown to be associated with the presence of a “no reflow” phenomenon (209,277). A more sophisticated index calculated from the slope of the instantaneous relationship between coronary flow velocity and pressure in diastole during maximal hyperemia (278) has also shown good correlation with recovery of regional wall motion (279). Besides having prognostic value, the measurement of CFR can also detect the protective effect of pharmacologic interventions to prevent myocardial damage during reperfusion: A higher maximal hyperemic velocity and an improved regional and global left ventricular function were observed in patients undergoing

PTCA after treatment with the IIb-IIIa platelet receptor inhibitor abciximab (280).

Limitations of Doppler Techniques

The blood volume sampled by the transducer in Doppler devices is small and may not accurately reflect the velocity of the whole bloodstream at the interrogated location. This problem is particularly important in zones of turbulent flow (such as areas distal to severe stenoses) or lumen segments with odd geometric configuration, in which different strata of the bloodstream may move at different velocities. The blood flow velocity measured in coronary arteries is a surrogate for the actual volumetric flow. The Doppler guidewire device is significantly dependent on positioning within the coronary, and this may explain the variability of serial measurements made during the same procedure and in repeated studies (251). In many cases, artifacts related to wall motion and signals from adjacent venous structures can be eliminated by repositioning the device to a more central location or by adjusting the J curve of the tip. Considerable care, patience, and time are often required to obtain accurate and reproducible blood flow velocity measurements, however, particularly during an operator's initial experience.

Although the concept of coronary flow reserve can be applied in optimal situations in humans, one must recognize that flow reserve is influenced by several factors that are independent from the hydrodynamic characteristics of the stenotic lesion. Because flow reserve is a ratio, the occurrence of changes in resting flow without changes in hyperemic flow considerably influences the result. Furthermore, factors such as heart rate, preload, myocardial hypertrophy, and disease of the microvasculature alter the hyperemic pressure flow relationship and modify the flow reserve (281). The experience gained with intracoronary Doppler devices is important because these limitations also apply to new techniques able to measure coronary velocity and CFR noninvasively (282,283,284 and 285).

INTRACORONARY PRESSURE MEASUREMENTS

Fractional Flow Reserve

Fractional coronary flow reserve (FFR) represents one of the most recent additions to the intracoronary diagnostic armamentarium for evaluation of coronary disease severity. Although the mathematical derivation of this approach shown later is complex, the principles can be easily understood. The flow to an area of myocardium providing resistance is determined by the pressure drop across that resistance. In the myocardial vasculature, this resistance can be located in the epicardial conduit, representing a coronary artery stenosis, or in the small vessels, the "resistance" vessels of the microcirculation. Because FFR is used to determine the functional significance of an epicardial stenosis, the resistance of the microcirculation must be minimized and maintained constant using maximal pharmacologic vasodilatation. Further, the second component of the pressure drop, the right atrial pressure, can be neglected (if venous pressure is not increased) as it is too small to affect results under normal conditions. In the presence of a stenosis, the ratio between the actual driving pressure (poststenotic pressure) and the arterial (aortic or prestenotic) pressure is compared with the driving pressure in the hypothetical situation of absence of stenosis, which defines FFR (286). This measurement must be done under maximal hyperemic flow to minimize resistance of the microcirculation. Under these circumstances, the flow is limited solely by the epicardial resistance, which makes FFR a specific index for the determination of epicardial stenosis. FFR is equal to 1.0 for a normal vessel and falls progressively below 1.0 for stenoses of increasing severity.

The variables required to calculate FFR include mean arterial pressure, P_a; central venous pressure, P_v; coronary pressure distal to the stenosis, P_d; and coronary wedge pressure (pressure in the distal coronary with the vessel occluded), P_w. Q is the total blood flow through the supplying coronary artery (sum of Q_s, antegrade flow in the coronary, plus Q_c, collateral flow). If no stenosis is present, Q and Q_s are called Q^N and Q_s^N and are assumed to be equal. From these variables, FFR_{cor}, fractional coronary flow reserve, and FFR_{myo}, fractional myocardial flow reserve, can be calculated:

$$FFR_{cor} \quad \frac{Q_s}{Q_s^N} = \frac{P_d - P_v}{P_a - P_w}$$

$$FR_{myo} \quad \frac{Q}{Q^N} = \frac{P_d - P_v}{P_a - P_v}$$

The difference between coronary and myocardial FFR represents the contribution of collateral blood flow (287). The technique for measuring the variables and computing FFR has been validated in a sophisticated *in vitro* model of pulsatile flow (288) and in an animal model using a Doppler flow meter surgically implanted on the epicardial vessel (289).

FFR is a measure of the maximum flow capacity for a stenotic vessel compared to flow capacity for the same vessel without the stenosis. Unlike measurements with Doppler methods, FFR measurements are unaffected by any increase in basal flow because all measurements are performed in a pharmacologically induced state of maximum vasodilatation; they are also unaffected by changes in the hemodynamic conditions at the time of assessment (arterial pressure, inotropic state, heart rate) (281). Uniquely, the FFR method allows calculation of both the antegrade and collateral components of flow (290).

Equipment and Technique

Available Systems

To avoid the effects of placing large catheters across the stenosis, pressure is measured using a 0.014-in. micromanometer-tipped guidewire. Currently, two systems approved by the U.S. Food and Drug Administration are commercially available (PressureWire, Radi Medical Systems, Uppsala, Sweden; and WaveWire, Endosonics-Jomed, Rancho Cordova, CA) (286,291,292). Both wires can be disconnected and used as primary angioplasty wires. The steerability is comparable to that of a regular floppy guidewire and is continuously improving. Both systems must be calibrated before use, and the operator must ensure that equal pressures are recorded by both the guide catheter and the pressure wire at the ostium of the vessel at the beginning of the procedure. Pressure signal drift can be observed during the procedure on occasion (depending on the quality of the particular wire and the duration of the procedure) and can be accounted for by comparing the pressure obtained by the guidewire with the guide catheter pressure at the end of the procedure. The pressure sensor is mounted 3 cm from the tip of the wire, which allows the operator to advance and retract the wire across the stenosis without losing position and confirm the exact location of the lesion by the pressure drop. More importantly, when a complete pullback through the entire vessel is performed at maximal hyperemia (either by a continuous infusion of adenosine or by intracoronary papaverine) the physiologic significance of all lesions within the vessel can be studied and potential interventions can be planned accordingly. Sometimes, the presence of diffuse disease can be revealed by a gradual decrease in the hyperemic pressure gradient; this makes a focal intervention unfeasible and medical treatment the therapy of choice.

Induction of Hyperemia

Once the pressure sensor has passed the stenosis, a maximum hyperemic stimulus is required to eliminate the microcirculatory resistance and allow evaluation of the hemodynamic significance of the epicardial lesion. Intravenous adenosine was initially recommended to achieve a stable steady-state poststenotic pressure drop. The simplicity and lower cost of intracoronary bolus injection of adenosine has prompted studies to compare the two methods. These studies showed that a clinically relevant overestimation of FFR (and thus underestimation of lesion severity) occurred in 8% of lesions when intracoronary adenosine was given (293). Larger adenosine boluses can be safely used after the initial test dose, especially in the left coronary artery, and are recommended to exclude a suboptimal hyperemic response in cases with borderline results (slightly above the cutoff criteria) (196). Intracoronary administration of adenosine has several advantages over intravenous infusion, including easier and faster administration, rapid onset of action and an ultrashort half-life (ideal for repetitive measurements), fewer side effects, and a significant reduction in cost. However, a pressure pullback curve as described earlier cannot be performed with intracoronary adenosine because of its short half-life. For that purpose, a continuous intravenous infusion of adenosine or intracoronary papaverine (which has a half-life of 30 to 45 seconds) can be used. Further, if guide catheters with side holes are used, intracoronary adenosine should be avoided, because part of the intracoronary bolus will be delivered into the aorta and the precise amount of drug reaching the microcirculation cannot be determined reliably.

Clinical Applications

Assessment of Intermediate Lesions

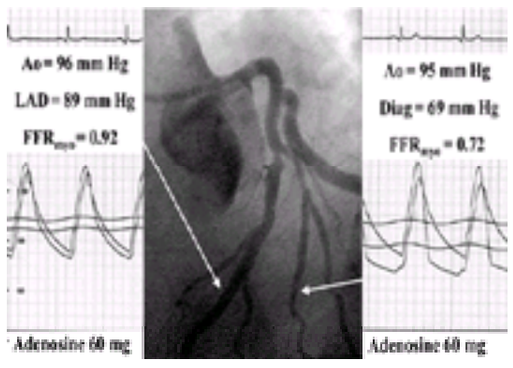
At present, the best-established and most widely used applications of intracoronary pressure measurements and calculation of the FFR is the diagnosis of hemodynamically significant coronary artery lesions found at angiography. Several carefully conducted studies have confirmed the clinical usefulness of FFR measurements in the setting of "intermediate" or undetermined degree of stenosis. In the first clinical validation study, a closer correlation was observed between FFR and relative flow reserve obtained from positron emission tomography than between relative flow reserve measured by positron emission tomography and various

angiographic parameters; these results illustrate the usefulness of FFR measurements in physiologic lesion assessment (294). These findings were confirmed in other studies assessing lesions of intermediate severity by angiography with nuclear perfusion imaging (295,296). Another study, which included 60 patients with single-vessel disease who had positive stress test results that became normal after PTCA, established that an FFR cutoff value of 0.75 can distinguish patients with and without ischemic changes in the distribution area of the assessed artery (297). Similar cutoff criteria were derived from the comparison with other noninvasive methods of detection of regional ischemia, such as dobutamine stress echocardiography (298). Pijls et al. compared FFR measurements with conventional noninvasive methods, performing bicycle exercise testing, thallium scintigraphy, stress echocardiography, and quantitative angiography in 45 patients with single-vessel disease, angiographically identified intermediate stenoses, and chest pain of uncertain origin (10). In all 21 patients with an FFR of less than 0.75, reversible myocardial ischemia was demonstrated in at least one of the noninvasive tests. Of the remaining 24 patients with an FFR greater than 0.75, 21 had negative results on all of the noninvasive tests. None of the 24 patients with an FFR greater than 0.75 was treated, and all remained free of cardiac events for a mean follow-up of 14 months. The mean stenosis diameters by quantitative angiography were similar in both groups, which demonstrates the lack of sensitivity of angiography in discriminating lesions capable of producing ischemia.

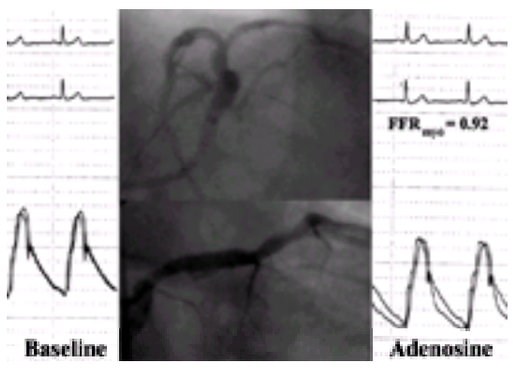
After establishing these cutoff values for myocardial ischemia, a retrospective analysis evaluated the clinical outcome of patients with single-vessel disease and angiographically intermediate stenosis who were referred for PTCA but in whom the intervention was deferred based on an FFR value of more than 0.75 (299). Of the 100 patients included in the study, 90 patients remained free of any coronary events at a mean follow-up of 18 months, with most patients asymptomatic or minimally symptomatic. Based on these encouraging results, a large prospective randomized study tested the hypothesis that percutaneous coronary intervention can be safely deferred based on FFR measurements (300). Patients referred for angioplasty underwent FFR measurement, and all patients with FFR above the ischemic threshold were randomly assigned to intervention or deferral of the intervention. Although results have not yet been reported in full detail, no statistically significant difference was seen in event-free survival between the two groups at 1 and at 2 years. Furthermore, a significant increase in functional status was observed in both groups independent of the performance of the intervention.

A more complex set of equations is used to determine the individual relevance of serial stenoses within the same artery. An animal study has validated this concept (301), and an elegant clinical study of 32 patients with two stenoses in the same artery demonstrated that the predicted FFR of one stenosis derived from the pressure measurements made before treatment was confirmed by a second measurement performed after the elimination of the second stenosis (302).

In summary, the main application for FFR measurements lies in the arena of angiographically ambiguous lesions whose hemodynamic significance is unclear. FFR can be used to justify coronary revascularization but also to safely avoid intervention for nonsignificant lesions (*e*Fig. 85.0.33 and *e*Fig. 85.0.34). Further, pressure gradient measurements help to unmask angiographically occult lesions, to determine the exact location of the lesion, and to evaluate multiple lesions within one vessel.



***e*FIGURE 85.0.33** Angiogram in the left anterior oblique view of the left coronary artery with two intermediate lesions in the middle segment of the left anterior descending coronary artery (LAD) and proximal segment of the major diagonal branch (Diag). Arrows indicate the position of the pressure transducer in the distal LAD and diagonal branch. Note the small gradient in the LAD and the large pressure gradient in the diagonal branch after a relatively large dose of intracoronary adenosine. The fractional flow reserve is within the normal range in the LAD (0.92); however, it is abnormal in the diagonal branch (0.72). Ao, aorta; FFR_{myo}, fractional myocardial flow reserve.

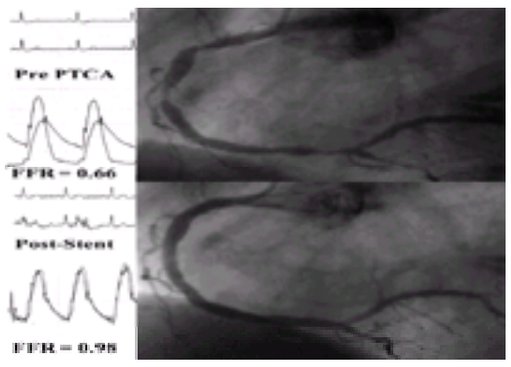


***e*FIGURE 85.0.34** Left coronary angiogram of a patient who was referred for coronary artery bypass surgery because of severe left main coronary ostial stenosis. Minimal gradient is seen between the aorta and the mid left anterior descending artery in the hyperemic state induced by intravenous adenosine infusion. Fractional myocardial flow reserve (FFR_{myo}) is greater than 0.90.

Coronary Interventions

The value of FFR for guidance of coronary interventions has been assessed in multiple studies. FFR measurement has been shown to be useful in evaluating PTCA results, and the complementary value of FFR and angiography in this setting has been demonstrated. In a study involving patients treated with PTCA, those who had an FFR above the cutoff value of 0.90 in combination with a residual diameter stenosis of less than 35% showed a significantly more favorable outcome at 24 months of follow-up, with an event rate of only 12% among this group compared with 41% in the group not meeting these criteria (303). Further studies are warranted to confirm these data in a prospective analysis and to evaluate this strategy for provisional stenting.

An important potential application of FFR measurements is the evaluation of coronary stenting. The hypothesis has been put forward that, after optimal coronary stenting, FFR should return to normal in the absence of concomitant disease within the same vessel, or that at least the hyperemic gradient across the stented segment should be diminished in the presence of disease elsewhere in the vessel (*e*Fig. 85.0.35). FFR in normal subjects without coronary stenosis varies from 0.94 to 1.00 (289), so that 0.94 is the lower limit of normalcy after an optimal stent result. In one study, 81 paired observations were made comparing FFR measurements after stent deployment to the current gold standard, IVUS (304). An excellent correlation was found, with 91% concordant results between FFR values and ultrasonographic findings, which demonstrates the usefulness of FFR in poststent assessment. Quantitative coronary angiography, on the contrary, showed a low concordance rate with both IVUS results and FFR. Despite the good correlation found, the pressures and type of stent used do not reflect current practice and suggest that the method may be applicable only in cases of rather severe residual stenosis. More recently, a multicenter study investigated the relationship between FFR measurement and IVUS after coronary stenting and found that an FFR of less than 0.96, measured after stent deployment, predicts a suboptimal result based on IVUS imaging, whereas an FFR higher than 0.96 does not reliably predict an optimal stent result (305). The use of FFR measurement in coronary stenting is therefore not yet established.



***e*FIGURE 85.0.35 Top:** A large right coronary artery with three lesions in series. Fractional flow reserve (FFR) is very abnormal. **Bottom:** After implantation of three stents, the FFR normalized completely. PTCA, percutaneous transluminal coronary angioplasty.

The coronary collateral circulation represents an alternative source of blood supply to a myocardial area that is not adequately perfused due to a stenotic or occluded vessel. Until recently, few modalities were available to assess coronary collateral flow, and a precise quantitative assessment was not possible. With the development of pressure-sensitive guidewire devices, the coronary wedge pressure distal to a balloon-occluded vessel can now be studied and the functional variables for coronary collateral flow calculated (306). Use of this method in humans during coronary interventional procedures allows investigation of the pathophysiology and therapeutic promotion of collateral flow *in vivo*. Studies have demonstrated an association between collateral flow and intracoronary concentration of vascular endothelial growth factor in patients with coronary artery disease (307). Moreover, patients with well-developed collaterals have been shown to have a better increase in collateral flow after adenosine administration (308) but to be prone to restenosis after PTCA compared to patients with little collateral supply, possibly due to increased competitive flow (309). Further work in this area is expected to greatly expand the knowledge and understanding of collateral circulation in health and disease.

Limitations of Fractional Flow Reserve Measurement

FFR predictably underestimates the severity of the flow impairment due to epicardial stenosis when conditions other than the stenosis restrict the increase in flow and pressure gradient after pharmacologic vasodilation. Known conditions that impair accuracy of this method include left ventricular hypertrophy, diffuse or small-vessel coronary disease, and previous myocardial infarction. In left ventricular hypertrophy, vascular supply is inadequate for the increase in muscle mass, which affects the natural physiologic reserve and pushes up the cutoff value indicating myocardial ischemia. Currently, no study has established the ischemic threshold, which makes the interpretation of FFR in the presence of left ventricular hypertrophy difficult. Microvascular disease cannot be detected by coronary pressure measurements alone. Small-vessel disease may influence FFR, however, as only submaximal flow can be achieved with hyperemic stimuli alleviating the pressure gradient across the epicardial conduit. In those cases, FFR may be artificially high, so that the severity of the stenosis is underestimated. The same is true for FFR measurements taken after previous myocardial infarction. In such cases, only a small gradient and a high FFR may be present despite a severe angiographically identified stenosis (310). This represents only a theoretical limitation of FFR, however. In clinical practice, FFR still reliably indicates the degree to which myocardial blood flow is restored by revascularization of the epicardial conduit. In the presence of severe small-vessel disease or myocardial necrosis after myocardial infarction, revascularization of even a severe stenosis may not improve distal perfusion. Two small studies indicate the potential application of FFR measurement in this setting (311,312). Simultaneous assessment of pressure and flow may overcome these limitations, but the use of two sensor-tipped wires makes this assessment impossible in clinical practice (313), and methods to derive CFR from pressure measurements in basal and hyperemic conditions still lack clinical validation (314).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Additional information obtained with IVUS, angioscopy, Doppler flow, and pressure measurements can improve the routine care of patients presenting with acute and chronic coronary syndromes. The valuable pathophysiologic and mechanistic observations provided by these diagnostic modalities shaped our understanding of coronary atherosclerosis and have had considerable impact on catheter-based interventions. Although these techniques have been used since the 1980s, they are currently not used routinely during either diagnostic or interventional catheterization. The existing data are not sufficient to recommend use of these techniques in every patient who is studied in the catheterization laboratory. In our clinical practice, we therefore use these techniques when coronary angiography does not provide adequate answers to the clinical question. We carefully choose between an additional morphologic test such as IVUS (e.g., unclear left main lesion, assessment of post-interventional lumen) or a functional test such as the FFR (e.g., intermediate lesions with positive stress test) or Doppler flow measurement (e.g., microvascular angina). In these situations, the potential benefit for the individual patient is large enough to justify the added risk, time, and cost of these exciting modalities.

Techniques assessing the coronary morphology and physiology will continue to help us to advance atherosclerosis research. Several ongoing, randomized pharmacologic trials assessing progression and regression of atherosclerosis use serial IVUS. Combined use of these techniques will shed new light on the interaction between coronary anatomy and physiology. Furthermore, emerging techniques using intracoronary thermometers, infrared imaging catheters, optical coherence tomography wires, and others will open new windows to this research.

THE FUTURE

The four modalities—IVUS, angioscopy, Doppler flow measurements, and FFR measurements—each provide important new opportunities to study the coronary circulation in health and disease. IVUS will play an increasingly important role in arteriosclerosis research. As new pharmacologic interventions targeting the atherosclerotic plaque are developed, ultrasonography will be used in assessing the efficacy of these interventions. Automatic border detection and measurement, three-dimensional reconstruction, and volumetric measurements will probably be used more frequently in future studies. Tissue characterization by IVUS is an important element in the assessment of various plaque types. Further research is needed to establish the accuracy and reproducibility of this technique before it can be used in the histology-like examination of the plaque. IVUS will continue to be an indispensable tool for optimizing the application of new therapeutic devices such as coated stents. (Angioscopy equipment is currently not available in the United States.)

Measurement of FFR will continue to be a useful tool for the assessment of borderline lesions. Combination devices are in development that will allow pressure and velocity measurements to be made by a single device.

Over time, the most developed of these techniques, IVUS and FFR measurement, will likely be integrated into the state-of-the-art practice of interventional cardiology, particularly in complex diagnostic situations. Although coronary angiography will not be replaced, these new modalities will provide critical ancillary information in selected patients for many years to come.

OVERVIEW

Fifteen years of experience with percutaneous valve dilatation for acquired valve stenoses has shown the following:

- Percutaneous mitral valvuloplasty is an effective treatment in a wide range of patients with mitral stenosis. Its risk is low when it is performed by experienced teams, and follow-up at more than 10 years demonstrates excellent durability of the procedure. The prediction of immediate and midterm results is multifactorial and based on clinical and anatomic variables.
- Percutaneous aortic valvuloplasty for degenerative calcified aortic stenosis provides short-term palliation of symptoms at the cost of high periprocedural risk. Its role is in question.
- Percutaneous tricuspid or multivalve dilatation is used in exceptional cases.
- Percutaneous dilatation of a bioprosthesis has no future.

HISTORICAL PERSPECTIVE

Until the early 1980s, surgery was the only possible treatment for severe valvular stenoses; thereafter a new alternative appeared: percutaneous balloon valvuloplasty.

HEART SOUNDS

Audio 86.1 Severe mitral stenosis. Auscultation performed in a 42-year-old female patient with rheumatic mitral valve disease, leading to severe stenosis and mild regurgitation. The peak and mean diastolic gradients across the mitral valve were 14 and 9 mm Hg, respectively. The mitral valve area by pressure half-time was 0.8 cm^2. Note the loud S1, opening snap, mid-diastolic rumble, and presystolic accentuation. Left upper sternal border **(A)** and apex **(B)**. (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics, Inc.) *This video must be viewed with QuickTime. The first to perform balloon valvuloplasty as an alternative to surgery in the treatment of mitral stenosis was K. Inoue in 1982 during open-heart surgery. The initial report of percutaneous balloon valvuloplasty was published in 1984 (1); most subsequent reports concerning the technique have been published since 1986. As was to be expected from earlier experience with closed surgical commissurotomy, the good immediate and midterm results obtained during this period led to increasing worldwide use of the technique, which became the second most important in the field of interventional cardiology.

In the field of aortic stenosis, percutaneous valvuloplasty was used for the first time by Cribier et al. in 1985 in an elderly patient with severe calcific aortic stenosis (2). Despite great initial enthusiasm related to encouraging preliminary immediate reports, the technique has largely lost favor because of the lack of midterm benefit, and today it has a very limited role, if any.

Percutaneous balloon valvuloplasty is therefore still a recent innovation that, despite marked changes in practice during the first decade of its use, will continue to be refined and subjected to long-term surveillance.

This chapter deals with percutaneous balloon valvuloplasty for acquired valvular stenoses in the fields of mitral stenosis, aortic stenosis, and the less frequent lesions of tricuspid, bioprosthesis, and multivalve stenoses.

Mitral stenosis. Left atrial enlargement and right ventricular hypertrophy have developed secondary to mitral stenosis, causing fixed pulmonary hypertension.

PERCUTANEOUS MITRAL VALVULOPLASTY

Rheumatic fever continues to be endemic in developing countries where mitral stenosis is the most common valve disease. Although the prevalence of rheumatic heart disease has greatly decreased in Western countries, it continues to represent an important clinical entity because of out-migration from developing countries and the presence of restenosis after previous surgical commissurotomy (3).

Mechanisms

Balloon dilatation acts in the same way as surgical commissurotomy by opening the fused commissures (4); therefore, a more appropriate term for the procedure is probably *percutaneous mitral commissurotomy* rather than *percutaneous mitral valvuloplasty*. Balloons are also able to enlarge the valve area by fracturing nodular deposits in patients with calcified valves (5).

Technique

The techniques and devices used have varied over time and from group to group.

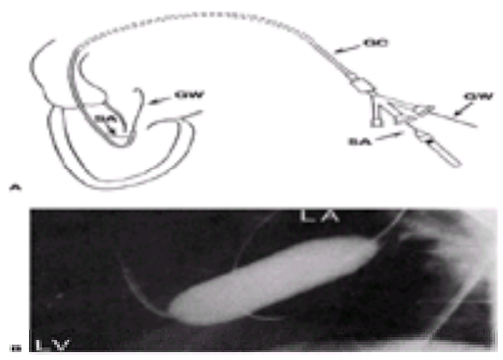
Approaches

At the present time, two approaches are used: transarterial and transvenous.

The *transvenous* or *antegrade approach* is the most widely used. Transseptal catheterization, which allows access to the left atrium, is the first step in the procedure and one of the most crucial. It is performed through the femoral vein or, in exceptional circumstances, through the jugular vein (6).

The *retrograde approach* using transseptal catheterization, described by Babic, has now been abandoned. In the retrograde technique without transseptal catheterization (eFig. 86.0.1) described by Stefanadis (7), the balloon is introduced through the femoral artery or, less frequently, the brachial artery. The passage from

the left ventricle to the left atrium is achieved using preshaped, steerable catheters, by which exchange guidewires are positioned in the left atrium. The specific advantage to this approach is that it avoids transseptal catheterization. Retrograde left atrial catheterization is not always easy, however, and it carries the risk of inserting the guidewire between the chordae tendineae and damaging the subvalvular apparatus on balloon inflation, which causes severe mitral regurgitation. It has been used with single, double, or Inoue balloons with good results and no serious complications. The number of patients treated in this way has been limited, however, and further studies are needed to evaluate its place. Knowledge of this approach does provide an alternative in the rare cases in which use of the transseptal approach is contraindicated.



***e*FIGURE 86.0.1** Mitral valvuloplasty: retrograde technique. **A:** Schematic representation of the steerable catheter. Retrograde nontransseptal mitral valvuloplasty. In: Topol EJ, ed. *Textbook of interventional cardiology.* Philadelphia: WB Saunders, 1994:1253, with permission.)

Devices

Currently, two main techniques are used: balloon commissurotomy and metallic commissurotomy.

Balloons

In the double-balloon technique (8,9 and 10), a floating balloon catheter is used to catheterize the left ventricle; then two long exchange guidewires are positioned in the apex of the left ventricle or, less frequently, the ascending aorta. The interatrial septum is dilated. Finally, the balloons are positioned across the mitral valve. The balloons used are two round conventional balloons or a combination of the trefoil balloon and a conventional balloon. The double-balloon technique is effective but demanding and carries the risk of left ventricular perforation by the guidewires or the tips of the balloons.

The Multi-Track system is a refinement of the double-balloon technique, as it uses a monorail system that requires the presence of only one guidewire and eases the performance of the dilatation in comparison with the standard double-balloon technique. Clinical experience with this device is still limited. Preliminary results indicate that the efficacy is good but a risk remains of perforation with the guidewire or the tips of the balloons in the apex (11).

The Inoue technique (Fig. 86.1) was the first to be developed (1,12,13 and 14). The Inoue balloon, made of nylon and rubber micromesh, is self-positioning and pressure extensible. Because the balloon has three distinct parts, each with a specific elasticity, each part can be inflated sequentially. This sequence allows fast and stable positioning across the valve. The Inoue balloon comes in four sizes (24, 26, 28, and 30 mm), and each is pressure dependent, so that its diameter can be varied by up to 4 mm as required by circumstances. Inoue recommends the use of a stepwise dilatation technique under echocardiographic guidance: the first inflation is performed to the minimal diameter of the balloon chosen. The balloon is then deflated and withdrawn into the left atrium. If mitral regurgitation has not increased and valve area is insufficient, the balloon is readvanced across the mitral valve, and inflation is repeated with the balloon diameter increased by 1 to 2 mm.

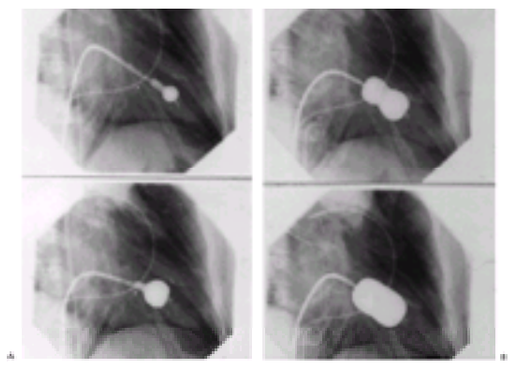


FIGURE 86.1 Mitral valvuloplasty: Inoue technique. **A:** Inflation of the distal portion of the balloon, which is thereafter pulled back and anchored at the mitral valve. **B:** Subsequent inflation of the proximal and middle portions of the balloon. At full inflation, the waist of the balloon in its midportion has disappeared.

Although a number of retrospective studies have compared the efficacy of the two balloon techniques, comparison is still difficult because only a few small randomized studies are available (15). They suggest, first, that the Inoue technique makes the procedure much easier. The suggestion has even been made that experienced operators can avoid an arterial line, which decreases the risks and allows the procedure to be performed on an outpatient basis (16). Second, these studies suggest that the Inoue technique has grossly similar efficacy to that of the double-balloon technique, although the latter may result in a slightly larger valve area. Furthermore, long-term results are equivalent (17). Finally, these studies suggest that the Inoue technique carries a lower risk because the risk of ventricular perforation is avoided and the stepwise technique allows early diagnosis of mitral regurgitation and could decrease the development of severe regurgitation.

Whatever balloon is used, the *preselection of balloon size* remains controversial. The desire for greater improvement in valve area must be balanced against the risk of producing severe mitral regurgitation. Balloon size is usually chosen according to patient characteristics: height (12), body surface area (18), or diameter of the mitral annulus (19).

Metallic Dilator

In the late 1990s, Cribier introduced the metallic commissurotomy (Fig. 86.2), which uses a device similar to the Tubb dilator used during closed commissurotomy (20). The performance of the technique is similar to performance of the previous single-balloon technique, as it requires the positioning of a guidewire in the left ventricle using a floating balloon catheter. The septum is dilated using an 18-Fr dilator. Then the metallic dilator is introduced. It is made of stainless steel, is shaped like a cylinder, and is 5 cm long. The metallic head is screwed on the distal end of the catheter and is detachable. Manual pressure allows the dilator to be opened up to 40 mm. The experience with this device is only preliminary and comprises approximately 1,000 cases, mainly in developing countries; it is reported almost exclusively by the promoter of the method (20,21). The initial results suggest that this method is similar in efficacy to the balloon commissurotomy, but the risk of hemopericardium seems higher due to the type of device and the presence of a stiff guidewire in the left ventricle. In addition, this technique is more demanding for the operator than the Inoue technique. The potential advantage of the metallic commissurotomy is that the dilator is reusable, which reduces the cost of the procedure.

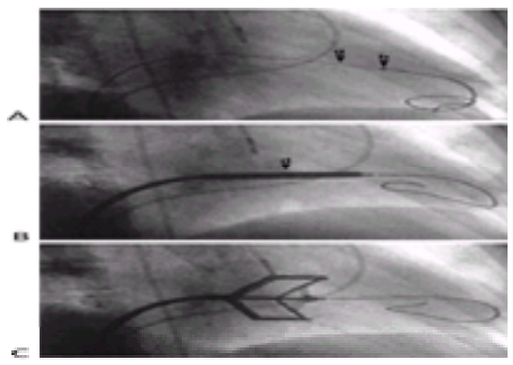

FIGURE 86.2 Percutaneous metallic commissurotomy. **A:** Guidewire (g) is placed in left ventricle after transseptal catheterization. Metallic bead (b) is positioned at midventricle, beyond mitral valve. **B:** After dilation of septal puncture site, device is pushed over guidewire and metallic dilator (d) is positioned across mitral valve. Metallic bead is placed in contact with distal end of dilator. **C:** Commissurotomy is performed by opening dilator to its maximum extent of 40 mm. (Adapted from Cribier A, Eltchaninoff H, Koning R, et al. Percutaneous mechanical mitral commissurotomy with a newly designed metallic valvotome: immediate results of the initial experience in 153 patients. *Circulation* 1999;99:793–799.)

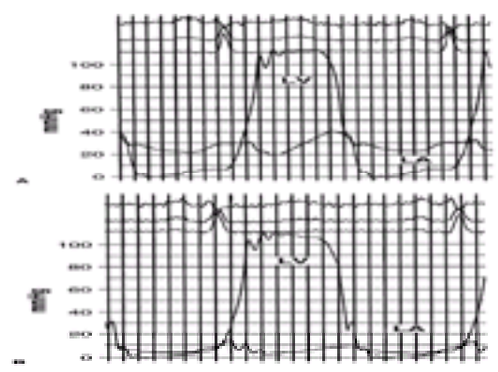
Monitoring of the Procedure and Assessment of Immediate Results

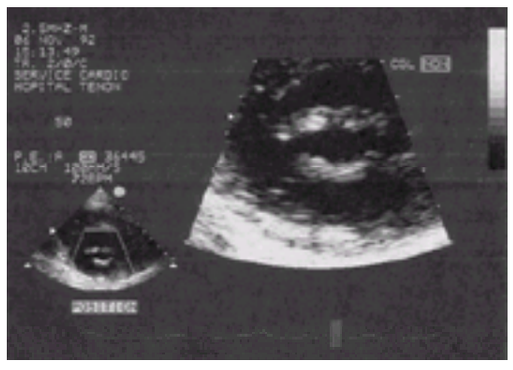
Two means are used to assess immediate results in the catheterization laboratory: hemodynamics and echocardiography. Although echocardiography may be difficult to perform in the catheterization laboratory for logistic reasons, it provides essential information. First, echocardiography enables detection of early complications such as a pericardial hemorrhage or severe mitral regurgitation. Second, it may facilitate puncturing the interatrial septum and also perhaps crossing the valve. This has been accomplished primarily with the transesophageal approach (22), which is superior to the transthoracic approach in imaging the interatrial septum. Nevertheless, echocardiography using the transesophageal approach is not easy to perform in the catheterization laboratory, and its use should probably be restricted to cases in which technical difficulties such as severe anatomic distortion are encountered. Intracardiac echocardiography has been used in such cases (23). Third, echocardiography provides essential information on the course of the mitral opening, which is of utmost importance when using the stepwise Inoue technique (12,14).

Assessment of the following parameters has been suggested for the guidance of the procedure:

- Mean left atrial pressure and mean valve gradient (eFig. 86.2.1). These measures can be criticized because of variations that may occur, particularly with respect to change in heart rate or cardiac output.
- Hemodynamic measurements of the valve area. Repeated evaluation of the valve area during the procedure by hemodynamic measurements lacks practicality and may be subject to error because of the instability of the patient's condition and the inaccuracy of Gorlin's formula in the presence of atrial shunts or in cases of mitral regurgitation. The accuracy of Doppler measurements during valvuloplasty is low (24), so that planimetry from two-dimensional echocardiography appears to be the method of choice when it is technically feasible.
- Changes in the degree of regurgitation. Color Doppler ultrasonography assessment is the method of choice for sequential evaluation.
- Commissural morphology. This can be assessed by two-dimensional echocardiography using the short-axis view (eFig. 86.2.2).



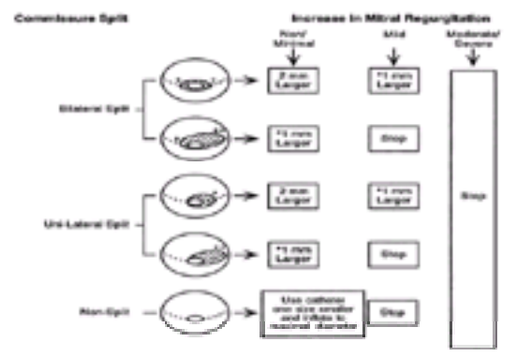
***e*FIGURE 86.2.1** Hemodynamic changes before **(A)** and after **(B)** mitral valvuloplasty. LA, left atrium; LV, left ventricle.



***e*FIGURE 86.2.2** Transthoracic echocardiogram (parasternal short-axis view) showing bicommissural opening.

The following criteria have been proposed for the desired end point of the procedure: (a) mitral valve area greater than 1 cm^2 per square meter of body surface area, (b) complete opening of at least one commissure, or (c) appearance or increment of regurgitation greater than 1 in the Sellers 0 to 4 classification.

Tailoring the strategy to the individual circumstances is vital; clinical factors as well as anatomic factors and the cumulative data of periprocedural monitoring should be taken into account. For example, balloon size, increments of size, and expected final valve area are smaller in elderly patients; in cases of very tight mitral stenosis or extensive valve and subvalvular disease; and in cases of nodular commissural calcification (25). A summary of decision making in the stepwise dilatation technique using the Inoue balloon under echocardiographic guidance is provided in eFigure 86.2.3.



***e*FIGURE 86.2.3** Decision making in the stepwise dilation technique based on echocardiographic findings after each balloon dilation. +, incomplete split; ++, complete split; *, stop in cases of severely diseased valve or age older than 65 years. (Adapted from Inoue K, Hung JS. Percutaneous transvenous mitral commissurotomy: the Far East experience. In: Topol EJ, ed. *Textbook of interventional cardiology.* Philadelphia: WB Saunders, 1994:1226–1243.)

The strong predictive value of the quality of the immediate results for long-term outcome stresses the importance of a careful evaluation of the immediate results. After the procedure, the most accurate evaluation of valve area is provided by echocardiography (26). To allow for the slight loss occurring during the first 24 hours, echocardiography should be performed 1 or 2 days after mitral valvuloplasty (27), when calculation of the valve area may be done by planimetry, the half-pressure time method, or the continuity equation method. The final assessment of the degree of regurgitation may be made by angiography or by Doppler color flow imaging. Transesophageal examination is recommended in cases of severe mitral regurgitation to determine the mechanisms involved. The most sensitive method for the assessment of shunting is Doppler color flow imaging, especially when transesophageal examination is used, which shows the importance of the defect and detects shunting in a more sensitive way than does assessment of hemodynamics.

Immediate Results

The technique of mitral valvuloplasty has now been evaluated in several thousand patients with different clinical conditions and valve anatomy (7,10,11 and 12,14,21,28,29,30,31,32 and 33).

Hemodynamics

The results shown in Table 86.1 demonstrate the efficacy of mitral valvuloplasty, which usually provides an increase of over 100% in valve area.

TABLE 86.1 VALVE AREA AFTER PERCUTANEOUS MITRAL VALVULOPLASTY (PMV)

The improvement in valve function results in an immediate decrease in left atrial pressure and a slight increase in cardiac index. A gradual decrease in pulmonary arterial pressure and pulmonary vascular resistances is seen. High pulmonary vascular resistances continue to decrease over the first 24 hours after the procedure and decrease further later in the absence of restenosis (34).

Valvuloplasty has a beneficial effect on exercise hemodynamics and exercise capacity, which improves further in the following weeks because of structural and metabolic alterations in skeletal muscle (35,36). The procedure also improves right ventricle function (37) and, to a lesser extent, left ventricle function (38). In addition, studies have shown that this technique improves left atrial and left atrial appendage (39,40) pump function and decreases left atrial stiffness. It also results in a decrease in the intensity of spontaneous echo contrast in the left atrium (41) and improves local hemostasis in the left atrium (42).

Failures

The failure rates range from 1% to 17% (7,14,21,28,29,30,31,32 and 33). Most failures occurred in the early part of the investigators' experience. Others were due to unfavorable anatomy, such as severe left atrial enlargement or cardiothoracic deformity.

Risks

Procedural mortality ranges from 0% to 3% in most series (18,28,29,30,31,32 and 33,43) (Table 86.2). The main causes of death are left ventricular perforation or the poor general condition of the patient. The incidence of hemopericardium varies from 0.5% to 12%. Pericardial hemorrhage may be related to transseptal catheterization or to apex perforation by the guidewires or the balloon itself when exaggerated movement occurs. Embolism is encountered in 0.5% to 5% of cases. It is rarely the cause of permanent incapacitation and even more rarely of death. Embolism may be cerebral or coronary in location, and it may be due to fibrinothrombotic material from a thrombus that was preexistent or developed during the procedure (44), less frequently to gas, and very seldom to calcium. In most cases, the degree of mitral regurgitation remains stable or increases slightly after valvuloplasty. In a few cases, however, the degree of mitral regurgitation may decrease. Severe mitral regurgitation is rare; its frequency ranges from 2% to 19% (45,46,47,48 and 49). Surgical findings (46,47 and 48) have shown that it is related to noncommissural leaflet tearing, which is often associated with chordal rupture. In these cases, one or both commissures are often too tightly fused to be split. Severe mitral regurgitation may also be due to excessive commissural splitting or, in very rare cases, rupture of a papillary muscle. In the majority of cases, severe mitral regurgitation occurred in patients with unfavorable anatomy. The suggestion has been made that the development of severe mitral regurgitation after percutaneous mitral commissurotomy depends more on the distribution of morphologic changes than on their severity (5,49). Severe mitral regurgitation may be well tolerated, but more often it is not, and surgery on a scheduled basis is necessary. In most cases, valve replacement is required because of the severity of the underlying valve disease. Conservative surgery has been successfully performed in cases of less severe valve deformity (47). The frequency of atrial septal defect reported after valvuloplasty varies from 10% to 90% depending on the technique used for its detection (50,51). These shunts are usually small. Right to left shunts can occur on rare occasions in patients with elevated right heart pressures and pulmonary hypertension (52). The incidence of transient, complete heart block is 1.5%, and it seldom requires implantation of a permanent pacemaker (53). After the transvenous approach, vascular complications are the exception. Finally, endocarditis is extremely rare (54). Although urgent surgery (within 24 hours) is seldom needed for complications, it may be required for massive hemopericardium resulting from left ventricular perforation intractable to treatment by pericardiocentesis or, less frequently, for severe mitral regurgitation leading to hemodynamic collapse or refractory pulmonary edema (47).

TABLE 86.2 MAJOR COMPLICATIONS OF MITRAL VALVULOPLASTY

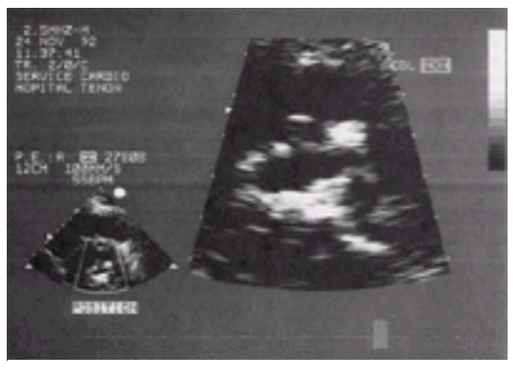
Predictors of Immediate Results

The results from multicenter studies (21,31,55) and large single-center studies (29,30,33), which include a wide population of patients with varied characteristics, enable us to identify predictors of the results to be identified and the strength of these predictors to be evaluated.

Evaluation of the immediate results is based mainly on anatomic criteria. The definition of good immediate results varies from series to series. The two definitions usually used are a final valve area larger than 1.5 cm^2 and an increase in valve area of at least 25%, or a final valve area larger than 1.5 cm^2 without mitral regurgitation greater than 2/4.

Valve anatomy was initially considered (56,57) to be the main predictor of the results, but later it appeared to be only a relative predictor (33,55,58,59). In fact, prediction of results is multifactorial (33,57). Several studies have shown that, in addition to morphologic factors, preoperative variables such as age, history of surgical commissurotomy, functional class, small mitral valve area, presence of mitral regurgitation before valvuloplasty, atrial fibrillation, high pulmonary artery pressure, and presence of severe tricuspid regurgitation, as well as procedural factors such as balloon type and size, are all independent predictors of the immediate results.

The identification of variables linked to outcome enabled the development of predictive models, from which it appears that the sensitivity of prediction is high. Nevertheless, specificity is low, which indicates insufficient prediction of poor immediate results. This latter finding is particularly true with regard to the lack of accurate prediction of severe mitral regurgitation (33,60). This low specificity is related to the intrinsic limitations of the prediction of immediate results, that is, to the possibility of good results in patients who are at high risk for poor results. The possibility of good results in theoretically unsuitable cases has been demonstrated in experimental studies (5) and confirmed clinically (33,59) (*e*Fig. 86.2.4).



***e*FIGURE 86.2.4** Transthoracic echocardiogram (parasternal short-axis view) after valvuloplasty: bicommissural opening, including a calcified commissural area where the balloon has cracked the calcium nodulus, located in the anterior commissure.

Long-Term Results

Data from follow-up at more than 10 years can now be analyzed. In clinical terms, which are the most widely used, the overall long-term results of valvuloplasty are good in a large population of patients comprising a variety of patient subsets (61,62,63,64,65,66,67,68,69 and 70) (Table 86.3). As shown for surgical commissurotomy (71,72 and 73), late outcome after valvuloplasty differs according to the quality of the immediate results (Fig. 86.3).

TABLE 86.3 FOLLOW-UP AFTER MITRAL VALVULOPLASTY

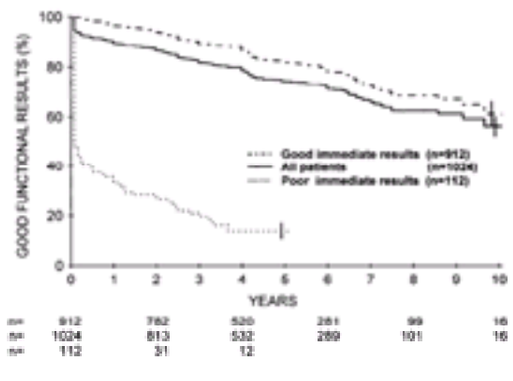

FIGURE 86.3 Long-term results of mitral valvuloplasty. “Good functional results” refers to survival considering cardiovascular-related deaths with no need for mitral surgery or repeat dilatation and in New York Heart Association functional class I or II. (Adapted from Iung B, Garbarz E, Michaud P, et al. Late results of percutaneous mitral commissurotomy in a series of 1024 patients: analysis of late clinical deterioration: frequency, anatomic findings, and predictive factors. *Circulation* 1999;99:3272–3278.)

When the immediate results are unsatisfactory, patients experience only transient or no functional improvement. In these cases, late symptomatic deterioration may be related to lasting poor initial results. In cases of severe mitral regurgitation, the prognosis after surgical commissurotomy or balloon valvuloplasty is usually poor, with lack of improvement in symptoms and secondary objective deterioration; surgical treatment is usually undertaken during the following months. In cases of insufficient initial opening, delayed surgery is usually performed when the extracardiac conditions allow. Here, valve replacement is necessary in almost all cases because of the unfavorable valve anatomy responsible for the initial poor results. In some patients, however, moderate initial improvement in valve function provides functional improvement for several years, although such patients must be carefully followed to allow for a timely operation.

Conversely, if valvuloplasty is initially successful, then survival rates are excellent, functional improvement occurs in the majority of cases, and the need for secondary surgery is infrequent (69). When clinical deterioration occurs in these patients, it is late and mainly related to mitral restenosis.

Determining the incidence of restenosis by echocardiography is compromised by the absence of a uniform definition. It has generally been defined as a loss of more than 50% of the initial gain with a valve area less than 1.5 cm^2. After a successful procedure, the incidence of echographically identified restenosis is usually low,

ranging from 2% to 40% at time intervals of 3 to 5 years (29,31,68,69,74,75). The possibility of repeating valvuloplasty in cases of recurrent mitral stenosis is one of the potentials of this nonsurgical procedure. Repeated valvuloplasty can be proposed if recurrent stenosis leads to symptoms, if it occurs several years after an initially successful procedure, and if the predominant mechanism of restenosis is commissural refusion. At the moment, results of only a small number of series on revalvuloplasty are available; these show good immediate and midterm outcome in patients with favorable characteristics (76). Although the results are less favorable in patients presenting with worse characteristics, repeat valvuloplasty has a palliative role in patients who are not surgical candidates (77). These preliminary results are encouraging; however, defining the exact role of revalvuloplasty must await larger series with longer follow-up.

Predictors of Long-Term Results

Prediction of long-term results is also multifactorial (62,63,64,65,66,67,68 and 69,78,79) and is based on clinical variables such as age; valve anatomy as assessed by different echocardiography scores [one study has shown the negative prognostic value of the presence of commissural calcification (80)]; factors related to the evolutional stage of the disease, that is, a higher New York Heart Association class before valvuloplasty; history of previous commissurotomy; severe tricuspid regurgitation; cardiomegaly; atrial fibrillation; high pulmonary vascular resistances; and the results of the procedure, that is, final valve area, final gradient, and degree of regurgitation. The quality of the late results is generally considered as independent of the technique used (69).

The identification of these predictors provides important information for patient selection and has a relevance to follow-up: patients who have good immediate results but who are at high risk of further events must be carefully followed to detect deterioration and allow for timely intervention. Awareness of these predictors explains the discrepancies in the follow-up results from studies that included patients with different characteristics: late results are clearly less satisfactory in North American or European series (25,62,64,65,67,68 and 69), in which patients are older and frequently have severe valve deformities, than in studies from developing countries, where the patients studied have more favorable characteristics (29,30,61).

Despite interpatient variability, the degree of mitral regurgitation generally remains stable or slightly decreases during follow-up (46,48,51). Atrial septal defects are likely to close over time in the majority of cases because of reduction in the interatrial pressure gradient. The persistence of shunts is related to their magnitude or to unsatisfactory relief of the valve obstruction (81). Finally, clinical series of surgical and balloon commissurotomy suggest that intervention reduces the risk of embolism even if it does not eliminate it (69,82).

Indications

The decision to perform valvuloplasty must be based on both clinical and anatomic variables.

Clinical Variables

Clinical evaluation of patients concentrates mainly on functional disability and the alternative risk with surgery.

For symptomatic patients, the indication for valvuloplasty is perfectly clear. Truly asymptomatic patients, however, are not usually candidates for the procedure because of the small but definite risk inherent in the technique. For patients in the latter group, balloon commissurotomy may be considered in the following cases: patients at high risk of thromboembolism, for example, patients with a previous history of embolism or with heavy spontaneous contrast in the left atrium; and patients with recurrent atrial arrhythmias. Pulmonary hypertension is an adverse prognostic indicator, and patients with pulmonary hypertension are likely to become symptomatic in the near future. Guidelines recommend balloon valvuloplasty for patients with systolic pulmonary pressures higher than 50 mm Hg at rest or 60 mm Hg on exercise (83). Finally, balloon valvuloplasty can be considered for patients requiring major extracardiac surgery or to allow for pregnancy.

Valvuloplasty is the only solution when surgery is contraindicated. It is also preferable to surgery, at least as a first attempt, in patients with an increased risk for surgery of cardiac origin, as in patients with restenosis after surgical commissurotomy. Available data show that the results of the procedure are good in such cases, even if slightly less satisfactory than those obtained in patients without previous surgery (33,84,85 and 86). This suggests that valvuloplasty may well postpone reoperation in selected patients, provided anatomy is still suitable and restenosis is due mainly to commissural refusion. The same reasoning applies in cases of patients who have undergone aortic valve replacement. Preliminary reports have suggested that valvuloplasty can be performed safely and effectively in patients with pulmonary hypertension (87). In cases of coexistence of mitral stenosis and moderate aortic valve disease (88), balloon valvuloplasty can be performed as a means of postponing the inevitable later surgical treatment of both valves.

In Western countries, many patients with mitral stenosis have concomitant noncardiac disease, which may also increase the risk of surgery. Valvuloplasty can be performed as a lifesaving procedure in critically ill patients (89,90 and 91)—as the sole treatment in case of absolute contraindication to surgery or as a bridge to surgery in the other cases. In elderly patients, valvuloplasty results in moderate but significant improvement in valve function at an acceptable risk, although subsequent functional deterioration is frequent (92,93 and 94). In such cases valvuloplasty may be an effective treatment in patients with favorable characteristics. It is also a useful palliative procedure for those who are unsuitable for surgery. In pregnant patients the procedure is efficacious in terms of improving the mother's hemodynamic status; it is also well tolerated by the fetus if performed after the twentieth week. Due to the ever-present risk of complication, use of valvuloplasty should be limited to patients who remain symptomatic despite appropriate other treatment (95,96 and 97).

Anatomic Aspects

The assessment of anatomy has several aims with respect to establishing indications and prognostic considerations. Assuring that no anatomic contraindications exist to use of the technique is very critical (Table 86.4). The first contraindication is the presence of left atrial thrombosis, which must be excluded by the systematic performance of transesophageal echocardiography a few days before the procedure. A contraindication to valvuloplasty is self-evident if the thrombus is floating, localized in the cavity, or on the atrial septum. Second, mitral regurgitation greater than grade 2 in the Sellers classification contraindicates valvuloplasty. Third, in cases of combined mitral stenosis and severe aortic disease, the indication for surgery is obvious in the absence of contraindication for surgery. Fourth, the existence of tricuspid regurgitation is not a contraindication for the procedure even though it represents a negative prognostic factor (98). On the other hand, the presence of combined severe tricuspid stenosis and tricuspid regurgitation with clinical signs of heart failure is an indication for surgery on both valves.

Left atrial thrombosis
Mitral regurgitation greater than 2/4
Massive or bicommissural calcification
Severe aortic valve disease, or severe tricuspid stenosis + regurgitation associated with mitral stenosis
Severe concomitant coronary artery disease requiring bypass surgery

TABLE 86.4 CONTRAINDICATIONS FOR MITRAL VALVULOPLASTY

For prognostic purposes, echocardiographic assessment allows the classification of patients into anatomic groups with a view to predicting the results. Most investigators use the Wilkins score (Table 86.5) for categorization, whereas others, such as our group, use a more general assessment of valve anatomy (Table 86.6). In fact, today none of the scores available has been shown to be superior to the others, and all echocardiographic classifications have the same limitations: (a) technical factors; (b) the difficulty of reproducibility, as they are only semiquantitative; (c) underestimation of the lesions, especially regarding the assessment of subvalvular disease; and (d) the inability of scores describing the degree of overall valve deformity to identify localized changes in very specific portions of the valve apparatus (leaflets, commissures) that may increase the risk of severe mitral regurgitation. Therefore, the use of the system with which one is most familiar and at ease is recommended. More recently, scores that take into account the uneven distribution of the anatomic deformities of the leaflets or the commissural area have been developed (49,99). Preliminary results for their use are promising (100,101) but disputed (102); therefore, further studies are needed to determine their exact value (*e*Table 86.6.1).

Leaflet mobility
1. Valve is highly mobile, with restriction of only the leaflet tips.
2. Midportion and base of leaflets have reduced mobility.
3. Valve leaflets move forward in diastole mainly at the base.
4. No or minimal forward movement of the leaflets occurs in diastole.
Valvular thickening
1. Leaflets near normal (4–5 mm).
2. Midleaflet thickening, marked thickening of the margins.
3. Thickening extending through the entire leaflets (5–8 mm).
4. Marked thickening of all leaflet tissue (≥8–10 mm).
Subvalvular thickening
1. Minimal thickening of chordal structures just below the valve.
2. Thickening of chordae extending up to one-third of chordal length.
3. Thickening extending to the distal third of the chordae.
4. Extensive thickening and shortening of all chordae extending down to the papillary muscle.
Valvular calification
1. A single area of increased echo brightness.
2. Scattered areas of brightness confined to leaflet margins.
3. Brightness extending into the midportion of leaflets.
4. Extensive brightness through most of the leaflet tissue.

Note: The final score is found by adding the scores for each of the components.

***e*TABLE 86.6.1** CALCULATION OF ECHOCARDIOGRAPHIC SCORE TO PREDICT MITRAL REGURGITATION AFTER PERCUTANEOUS MITRAL VALVULOPLASTY

A/BCalcification/fibrosis of leaflets

*(Score anterior***and***posterior leaflet)*

1. Thickening normal (4–5 mm) or only one thick segment.
2. Evenly fibrotic/calcified without thin areas.
3. Uneven distribution of calcification/thickening. Thinner segments are mildly thickened (5–8 mm).

Uneven distribution of calcification /thickening. Thinner segments are near normal (4–5 mm).

C Fibrosis/calcification of commissures

1. Only one commissure affected.
2. Both commissures mildly affected.
3. Calcification of both commissures: one severely affected.
4. Marked calcification of both commissures.

D Subvalvular disease

1. Minimal chordal thickening just below valve.
2. Chordal thickening to one-third of length.
3. Thickening to distal one-third of chordae.
4. Shortening/fibrosis of all chordae to papillary muscle.

Adapted from Padial LR, Freitas N, Sagie A, et al. Echocardiography can predict which patients will develop severe mitral regurgitation after percutaneous mitral valvulotomy. *J Am Coll Cardiol* 1996;27:1225–1231.

Thus, even if it is not the sole criterion, anatomy is a simple and practical way of selecting patients for valvuloplasty. In patients with good anatomy—that is, pliable valves and moderate subvalvular disease (echocardiographic score of 8 or less)—results of valvuloplasty are generally excellent. Results of several randomized studies with follow-up comparing valvuloplasty and surgical commissurotomy are available (103,104 and 105). They show that valvuloplasty is at least comparable to surgical commissurotomy as regards immediate and long-term results and is no doubt more comfortable for the patient. Valvuloplasty would thus appear to be the procedure of choice for these patients, provided that it is affordable. In addition, if restenosis occurs, patients treated by valvuloplasty could undergo repeat balloon procedures or surgery without the difficulties and inherent risk resulting from pericardial adhesions and chest wall scarring (eTable 86.6.2).

On the other hand, much remains to be done in refining the indications for valvuloplasty in other patients, especially those with unfavorable anatomy (106,107,108 and 109), who are more common in Western countries. For this group, some favor immediate surgery because of the less satisfying results of valvuloplasty, whereas others prefer valvuloplasty as an initial treatment for selected candidates and reserve surgery for cases in which this treatment fails.

PERCUTANEOUS AORTIC VALVULOPLASTY

As reviewed in Chapter 22, Aortic Valve Disease, severe degenerative calcified aortic stenosis is the most frequent valve disease in Western countries, which accounts for the initial interest in its potential treatment by interventional cardiology.

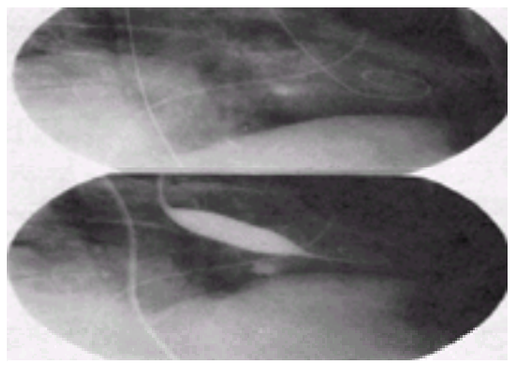
Mechanisms

In degenerative calcific aortic stenosis, calcium deposits are located at the base of the aortic cusps and commissural fusion is rare. These anatomic findings explain why dilation by a balloon has a very limited and transitory effect; results show little macroscopically and are only detectable by microscopic or radiologic studies (110,111). The mechanisms of action proposed are the cracking of the calcified nodulus, which may increase the flexibility of the leaflets, and the stretching of the aortic wall. These mechanisms easily explain the loss of effect that occurs in the hours or days after the procedure; this is secondary to valvular and aortic wall elastic recoil. In addition, later loss may be due to organization and collagenization of scar tissue, which results in fibrosis and ossification (112,113). In rheumatic aortic stenosis, in which commissural fusion does occur, valvuloplasty, which creates commissural splitting, may be theoretically more effective (114).

Technique

Approaches

The femoral retrograde approach is most frequently used (115,116). After placement of an introducer sheath, the aortic valve is crossed (eFig. 86.3.1); this represents the most difficult technical part of the procedure. Then, a stiff wire is inserted into the apex of the left ventricle to stabilize the balloon during inflation (115,116 and 117).



***e*FIGURE 86.3.1** Aortic valvuloplasty: retrograde technique. **Upper panel:** Crossing of the valve with a stiff guidewire with a preshaped tip. **Lower panel:** Dilatation of the valve with a conventional balloon (23 mm).

The alternative is the anterograde approach, which necessitates a transseptal catheterization. This latter technique is a difficult procedure but constitutes a recourse in case of inaccessibility of the femoral approach (117).

Balloons

Valvuloplasty is performed with balloons from 15 mm to 25 mm in diameter, from 3 cm to 5 cm in length, and of variable form: conventional, bifoil, trefoil, or, more recently, double size, which has the advantage of a low profile.

Selection of the balloon size is controversial. The ratio between the size of the balloon and the diameter of the aortic ring must not exceed 1.2 to 1.3 to obtain satisfactory results without increasing risk.

Monitoring of the Procedure and Assessment of Immediate Results

Methods for evaluating immediate results during the procedure include the monitoring of the transaortic gradient and cardiac output, which enables repeated calculation of the valve area. Nevertheless, because of the hemodynamic instability of the patient during the procedure and very early loss in valve area after the procedure, the most viable method is measurement of the valve area by Doppler echocardiography in the days after the procedure (118). Aortography before and after the procedure evaluates any change in the degree of aortic incompetence.

Immediate Results

The technique has been used in several hundred patients, and the results from single-center (115,116 and 117) and multicenter registries (119) can be evaluated. The series reported concern essentially aortic stenosis in older subjects. Any analysis of the results must take into account the severity of the cardiac disease and comorbidities found in such an aged population.

Hemodynamics

Immediately after the procedure the transvalvular pressure gradient is reduced; cardiac output is little modified. Overall, percutaneous aortic valvuloplasty (PAV) reduces tight stenosis to moderate stenosis with a final area between 0.7 and 1.1 cm^2 (115,116,117 and 118,120,121). These results are clearly inferior to those obtained with a valvular prosthesis, which usually provides a valve area over 1.5 cm^2(eTable 86.6.3).

Risks

Mortality and morbidity of the procedure are high (115,116 and 117,119,120,121,122,123 and 124) (Table 86.7). Hospital mortality varies from 3.5% to 13.5%, and 20% to 25% of the patients have at least one serious complication within the first 24 hours. The most frequent complications are vascular complications at the puncture site, which necessitate an intervention in nearly half of the cases. Ventricular perforations are responsible for tamponade. Acute aortic incompetence is rare. Embolic complications are also rare. Two complications are exceptional but can be fatal: mitral regurgitation and the rupture of the aortic ring.

TABLE 86.7 IMMEDIATE COMPLICATIONS OF AORTIC VALVULOPLASTY

Predictors of Immediate Results

The immediate outcome is linked to the clinical status of the patient (age, New York Heart Association class, and presence of congestive heart failure) or to procedural complications. Depressed left ventricular function, low cardiac output, and the existence of diffuse coronary lesions are all important covariates associated with worse outcome (115,120,124). Finally, a final valve area smaller than 0.7 cm^2 carries a negative prognosis (124).

Long-Term Results

Despite a relatively modest improvement in valve function, a degree of functional improvement is commonly noted during the first weeks or months. This is of short duration, however. PAV seems to improve survival rates at 1 year and especially improves the quality of life. The benefit decreases, however, and finally disappears after 2 years (115,124,125,126,127 and 128) (Table 86.8). In selected patients, an aortic valve replacement has been subsequently performed with good results (129); on the other hand, the prognosis of the other patients is particularly poor (129,130 and 131) (Fig. 86.4). Overall, the opinion is now that PAV alone does not change the natural course of the disease (132). These poor long-term results are mainly due to the clinical status of the patients and to the moderate and transient improvement in valve function obtained by PAV.

TABLE 86.8 RESULTS OF CLINICAL FOLLOW-UP AFTER AORTIC VALVULOPLASTY

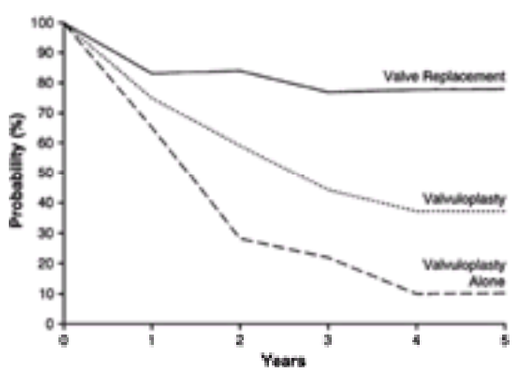

FIGURE 86.4 Long-term survival rate after aortic valve replacement or balloon valvuloplasty. (From Bernard Y, Etievent J, Mourand JL, et al. Long-term results of percutaneous aortic valvuloplasty compared with aortic replacement in patients older than 75 years. *J Am Coll Cardiol* 1992;20:796–801.)

Indications

Comparison with surgical results is difficult because the patients included in the dilatation series are older, are in a more precarious clinical condition, and very frequently have associated comorbidities. After the operative period, surgical results are good, and most of the survivors have good functional status and closely resemble other populations of the same composition of age and gender in terms of life expectancy and quality of life (133,134 and 135). In the absence of randomized studies, the comparison between surgery and PAV is based on retrospective studies such as that of Bernard and colleagues (136), which compared surgical results and results of balloon valvuloplasty in patients over 75 years of age, comparable in age, functional status, and hemodynamics. Therefore, the indications should take into account the excellent results of surgery when it is possible and the poor results of PAV.

In practice, aortic valve replacement is the treatment of choice for symptomatic patients with tight aortic stenosis. Valvuloplasty can be considered only in the following circumstances:

- For critically ill patients with cardiogenic shock with multivisceral failure. Good midterm results have been obtained in limited series if surgical intervention was possible secondarily (137). For this group of patients, valvuloplasty can be considered a bridge to surgery, permitting the secondary operation with less risk.
- For patients with severe, poorly tolerated aortic stenosis who require significant emergency noncardiac surgery.
- For patients who have an absolute, but not life-threatening, short-term contraindication to surgery and have a significant functional disability.
- For patients who refuse surgery.

OTHER PERCUTANEOUS VALVE DILATATIONS

Unlike percutaneous valvuloplasty for mitral and aortic stenosis, other applications of percutaneous valve dilatation have been used only sparingly. The few interventions performed show that the procedures are feasible, but the cases are insufficient in number to allow evaluation of results and establishment of indications.

Percutaneous Tricuspid Valvuloplasty

The indications of tricuspid valvuloplasty are rare. The procedure is reserved for symptomatic patients presenting with tight tricuspid stenosis, pure or associated with mild regurgitation (138,139 and 140). In all other cases in which the tricuspid stenosis is accompanied by significant or moderate regurgitation, or is associated with another valvular disease necessitating surgical treatment, the treatment must be surgery.

Percutaneous Dilatation of Bioprostheses

Anatomic findings and experimental dilatations lead one to conclude that dilatations of bioprostheses do not produce good results (141,142,143,144,145 and 146). They may give rise to severe immediate complications at the level of the left heart (145) and give poor midterm results in the tricuspid position. Percutaneous dilatation may in certain rare cases be performed as a palliative treatment for stenotic degeneration of a bioprosthesis in the tricuspid position (146,147 and 148).

Multiple Dilatations

Actual experience allows one to say only that multiple dilations are technically feasible in selected patients (149,150 and 151). One application that might be imagined in the field of rheumatic pathology is in cases of contraindication to surgery or high surgical risk, such as during pregnancy.

Percutaneous Valve Dilatation and Coronary Angioplasty

Because of the aging of the population in Western countries, the association of calcified aortic stenosis and coronary pathology is frequently encountered; however, the association of a tight mitral stenosis and obstructive coronary lesions is observed much less frequently. Few cases of percutaneous valve dilatations for calcified aortic stenosis and coronary angioplasty in either one or two sessions have been reported (152). In addition, a single case was reported in which dilation for mitral stenosis and coronary angioplasty with stent placement was performed with success (153). The rarity of the indications for aortic dilatation suggests that such a combined procedure has little practical application.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Mitral valvuloplasty is the valvuloplasty technique used most frequently, if not exclusively (154). Because of the good results that have been obtained with mitral valvuloplasty, currently this technique has an important place in the treatment of mitral stenosis. The main objects of controversy and the main questions still to be solved concern economic aspects, the technique itself, and the respective indications for treatment by balloon valvuloplasty or surgery.

Further developments of the technique depend on the possibilities for application in countries where mitral stenosis is endemic and where means are lacking. In such countries, limitations in finances restrict the use of the Inoue balloon or leads to its reuse, with the attendant risks. With this in mind, the price of the devices must be reduced by making them reusable, as with the metallic commissurotome, or by simplifying them, as with the Multi-Track system.

Regarding the choice of technique, the Inoue technique has become the most popular in the world and has been used in more than 30,000 patients with good and reproducible results. The experience with the metallic commissurotome is only preliminary and almost exclusively reported by the promoter of the method. Comparison of the respective merits of this new technique and the Inoue technique requires accumulation of further data concerning the metallic commissurotome and randomized comparisons of the two techniques. In the author's opinion, the efficacy, safety, and applicability of the Inoue technique are clearly established, whereas those of the metallic commissurotome are yet to be fully proven. This new device is unlikely to replace the Inoue balloon in Western countries because safety is probably decreased and the technique is more demanding. On the other hand, a potential exists for the application of the metallic commissurotome in developing countries.

The considerable simplification resulting from use of the Inoue balloon could lead to a false sense of security in the application of the technique and should not overshadow the importance of training. In the author's opinion, performance of percutaneous valvuloplasty should be restricted to groups whose experience with transseptal catheterization has been positive and who have been able to carry out an adequate number of procedures and thus improve their technical performance and ability to select patients. This recommendation carries even more weight in Western countries, where mitral stenosis is infrequent. In particular, valvuloplasty should be performed only in centers with sufficient experience, in cases where patients have minimal symptoms, during pregnancy, or in cases of cardiothoracic deformity. The decision to perform valvuloplasty also depends on the results of surgery at the institution concerned. The potential for valve repair in case of traumatic regurgitation is an important incentive in favor of performing valvuloplasty at an earlier stage of the disease.

The debate on how best to perform the technique must not overshadow other, probably more important matters such as the selection of candidates. Regarding indications, no problems are presented in cases in which surgery is contraindicated or for "ideal candidates," such as young adults (155) with favorable characteristics. On the other hand, much remains to be done in refining the indications for other patients, especially those with minimal symptoms and those with unfavorable anatomy (156).

The level of evidence for performing valvuloplasty in asymptomatic patients is low because no data exist comparing the results of valvuloplasty and medical therapy for such patients. For these patients, the goal is not to prolong life or to decrease symptoms but rather to prevent thromboembolism. The efficacy of valvuloplasty for the specific problem of embolism is not established, but the different findings previously mentioned consistently show the beneficial effect of valvuloplasty on the causes of thromboembolism: intensity of left atrial echocardiographic contrast, size of the atrium, left atrial function, and coagulation activity in the left atrium. No direct evidence exists that valvuloplasty reduces the incidence of atrial fibrillation, even if its favorable influence on predictors of atrial fibrillation, such as atrial size or degree of obstruction, seems to indicate that this is indeed the case. In such patients, valvuloplasty should be performed only by experienced interventionists and when valve anatomy is favorable, in which case a safe and successful procedure can be expected.

Among patients with less favorable valve anatomy (echocardiographic score higher than 8) as a result of extensive subvalvular disease or mild valve calcification, the comparison between the results of valvuloplasty and of surgery is much more difficult. Unfortunately, no randomized study has been performed examining this issue, and comparison of the results of balloon commissurotomy with those of surgical series is difficult due to differences in the patient populations and the fact that the surgical alternative can include surgical commissurotomy, in practice seldom, and also valve replacement in most cases. Valve replacement has its drawbacks: namely, operative mortality, particularly in the elderly, and prosthesis-related complications whose cumulative incidence compromises late outcome, particularly in young patients who are most exposed to the risk of long-term deterioration.

The indications in this subgroup of patients must take into account their heterogeneity with respect to anatomy, especially the extent and location of calcification. The clinical status is even more vital because this subgroup includes patients in good clinical condition and others who are not surgical candidates because of an associated comorbid condition. For this group of patients, an individualistic approach is favored that allows for the multifactorial nature of prediction (Fig. 86.5). The possibility of good results in poor candidates cannot be excluded; consequently, wider indications are proposed for valvuloplasty as an initial treatment in selected patients. Current opinion is that surgery can be considered the treatment of choice in patients with bicommissural or heavy calcification. On the other hand, in the author's opinion, balloon valvuloplasty can be attempted as a first approach in patients with extensive lesions of the subvalvular apparatus or moderate or unicommissural calcification, the more so because their clinical status argues in favor of this. Surgery should be considered reasonably early after unsatisfactory results or secondary deterioration. Extending knowledge regarding this group requires evaluation of new anatomic scores that may be developed in the future using new echocardiographic methods such as three-dimensional imaging (157), predictive models that take into account the multifactorial aspect of the prediction, and, ideally, the conduct of randomized studies on an "intent-to-treat" basis that compare balloon valvuloplasty with surgery. Such studies should include follow-up and should simultaneously be cost-effective.

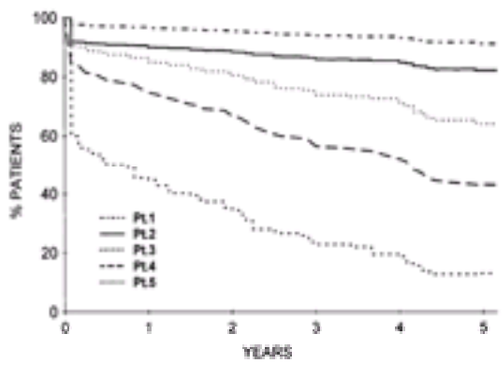

FIGURE 86.5 Multifactorial nature of the prediction of the results of mitral valvuloplasty. Predicted probability of good immediate results (valve area at least 1.5 cm^2 without regurgitation, Seller's grade greater than 2) and good late functional results [survival with no intervention and in New York Heart Association (NYHA) class I or II] according to patient characteristics. Values are given for a procedure using an Inoue balloon with an effective balloon dilating area of at least 5.5 cm^2 (i.e., a final diameter greater than or equal to 27 mm). Pt. 1, less than 50 years, NYHA class II, sinus rhythm, calcium grade I, valve area 1.25 to 1.5 cm^2; Pt. 2, less than 50 years, NYHA class II, sinus rhythm, calcium grade 2, valve area 1 to 1.25 cm^2; Pt. 3, 50 to 70 years, NYHA class III, sinus rhythm, calcium grade 2, valve area 1.25 to 1.5 cm^2; Pt. 4, 50 to 70 years, NYHA class III, atrial fibrillation, calcium grade 2, valve area 1.25 to 1.5 cm^2; Pt. 5, at least 70 years, NYHA class III, atrial fibrillation, calcium grade 3, valve area 0.75 to 1 cm^2. (Adapted from Iung B, Garbarz E, Doutrelant L, et al. Late results of percutaneous mitral commissurotomy for calcific mitral stenosis. *Am J Cardiol* 2000;85:1308–1314.)

In addition, no consensus has been reached regarding indication for valvuloplasty in patients with left atrial thrombosis located in the left atrial appendage and in patients with moderate stenosis.

A number of small series have reported that valvuloplasty is feasible for patients with thrombosis localized in the left atrial appendage (158,159). However, these studies have not satisfactorily shown that even use of the Inoue technique under transesophageal echocardiographic guidance precludes a risk of embolism. In such cases, the indications for valvuloplasty are limited to patients with contraindications to surgery or those without urgent need for intervention, when oral anticoagulation

can be given for at least 2 months and provided a new transesophageal echocardiographic examination shows the disappearance of the thrombus.

The suggestion has been made that valvuloplasty be performed in patients with moderate stenosis in the hope of delaying the natural course of the disease (160). These patients are usually candidates for medical treatment, however, and the risks of valvuloplasty probably outweigh the benefits. To define a threshold of valve area above which valvuloplasty should not be performed is somewhat arbitrary because, besides measuring valve area, one must take into account functional disability and pulmonary pressures at rest and on exercise. The author's current practice is usually to avoid valvuloplasty in patients with a valve area over 1.5 cm^2 or greater than 1 cm^2 per square meter of body surface area for unusually large patients.

Finally, the comparison between percutaneous valvuloplasty and surgery in the future will need to include minimally invasive surgery. In comparison with traditional surgery, these new techniques seem promising from an aesthetic point of view, because they lower potential risk by obviating or limiting the sternotomy, and because they use new videoscopic techniques. Few patients have so far been treated in this way, however, and data are still insufficient to evaluate the efficacy and the safety of the method; moreover, the expectation is that such methods will be reserved for surgeons of wide experience in the field of conservative surgery.

The question today is whether aortic valvuloplasty still really has a place (161,162). Most groups have abandoned the technique, but others see some role for it, albeit a very limited one. The remaining indication is mainly cardiogenic shock, with multivisceral failure if secondary operation is not definitely contraindicated. The use of valvuloplasty to treat rheumatic aortic stenosis should be better evaluated, however, because this might ultimately be an attractive application of the method.

Other percutaneous valve dilatation techniques will probably be used in exceptional cases in tricuspid stenosis or multiple valve disease. Percutaneous dilatation of bioprostheses seems to have no future.

Publication of a report of the first case of percutaneous valve replacement leaves the door open for the future (163).

THE FUTURE

After nearly 15 years of extensive clinical evaluation, the technique of percutaneous valve dilatation, which for practical purposes can be summed up as percutaneous mitral valvuloplasty, is now here to stay. This is because of its proven efficacy in the treatment of mitral stenosis as a substitute for surgical commissurotomy (164) and as a complement to valve replacement.

OVERVIEW

Transcatheter therapy is routinely performed in many centers for treatment of a wide variety of congenital cardiac defects. These techniques are appropriate for children and adults with congenital heart disease. This chapter describes current interventional therapies available to the practitioner for treating common congenital heart defects. A brief history, technical aspects, indications and contraindications, and early and long-term outcome data, where available, are reviewed for the more common interventions. The uses of implantable devices, such as embolization coils, endovascular stents, and septal occluders, are also examined. Newer technologies representing major advances in transcatheter therapy for congenital heart disease are also discussed.

GLOSSARY

Aortopulmonary shunt: Direct surgical anastomosis or tube-graft (usually Gore-Tex) interposition between the aorta or one of its branches (carotid, innominate, subclavian) and the ipsilateral pulmonary artery that augments pulmonary flow in patients with anatomic limitations to flow. Examples of this type of shunt include Blalock-Taussig shunt, Waterston shunt, and Potts shunt.

Balloon atrial septostomy: Palliative technique pioneered by William Rashkind by which pulling an inflated balloon-tipped catheter through the atrial septum (from left atrium to right atrium) produces an atrial septal defect (ASD) that affords improved mixing of oxygenated and deoxygenated blood.

End-to-end anastomosis: Surgical technique for repair of aortic coarctation by which stenotic aortic segment is resected and the two ends of the nonstenotic aorta are anastomosed.

Fontan operation: Operation used in patients with single ventricle anatomy. Total anastomosis of superior and inferior venae cavae to the pulmonary arteries redirects systemic venous return to the lungs, bypassing the single ventricular chamber.

Glenn procedure: Anastomosis between superior vena cava and pulmonary artery. It may be *bidirectional* (anastomosis to continuous pulmonary arteries) or *unidirectional* ("classic") (anastomosis to single right pulmonary artery).

Modified hepatoclavicular position: Camera angulation during angiography. Position is approximately 40 degrees left anterior oblique/30 degrees cranial in the lateral plane.

Paradoxical hypertension: Acute hypertensive crisis after either surgical correction or rarely after balloon angioplasty for aortic coarctation. These hypertensive episodes are postulated to be secondary to damage to the sympathetic and parasympathetic innervation of the aorta. It is treated with intravenous antihypertensive

drugs.

Prostaglandin E_1: A naturally occurring prostaglandin that can be administered intravenously to induce reopening (or continued patency) of the ductus arteriosus, to permit continued ductal shunting when physiologically advantageous. Used in neonates with severe semilunar valvular obstruction or as palliation in the cyanotic newborn before surgical or transcatheter intervention.

Restrictive patent ductus arteriosus (PDA): PDA internal diameter small enough to restrict flow and pressure from aorta to the pulmonary artery.

Shone's complex: Complex of multiple left-sided heart lesions, usually valvular, subvalvular, or both aortic stenosis; mitral stenosis; and aortic coarctation. In some cases, this complex may also include a ventricular septal defect.

Static balloon dilation: Inflation of the balloon valvuloplasty catheter across the valve annulus, leading to tearing of the fused commissures.

Transposition: D-transposition of the great arteries (pulmonary artery arising from left ventricle, aorta from right ventricle, with atrioventricular concordance).

INTRODUCTION AND HISTORICAL PERSPECTIVE

Pediatric interventional cardiac catheterization was first described by Rashkind (1) in 1966 when he reported the technique of balloon atrial septostomy in infants with transposition; the procedure now carries his name. The field of pediatric interventional cardiology then remained quiescent until 1982 when Kan (2) described percutaneous balloon dilation in children with pulmonary valve stenosis. From 1983 to 1987 a number of centers explored the use of transcatheter therapy for a wide variety of congenital cardiac defects. These included pulmonary valve stenosis, pulmonary artery stenosis, aortic valve stenosis, coarctation of the aorta (i.e., postoperative recurrent stenosis, or native stenosis), PDA, and ASD. By the late 1980s, the field of pediatric interventional cardiology was established as a new subspecialty within pediatric cardiology.

At present, transcatheter therapies are available for 30% to 40% of children with congenital heart disease. Percutaneous balloon dilation is widely regarded as the treatment of choice in children with congenital pulmonary valve stenosis, aortic stenosis, pulmonary artery stenosis, postoperative recurrent coarctation, and PDA. Balloon expandable stent implantation has proven invaluable for treating children with pulmonary artery stenosis, whether it occurs as an isolated lesion or in association with tetralogy of Fallot. Newer data regarding stent therapy for aortic coarctation are encouraging. Promising clinical trials are under way to evaluate the effectiveness of transcatheter occlusion devices as alternatives to surgery in children with a secundum ASD or a muscular ventricular septal defect. Even more novel interventions are being evaluated, the most recent being transcatheter implantation of stent valves in the right ventricular (RV) outflow tract.

This chapter provides an overview of the field of interventional pediatric cardiology. The most common transcatheter therapies currently in use are discussed, with a focus on their indications, contraindications, acute and long-term results, as well as associated complications. Because interventional pediatric cardiology embodies a large number of procedures for a wide variety of cardiac defects, discussion of each procedure is brief.

BALLOON DILATION FOR CONGENITAL AORTIC VALVE STENOSIS

Historical Perspective

Balloon dilation of a congenitally stenotic aortic valve was first described by Lababidi et al. (3,4) in 1983. The procedure was subsequently evaluated in numerous centers (5,6,7,8,9,10 and 11). It soon became apparent that percutaneous balloon dilation provides good short-and intermediate-term relief of aortic valve obstruction in patients with congenital valve stenosis. Initial concerns regarding iliofemoral artery injury in children have diminished with the introduction of small-caliber balloon dilation catheters. To date, there are no prospective trials comparing the outcomes of balloon dilation with those of surgical valvotomy in patients with congenital aortic valve stenosis. Nevertheless, there is widespread agreement that the results of balloon dilation, specifically regarding gradient relief and the occurrence of important valve regurgitation, compare favorably with those of surgery. Thus, percutaneous balloon dilation has been widely adopted as the treatment of choice in this group of patients.

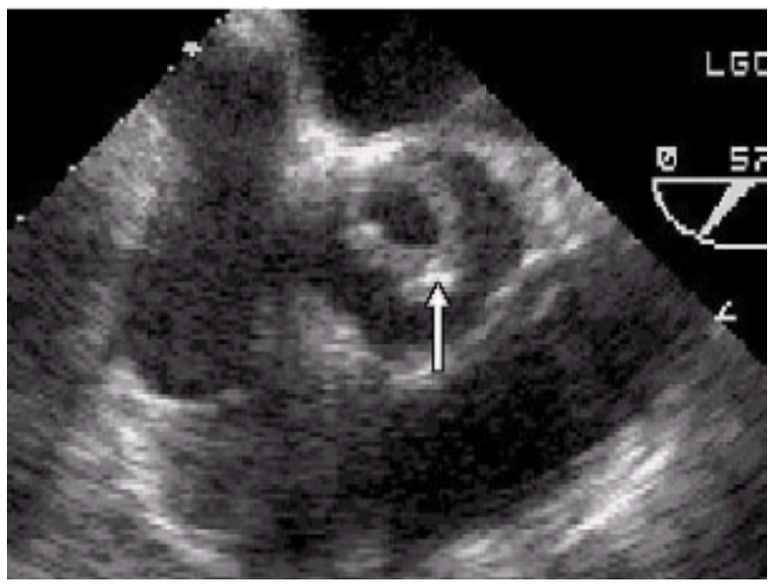
Indications and Contraindications

Indications for percutaneous balloon aortic valvotomy have generally paralleled those previously adhered to for surgical valvotomy. In more recent years, some centers have relaxed their clinical indications due to the perception that the risk-benefit ratio of a percutaneous procedure is probably superior to that of open heart surgery. Currently in our practice, the indications for performing balloon valvotomy in patients with congenital valvar aortic stenosis are (a) peak systolic gradient greater than or equal to 65 mm Hg in an asymptomatic child; (b) peak systolic gradient 45 to 65 mm Hg in a child with electrocardiographic evidence of myocardial ischemia (at rest or during exercise), or with symptoms attributable to myocardial ischemia; and (c) the presence of critical aortic stenosis in an infant with low cardiac output, regardless of gradient.

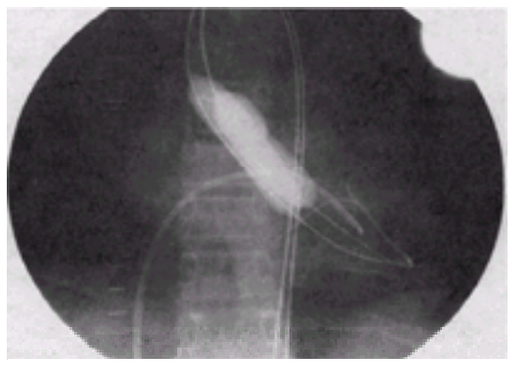


Short-axis transesophageal view of a unicuspid aortic valve with aortic stenosis. The arrow designates the single commissure present in this aortic valve. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)

The contraindications currently adhered to at our institution include (a) mild to moderate aortic valve stenosis in an asymptomatic child, (b) the presence of associated severe aortic regurgitation (of sufficient severity to warrant valve replacement), (c) important hypoplasia of the aortic valve annulus (e.g., less than 5 mm in a newborn), and (d) calcific aortic valve stenosis.

Technique

The technique of percutaneous balloon dilation for congenital aortic valve stenosis has been previously reported in detail. The procedure is most often performed using a retrograde transarterial approach, although an antegrade transvenous route has been used in some centers. In newborns, we often use a transumbilical arterial approach (12), thus sparing the newborn femoral artery. A carotid artery cutdown has also been described by Fischer et al. (13) to minimize femoral complications in neonates. This approach has been used in newborns as small as 1,600 g (14). The transcarotid approach also has an additional advantage in patients with associated coarctation of the aorta, which may make catheter manipulation around the arch difficult. Once arterial access is obtained, the stenotic valve is crossed in a retrograde fashion. A soft-tipped wire must be used in newborns and with extreme caution to avoid perforating an aortic valve cusp. A balloon with an inflated diameter of 90% to 100% of the measured diameter of the aortic valve annulus is used (eFig. 87.0.1). Balloons with an inflated diameter that is wider than that of the aortic annulus are avoided because they increase the risk for important valve regurgitation. Throughout the procedure, left ventricular (LV) pressure is monitored in infants by an antegrade catheter placed across the foramen ovale or by a transseptal puncture in older patients. Patients are fully heparinized, and the activated clotting time is monitored (target, 250 to 300 seconds), with the exception of critically ill acidotic newborns. The balloon (or balloons, in the case of a double-balloon technique) is inflated briefly by hand one to four times, with care taken to observe the waist of the stenotic valve near the midportion of the balloon. After dilation, repeat hemodynamic measurements are obtained, and an aortic root angiogram is performed to document the presence and severity of any aortic regurgitation that may have been produced.



***e*FIGURE 87.0.1** Double-balloon aortic valve dilation in a 9-year-old boy with congenital aortic valve stenosis. A 12-mm balloon and a 15-mm balloon are used in tandem to effectively dilate an aortic valve annulus measuring 21 mm in diameter.

Acute and Long-Term Results

The largest study describing the acute outcome after balloon dilation in children with congenital aortic stenosis was reported by the Valvuloplasty and Angioplasty of Congenital Anomalies Registry (11) in 1990. The Valvuloplasty and Angioplasty of Congenital Anomalies Registry reported data from 240 children whose short-term data were submitted to the registry after balloon dilation procedures performed between 1986 and 1992. It should be noted that the registry made no attempt to standardize the dilation procedure itself or data analysis practices. The patients in this report ranged in age from newborn to young adult, with a mean age of 10.1 years. All patients had congenital valvular aortic stenosis of a moderate to severe degree. Balloon dilation of congenital aortic valve stenosis can generally be expected to decrease peak systolic gradient to a range of 25 to 35 mm Hg (i.e., mild), with a 10% incidence of increase in aortic valve regurgitation. Less satisfactory gradient relief typically indicates either a suboptimal technical procedure or the presence of complex LV outflow tract disease (i.e., annulus hypoplasia, subvalvular stenosis, or calcific stenosis).

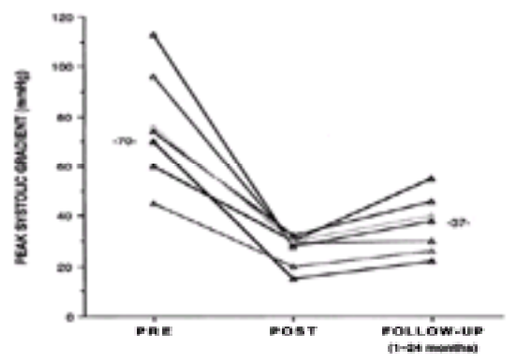
The longer-term results of aortic valve balloon dilation for congenital stenosis indicate that, as with surgery, the procedure is palliative. Several studies (15,16 and 17) have shown satisfactory gradient relief for a period of 2 to 5 years, and longer-term benefits can be expected. Shim et al. (18) noted that successful balloon aortic valvuloplasty was effective in decreasing LV mass in children with isolated aortic stenosis. In this study, the decrease in LV mass was gradual and was not statistically

significant until the second year after successful valvuloplasty.

As with surgical valvotomy, balloon dilation can only be expected to palliate patients with congenital valvular aortic stenosis (19). It is to be expected that a substantial proportion of patients experience progressive restenosis or important valve regurgitation on late follow-up after aortic valve dilation. Repeat balloon dilation is effective in most patients who experience restenosis after aortic balloon valvotomy (20), as it is with restenosis after surgical valvotomy (21).

Neonates

Neonates with critical aortic stenosis constitute a high-risk complex subgroup that deserves special mention. Newborns with critical aortic stenosis present with severe LV dysfunction and shock. Often these patients must be resuscitated with prostaglandin E_1 and inotropic support. As with older children, balloon dilation has been shown to be an effective palliative therapy in newborns with critical aortic valve stenosis (12,22,23 and 24) (*e*Fig. 87.0.2). Egito et al. (24) described the results of balloon dilation in 33 neonates ranging in age from 1 to 33 days. Twenty-seven of these newborns had LV dysfunction, and most were receiving prostaglandin E_1 infusions and were intubated. The procedure was performed from the umbilical artery in 11, from the femoral artery in 20, and antegrade across a patent foramen ovale (PFO) in two children. A second valve procedure was required in 12 children during the follow-up period, underscoring the palliative nature of this procedure in newborns. Mosca et al. (25) compared the results of neonatal balloon dilation with those of surgical valvotomy for critical aortic stenosis and found no significant difference between the procedures in the degree of gradient reduction, aortic regurgitation, or patient survival.



***e*FIGURE 87.0.2** Peak systolic aortic valve gradient in seven newborn infants with critical aortic valve stenosis. Measurements are made immediately before (PRE), immediately after (POST), and at 1 to 24 months after transumbilical aortic valve dilation. In these patients the peak systolic gradient was reduced from 70 to 37 mm Hg at follow-up.

Complications

Beyond the newborn period, balloon aortic valvotomy is a relatively safe procedure. Immediate postoperative complications that have been reported include aortic valve regurgitation, iliofemoral artery injury, hemorrhage, ventricular rrhythmia, endocarditis, valve leaflet or ventricular perforation, injury to the anterior mitral leaflet, and death. Death has been exceedingly uncommon after elective balloon dilation in childhood. The complications of greatest concern have been valve regurgitation and arterial injury. In the Valvuloplasty and Angioplasty of Congenital Anomalies Registry (11), aortic regurgitation reportedly occurred in only 10% of the children studied. More recent experience (15) suggests that balloon dilation produces new aortic insufficiency in 25% to 30% of patients, in most of whom it is mild. Severe aortic insufficiency is detected in approximately 5% to 6% of patients after the procedure. The occurrence of aortic insufficiency may relate to a balloon-annulus ratio that exceeds 1.0 (11) or to valve morphology (7).

Injury to the iliofemoral artery most frequently occurs in infants younger than 12 months. For this reason, the authors advocate use of the transumbilical route whenever possible for balloon dilation in newborns with critical aortic stenosis (12). Infants are at particular risk for iliofemoral artery injury because of the relatively large profile of the balloon catheters required in transfemoral arterial procedures. Although important clinical consequences of such vascular injury appear to be uncommon, subsequent transarterial procedures may be difficult or impossible to perform. Development in the future of lower profile valvuloplasty balloon catheters may well help to alleviate this problem.

Complications are substantially more frequent and more severe in neonates. The mortality in newborns with critical aortic stenosis is high and ranges from 10% to 20% after balloon dilation in this patient population (24,25). Other important complications in the newborn include LV perforation with the wire or catheter, aortic valve leaflet perforation and subsequent dilation producing severe valvular insufficiency, arrhythmia, hemorrhage, sepsis, and endocarditis. To avoid perforating the valve, retrograde entrance into the LV must be performed with a soft wire; perforation of a leaflet may be recognized if the wire does not pass freely through the subvalvular area and into the LV apex. To avoid sepsis or endocarditis, vancomycin should be administered for all transumbilical dilation procedures.

BALLOON DILATION OF CONGENITAL PULMONARY VALVE STENOSIS

Historical Perspective

Balloon valvotomy was first performed for pulmonary stenosis. The rationale for this technique was provided by early surgical experience that demonstrated the efficacy of transventricular dilation of stenotic pulmonary valves. In 1979 Semb et al. (26) reported a dynamic technique in which a gas-filled balloon was withdrawn across a stenotic pulmonary valve. In 1992, Kan et al. (2) reported the first static balloon dilation in children with pulmonary valve stenosis; this technique is still used today. After these early reports, many institutions confirmed the safety and efficacy of percutaneous balloon dilation for pulmonary valve stenosis. The technique can be expected to reduce the peak systolic valve gradient to approximately 20 to 30 mm Hg, which represents mild clinically insignificant pulmonary stenosis. With the exception of neonates, pulmonary valve dilation is associated with few complications. The procedure has clearly replaced surgical valvotomy as the treatment of choice in congenital pulmonary valve stenosis (27,28,29,30,31 and 32).

Indications and Contraindications

Balloon dilation effectively treats typical, congenital valvular pulmonary stenosis. Indications for such therapy at our institution include (a) a peak systolic gradient greater than or equal to 35 mm Hg; and (b) critical pulmonary valve stenosis in an infant regardless of gradient (pressure gradient may be diminished by right-to-left atrial shunt, a patent ductus, or both).

The only contraindication to this procedure in a child with valvar pulmonary stenosis is the presence of mild asymptomatic stenosis having a peak systolic gradient less than 35 mm Hg. Conditions under which balloon dilation often fails to provide definitive therapy, and which therefore may be considered relative contraindications, include (a) a dysplastic pulmonary valve (e.g., in Noonan's syndrome); and (b) a hypoplastic pulmonary valve annulus (less than 7 mm in newborns).

It should be noted, however, that children with these two relative contraindications may derive significant palliation from balloon dilation despite a dysplastic or hypoplastic valve.

Technique

Percutaneous balloon pulmonary valvotomy can be performed using a relatively straightforward technique. Once baseline hemodynamics and valve annulus diameter are measured, an end-hole catheter is advanced across the valve and positioned in the left pulmonary artery. Using an exchange length wire, the catheter is then exchanged for a balloon dilation catheter of appropriate size (i.e., a balloon with a diameter that is approximately 25% to 30% wider than that of the valve annulus). A double-balloon technique is used in patients whose annulus diameter is greater than 15 to 18 mm. The balloon(s) are inflated and deflated rapidly by hand, with careful attention to ensure that the waist created by the stenotic valve occurs in the midportion of the balloon. After one to four inflations, the deflated balloons are withdrawn and repeat hemodynamics are measured. An RV angiogram may be obtained after dilation to document the site of any residual stenosis (particularly dynamic infundibular stenosis) and to assess any possible resultant increase in tricuspid valve regurgitation (rare).

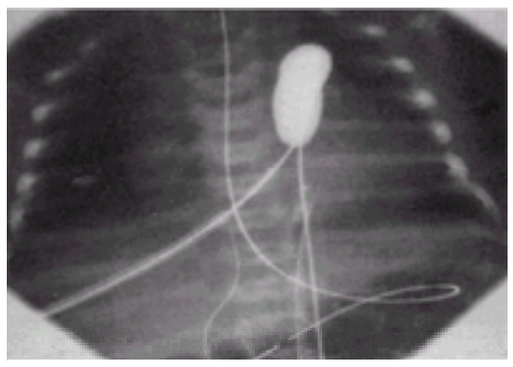
Acute and Long-Term Results

The immediate and long-term effectiveness of balloon dilation for congenital pulmonary valve stenosis has been documented by many institutions (27,28,29,30,31,32,33,34 and 35). The procedure generally decreases the systolic gradient to levels consistent with mild stenosis. An oversized balloon (i.e., one that is approximately 25% to 30% wider than the annulus diameter) is required for optimal dilation outcome (33). In some patients, an important element of the residual gradient is due to a transient dynamic subvalvar (infundibular) stenosis. The data indicate that balloon dilation is less effective in patients with dysplasia of the pulmonary valve, with or without Noonan's syndrome.

Thus far, longer-term results have been excellent (32,34,35). A report of late results (4 to 5 years) after balloon dilation in children with congenital pulmonary stenosis compared with those in a matched control group of children who had undergone surgical pulmonary valvotomy was encouraging (35). Noninvasive evaluation at follow-up documented excellent gradient relief in both groups. The Doppler peak instantaneous gradient at follow-up was 24.0 ± 2.7 mm Hg in the balloon dilation group compared with 16.0 ± 2.0 mm Hg in the surgical valvotomy group. At late follow-up, children who had undergone balloon dilation had no or only mild pulmonary valve insufficiency. In contrast, the surgical control group had substantially more valve insufficiency. The increase in ventricular arrhythmias at follow-up may relate to the greater prevalence and severity of pulmonary valve insufficiency and RV volume overload in the surgical group, although the duration of follow-up was also longer in these children. These data support the currently and generally accepted practice of using balloon dilation as the therapy of choice in children with pulmonary valve stenosis.

Neonates

Balloon dilation in neonates with critical pulmonary valve stenosis represents a special, more complex, and higher-risk subgroup. In most centers percutaneous transcatheter therapy has become the preferred mode of treatment for these children; however, it requires substantially more technical expertise in neonates than in older children (36,37,38,39 and 40). Newborns with critical pulmonary stenosis typically present with cyanosis (due to a right-to-left atrial shunt) and require prostaglandin E_1 infusion for medical palliation. A PDA is clearly advantageous during the dilation procedure. An open ductus arteriosus not only provides a reliable source of pulmonary blood flow during balloon inflation, but also provides a stable wire course (RV to pulmonary artery to ductus to descending aorta), which facilitates catheter exchanges (eFig. 87.0.3). The effectiveness of balloon dilation is related to right-sided heart anatomy, specifically the diameters of the pulmonary and tricuspid valves and the RV volume. In infants with an adequate right heart (i.e., with a tricuspid valve greater than 11 mm, a pulmonary valve annulus greater than 7 mm, and an RV volume greater than 30 mL per m^2), balloon dilation provides definitive long-term therapy (39). In infants with more hypoplastic right-sided heart structures, balloon dilation does not usually provide sufficient long-term therapy; in these children an early aortopulmonary shunt or an RV outflow tract patch may be required.



***e*FIGURE 87.0.3** Transhepatic balloon dilation of critical pulmonary valve stenosis in a newborn. The guidewire has been advanced down the ductus and is positioned in the descending aorta. There was no residual gradient measured immediately after the dilation procedure.

Complications

Outside of the newborn period, percutaneous balloon dilation for congenital pulmonary valve stenosis is quite safe (31). Complications, especially in newborns, include perforation of the RV outflow tract while attempting to cross a severely stenotic valve, important systemic hypotension during balloon inflation (in children without intracardiac shunting), arrhythmias, and pulmonary valve insufficiency. Pulmonary valve insufficiency is generally well tolerated, although severe valve insufficiency may be problematic in infants, particularly those who also have tricuspid insufficiency, who subsequently require an aortopulmonary shunt.

BALLOON DILATION FOR CONGENITAL MITRAL STENOSIS

Historical Perspective

Congenital mitral stenosis is a rare congenital heart lesion constituting less than 2% of autopsy-delineated congenital cardiac defects. Worldwide, most cases of mitral stenosis are still acquired as a result of rheumatic heart disease. Initial attempts at percutaneous mitral valvuloplasty were made by Reifart et al. and Inoue et al. in 1984 and 1985 in adult rheumatic heart disease (41,42,43 and 44). In 1985, Lock et al. (45) reported use of this technology in children with rheumatic mitral stenosis. Subsequently, there have been increasing numbers of single center reports in the pediatric literature (46,47).

Access to the mitral valve is secured by a transseptal approach after balloon dilation of the atrial septal perforation using an 8- to 10-mm angioplasty balloon. If large

12- to 14-Fr sheaths are used, no septal dilation is recommended. Grifka et al. (48) have shown that double-balloon or double-transseptal techniques result in no significant atrial shunts and fewer vascular problems in younger patients. A more secure wire position is initially achieved in children by passage of the exchange wire antegrade through the aortic valve into the descending aorta, which differs from the technique in adults. Some investigators (49) have described snaring of the exchange wire from the femoral artery and passage of the dilation balloons in a retrograde fashion. Once the dilation catheters are securely across the stenotic mitral valve, the guidewires are retracted into the LV apex and the balloons are inflated for 10 to 15 seconds.

Indications and Contraindications

As in older patients, symptoms of dyspnea, heart failure, pulmonary artery hypertension, or failure to thrive are indications for intervention. The patient's body size and requirements for large introducer sheaths may limit transcatheter intervention in children. The presence of valve calcifications may also limit the effectiveness of this procedure in some patients. Leaflet calcifications have proven to be a major hindrance to success in the adult population (50). Valve morphology also affects the outcome of balloon dilation therapy. Significant short-term restenosis and poor short-term gradient reduction are common in infants with asymmetric papillary muscles or a hypoplastic mitral valve annulus. A parachute mitral valve is not amenable to balloon dilation.

Acute and Long-Term Results

Early reports revealed 40% to 50% long-term success after the procedure in children (45,48,50,51). More recent single-center studies have demonstrated acute procedural success in more than 90% of patients (47) with long-term follow-up to greater than 4 years. This compares with data after surgical valvotomy, which provides 70% survival, 71% freedom from further surgeries, and 6% freedom from mitral valve replacement (52,53 and 54). Obviously, outcome data are affected by patient selection because valve morphology is such an important variable.

Complications

Balloon mitral valvuloplasty is relatively safe in the majority of children. Unlike adults, there are few instances of postdilation hemoptysis, pulmonary edema, or thromboembolic events reported in children. The incidence of acute severe mitral insufficiency due to torn or flail mitral leaflets varies from 3.3% to 6.3% in different series (46,47). Arrhythmias, particularly second- and third-degree atrioventricular block, have been reported in as many as 20% of children after mitral balloon dilation. Pericardial effusions from ventricular perforations and transient ischemic attacks have also been reported to occur rarely in children.

BALLOON DILATION FOR PULMONARY ARTERY STENOSIS

Historical Perspective

Isolated peripheral pulmonary artery stenosis represents 2% to 3% of congenital heart lesions, but has a high (20% to 40%) association with other forms of congenital RV outflow tract obstruction (i.e., tetralogy of Fallot, with or without pulmonary atresia). Acquired peripheral pulmonary artery stenosis also frequently occurs after surgical procedures. A significant association exists between peripheral pulmonary artery stenosis and maternal rubella syndrome, Williams syndrome, and Alagille syndrome, with a reported prevalence of 50% to 90% of these children. The initial report demonstrating the utility of balloon angioplasty in this condition appeared in 1980 (55), and data were reported from an experimental model of peripheral pulmonary artery stenosis by Lock et al. in 1981 (56). Transcatheter therapy for pulmonary artery stenosis plays an important role in staged therapy for many children with complex congenital heart disease.

HEART SOUNDS

Audio 87.6 Tetralogy of Fallot. Auscultation performed in a 25-year-old male with newly diagnosed tetralogy of Fallot. Note the mid-systolic ejection murmur probably related to right ventricular outflow tract obstruction. Left lower sternal border. Indications and Contraindications

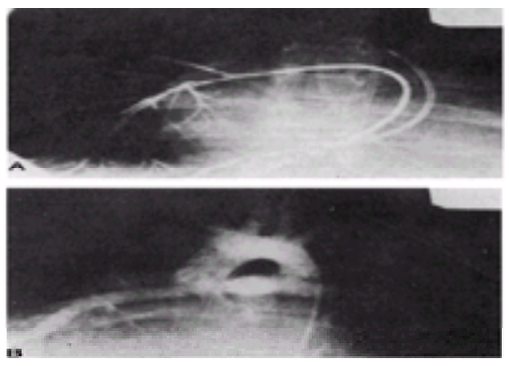
Isolated balloon angioplasty without concomitant endovascular stent implantation is primarily used in the very young child or in individual patients in whom stent implantation may be technically challenging. Clinical indications for intervention include (a) evidence of RV strain or hypertrophy, (b) RV failure, or (c) significant RV systolic hypertension of greater than 60% of systemic systolic pressure. In addition, because of the value of nuclear perfusion scanning in defining flow disturbances due to obstruction, evidence of significantly diminished perfusion to one lung has been used as an additional indication.

Acute and Long-Term Results

There have been numerous reports (57,58,59,60,61,62 and 63) of the acute and long-term results after balloon angioplasty. Although technical success (e.g., increased vessel diameter greater than 75%, decreased systolic pressure gradient and RV systolic pressure less than 50% systemic, increase of greater than 25% in pulmonary blood flow, increased ipsilateral lung perfusion) has been reported in more than one-half of patients (eFig. 87.0.4), sustained improvement beyond 6 months is less common. Syndromic patients (Williams or Alagille) tend to have the poorest outcomes after balloon angioplasty, probably as a result of significant vessel elastic recoil. In light of these mediocre results, Gentles et al. (64) have recommended using higher-pressure balloons (i.e., maximal inflation pressure of 17 to 20 atm). Nevertheless, because of intrinsic vessel elasticity, endovascular stenting is preferred to balloon angioplasty alone in many patients (65).



***e*FIGURE 87.0.4** Shown here are selective pulmonary angiograms before successful balloon angioplasty **(A)** and after successful balloon angioplasty **(B)**. There is marked improvement in the right pulmonary artery diameter. A patency of the ductus arteriosus is shown **(B)** with left-to-right shunting. (From Beekman RH, Rocchini AP, Rosenthal A. Therapeutic cardiac catheterization for pulmonary valve and pulmonary artery stenosis. *Cardiol Clin* 1989;7:331, with permission.)

Complications

Angioplasty of peripheral pulmonary artery stenosis is accompanied by relatively high morbidity (5% to 16%) and mortality (3.0% to 4.5%) compared with other transcatheter procedures for congenital heart disease. Major complications include wire perforation of the distal pulmonary artery, vessel tear by the dilation itself, need for surgical repair, and, rarely, death. Significant aneurysm formation of the dilated vessel occurs in 0.5% to 5.0% of patients, although smaller aneurysms have reportedly been detected by intravascular ultrasound in greater than 80% of patients undergoing the procedure (66). Segmental pulmonary edema distal to the dilated segment occurs in 0.5% to 3.0% of patients (67).

BALLOON DILATION: COARCTATION OF THE AORTA

Historical Perspective

Surgical therapy for coarctation of the aorta was first described in 1945 by Gross and Hufnagel (68) and by Crafoord and Nylin (69). The multitude of surgical and transcatheter therapies that have subsequently been reported for coarctation suggests that the optimal form of treatment is not yet clearly identified. Nevertheless, currently balloon angioplasty is widely regarded as the treatment of choice for discrete recurrent coarctation that develops late after surgical repair. In contrast, the role of angioplasty in the treatment of native (unoperated) aortic coarctation remains controversial. Early *ex vivo* human and *in vivo* animal experiments (70,71 and 72) revealed 1-to 3-mm intimal tears with variable but nontransmedial extension into the media that healed within 8 weeks and no significant aneurysm formation.

Left ventricular hypertrophy is also present. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

The technical approaches to balloon angioplasty of coarctation vary. Aortography is performed to visualize the coarctation and to obtain measurements for selecting the appropriate balloon catheter. Most cardiologists use a standardized aortic measurement (i.e., the aortic isthmus diameter above the coarctation, approximately three times the coarctation diameter itself, or the descending aortic diameter at the level of the diaphragm) to determine balloon size. There are no data to support that using any one method of choosing balloon size is better than another. Most agree, however, that the balloon diameter should not exceed by more than 1 to 2 mm the aortic diameter at the diaphragm. Pressure measurements and aortography are obtained after angioplasty to evaluate residual systolic gradients and to visualize acute intimal dissections or early aneurysm formation. Importantly, postangioplasty manipulation across the coarctation region with unguided wires or catheters must be avoided to prevent vessel perforation. Early data (73,74 and 75) suggest that stent implantation may avoid the early aortic recoil that is noted relatively often after naked balloon angioplasty.

Indications and Contraindications

Indications for intervention include an anatomically discrete stenosis in association with a resting systolic pressure gradient of greater than or equal to 20 mm Hg. Some consider intervention for smaller resting gradients if they are associated with significant upper extremity hypertension at rest or with exercise. Tubular nondiscrete coarctations are not as amenable to balloon angioplasty alone (78) as more discrete lesions (although stenting may offer promise in these more complex lesions). Balloon angioplasty of native coarctations in the neonate or young infant is almost invariably complicated by early restenosis, and therefore most centers do not perform angioplasty in this age group.

Acute and Long-Term Results

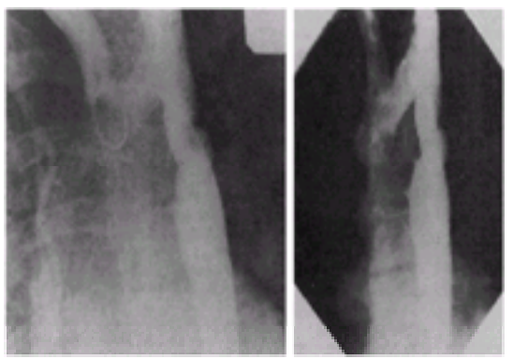
Many centers have reported their short-term results after balloon angioplasty for native coarctation (76,77,78,79,80 and 81). In the majority of patients, the resting gradient is reduced to less than 20 mm Hg. Early studies that compared older patients with younger patients demonstrated similar acute results in neonates and infants, but significantly worse long-term results in these younger children (82,83,84,85 and 86). Complete relief of hypertension (i.e., blood pressure less than 140/90 mm Hg, no requirement for medications) has been reported in approximately 40% of older children (78); however, in the adult population, the need for antihypertensive medications postprocedure remains significant (76). Interventions performed at younger age (younger than 1 year) may reduce late-onset systemic hypertension (87). More recent studies (88) have demonstrated an inverse relationship between procedural success and higher predilation and postdilation gradients, degree of transverse arch hypoplasia, or both, whereas a direct relationship exists between insufficient tearing of the intima and media and procedural failure. The incidence of late aneurysm formation at the dilation site is 5% to 10% in patients with a native coarctation, similar to that reported in patients with recurrent postoperative coarctation.

Good clinical results have been reported in more than 300 patients with recurrent aortic coarctation (89,90,91,92,93,94 and 95). More recent studies of balloon angioplasty in postsurgical recoarctation reveal an equivalent 16% restenosis rate between younger and older patients at mean 56-month follow-up (96). The incidence of aneurysm formation postangioplasty in the patient with recurrent coarctation is 5% to 10%. As with patients with native coarctations, long-term success of this procedure may be related to arch anatomy and balloon size. Anjos et al. (93) observed that if the ratio of aortic isthmus diameter to diaphragmatic aortic diameter was less than 0.8, 80% of patients had a poor result at follow-up, whereas if the ratio was greater than 0.9, 81% had sustained improvement. The type of previous surgical repair, age at surgery, and predilation systolic pressure gradients did not affect long-term outcomes.

Complications

Aneurysms

The reported incidence of late aneurysm formation after coarctation angioplasty varies from 4.5% to 13.4% (82,85) (*e*Fig. 87.0.5). It is postulated that aneurysms develop after the creation of intimal and transmedial tears in an intrinsically abnormal aortic wall. Isner et al. (97) demonstrated cystic medial necrosis of varying degrees in 80% of excised human coarctation specimens. Similar problems of aneurysm formation, spontaneous aortic dissection, and rupture have been reported in 17% to 23% of untreated patients with aortic coarctation (98,99). Postangioplasty aneurysms appear to be less common in infants and younger children than in older adolescents and young adults. More follow-up data are needed to better define the risk for aortic aneurysms after coarctation angioplasty.



***e*FIGURE 87.0.5** In this figure, spot cineangiograms are shown 2 years **(left)** and 8 years **(right)** after coarctation balloon angioplasty. The small, saccular aneurysm at the coarctation site remains stable in size and configuration at long-term follow-up. (From Mendelsohn AM, Lloyd TR, Crowley DC, et al. Late follow-up of balloon angioplasty in children with a native coarctation of the aorta. *Am J Cardiol* 1994;74:696, with permission.)

Restenosis

In contrast to aortic aneurysms, restenosis or recurrent coarctation after balloon angioplasty appears to be much more common in younger patients (*e*Fig. 87.0.6). In neonates and infants, 12-month follow-up restenosis rates vary from 30% to 70% (83,84), whereas restenosis occurs in only 7% to 11% of older patients (84,85 and 86). If additional intervention is required, standard surgical techniques or repeat balloon angioplasty (and possibly stenting) generally yield excellent results.

***e*FIGURE 87.0.6 A:** Serial spot cineangiograms are shown from a 4-month-old child before balloon angioplasty (*left*) and after balloon angioplasty (*right*). Systolic gradient balloon angioplasty decreases from 54 to 8 mm Hg. **B:** Within 9 months there was angiographic evidence of recurrent coarctation (*left*). Coarctation was retreated successfully with angioplasty (*right*), and systolic gradient decreased from 45 to 15 mm Hg. (From Mendelsohn AM, Lloyd TR, Crowley DC, et al. Late follow-up of balloon angioplasty in children with a native coarctation of the aorta. *Am J Cardiol* 1994;74:696, with permission.)

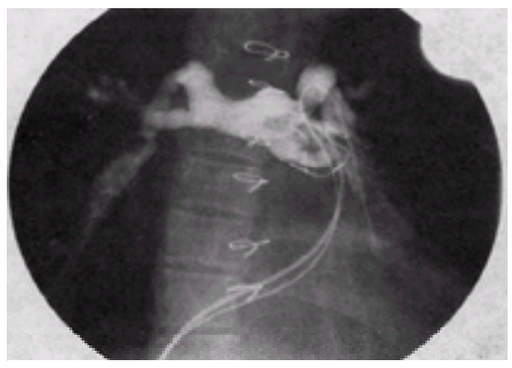
Paradoxical Hypertension

Episodes of paradoxical hypertension occur rarely after balloon angioplasty (100) and less frequently in patients after angioplasty than in patients after surgical repair (101,102). This may potentially be due to lower serum renin and catecholamine levels in the postangioplasty patients, disruption of the afferent thoracic sympathetic fibers with surgical coarctectomy, or both (101).

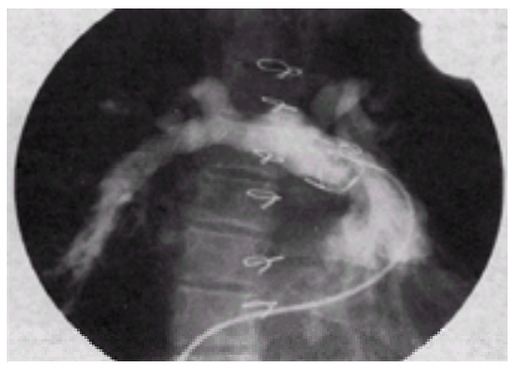
ENDOVASCULAR STENTS IN CONGENITAL HEART DISEASE

Historical Perspective

Balloon expandable stents have rapidly assumed an important role in interventional pediatric cardiology. For patients with congenital or acquired vascular stenosis, balloon angioplasty alone or surgery often fail to provide adequate relief of obstruction. By providing an endovascular buttress to maintain vessel patency, balloon expandable stents have radically improved the treatment options for children with these lesions. Stenting is particularly useful in pulmonary artery stenosis or hypoplasia occurring as an isolated lesion, in tetralogy of Fallot, or pulmonary atresia and ventricular septal defect, often after initial palliative surgical procedures (*e*Fig. 87.0.7 and *e*Fig. 87.0.8). Stenting has also proven valuable in patients with systemic venous obstructions such as superior vena cava stenosis or systemic venous baffle obstruction after the Mustard procedure. Data have appeared indicating that stenting is also an effective intervention for selected patients with coarctation of the aorta.



***e*FIGURE 87.0.7** A pulmonary arteriogram is shown from a 13-year-old girl with pulmonary atresia and ventricular septal defect demonstrating severe right pulmonary stenosis.



***e*FIGURE 87.0.8** A Palmaz P308 stent has been implanted in the lower right pulmonary artery, effectively relieving all obstruction at that level. The patient subsequently underwent successful surgical ventricular septal defect closure.

Dotter and Judkins (103) proposed stenting in 1964 when they described an endovascular splint to maintain vascular patency. In 1969, Dotter (104) reported the first animal experiments that clearly identified the exciting potential of stent therapy. The stainless steel balloon expandable stent most commonly used in pediatric cardiology was developed by Palmaz and Schatz (105) in the mid-1980s. Investigations at several pediatric centers (106,107 and 108) using experimental animal models demonstrated the effectiveness of stents in treating pulmonary artery and systemic venous stenosis. Shortly thereafter, clinical trials (109,110,111 and 112) documented excellent short-term results with balloon expandable stents in children with these vascular stenoses. Endovascular stenting with the Palmaz stainless steel stent (Johnson & Johnson Interventional Systems, Warren, NJ) is now the treatment of choice at many centers for patients with pulmonary artery or systemic venous obstruction. More recent intermediate follow-up data (113,114) have documented the favorable effect of pulmonary artery stenting on patient management, noting that restenosis is relatively infrequent when stents are implanted in large pulmonary arteries or systemic veins (112,113,114,115 and 116), and that pulmonary artery stents can be redilated safely after a child has grown (112,116,117 and 118). Data have also demonstrated that stenting is more cost effective than balloon dilation alone in patients with pulmonary artery stenosis (119).

Indications and Contraindications

Indications for endovascular stents are rapidly evolving; however, stenting is now considered a primary therapeutic modality for many children. The size of the patient is an important consideration for several reasons. A stent implanted in a small child may well require redilation once the child has grown, and there is minimal long-term experience with stent redilation. We therefore prefer to implant a stent initially to the largest diameter appropriate for the child. Larger stents with an outside diameter of 3.4 mm must be delivered through an 8- to 10-Fr sheath; thus, percutaneous implantation in children smaller than 8 kg may be difficult. We have used the transhepatic approach in some patients to overcome limitations of traditional peripheral venous access. Intraoperative implantation of large stents may prove useful in some small children, particularly if such implantation can be incorporated into another surgical procedure (111). The indications for endovascular stents in children are (a) pulmonary artery stenosis or hypoplasia of moderate to severe degree; (b) stenotic RV to pulmonary artery conduits; (c) superior vena cava stenosis; (d) stenosis of the systemic venous baffle (superior or inferior limb) after atrial repair of transposition; (e) stenotic aortopulmonary collaterals in selected patients with tetralogy of Fallot or pulmonary atresia; and (f) recurrent postoperative coarctation, and possibly native coarctation, in patients able to safely accept 8- to 9-Fr arterial sheaths.

Contraindications to endovascular stenting include (a) a stenosis that is not balloon dilatable; (b) small patient size precluding use of a large delivery sheath (transhepatic or intraoperative delivery may be considered); and (c) pulmonary venous obstruction (pulmonary venous stenting is invariably unsuccessful).

Technique

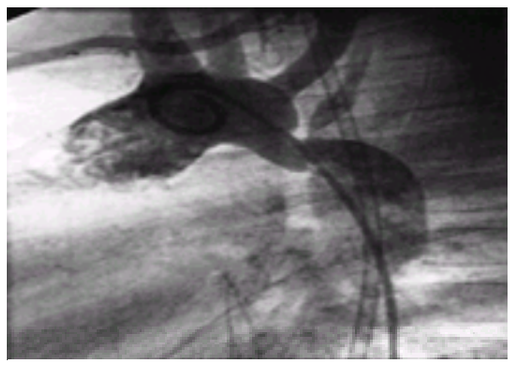
The Palmaz stainless steel balloon expandable stent is the stent most often used in congenital cardiovascular disease. Self-expanding stents limit future redilation when a child has grown and are therefore rarely used in children. The Palmaz P308 stent has a length of 30 mm and an outer diameter of 3.4 mm and can be expanded to a maximal diameter of 19 to 20 mm; it requires an 8- to 10-Fr delivery sheath. The Palmaz 204 stent has a length of 20 mm and an outside diameter of 2.4 mm, and it can be dilated to a maximum diameter of 9 to 10 mm; it requires a 6- to 7-Fr delivery sheath. Stent implantation is performed after a complete hemodynamic and angiographic evaluation. The diameter of the stenosis is carefully measured, as is the vessel proximal and distal to the stenosis to determine the stent and balloon size most appropriate for the lesion. We typically do not predilate vascular stenoses, but do predilate conduits to assess whether the stenosis is dilatable. With a 0.035- to 0.038-in. stiff exchange wire positioned across the stenosis, an appropriate delivery sheath is advanced across the area to be stented. The stent is mounted and tightly hand crimped on the balloon to ensure that the stent does not strip off within the sheath. We often use a front-loaded, or modified front-loaded, technique to minimize the need to advance the stented balloon through the delivery sheath; this is especially important with tortuous catheter and sheath courses. Once the stent is positioned within the delivery sheath at the site of stenosis, the sheath is carefully withdrawn to a point just proximal to the balloon. Contrast is injected through the side arm of the sheath or through a second catheter to document that the stent is properly positioned. The balloon is inflated using an inflation manometer, and the stent is implanted. The deflated balloon is then withdrawn through the sheath, leaving the exchange wire in place. The stent can then be dilated with a larger balloon if

necessary. Angiography is performed again to document the position of the stent, its diameter, the status of side branches that may originate through the stent, and to rule out any important vessel tear or perforation. Patients are discharged on low-dose aspirin or warfarin when stents are implanted in the venous circulation of patients with a univentricular heart (after the Glenn or Fontan procedures).

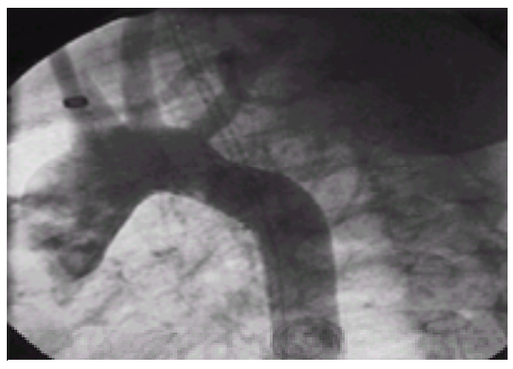
Acute and Long-Term Results

In pediatric cardiology, stenting is most often used to treat pulmonary artery stenosis or hypoplasia. Several centers (109,110,111,112,113 and 114) have reported favorable short- and intermediate-term results. Angiographic evidence of modest 1- to 2-mm neointimal ingrowth is commonly observed, but is rarely physiologically important in large vessels. Data indicate that endovascular stenting provides important intermediate-term clinical benefits to many patients with pulmonary artery stenosis. Pulmonary artery stents can be safely redilated to larger dimensions, if necessary, in growing children up to 3 years after stent implantation (112,113,117); longer-term studies of redilation are needed to document that stents can be safely enlarged more than 3 years after implantation.

Recent data suggest that stenting also provides effective treatment for coarctation of the aorta (73,74 and 75,120). In patients with postoperative recurrent coarctation (*e*Fig. 87.0.9 and *e*Fig. 87.0.10) or native unoperated coarctation, stenting generally reduces the resting gradient to less than 5 mm Hg. In addition to typical discrete coarctation, transverse arch hypoplasia may also respond favorably to stenting (121). Limited follow-up data suggest that restenosis and aneurysm formation are uncommon. However, before coarctation stenting is widely accepted as routine, longer-term follow-up data are needed regarding restenosis, aneurysm formation, safety of late stent redilation, and blood pressure response to exercise after this novel therapy.



***e*FIGURE 87.0.9** Lateral angiogram showing a moderate arch stenosis in a 7-month-old child with hypoplastic left ventricle, after a Norwood reconstruction.



***e*FIGURE 87.0.10** After implantation of a Palmaz 308 stent (through a right carotid cutdown because of the patient's small peripheral vessels). There is no residual stenosis. Same patient as in *e*Figure 87.0.9.

Complications

Complications of endovascular stenting include (a) stent embolization, (b) vessel tear or perforation, (c) in-stent thrombosis, (d) side branch compromise, (e) transient distal reperfusion injury after pulmonary artery stenting, and (f) stent fracture at redilation (112). In a multiinstitutional study, O'Laughlin et al. (112) reported one possible stent-related death after the Fontan procedure in a patient who had embolization of a preexisting right atrial clot to the stented lung. Six stents embolized or were positioned incorrectly and were removed either at surgery or through a large percutaneous sheath. Stents placed in pulmonary arteries of patients with a univentricular heart after Fontan or Glenn procedures are at increased risk for thrombosis, particularly if postoperative events such as atelectasis diminish pulmonary arterial flow to the ipsilateral lung. To avoid these complications, aggressive anticoagulation is advocated in such patients for a minimum of 6 months after stent implantation.

PERCUTANEOUS COIL EMBOLIZATION OF PATENT DUCTUS ARTERIOSUS

Historical Perspective

PDA is a relatively common condition that, with the exception of newborns, is usually treated electively. For decades pediatric cardiologists have pursued a method for nonsurgical closure (122,123,124,125,126,127 and 128). It was not until 1992, however, that the technique of percutaneous coil embolization of the PDA was first reported (129). Coil occlusion of the PDA has rapidly become the treatment of choice in many institutions for small to moderate restrictive PDA (130,131,132,133,134,135,136 and 137).

The Gianturco coil (Cook Incorporated, Bloomington, IN) is the most frequently used embolization device for closing PDA. This coil is made of a stainless steel wire with Dacron strands to promote thrombus formation (138,139). Vascular occlusion occurs after coil implantation as the result of thrombus formation and subsequent organization (140). The Gianturco coil has been used since the 1970s for transcatheter occlusion of a variety of arterial vessels and venous channels. Percutaneous coil embolization with the Gianturco coil is widely regarded as safe and effective transcatheter therapy for PDA. There have been several modifications to the Gianturco coil, which may make them more suitable for PDA coil occlusion. These modifications include the shape of the coil (e.g., Tornado coil), which allows itself to more readily conform to the shape of the PDA, and ampulla, which may decrease the likelihood of residual shunting. Also, detachable coils have made coil occlusion technically easier with less chance of embolization. However, all these modifications increase the cost of the coil, and for the small (less than 2.5 mm) PDA, standard Gianturco coil embolization remains the procedure of choice.

Indications and Contraindications

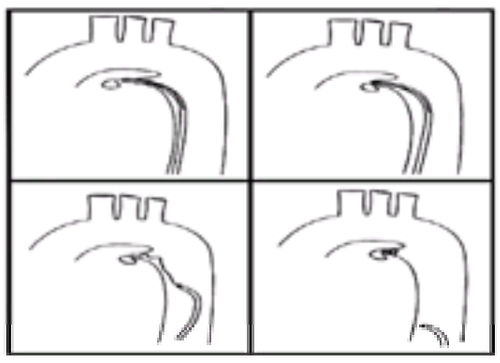
Percutaneous coil embolization provides effective nonsurgical treatment for the restrictive PDA. Here, the clinical objective usually is to diminish the long-term risk for infective endarteritis, and much less frequently, to treat the physiologic consequences of a significant left-to-right shunt. In our program, the most common indication for this procedure is a restrictive PDA with a minimal angiographic diameter of less than 4 mm.

Conditions that are currently considered to be contraindications to coil occlusion include (a) a large nonrestrictive PDA (e.g., a PDA in a neonate); (b) pulmonary vascular obstructive disease with a right-to-left ductus shunt; and (c) associated heart disease requiring surgical intervention.

Technique

Occlusion coils can be delivered to a PDA either retrogradely using a transarterial approach or antegradely from the venous circulation. The transarterial approach is preferred, because it requires only a single catheter for coil delivery and angiography. A 4- to 5-Fr pigtail catheter is introduced percutaneously through an arterial sheath, and the patient is given heparin (100 U per kg; maximum dose, 3,000 U). The pigtail catheter is then used to obtain complete left-sided heart hemodynamics.

An aortic angiogram is filmed in the anteroposterior and lateral projections, and the minimum ductus diameter is measured from the lateral image. A Gianturco coil with a helical diameter two to three times that of the minimum angiographic ductus diameter is used. The length of the coil must be sufficient to allow three or four loops of coil to form on implantation (two or three loops in the aortic ampulla). We prefer to use a 0.038-in. Gianturco coil. Using a 4- to 5-Fr Judkins right coronary catheter (a Bernstein catheter is also frequently used), the ductus is crossed in a retrograde fashion. Pulmonary artery pressure is then measured and a blood sample is obtained to measure oxygen saturation. The Gianturco coil is then advanced to the tip of the delivery catheter and approximately two-thirds of one complete loop is extruded in the main pulmonary artery (eFig. 87.0.11). The catheter-coil unit is then withdrawn until the distal coil engages the narrowest portion of the ductus. The pushing wire is then held steady so as not to push more coil into the pulmonary artery while the delivery catheter is withdrawn off the intraaortic portion of the coil. When the coil is released from the catheter its intrinsic elasticity causes it to seat within the aortic ampulla. A repeat aortogram is then filmed 10 to 15 minutes after coil delivery to document the degree of occlusion (eFig. 87.0.12 and eFig. 87.0.13). If more than a trivial shunt persists, a second, usually smaller, coil is implanted. We have not found it necessary to enter the right side of the heart unless there is significant associated intracardiac disease or the coil has to be retrieved. Patients are discharged after 4 to 6 hours of observation.



***e*FIGURE 87.0.11** Schematic illustration of the transarterial method for patent ductus arteriosus coil occlusion. This technique differs from the method used to occlude aortopulmonary collaterals. Approximately three-fourths of one coil loop is advanced into the pulmonary artery. The delivery catheter is then withdrawn into the aorta, releasing two or three coil loops in the ductus ampulla. (From Hijazi ZM, Lloyd TR, Beekman RH, et al. Transcatheter closure with single or multiple Gianturco coils of patent ductus arteriosus in infants weighing < or = 8 kg: retrograde versus antegrade approach. *Am Heart J* 1996;132:827, with permission.)

***e*FIGURE 87.0.12** This figure shows a lateral aortogram demonstrating a small conical patent ductus arteriosus.

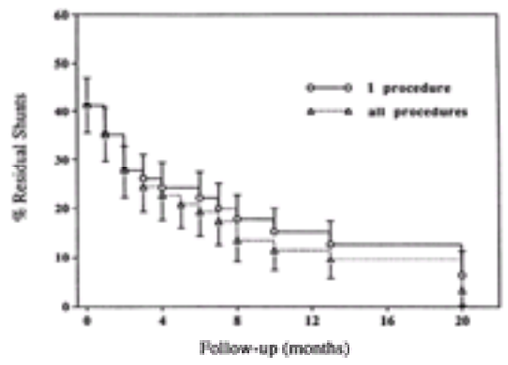
***e*FIGURE 87.0.13** In this figure, there is no residual shunt noted on angiography immediately after percutaneous coil occlusion.

A number of modified PDA coil occlusion techniques have been described. Some investigators have delivered coils antegradely from the venous circulation; however, this usually also requires an arterial line to perform arteriography after occlusion. Using a wire snare to hold the pulmonary artery end of the coil during transarterial delivery has proved helpful in some centers (133) to diminish the incidence of coil embolization to the pulmonary artery. Besides the Gianturco stainless steel coil, other coils have also been used, including platinum microcoils for a tiny ductus and, more recently, detachable coils that may decrease the risk for extraductal coil embolization.

Acute and Long-Term Results

Acute and intermediate-term results of coil embolization for small to moderate PDAs have proved to be excellent (141,142). The PDA Coil Registry (141) has reported the results of its first 535 procedures performed in 38 cardiology centers. Complete early occlusion was shown to be significantly related to ductus diameter. In those patients with complete and immediate occlusion, the minimum ductus diameter was 1.9 mm, compared with 2.4 and 2.9 mm in patients who experienced partial occlusion or in whom coil implantation failed, respectively. The data also indicated that failure to successfully implant a coil was significantly more frequent in patients with a short angiographic type B ductus. A more recent study (142) has also shown that percutaneous coil retrograde or antegrade occlusion may well prove successful in a high proportion of infants weighing less than 8 kg.

There are few longer term follow-up data available for coil occlusion of the PDA. The available data indicate, however, that intermediate-term effectiveness of this technique is excellent and that complications are few. In a series of 75 patients (136), the prevalence of residual shunts was high (41%) immediately after percutaneous coil embolization, a manifestation of ignoring small residual shunts early on. Follow-up Doppler-echocardiography documented a high incidence of spontaneous closure of these small residual shunts. Actuarial analysis estimated that the prevalence of residual shunts at 20 months after a single coil procedure was 6% (eFig. 87.0.14). When analysis included five patients who had undergone a second coil procedure for residual shunting, the prevalence of residual shunting dropped to 3% at 20 months. The relationship of ductus diameter to outcome was similar to that reported by the PDA Coil Registry (141). The minimal angiographic diameter was 1.2 mm in those patients with immediate and complete occlusion after a single coil implantation, 1.9 mm in patients who had a small residual shunt that closed spontaneously during follow-up, and 2.5 mm in patients who required two coils for immediate and complete occlusion of the ductus.



***e*FIGURE 87.0.14** A Kaplan-Meier analysis demonstrates the relationship between proportion of patients with residual ductal shunting and duration of follow-up in months. After single-coil procedures, the actuarial estimate of the prevalence of residual shunt is 15% at 10 months and 6% at 20 months of follow-up. These data document the high incidence of spontaneous closure of small residual shunts after coil occlusion of patent ductus arteriosus. (From Shim D, Fedderly RT, Beekman RH, et al. Follow-up of coil occlusion of patent ductus arteriosus. *J Am Coll Cardiol* 1996;28:207, with permission.)

Complications

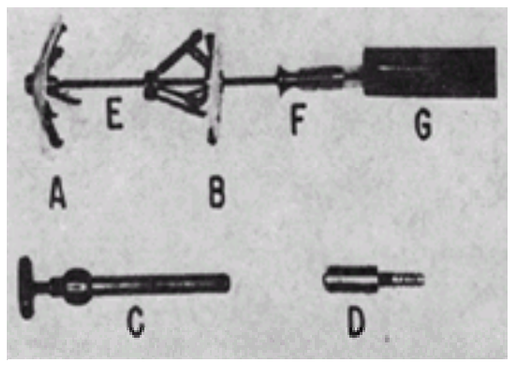
The most common complications reported with coil embolization for a PDA are failure to successfully implant the coil and extraductal coil embolization. The PDA Coil Registry currently contains data regarding 817 PDA coil occlusion procedures in 800 patients from 46 institutions. In 5% of patients, a coil could not be implanted in the ductus because of technical or patient-related issues (e.g., patients with a ductus that was too large). In another 11%, a coil embolized to an extraductal vascular structure, most frequently a distal pulmonary artery branch. Ninety-five coils embolized to a distal pulmonary artery in 75 patients. Seventy-five coils were percutaneously retrieved, but 20 were left in the pulmonary artery without evident clinical complications. One coil was left in a small splenic artery branch, and no clinical consequence was reported. Other complications occurred in 29 patients and were regarded as general complications of cardiac catheterization procedures. A femoral hematoma was reported in 2.0% of patients, fever in 0.5%, oversedation in 0.4%, and drug allergy in 0.4%, and transfusions were required in 0.2% of patients. There were no deaths attributable to coil occlusion. Significant hemolysis relating to residual shunting across a PDA has also been reported after coil implantation (143). Because a portion of the coil is positioned in the proximal left pulmonary artery, some investigators have expressed concern as to whether pulmonary artery stenosis may develop after this procedure; however, preliminary studies suggest that this is not the case (144).

Radiation exposure associated with coil occlusion of PDA has been shown to be comparable with those undergoing standard diagnostic catheterization and pulmonary balloon valvuloplasty (145). Total fluoroscopy time was 10.1 ± 1.8 minutes in patients receiving coil occlusion of their PDA. This was also comparable with the patients receiving diagnostic catheterization and was significantly less than patients undergoing pulmonary balloon valvuloplasty.

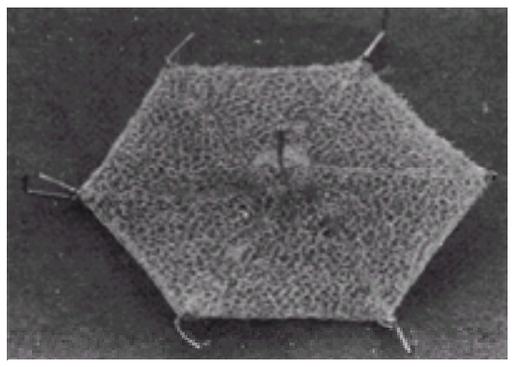
TRANSCATHETER CLOSURE OF ATRIAL SEPTAL DEFECTS

Historical Perspective

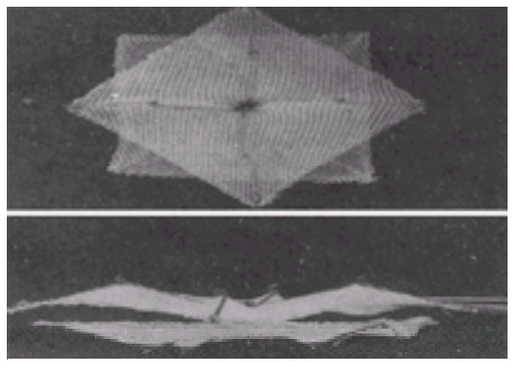
Surgical repair (146) is the conventional method for closing the secundum ASD, but this is about to change. Over the past 20 years, design improvements have led to significant progress in the transcatheter approach to ASDs. Initial attempts at device closure of ASDs were first reported in 1959 by Hufnagel and Gillespie (147), who implanted plastic buttons in ASDs at the time of thoracotomy. In 1974, King and Mills (148) created the first ASD occlusion device suitable for transcatheter implantation (*e*Fig. 87.0.15). This was closely followed by the single-disk Rashkind ASD occlusion device (*e*Fig. 87.0.16) (149,150). The Clamshell occluder (now CardioSEAL) has been under evaluation since 1989 (*e*Fig. 87.0.17) (151,152 and 153). The Sideris buttoned device is now in its fourth generation (*e*Fig. 87.0.18) (154,155 and 156). Unlike the previous devices described, this device is manufactured as two separate components that are physically connected (or buttoned together) during cardiac catheterization. The Das Angel Wings device was introduced into clinical trials in 1993 (*e*Fig. 87.0.19) (157,158 and 159). Most recently, promising experience with the Amplatzer Septal Occluder device have been reported (*e*Fig. 87.0.20) (160,161 and 162).



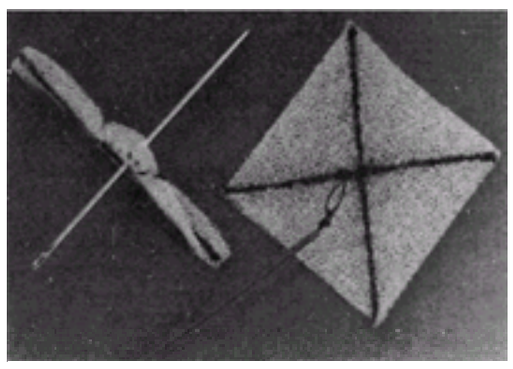
***e*FIGURE 87.0.15** King and Mills device. Teflon-coated, stainless steel skeleton composed of two interlocking disks with central connecting pin on which a Dacron patch was mounted. (From King TD, Mills NL. Nonoperative closure of atrial septal defects. *Surgery* 1974;75:383, with permission.)



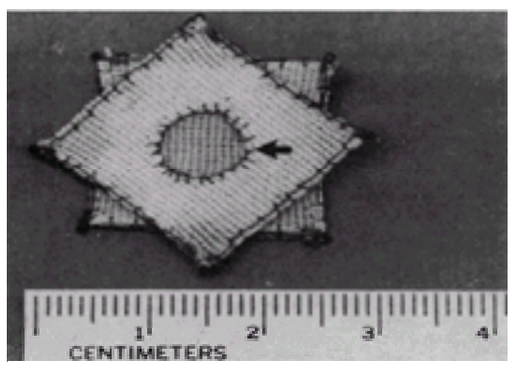
***e*FIGURE 87.0.16** Rashkind occlusion device. A single disk of polyurethane foam mounted on a stainless steel skeleton. The hooks are designed to appose firmly to left atrial septal surface. (From Rashkind WJ. Interventional cardiac catheterization in congenital heart disease. *Int J Cardiol* 1985;7:1, with permission.)



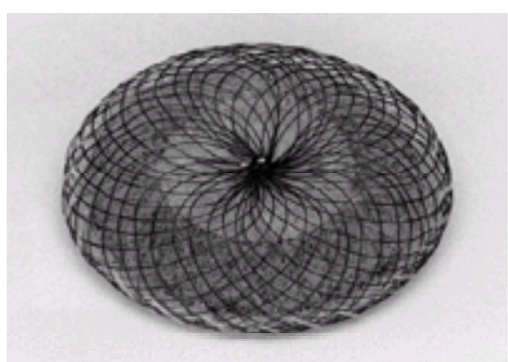
***e*FIGURE 87.0.17** Clamshell occluder. This occluder is composed of two stainless steel frames with multiple articulated arms and Dacron fabric overlay. (From Rome JJ, Lock JE, Davis R, et al. Transcatheter closure of atrial septal defects: experimental studies. *Circulation* 1989;79:1091, with permission.)



***e*FIGURE 87.0.18** Sideris "button" occluder. A two-component system comprised of an occluder, an X-shaped stainless steel wire frame with polyurethane fabric, and counteroccluder, a rhomboid-shaped wire of polyurethane construction with a central rubber grommet through which the knotted button is passed. (From Sideris EB, Sideris SE, Thanopoulos BD, et al. Transvenous atrial septal defect occlusion by the buttoned device. *Am J Cardiol* 1990;66:1524, with permission.)



***e*FIGURE 87.0.19** Das Angel Wings occluder. This occluder consists of two square frames of nitinol covered by polyester fabric. A central hole removed from right atrial disk allows two disks to be sewn together. (From Das GS, Voss G, Jarvis G, et al. Experimental atrial septal defect closure with a new transcatheter, self-centering device. *Circulation* 1993;88:1754, with permission.)



***e*FIGURE 87.0.20** The Amplatzer atrial septal occluder device is composed of nitinol wire mesh woven into a left and right atrial disk, connected by a central waist whose diameter corresponds to the atrial septal defect size. The disks are filled with thin polyester patches. This figure shows the left atrial side of an Amplatzer device.

Technique

Indications and contraindications to transcatheter therapy are similar to those for standard surgical repair. The devices are appropriate only for the secundum-type ASD, and then only when there is sufficient septal rim surrounding the defect. At present, there are no age limitations precluding device implantation, although the large introducer sizes necessary for implantation of some devices limit applicability to patients who weigh greater than 8 to 10 kg. A reported advantage of the Amplatzer device is the smaller introducer system needed for device implantation (6 to 7 Fr).

Preliminary measurements of the ASD and atrial septum length are made in multiple planes by transthoracic or transesophageal echocardiography (TEE). Procedures are usually performed under general anesthesia to minimize patient movement and to allow for transesophageal monitoring. Patients are heparinized to maintain an activated coagulation time greater than 250 seconds throughout the procedure. Standard right-sided heart catheterization is performed to document hemodynamic data and to determine the magnitude of the interatrial shunt. Continuous TEE monitoring is used during device deployment. The defect is balloon sized using occlusion balloon catheters of known dimension to assess defect size and septal compliance. Balloon occlusion with guidance from TEE is also helpful to detect additional smaller septal defects. Rao et al. (163) found that the balloon-stretched diameter of the ASD correlates fairly well with the echocardiographically determined ASD diameter (stretch diameter of defect = 1.05 × echocardiographic diameter + 5.49 mm; p <.01).

After ASD sizing, the delivery system is advanced across the atrial septum, and the left atrial component of the device is deployed. After the left side is properly aligned by echocardiographic guidance, the right atrial component (if applicable) of the device (i.e., right atrial disk in Amplatzer, Clamshell, and Das devices, counteroccluder in Sideris device) is deployed. Once echocardiography confirms the position and stability of the device, it is released from its wire or cable. TEE is used to evaluate residual shunts and the relationship of the device to nearby structures (e.g., right upper pulmonary vein, superior vena cava, mitral valve). The degree of residual shunt may also be measured by repeat hemodynamic study.

Results

King and Mills Device

The clinical applicability of this device to children was limited by the need for a 23-Fr introducer sheath requiring saphenofemoral cutdown for access (*e*Fig. 87.0.15). It is no longer in use.

Rashkind Single-Disk Device

Use of the Rashkind device (*e*Fig. 87.0.16) has been examined by several investigators (149,150) with mixed results. A large (15 Fr) introducer sheath was required, and the device could not be retrieved because of the presence of hooks. It is no longer under investigation.

Clamshell/CardioSEAL Device

Latson et al. (164) reported a multicenter trial of 400 patients in whom the Clamshell device (eFig. 87.0.17) was implanted. This device requires an 11-or 12-Fr sheath. Implantation failed or embolization occurred in 7 and 17 patients, respectively. In the 376 patients in whom the device was implanted, there was a 33% rate of residual shunts on echocardiography at follow-up, a 7% complication rate, and one late death. There have been reports of fractures of the device arms at follow-up in more than one-half of patients; the clinical significance of these fractures has been questioned. At present, the newer CardioSEAL design is being evaluated. Early single center experiences have reported similar defect closure rates (46% residual shunt at mean 9.9 months) and a reduced incidence (14%) of arm fractures (153).

Sideris Button Device

In the initial multicenter trial (155), 57 patients underwent implantation of the Sideris button device (eFig. 87.0.18), with successful implantation in 81%. There was an 8% unbuttoning rate, requiring surgical removal of the device and closure of the defect. Total, long-term follow-up results have been encouraging with lower rates of unbuttoning (0.9%) and similar degrees of occlusion (90%) with the fourth-generation model (156).

Das Angel Wings Device

Das Angel Wings device (eFig. 87.0.19) (157,158 and 159) represents a modification of previous concepts, incorporating a self-centering design. Initial clinical results appeared promising (158). In the first 24 patients who underwent closures in the United States, devices were deployed with either no shunting or trivial residual shunting in 92% of patients. The novelty of this device was reported to be the ability to implant devices with a smaller device-to-defect ratio than reported for other devices (diameter ratio, 1.1:2.0). A 12- or 13-Fr sheath is required for implantation of the device. At present, further clinical trials have been postponed as attempts at design improvement continue.

Amplatzer Septal Occluder

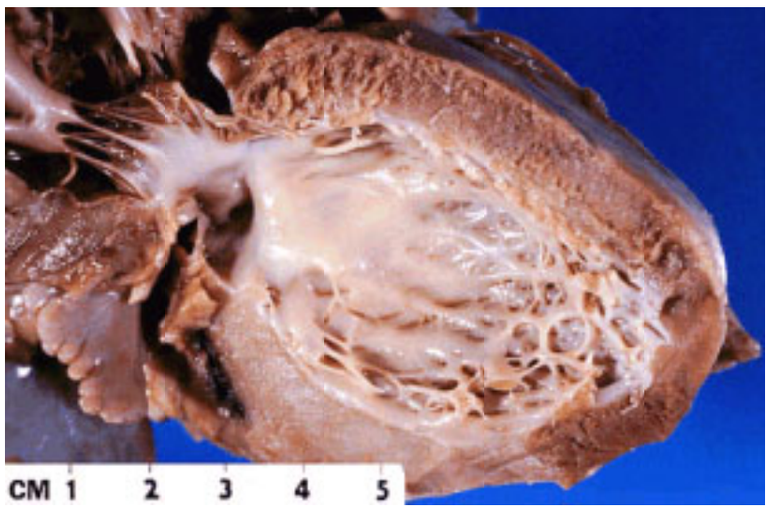
The Amplatzer Septal Occluder (eFig. 87.0.20) is the newest of the devices currently under investigation. It is gaining international popularity, as evidenced by multiple single center and multicenter reports constituting over 1,000 device implantations (160,161 and 162). The advantages of the Amplatzer device relate to its ease of implantation and maneuverability, retrievability, smaller introducer systems (6 to 7 Fr), highly effective defect closure rates (greater than 95%), and low complication rates.

Complications

Typical cardiac catheterization complications have been reported after transcatheter ASD occlusion, including arrhythmias and vascular injury. A low incidence of cerebrovascular events also has been reported. Mild regurgitation of an atrioventricular valve may occur if a device impinges on the valve. Device embolization after deployment has also been reported in a small minority of patients. The need for surgical intervention after device implantation has been reported in up to 8% of patients, primarily for repair of residual shunts (165), but this is expected to decrease with newer devices. The mortality for transcatheter ASD closure is extremely low.

TRANSCATHETER CLOSURE OF PATENT FORAMEN OVALE

One of the more controversial uses of transcatheter ASD occlusion technology is closure of a PFO after presumed paradoxical embolic stroke or transient ischemic attack. In multiple studies (166,167) of patients with transient ischemic attacks and stroke but with no clinical evidence of cardiovascular disease, a PFO was noted in up to 12% of patients. The association of the anatomic combination of PFO and atrial septal aneurysm with strokes is quite high (odds ratio, 4.96), particularly in patients younger than 55 years. In patients with a PFO alone, the odds ratio is also increased (odds ratio, 1.83) (168). This has been borne out by long-term studies demonstrating a rate of recurrent neurologic events of 3.3% to 12.5% per year without defect closure (169,170). Similar associations have been reported between the presence of PFO and symptomatic migraine headaches, orthodeoxia/platypnea syndrome, or both. Some have advocated transcatheter PFO closure as a curative procedure for these conditions (171). Others, however (172,173), believe that the association between a PFO and neurologic symptoms may not be causal, and that the etiology of stroke in these patients may be related to rheumatic mitral valve disease or thrombus formation within the atrial appendage exacerbated by atrial dysrhythmias. In a multicenter trial, Bridges et al. (174) reported 36 patients with documented right-to-left atrial shunting and presumed paradoxical emboli who underwent PFO closure with a Clamshell device. Of the 34 patients in whom devices were implanted, no recurrent strokes occurred during a mean follow-up period of 8.4 years. More recent studies have revealed the risk of recurrent stroke or other neurologic events after transcatheter PFO closure to vary from 3.2% to 3.4% per year (175,176), possibly lower than the recurrence risk without closure. Additional investigation is needed to elucidate the interplay between idiopathic strokes, congenital atrial septal patencies, and outcome after closure of such defects.



Fibroelastosis and hypertrophy of the left ventricle. This specimen was obtained from a 3-month-old child with incomplete closure of the foramen ovale.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Advances in imaging technologies (particularly echocardiography and magnetic resonance imaging) have permitted surgical intervention in many patients with simple (e.g., ASD, ventricular septal defects, PDA, aortic coarctation) or complex (e.g., D-transposition of the great arteries, hypoplastic left-sided heart syndrome) lesions to proceed based solely on noninvasive studies. This, in turn, has led to changes in the patterns of cardiac catheterization in children. At our institution, for example, approximately 80% of the cardiac catheterizations performed in the late 1980s were for diagnostic purposes. With smaller catheters and our ability to perform interventional procedures safely in neonates and children, the ratio has reversed, with 60% to 70% of patients currently entering the catheterization suite for interventional procedures. We anticipate that this trend will continue and grow over time.

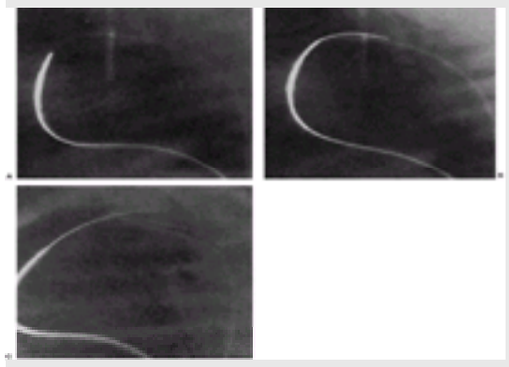
In this chapter, we have described most of what is available to the interventional cardiologist for the transcatheter treatment of congenital heart disease. However, not all of the interventions described have met with universal acceptance. In most centers, but not in all, balloon valvuloplasty is considered the treatment of choice in children with valvar pulmonic or aortic stenosis. However, many cardiologists still refrain from transcatheter treatment of native aortic coarctation out of concern for the development of aneurysms or restenosis; in the future, coarctation stenting may effectively address these issues. Other device implantation procedures such as coil embolization for PDA and endovascular stenting for pulmonary artery stenosis are now widely accepted as the treatment of choice for these lesions. Development of effective transcatheter technology for intracardiac lesions such as ASDs and ventricular septal defects has proceeded rapidly, but unfortunately, in 2001, U.S. Food and Drug Administration approval for these devices lags far behind their general acceptance worldwide.

THE FUTURE

Because of advances in interventional catheter design, particularly miniaturization of catheters and devices, and the development of laser-tipped catheters, a number of new technologies, as described here, are being applied in a novel fashion to congenital cardiac lesions.

Laser-Assisted Valve Dilation

Bommer et al. (177) first demonstrated the applicability of laser ablation technology to creation of experimental ASDs. Riemenschneider et al. (178) later reported the application of lasers to other forms of congenital heart disease. Qureshi et al. (179,180) first reported the use of 0.018-in. neodymium:yttrium-aluminum-garnet laser guidewires to perforate atretic pulmonary valves. Passage of the laser wire in pulmonary atresia was performed after adequately aligning catheters in the infundibulum and main pulmonary artery through the PDA (eFig. 87.0.21). Standard balloon valvuloplasty techniques are used after perforation with the laser wire (3 to 5 seconds, 3.5 W).



***e*FIGURE 87.0.21** Shown here are fluoroscopic images demonstrating alignment of catheters before laser catheter perforation of the pulmonary valve **(A)**, passage of the laser wire into the main pulmonary artery **(B)**, and snaring of the wire through the ductus arteriosus **(C)**. (From Rosenthal E, Qureshi SA, Kakadekar AP, et al. Technique of percutaneous laser-assisted valve dilation for valvar atresia in congenital heart disease. *Br Heart J* 1993;69:556, with permission.)

Stent Valves

Bonhoeffer and colleagues reported the percutaneous transcatheter implantation of functional valves into the RV outflow tract. Initially in a lamb model (181) and later in a 12-year-old child (182), a stent-mounted valve was implanted and shown to be nonstenotic and competent on follow-up. Larger trials with longer-term data are needed, but this technique promises to greatly improve the care available to patients (e.g., postoperative tetralogy of Fallot patients), who currently require reoperations for pulmonary valve insufficiency.

OVERVIEW

Heart failure continues to emerge as an enormous public health problem in the new millennium. The aging population continues to grow around the world, and the incidence of heart failure continues to climb commensurate with the graying of the world population. It is estimated that 10% of patients older than 75 years have heart failure. Because it is a syndrome and not a specific disease, heart failure has many forms and faces. This has led to persistent controversy and lack of agreement regarding the definition. The confusion regarding the definition stems in part from the differences between historical bedside observations (e.g., cardiomegaly, third heart sound gallop, rales, fluid retention, oliguria, breathlessness, and fatigue) and elaborations emanating from careful laboratory exercises performed from 1950 to 2000 (e.g., measurement of contractile abnormalities, isolated papillary muscle function, identification of key molecular abnormalities). The clinical definition of *heart failure*, a syndrome readily diagnosed by a careful history and physical examination, is considered in very broad terms to be an abnormality of the heart with a characteristic pattern of hemodynamic and neuroendocrine responses. The clinical picture is dominated by secondary organ abnormalities in the lungs (shortness of breath), the kidneys (salt and water retention), and the skeletal muscles (fatigue), but the central problem is always in the heart. The syndrome of heart failure is the expression of the final common pathway by which many etiologic factors can damage the heart, including acute myocardial infarction, inflammatory myocarditis, gene mutations with abnormal contractile function, valvular heart disease, severe undertreated hypertension, and so forth. Virtually any form of heart disease can culminate in the syndrome of heart failure.

We now understand that chronic systolic heart failure is often characterized by progressive remodeling of the left ventricular (LV) chamber. The other three chambers are also frequently involved and can progressively dilate as well. The LV becomes larger and more spherical over months to years, obligating a reduction in LV ejection fraction. The process of remodeling is highly complex and is addressed in detail later in this chapter. However, the remodeling process is central to the pathophysiology of heart failure and is now the prime target for two major effective forms of treatment—angiotensin-converting enzyme (ACE) inhibitors and beta-adrenergic blockers. The observation by clinicians that treatment designed to block various neuroendocrine responses can result in inhibition and, in some cases, reversal of LV remodeling has been an epiphany. Although there are many gaps in our knowledge of pathophysiology, especially in cellular biology, we are beginning to recognize complex but coherent patterns that develop in the pathogenesis of heart failure. The purpose of this chapter is to feature the most current thinking as it relates to the pathophysiology.

HISTORICAL PERSPECTIVE

Although heart failure has been recognized in retrospect by medical historians to have been evident throughout history, the timing of when the medical concept of heart failure first arose is difficult to be confident about. In 1832, Hope put forth both the term *cardiac failure* and attempted to explain the idea of edema on the basis of increased filling pressure of the heart (1). He presumed that increased heart pressure was subsequently transmitted back to the veins and the capillaries, where it was associated with extravasation of fluid. At the time, Hope was aware of the even now popular belief that heart failure is associated with an abnormal mechanical load, which leads to adaptive hypertrophy of the myocardium. He also recognized that at a certain point, the hypertrophy becomes insufficient to overcome the loading impediments and is associated with the clinical onset of heart failure. Of interest, the very same concept is now considered to be one of the foremost questions in contemporary cardiology and the subject of intense research in recent years. The transition from adaptive hypertrophy to heart failure remains poorly understood but is fundamental to our understanding of heart failure.

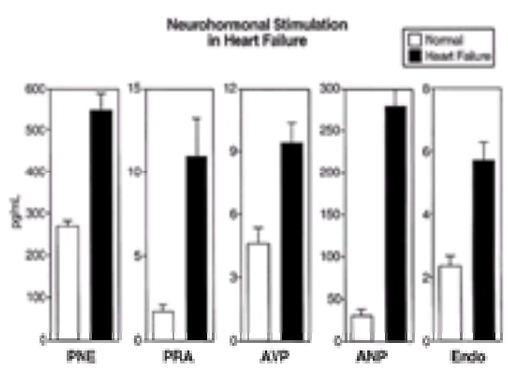
Hope's concepts persisted throughout the nineteenth century. It was Starling in 1886 who developed his now famous equation explaining the movement of fluid across the capillary bed (2). Starling also instilled fluid into the pericardial sac of anesthetized dogs to produce "heart failure," what we now consider to be cardiac tamponade. However, he incorrectly concluded that "in heart disease the capillary pressure is not higher, but rather lower, than in a normal animal." Starling believed that extravasation of fluid was a fundamental defect in heart failure.

Starling's preeminence in the field perpetuated the concept that heart failure was associated with an increased capillary permeability. Even the master clinician Mackenzie suggested, in 1913, that blood was passing through the capillaries at such a slow rate in heart failure so as to impair nutrition and allow transudation (3). At the time of Mackenzie the condition of heart failure was referred to as "dropsy."

By the turn of the century there were rival theories about heart failure, including the so-called backward theory and forward theory. The backward theory of heart failure eventually emerged to explain the traditional concepts of heart failure, but the theory failed to take into account the concept of systemic edema and anasarca. Moreover, blood volume was noted to increase during heart failure and not diminish, as might be expected from the backward theory. It was Starr who challenged the current dogma and carried new ideas from the laboratory to the bedside (4,5). He proposed the opposite idea that “static pressure” in patients dying from heart failure is higher than normal. Subsequent clinical studies by Warren and Stead (6) demonstrated that as patients develop edema, their weight increases even before there is any detectable change in venous pressure, suggesting tremendous potential for the venous capacitance to increase its volume.

A clear shift in the thinking about heart failure occurred after the studies of Merrill (7). These important studies demonstrated that there was diminished renal blood flow in patients with heart failure. It was assumed that patients with heart failure had a reduced cardiac output, but this concept had to await the introduction of cardiac catheterization to be confirmed. About this time (1950s), in the early days of cardiac catheterization, it was popular to define heart failure as a condition whereby the heart fails to maintain adequate circulation for the needs of the body. The implication of this definition was that entry of oxygen into the circulation was dependent on the cardiac output, and therefore the needs of the body for oxygen could not be met during heart failure. However, this concept is flawed, as it has been known since at least 1948 that the uptake of oxygen at rest is normal in patients with heart failure (8).

The definition of heart failure became further complicated when it was recognized that some patients suffered from “high-output heart failure.” Such patients also had peripheral edema and lung congestion and typically presented with conditions such as thyrotoxicosis, severe anemia, cor pulmonale, arterial-venous shunts, beriberi, and Paget’s disease of bone. Patients with high-output heart failure often have cardiac outputs two or three times normal, thus casting doubt on the whole concept of “forward heart failure.” In the 1950s, the work of Barger and others emphasized the fact that retention of sodium by the kidney was due not only to abnormal renal blood flow but also to systemic activation of the renin-angiotensin-aldosterone system (9,10). The primary stimulus for the release of renin was discovered to be a reduction in the “effective circulating volume” and reduced blood pressure. Subsequently, a long series of studies was performed substantiating the fact that heart failure was characterized by many neuroendocrine abnormalities that we now appreciate as highly important in the pathogenesis of the syndrome (11,12,13,14,15,16,17,18 and 19). It is now clear that the sympathetic nervous system is activated in heart failure (20). There is an incremental change in plasma renin activity (PRA) (21) and a host of other vasoactive substances, including arginine vasopressin (AVP) (22), natriuretic peptides, and endothelin (*e*Fig. 88.0.1) (23). Presumably these neurohormones are increased in an attempt to maintain blood pressure in the face of a falling cardiac output. It is as if blood pressure is being “protected” by endogenous vasoconstrictors, presumably a major evolutionary advantage (24,25). The vasodilator/natriuretic peptides are released as heart failure progresses and include atrial natriuretic factor (ANF), brain natriuretic peptide (BNP), and prostaglandins. These are presumed to affect the local control of blood volume, arteriolar tone, baroreceptor reflex control mechanisms, and excretion of salt and water (26,27,28,29 and 30). BNP has recently emerged as a marker of elevated cardiac filling pressure (31,32 and 33). The recognition of neuroendocrine activation as an important component of heart failure has culminated in the development of a currently popular hypothesis—the neurohumoral hypothesis—which implies that neuroendocrine abnormalities are responsible for much of the disturbed pathophysiology and progression of abnormalities common to the syndrome of heart failure.



***e*FIGURE 88.0.1** Patients with chronic heart failure are known to have increased plasma levels of plasma norepinephrine (PNE), plasma renin activity (PRA), arginine vasopressin (AVP), atrial natriuretic peptide (ANP), and endothelin (Endo). (Courtesy of Dr. J.N. Cohn.)

Recently there has been the development of a plethora of transgenic mouse models of heart failure, usually created by overexpression or “knockout” of specific genes, sometimes with cross-breeding to create specific molecular lesions. The phenotypes produced by these models are somewhat similar and include myocardial hypertrophy, reduced myocardial function, LV dilation, and edema formation. Although these studies have shed much light on underlying molecular mechanisms of heart failure, there are now more than 40 models, and the number is rapidly growing. Although these animal models may phenotypically resemble dilated or hypertrophic cardiomyopathy, direct extrapolation to the human condition of heart failure has remained speculative for the most part. In some cases, genes unheard of by cardiovascular researchers have been found to have a profound effect on cardiac development. Altered contractile proteins, calcium regulatory proteins, receptors, transcription factors, and signal transduction molecules all can lead to experimental mouse heart failure. However, one can be confident that no single molecule or group of genes causes heart failure. Moreover, there are some shortcomings to the transgenic model strategy. These models allow little control over the time course of transgene expression, and the levels of expression are difficult to control. Many proteins implicated in the pathogenesis of heart failure have different functions during development than in mature, adult heart cells. Although many of these models will undoubtedly be useful, some transgenics will be overexpression artifacts or physiologically irrelevant. The transgenic work so far serves only to emphasize the enormous complexities of the molecular basis of disease. Much more work is required.

We then return to the question—what is heart failure? It is probably best to define *heart failure* as a complex clinical syndrome manifested by shortness of breath, fatigue, and abnormal heart function. The syndrome must be characterized by an abnormality of cardiac function to distinguish it from the syndrome of “circulatory congestion,” as might occur in a patient with a normal heart and acute renal failure.

Systolic Heart Failure

Abnormalities of systolic and diastolic function frequently coexist in the syndrome of heart failure, although today patients are somewhat arbitrarily determined to have either systolic heart failure or diastolic heart failure. The former condition is associated with a reduction in systolic performance of the heart, circulatory congestion, and progressive activation of various neuroendocrine systems (34,35,36 and 37). In the late stages, systolic heart failure is characterized by excessive sympathetic nervous system activity, tachycardia, a gallop rhythm, peripheral edema, ascites, and oliguria. Classically, patients with systolic failure have enlargement of the left ventricle with hypertrophy and remodeling of the chamber and markedly diminished LV performance. In most circumstances there is an increase in LV end diastolic and end systolic volume and a marked reduction in ejection fraction, a standard method of measuring cardiac systolic performance.

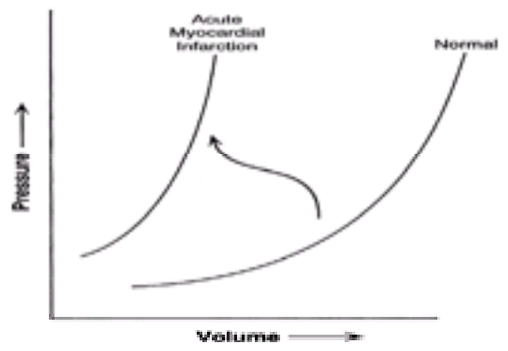
The heart adapts to diminished performance from any acute or chronic injury by altering its shape and size (i.e., remodeling). Cardiac output is temporarily maintained in the face of reduced stroke volume by chamber hypertrophy and dilatation. Hypertrophy tends to reduce wall stress via the Laplace relation (tension = pressure × radius/wall thickness), thereby maintaining systolic performance. However, when the heart is severely dilated, the tension in the walls of the heart is so great that it essentially outstrips the increase in wall thickness, leading to a decrease in systolic performance. The ventricles are designed so that the upper limit of normal filling pressure is achieved at the optimal length of the heart’s basic contractile unit—the sarcomere. A sarcomere length below 2.2 μ provides reserve for the Starling mechanism, whereas a sarcomere length above 2.2 μ does not further enhance systolic performance. The sarcomeres normally do not elongate beyond 2.2 μ (although the myocyte may increase the number of sarcomeres in series, thus elongating the cell and increasing the chamber diameter). When stretched beyond 2.2 μ, “slippage” may occur, leading to mitral regurgitation. Although there is no true descending limb to the Starling curve in the intact circulation, a continuously increased volume of the heart leads to mitral and tricuspid insufficiency. From this discussion it should be clear that LV remodeling with new sarcomeres in series, although initially adaptive, if progressive becomes very maladaptive and greatly contributes to diminishment in LV function. A clear understanding of this principle allows one to understand why treatment designed to reduce remodeling is so effective.

Diastolic Heart Failure

The syndrome of diastolic heart failure implies normal systolic function of the heart in the presence of clinical heart failure. It is now well documented that many patients with heart failure have normal LV systolic function. Diastolic heart failure may account for one-third or more of patients referred to specialty centers for the management of heart failure. Often, such patients are elderly women with severe systemic hypertension and LV hypertrophy (38). Characteristically, patients with diastolic heart failure present with the usual signs and symptoms of pulmonary vascular congestion but have a small heart or normal internal chamber diameter and a normal LV ejection fraction by echo or radionuclide left ventriculography (39). As with systolic heart failure, diastolic heart failure may, in many cases, be complicated by mitral regurgitation. Although the clinical manifestations of heart failure due to diastolic dysfunction are very similar to those of systolic dysfunction, the pathogenesis,

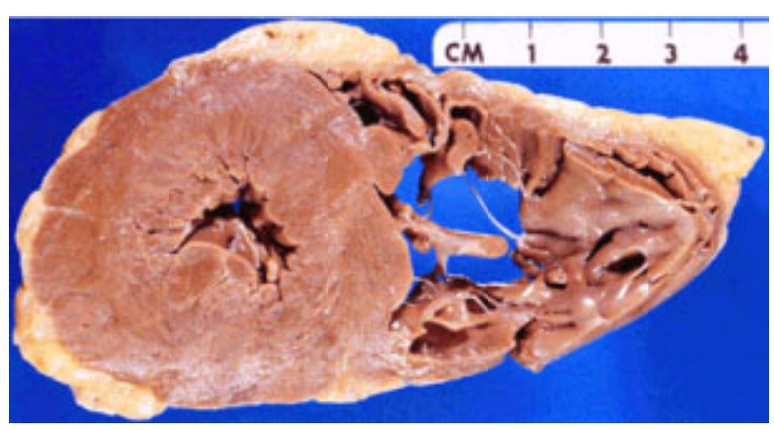
prognosis, and treatment of the two syndromes are different.

The clinical features of diastolic heart failure are virtually identical to those of systolic heart failure, but the fundamental causes are impaired diastolic function. The LV chamber is stiff, leading to an abnormal diastolic pressure–volume relationship (eFig. 88.0.2). The factors that raise LV filling pressure in diastolic heart failure may be due to a variety of active and passive processes that affect chamber and muscle stiffness. In marked contrast to systolic heart failure, patients with pure diastolic heart failure frequently have normal or, in many cases, enhanced contractile function of the left ventricle. A classic example is hypertrophic cardiomyopathy. Such hearts are characterized by marked hypertrophy, heightened ejection phase indices, and concomitant mitral regurgitation. Diastolic filling of the left ventricle is very impaired, leaving the patient with elevated LV filling pressures. It is presumed that the elevated filling pressures contribute to the sensation of breathlessness, although the mechanism of shortness of breath is more complex than this. Diastolic heart failure can also be caused by acute coronary insufficiency, which tends to increase chamber stiffness and decrease compliance of the left ventricle. In general, there is a shift of the pressure–volume relationship to the left, producing a higher pressure for any given diastolic volume.



***e*FIGURE 88.0.2** The fundamental consequence of diastolic heart failure is a shift in the pressure-volume relationship of the left ventricle so that for any given volume, there is a much higher left ventricular end diastolic pressure.

Other etiologic considerations of diastolic heart failure include long-standing systemic hypertension with LV hypertrophy, chronic coronary artery disease with excessive scar formation, and infiltrative cardiomyopathies such as cardiac amyloidosis and sarcoidosis. Despite the fact that patients may become markedly disabled by diastolic heart failure, the prognosis of these patients appears to be somewhat better than those with pure systolic heart failure (40). Still, such patients have a fourfold mortality risk compared with control subjects who are free of heart failure.



Left ventricular hypertrophy secondary to chronic hypertension with secondary ectasia of the right ventricle.

New criteria for diastolic heart failure have been proposed (41). The history, physical examination, and chest x-ray may well point toward a clinical diagnosis of diastolic heart failure, but the diagnostic test of choice is echocardiography (42). Doppler assessment of diastolic function by echocardiography provides information relevant to the patient's functional class, management, and prognosis. A continuum of Doppler patterns of diastolic function exists, including normal diastolic function, impaired relaxation, pseudonormal filling, restriction, constriction, and tamponade (42). These patterns evolve from one to another with changes in disease evolution. However, it has become clear with many years' experience that the Doppler abnormalities are sensitive to heart rate, loading conditions, age, and treatment. They can be lacking in specificity. Defining diastolic heart failure is not simple (43). It usually coexists with systolic dysfunction and may have multiple etiologies with various treatments. It is not a single, homogeneous entity.

Diastole has classically been divided into four phases: isovolumic relaxation, a rapid filling phase, a slow filling phase, and atrial systole. Isovolumic relaxation is the interval between aortic valve closure and mitral valve opening. During this phase, ventricular pressure rapidly declines without a significant change in ventricular volume. This process is energy dependent and may be susceptible to myocardial ischemia. Isovolumic relaxation is followed by the rapid filling phase, which also is energy dependent. As the rapid filling continues, an increase in LV size is limited by passive elements affecting stiffness of the myocardium. A slow filling phase of diastole is then primarily dependent on the stiffness of the heart, which may increase as LV volume increases. Passive stiffness of the heart will also be increased by fibrosis related to previous myocardial infarction, or from various infiltrative processes. The last phase of diastole is the result of atrial contraction, which actively propels blood into the left ventricle and produces a final increase in LV volume and pressure. Normally the atrium contributes approximately 15% to 25% of the ventricular diastolic volume. Actual contribution from atrial contraction relates to underlying ventricular compliance and chamber stiffness, the contractile function of the atria, and the ventricular diastolic pressure at which point atrial contraction begins.

Most patients with diastolic heart failure have abnormal active and passive diastolic function. Varying disease states may be associated with different aspects of diastolic function. For example, LV hypertrophy is associated with slowing of both active relaxation and increased passive chamber stiffness. Acute myocardial ischemia causes a transient reduction in the ability of the left ventricle to completely relax, and infiltrative cardiomyopathies cause increased passive chamber stiffness due to the deposition of material in the interstitial spaces. It is also important to remember that ventricular diastolic properties of the heart are altered by age. Relaxation is prolonged with increased age, and older patients are more likely to often have concomitant myocardial fibrosis and LV hypertrophy.

Although there is no uniformly agreed-on therapy for pure diastolic heart failure, control of blood pressure is seemingly critical to the patient's well-being. Beta-adrenergic–blocking drugs may be useful in that they slow the heart rate and prolong diastole. In principle, prolongation of diastole should improve filling. Calcium channel blockers and ACE inhibitors are also useful treatment for the management of chronic diastolic heart failure (44). More recently, nitric oxide (NO) donors, or drugs that enhance NO release, have been shown to improve diastolic function in humans (45).

Circulatory Congestion Is Not Synonymous with Heart Failure

Over the years it has become clear that the two major features of heart failure are circulatory congestion and reduced flow to vital organs. Congestion behind the right ventricle, principally as a result of elevated right ventricular filling pressures, produces the characteristically distended neck veins, enlarged liver, and edema. Heightened LV filling pressures are responsible in part for dyspnea, orthopnea, and pulmonary rales, although exercise intolerance in patients with chronic heart failure does not always relate directly to the degree of elevated LV filling pressure (46).

It is somewhat unfortunate that over the years the presence of circulatory congestion, regardless of the circumstances under which it appears, has traditionally become accepted as tantamount to the diagnosis of heart failure (47). It is likely that this traditional concept is incorrect. Administration of excessive intravenous infusions to a patient with a normal heart results in a state of circulatory congestion. The blood volume is artificially increased and venous distention occurs. Indeed, the clinical picture can be indistinguishable from that of heart failure. However, one must question whether the heart has truly failed. In fact, the hemodynamic disturbance that occurs as a result of excessive administration of fluids in the face of a normal heart is a consequence of noncardiac circulatory congestion. It is now clear that both systemic and pulmonary vascular congestion can arise from noncardiac causes to produce a clinical syndrome that simulates that of heart failure. Examples might include acute renal failure, constrictive pericarditis, and pure mitral stenosis. In each of these cases, LV performance remains intact, and circulatory congestion ensues as a consequence of factors other than those due to reduced myocardial performances. Characteristically, in circulatory congestion the heart size is normal, as opposed to the cardiomegaly that occurs in the condition of true systolic heart failure. Circulatory congestion from noncardiac causes rarely responds to inotropic stimulation, whereas patients with systolic heart failure usually respond quickly to inotropic stimulation with drugs such as dobutamine. It is therefore important to

recognize that circulatory congestion is a nonspecific hemodynamic disturbance that may arise even when the heart is not failing as a pump. The term *congestive heart failure* should be reserved for those patients with circulatory congestion due to inadequate myocardial pump function. Because many patients today with severe chronic heart failure fail to demonstrate circulatory congestion, in part because of the common usage of potent loop diuretics and other therapies, the term *heart failure* is preferred by some over the previously fashionable term *congestive heart failure*.

DIAGNOSIS AND EVALUATION OF HEART FAILURE

History and Physical Examination

Perhaps the most predominant symptom of heart failure is breathlessness. The medical term for breathlessness, *dyspnea*, is the awareness by the patient of increased respiratory effort. This may occur at rest or with minimal physical activity. The patient is aware of an uncomfortable sensation, not being able to get enough air. It is somewhat surprising that to this day the mechanism of dyspnea is poorly understood. In patients with acute pulmonary edema, hypoxemia probably contributes to the sensation of dyspnea. However, patients with more chronic forms of heart failure have dyspnea that bears no direct relationship to hypoxemia, elevated pulmonary capillary wedge pressure, or other central hemodynamics (46). Likewise, the level of dyspnea is not related in a simple manner to dead space inhalation. It is likely that chronic shortness of breath at rest or with minimal activity is due to multiple peripheral mechanisms, including fatigue of the respiratory muscles, increased physiologic dead space, reduced pulmonary compliance, increased airway resistance, endothelial dysfunction, abnormal skeletal muscle metabolism, and perhaps signals from the pulmonary J receptors and respiratory muscles (48,49).

Orthopnea and paroxysmal nocturnal dyspnea occur in the more advanced stages of heart failure. Neither orthopnea nor paroxysmal nocturnal dyspnea is specific for heart failure and can occur in other conditions. Patients with more advanced and chronic heart failure frequently have Cheyne-Stokes respirations. This type of periodic breathing in patients with heart failure, characterized by repeated episodes of apnea and hypopnea during sleep, is associated with severe nocturnal arterial blood saturation. It also carries a poor prognosis (50) and is correlated with an elevated pulmonary capillary wedge pressure (51). Central sleep apnea is common in patients with heart failure (52) and may be related to enhanced sensitivity to carbon dioxide (53). Continuous positive airway pressure improves cardiac function in patients with heart failure who demonstrate Cheyne-Stokes respiration or central sleep apnea (54). Coughing and wheezing can also occur in patients with heart failure and may be the predominant symptoms.

The second cardinal feature of heart failure is chronic fatigue. Fatigue is also a very nonspecific symptom and, like dyspnea, is rather poorly understood. In the past, fatigue was attributed to low cardiac output, but we now know that the mechanism is far more complex. Drugs that improve blood flow to exercising muscles in heart failure do not necessarily improve exercise tolerance or reduce fatigue (55,56). It is likely that abnormalities of skeletal muscle histology and biochemistry contribute to poor exercise tolerance and chronic fatigue (57,58,59 and 60).

Circulatory congestion is responsible for many of the physical signs of heart failure. Occasionally patients with new-onset heart failure present with severe right-upper-quadrant pain and abdominal fullness. This may be accompanied by nausea and vomiting and is probably due to engorgement of the liver and bowel from high venous pressure. Rarely, heart failure can even present as an acute surgical abdomen. However, peripheral edema and pulmonary rales are not invariably present in heart failure, even when cardiac filling pressure is markedly increased (61).

The physical findings in heart failure span the spectrum from very unimpressive to highly remarkable. In the current era of loop diuretics and ACE inhibitor therapy, patients frequently have an absence of the traditional findings, such as pulmonary rales, gallop rhythm, hepatomegaly, ascites, and peripheral edema. Even jugular venous distention may be absent in the face of severe LV dysfunction if the patient is well compensated. On the contrary, the presence of neck vein distention, a third heart sound, pulmonary rales, and peripheral edema is highly characteristic of the syndrome of heart failure. During the sequential follow-up of patients in the clinic over time, particular attention should be focused on examination of venous pressure. Sequential examination of the patient is most important, and examination of the neck veins is perhaps the single most useful physical finding. The presence or absence of venous distention is also most helpful in determining the dose of diuretic therapy.

The cardiac examination itself should be carried out with the patient in both the supine and the left lateral decubitus position. Often the cardiac apex impulse is displaced and sustained. A third heart sound gallop, when present, may be palpable. Patients with heart failure frequently have a murmur of mitral regurgitation that radiates to the axilla. Tricuspid regurgitation is also common in patients with heart failure, although sometimes more difficult to auscultate.

Routine Laboratory Tests

A number of routine laboratory tests useful in the evaluation of patients with heart failure are suggested in Table 88.1. Evaluation of a new patient with heart failure should also include a chest x-ray to assess the size of the heart and the pulmonary vascular markings. Occasionally the cardiac silhouette is normal in size, which should signal the possibility of pure diastolic heart failure. Enlargement of the cardiac silhouette can be due to either right, left, or biventricular enlargement. Heart failure is characterized by roentgenographic perihilar engorgement of the pulmonary vasculature with cephalization of lung vascular markings. Pleural effusions may be present and are more likely to occur on the right.

Test recommendation	Finding	Suspected diagnosis
Electrocardiogram	Acute ST-T-wave changes	Myocardial ischemia
	Atrial fibrillation, other tachyarrhythmia	Thyroid disease or heart failure due to rapid ventricular rate
	Bradyarrhythmias rate	Heart failure due to low heart rate
	Previous myocardial infarction (e.g., Q waves) left ventricular performance	Heart failure due to reduced contractile tissue
	Low voltage	Pericardial effusion
	Left ventricular hypertrophy	Diastolic dysfunction
Complete blood cell count	Anemia	Heart failure due to or aggravated by decreased oxygen-carrying capacity
Urinalysis	Proteinuria	Nephrotic syndrome
	Red blood cells or cellular casts	Glomerulonephritis
Serum creatinine	Elevated failure	Volume overload due to renal dysfunction
Serum albumin	Decreased	Increased extravascular volume due to hypoalbuminemia
T4 and TSH (obtain only if atrial fibrillation, evidence of thyroid disease, or patient age >65 yr)	Abnormal T4 or TSH	Heart failure due to or aggravated by hypo/hyperthyroidism

TSH, thyroid stimulating hormone.

TABLE 88.1 RECOMMENDED TESTS FOR PATIENTS WITH SIGNS OR SYMPTOMS OF HEART FAILURE

The cornerstone of evaluation remains the echocardiogram. Every new patient with heart failure should have an echocardiogram performed with Doppler interrogation to assess LV size, cardiac performance, as well as valvular architecture and function. The echocardiogram can be used to distinguish systolic from diastolic heart failure. It is also useful in diagnosing pericardial effusion, hypertrophic cardiomyopathy, regional wall motion abnormalities, and unsuspected valvular heart disease.

Although the radionuclide ventriculography can provide very precise information regarding ejection fraction, most laboratories prefer to use echocardiographic data because they provide a more comprehensive observation, are simpler to obtain, and are less costly. The use of transthoracic Doppler is also helpful. The features of both echocardiography and radionuclide left ventriculography are compared in Table 88.2.

Test	Advantages	Disadvantages
Echocardiogram	Permits concomitant assessment of valvular disease, left ventricular hypertrophy, and left atrial size	Difficult to perform in patients with lung disease
	Less expensive than radionuclide ventriculography in most areas	Usually only semiquantitative estimate of ejection fraction provided
	Able to detect pericardial effusion and ventricular thrombus	Technically inadequate in up to 10% of patients under optimal circumstances
	More generally available	
Radionuclide ventriculogram	More precise and reliable measurement of ejection fraction	Requires venipuncture and radiation exposure
	Better assessment of right ventricular function	Limited assessment of valvular heart disease and left ventricular hypertrophy

TABLE 88.2 ECHOCARDIOGRAPHY AND RADIONUCLIDE VENTRICULOGRAPHY COMPARED IN EVALUATION OF LEFT VENTRICULAR PERFORMANCE

The electrocardiogram continues to be useful in the evaluation of new patients with heart failure. It is inexpensive and provides information about the rhythm and conduction of the heart. The presence of old myocardial infarction, LV hypertrophy, left atrial enlargement, and underlying ischemic heart disease can also be suggested by a careful examination of the 12-lead electrocardiogram. Patients with advanced heart failure frequently have arrhythmias, which are usually diagnosed by simple electrocardiography. The presence of new atrial fibrillation on the electrocardiogram may provide a clue as to why a patient may have suffered acute decompensation. Approximately 20% to 30% of patients with heart failure have atrial fibrillation. In general, the electrocardiogram remains part of the standard initial evaluation but is probably not indicated for routine follow-up visits.

All new patients should have a complete blood count and urinalysis, serum electrolytes, blood urea nitrogen, serum creatinine, blood glucose, and, in some cases, an assay for thyroid-stimulating hormone. Measurement of the levels of plasma norepinephrine, plasma ANF, and PRA, although increased in patients with heart failure, is not considered routine or clinically necessary. Plasma neurohormone levels are primarily research tools. This may change with the emerging data on BNP (31,32 and 33). This peptide tracks with LV filling pressure and is an excellent tool to aid in the diagnosis of heart failure. It may also be useful in confirming vague physical findings, making decisions about hospital admission, and determining the response to therapy (62,63). The availability of a quantitative bedside “point-of-care” kit may facilitate the use of BNP for the diagnosis of heart failure.

Exercise Testing

Ambulatory patients with heart failure should always be considered for exercise testing. When available, gas exchange measurements should be made to assess anaerobic threshold and maximal oxygen consumption at peak exercise (53,64,65). Submaximal exercise end points such as anaerobic threshold are much less subjective motivational factors, which limits the utility of maximal exercise tolerance and the 6-minute walk test. Symptom-limited exercise testing is safe in patients with heart failure (66) and provides valuable information regarding the patient’s ability to withstand physical stress. Occasionally the exercise test is highly enlightening with regard to the patient’s perceived extent of disability. In addition to measurement of the heart rate and blood pressure, the duration of exercise should be noted, as well as the electrocardiographic response to exercise. The reasons for stopping the test should always be thoroughly explored. Patients with advanced heart failure usually discontinue exercise because of leg fatigue, although generalized fatigue and dyspnea are almost always also present. We now know that patients with a peak oxygen consumption of less than 14 mL per kg per minute and/or who exercise less than 50% of that expected for their age and size have a very poor prognosis and may be candidates for heart transplantation (67). In some cases, exercise testing will provide evidence of unsuspected myocardial ischemia. Such patients frequently have coronary angiography and in some cases improve with revascularization.

Cardiac Catheterization and Coronary Angiography

The need to do a right heart catheterization and coronary angiogram as part of the routine evaluation of patients with heart failure remains contentious (68). If the patient is being considered for heart transplantation, hemodynamic and coronary angiographic assessments are mandatory. In general, patients who are ill with advanced heart failure who demonstrate refractoriness to conventional therapy should be considered for hemodynamic evaluation. The acute response to therapy will, in some cases, predict the patient’s longer-term prognosis (69). Nevertheless, invasive investigation of the hemodynamic profile remains highly dependent on local customs and prerogatives of the individual attending physician. This issue is currently the subject of a large randomized trial. In general, there is no need to perform a right heart catheterization to diagnose heart failure. Rather, hemodynamic monitoring is used to help make judgments to aid in the management of patients with acute hemodynamic decompensation. Knowing whether there is underlying severe coronary disease is valued by some physicians and not by others. In general, it is useful to know the extent of underlying coronary disease and whether the patient may be a candidate for bypass graft surgery or other revascularization techniques. This is particularly true if the patient has angina or demonstrates myocardial ischemia. It is less clear in patients with no clinical evidence of coronary artery disease.

Myocardial Dysfunction Due to Chronic Ischemia and Its Reversibility by Revascularization

Severe LV regional dysfunction can result from myocardial necrosis, myocardial stunning (70), or hibernating myocardium (71). If enough regional dysfunction is present, global LV ejection fraction can be markedly depressed. We now know that simple assessment of LV function by contrast ventriculography or echocardiography cannot distinguish among these three mechanisms of reduced systolic function (i.e., necrosis, hibernation, and stunned myocardium). On the other hand, it is vitally important to be able to accurately and noninvasively assess myocardial viability to know whether severe cardiac dysfunction is due to irreversible cellular injury, stunning, or hibernation (72). This decision-making process permits the selection of patients for coronary artery bypass revascularization and is important in reassuring both the patient and the surgeons that a technically successful bypass operation can result in improved global LV function (73,74,75 and 76).

A number of strategies have been used to determine myocardial viability. Thallium-201 (Tl-201) imaging has been extensively studied in this regard (77,78,79,80 and 81). Irreversibly damaged myocardial cells cannot extract Tl-201 intracellularly, even after coronary reflow. Various approaches have been used in the assessment of Tl-201 imaging.

Often the clinical question is simply whether there is viability in a zone of severely reduced myocardial function. In such cases, early and delayed Tl-201 imaging performed in the resting state may be adequate.

New technetium-99m–labeled perfusion techniques have emerged in recent years and may be useful in assessing regional myocardial perfusion and viability. Technetium-99m sestamibi uptake is comparable to delayed Tl-201 uptake (82,83). The two imaging agents appear to be comparable for predicting enhanced regional systolic function after revascularization.

Positron emission tomography has also been used to differentiate viable from nonviable myocardium in patients with poor LV function (84,85,86 and 87). Noninvasive positron emission tomographic imaging with N-13 ammonia or fluorine 18-fluorodeoxyglucose is helpful in distinguishing patients with severe LV dysfunction secondary to coronary artery disease from those with nonischemic cardiomyopathy (88). Multiple metabolic tracers have been developed to define fatty acid metabolism (C-11 palmitate), glucose metabolism (fluorine 18-fluorodeoxyglucose), and overall oxidative metabolism (C-11 acetate). With the development of these isotopes, positron emission tomographic scanning has the potential for clearly distinguishing ischemic from nonischemic cardiomyopathy and is considered by many to be the gold standard. Unfortunately, it is expensive and not readily available.

Echocardiography is gradually replacing thallium perfusion tests in the determination of myocardial viability. Evaluation of wall thickening by echo during low-dose dobutamine infusion can be used to determine reversible LV dysfunction in patients with chronic coronary artery disease (89,90 and 91). Recent studies using dobutamine echocardiography have reported an 88% sensitivity and an 87% specificity in identifying viable but hypoperfused dysfunctional myocardial segments before revascularization (92). Dobutamine stress echocardiography is now the preferred method of assessing myocardial viability in patients with heart failure at many centers. However, it remains relatively nonquantitative. More recently, contrast-enhanced magnetic resonance imaging has emerged as an excellent tool to identify reversible myocardial dysfunction (92a,92b).

The determination of viable from nonviable myocardium is important for physicians caring for patients with severe heart failure. Those patients with reversible severe LV dysfunction will often respond favorably to coronary artery bypass surgery, whereas patients with nonviable tissue are perhaps more suitable for heart transplantation. This is an emerging field, and various centers rely more or less on the laboratory techniques that have served them best. Regardless of how one determines myocardial viability, the sensitivity and specificity of the test within each laboratory should be determined to provide a certain level of confidence for both the referring physician and the surgeon.

FACTORS KNOWN TO PRECIPITATE HEART FAILURE

Chronic heart failure is characterized by a waxing and waning of the signs and symptoms of circulatory congestion, sometimes culminating in severe pump dysfunction leading to death. It now seems apparent that approximately one-third to one-half of patients die suddenly and unexpectedly from a presumed arrhythmic death, whereas remaining patients appear to die from progressive pump dysfunction. However, recent experience with clinical trials has suggested that this distinction with regard to the mechanism of death in patients with heart failure is not a simple matter (93). Nevertheless, an undulating course characterized as compensation and decompensation is familiar to all physicians who care for these patients on a long-term basis. When patients acutely deteriorate, specific reasons for this acute deterioration should always be explored (Table 88.3).

Acute myocardial ischemia
Uncorrected high blood pressure
Obesity
Superimposed infection
Atrial fibrillation and other arrhythmias
Excessive alcohol consumption
Endocrine abnormalities (e.g., diabetes mellitus, hyperthyroidism, hypothyroidism)
Negative inotropic drugs (e.g., verapamil, nifedipine, diltiazem, beta-adrenergic blockers)
Nonsteroidal antiinflammatory drugs
Treatment and Na^+ noncompliance; lack of information given to patient about diet, medications, etc.

TABLE 88.3 CAUSES OF ACUTE DECOMPENSATION OF CHRONIC HEART FAILURE

Among the causes of acute decompensation of previously stable heart failure is the syndrome of acute myocardial ischemia. Although classic angina pectoris is not usually a prominent feature of patients with heart failure, we now know that approximately half or more patients with heart failure harbor severe underlying coronary artery disease. It is important to consider this etiologic factor when seeing patients with heart failure and acute decompensation. A 12-lead electrocardiogram should always be performed and compared with previous electrocardiograms. If there is any evidence for acute myocardial ischemia, patients should be considered for hospitalization, and acute myocardial infarction should be excluded. The importance of acute coronary events as a trigger for sudden death in patients with heart failure has likely been underappreciated (94).

Superimposed infections are well known to provide the nidus for acute decompensation. Even so-called simple viral illnesses can present a severe stress to the already compromised cardiovascular system of patients with advanced heart failure. Bronchial pneumonia is still a common cause of death in patients with chronic heart failure, and any infectious process occurring in the setting of decompensated heart failure may well be an indication for hospitalization and more aggressive therapy.

The onset of atrial fibrillation is well known to precipitate decompensation of previously stable heart failure. Although it is still not entirely clear if atrial fibrillation predicts an overall worse prognosis, ample anecdotal experience would suggest that the onset of new atrial fibrillation is often accompanied by worsening heart failure. With the loss of atrial contribution, cardiac output may be further reduced. Additionally, an excess ventricular response to the atrial fibrillation and inadequate filling of the left ventricle can both be contributory factors toward acute decompensation. When the atrial fibrillation is of 48 hours or more in duration, chronic anticoagulation with warfarin is usually indicated. Aggressive attempts toward restoration of normal sinus rhythm are sometimes in order, including the need for hospitalization and electrical cardioversion. In some cases, atrial fibrillation becomes chronic and is resistant to preventive antiarrhythmic therapy. In such cases, control of the heart rate may be the best strategy for the patient's well-being. Although digoxin has long been used to control heart rate in this setting, it may not be particularly effective in patients with heart failure who demonstrate excessive sympathetic activity. Agents with negative inotropic properties, such as beta-adrenergic blockers and diltiazem, are sometimes required as adjunctive therapy to digitalis. Low-dose amiodarone is sometimes highly effective in preventing recurrent atrial fibrillation in patients with advanced heart failure. A rapid ventricular response to atrial fibrillation that is sustained can cause heart failure, and atrioventricular node ablation should be considered in such patients (95).

Patients who acutely decompensate should always be queried on the excessive use of alcohol. Many patients are unfamiliar with the concept of alcoholic cardiomyopathy and need intensive education with regard to potential detrimental effects of alcohol in the setting of advanced heart failure. For patients with severe heart failure, it is probably prudent to recommend complete abstinence, although recently this has been called into question (96). It should be remembered that there is an epidemiologic link between chronic alcohol use and systemic hypertension, a situation to be clearly avoided in the patient with advanced heart failure. Patients with chronic alcoholism may have a tendency early to have abnormal ejection with a dilated ventricle, LV hypertrophy, and impaired LV relaxation (97).

Poorly controlled diabetes mellitus, hyperthyroidism, or hypothyroidism can all lead to acute decompensation of heart failure. Signs and symptoms of hypothyroidism can be difficult to elicit and/or can even be masked by episodes of depression and chronic fatigue. Poorly controlled diabetes mellitus can lead to substantial abnormalities in fluid and electrolyte balance and must always be aggressively corrected. In each case of acute decompensation of heart failure, possible endocrine or metabolic causes should be pursued.

Perhaps one of the commonest causes of worsening heart failure is noncompliance with drug therapy and dietary indiscretion. In general, medication compliance is approximately 75% in patients with heart failure, somewhat better than with hypertension. Nevertheless, patients must continually be educated about their medications and the need to take them on a regular basis. The importance of diet should be continually stressed. The most common cause for "diuretic resistance" is excessive dietary sodium, which can easily go unnoticed by the patient.

It is extremely important that the physician caring for the patient with heart failure be aware of the patient's full medication repertoire, including prescribed drugs and over-the-counter agents. Medications that are knowingly associated with negative inotropy, such as the first-generation calcium channel blockers and beta-adrenergic blockers, should be reduced or sometimes discontinued in the face of worsening heart failure. Nonsteroidal antiinflammatory agents are frequently a cause of excessive sodium and water retention and may offset the use of potent loop diuretics. Patients with advanced heart failure should be discouraged from using either prescribed or over-the-counter nonsteroidal antiinflammatory drugs. Such agents are well known to be associated with hemodynamic compromise (98).

MECHANISMS OF LEFT VENTRICULAR DYSFUNCTION

Abnormalities at the Molecular Level

Our current understanding of the mechanisms by which the myocardial cell fails to supply power for ventricular contraction is most uncertain. Despite extensive investigation into the fundamental properties of the failing heart, the precise molecular mechanisms responsible for diminished myocardial cell function, particularly at the molecular level, remain poorly defined. Undoubtedly, multiple mechanisms are operative. For many patients with congestive heart failure, the clinical problem is simply a loss of sarcomeres subsequent to myocardial infarction and replacement fibrosis. Nevertheless, the cellular counterpart of myocardial tension development in heart failure has been a subject of intense study for many years by many investigators. From the standpoint of normal physiologic responses, the cardiac power output is regulated by alterations of the molecular interactions between myosin cross-bridges and actin. The maximum intrinsic velocity for any one muscle type is dictated by the intrinsic characteristics of the myosin adenosine triphosphatase (ATPase). Under normal physiologic conditions, the primary regulator of contractility on a moment-to-moment basis in the normal cardiac cell is calcium flux. The sarcoplasmic reticulum is the internal membrane organelle that primarily functions in cardiac muscle to accumulate calcium and allow relaxation and subsequent release of calcium to initiate contraction.

Work in the 1960s indicated a reciprocal relationship between sodium and calcium exchange in cardiac muscle, suggesting that a sodium-calcium interaction may be important in providing incremental changes in intracellular calcium concentration. Although the mechanisms by which myocardial contractile abnormalities occur have been studied assiduously for the past 25 years, no general agreement has emerged regarding specific molecular, biochemical, or physiologic abnormalities associated with heart failure. In fact, there are frequent conflicts in the literature regarding potential biochemical abnormalities. Divergent results, which have stemmed from excellent laboratories, suggests that a number of methodologic problems in the study of cardiac tissue remains. For example, there is no consensus on identification of high-energy phosphate-level abnormalities during contractile failure. Although some studies have suggested abnormal sarcoplasmic reticulum abnormalities of calcium accumulation, the mechanism by which the sarcoplasmic reticulum function is altered in heart failure has yet to be clearly defined. More recently, isoform changes in cardiac muscle have been identified, but their role, if any, in human heart failure remains uncertain. Phospholamban is normally associated with regulation of sarcolemma Ca^{2+} transport and is reduced in heart failure due to dilated cardiomyopathy, coronary artery disease, and primary pulmonary hypertension; the expression level is inversely correlated with the myocardial ANF mRNA level (99). This has also been noted for Ca^{2+}-ATPase (99). It is possible that these changes are secondary to primary alterations in cardiac hypertrophy rather than heart failure, but this remains unclear. Protein levels of calcium-transporting ATPase, phospholamban, and calsequestran are not consistently diminished in failing human LV myocardium (100). It has been suggested that in dilated cardiomyopathy there is no alteration of contractile and regulatory proteins, but that the gating mechanism of calcium release from the sarcoplasmic reticulum is abnormal (101,102). Although mRNA expression of the calcium release channel or ryanodine receptor of the sarcoplasmic reticulum may be abnormal in end-stage human heart failure (103,104 and 105), it remains unclear whether these changes are mechanistically linked to abnormal contractile function or are simply epiphenomena related to the transition from normal to hypertrophy to failure (106).

Approximately 80% of the calcium flux involved in excitation-contraction coupling occurs across the sarcoplasmic reticulum membrane, but 20% of the calcium is moved across the cell membrane or sarcolemma by two transport systems. These sarcolemma transport systems include the sodium-calcium exchanger and the plasma membrane calcium pump. The sodium-calcium exchanger may be important in activation of contraction by providing a source of calcium to trigger the release of additional calcium from the cardiac sarcoplasmic reticulum. Recent data have indicated that the sodium-calcium exchanger gene expression is actually upregulated

in the failing human heart, suggesting that there is a compensation for depressed sarcoplasmic reticulum function (107). Membrane-bound Na^+-K^+-ATPase is also reduced in the failing heart (108). The decrease in the sarcoplasmic reticulum calcium ATPase mRNA in the myocardium may play an important role in the regulation of calcium movements. For example, impaired sarcoplasmic reticulum function may retard the removal of calcium in diastole, thereby contributing to diastolic dysfunction (109,110).

Abnormalities of Cellular Function

In addition to putative abnormalities in calcium-transporting ATPase, phospholamban, calsequestran, and myocardial ryanodine receptors, there remains the possibility that the production of intracellular cyclic adenosine monophosphate is deficient and hence an important cause of contractile dysfunction in patients with end-stage heart failure (111). It is well known that the time course of contraction and rate of relaxation are greatly prolonged in heart failure, and these abnormalities can be corrected when intracellular cyclic adenosine monophosphate is replenished by forskolin. Myocytes isolated from the left ventricles of patients with failing hearts demonstrate reduced contraction and slowed relaxation (112). At the cellular level, these findings suggest that abnormalities of myocyte function can contribute to both systolic and diastolic abnormalities in the failing human heart (113). Although no single chemical or molecular abnormality likely accounts for these abnormalities, it is of some interest to know that at physiologic frequencies, abnormalities of both contraction and relaxation can be detected at the level of the cardiac cells (96).

It has long been known that the failing heart adapts to the adverse circulatory conditions through a process of myocyte hypertrophy. However, fundamental knowledge regarding the transition from hypertrophy to failure is very incomplete. Adding new sarcomeres diminishes the rate of mechanical energy expenditure. Architectural changes in the hypertrophied heart can further exacerbate the imbalance between energy expenditure and energy production (114). For example, there may be an increase in the distance between capillaries that impairs the diffusion of substrates and oxygen essential for the production of energy by the hypertrophied heart. Long-standing hypertrophy may increase cell volume and myofibrils, thereby increasing the number of ATP-consuming myofibrils, thus further exacerbating an energy deficit. Although myocyte hypertrophy is a complex process that may be both adaptive and detrimental, the long-term effects of cellular enlargement may be deleterious to organ function. Abnormal protein isoforms may occur in response to hypertrophy due to well-known changes in gene expression. Although many of these changes are unique for various animal models, there is also a diminishment in the proportion of alpha-myosin heavy chain in the atria in patients during the development of left atrial pressure overload and enlargement.

As individual cardiac myocytes adapt to changing environmental conditions by increasing in size, a host of additional abnormalities occur. LV hypertrophy is associated with arrhythmias, some of which may be lethal (115). Abnormalities of relaxation occur, resulting in altered diastolic function of the heart. There is also a dynamic alteration in the connective tissue matrix of the heart during its response to injury or circulatory overload, leading to a rapid increase in collagen synthesis (116). The replacement of myocytes with connective tissue may additionally contribute to both systolic and diastolic abnormalities of organ function. Cardiac myocytes from failing hearts have a reduced responsiveness to sympathetic neurotransmitters (117). Not only do the cells become desensitized to beta-adrenergic receptor agonists through a downregulation of the $beta_1$-receptor, but there is also an uncoupling between the $beta_2$-receptor and the guanine nucleotide–binding (G) protein and an upregulation of the Gia subunit (118). Although such changes may be adaptive in the short term, protecting the heart from excessive sympathetic and inotropic drive, in the long term it is certainly possible that these changes contribute to the exacerbation of circulatory abnormalities well described in patients with congestive heart failure.

Abnormalities of Chamber Function

Heart failure is a very common clinical syndrome, but the pathophysiologic factors that affect chamber function vary considerably among patients. In my experience, coronary artery disease remains the most common cause of heart failure, although systemic hypertension continues to be the most common risk factor for heart failure in the Framingham studies (119). Differences between clinical trial patients and population-based cohorts may explain such differences, as well as difficulties with defining heart failure. Dilated cardiomyopathy and valvular heart disease also continue to be common causes of chronic heart failure.

The fundamental abnormality of the heart in the syndrome of heart failure is a diminished ability of the failing muscle to develop force and shorten at a given velocity and at specified loading conditions. The decreased velocity of shortening is conceptually related to the observed decrease in the maximal rate of force development. In general, there is little or no change in the passive length–tension relations of isolated failing heart muscle. Despite this, there can be dramatic changes in the passive pressure–volume relationship of the intact ventricle. Another elastic property of the heart muscle, the series elastic element, also does not appear to be grossly changed in the failing heart muscle. However, the failing left ventricle is exquisitely sensitive to afterload conditions (Fig. 88.1).

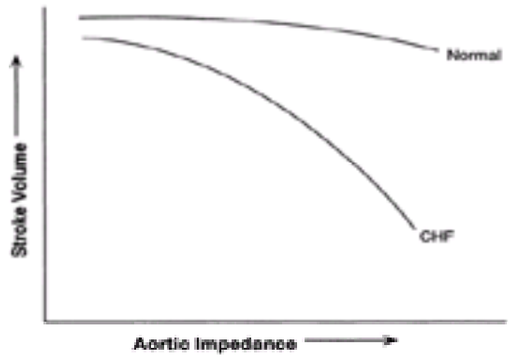

FIGURE 88.1 A hallmark of heart failure is the exquisite sensitivity of the left ventricle to an afterload stress. As impedance to ejection is raised, there is an impressive reduction in left ventricular performance. CHF, congestive heart failure.

To improve myocardial performance, several compensatory mechanisms are activated. One of these (previously discussed briefly) is the Frank-Starling mechanism, in which an increased preload enhances contractile force. The relationship between muscle length and the development of tension in cardiac muscle represents the basis of Starling's law of the heart. The dependence of the development of tension on muscle length arises from several observations, the most important of which is length-dependent activation of cardiac myofibrils by calcium. This effect is believed to be due to a change in the calcium sensitivity of the myofibrils. The failing heart does not generate a normal increase in force development when preload is enhanced (Fig. 88.2). Thus, Starling's mechanism fails to improve myocardial performance as much as normally expected in the failing heart (120). This becomes apparent clinically when it is noted that diuretic treatment, which reduces preload, is not necessarily accompanied by a diminishment in stroke volume. Experimentally, it has also been noted that the Frank-Starling mechanism is exhausted in dogs with rapid pacing–induced chronic dilation (121). In these animals, the application of an acute volume load fails to elicit a further increase in cardiac output or stroke volume, further substantiating a reduction in the Frank-Starling mechanism. Difference in the length-dependent force development in the failing heart may be due to either a change of calcium sensitivity in the myofibrils or an altered amount of calcium supplied to the myofibrils. Because contractile proteins are basically unchanged in severe heart failure, alterations in filament-regulatory proteins such as troponin T or troponin I and other isoform changes may play some role (122).

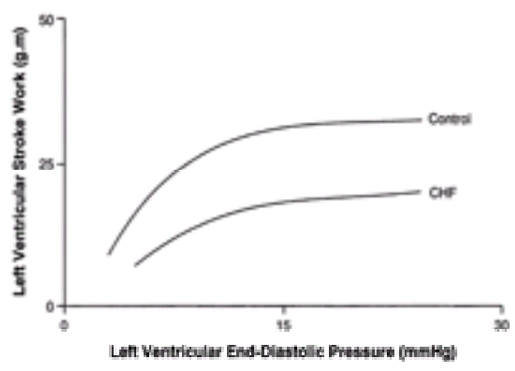

FIGURE 88.2 The Frank-Starling mechanism is altered in heart failure. The failing ventricle is unable to respond to an increase in preload with a normal increase in left ventricular stroke work. CHF, congestive heart failure.

It seems extraordinary that despite decades of investigations into the mechanism of heart failure, there still is not a coherent understanding of the precise sequence of events whereby LV performance is progressively diminished. Undoubtedly, multiple mechanisms are operative, including abnormalities of phenotypic gene expression, as yet imprecisely understood metabolic changes, and critically important peripheral adaptations, including activation of various neurohormones. The complexities inherent in the syndrome of heart failure make it unlikely that any single therapy is likely to emerge as solely effective. Current therapeutic strategies using polypharmacy to treat heart failure are consistent with this observation.

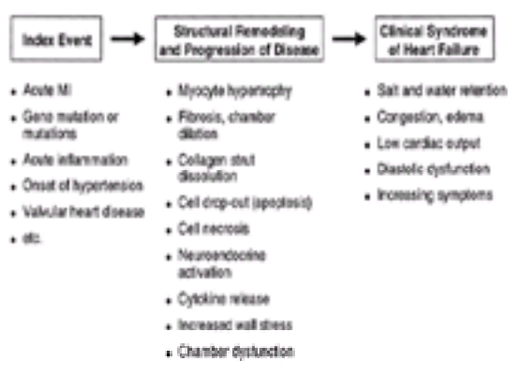
LEFT VENTRICULAR REMODELING

Ventricular remodeling is an alteration in the contour or volume of the ventricular cavity that is not attributed to acute changes in distending pressure (123). Cardiomegaly occurs and leads to a dilated and thinned-out left ventricle, a common but very complex finding in patients with congestive heart failure. The mechanism whereby LV remodeling occurs has been the subject of intensive study during the past decade (124,125). Multiple mechanisms drive this process, including myocyte loss, replacement scarring, and reactive growth mechanisms in the remaining viable cells. Although the early sequence of events at the molecular level are still not unraveled, much clinical and experimental data support the old concept that ventricular dilatation after myocardial infarction is a most accurate predictor of an unfavorable long-term prognosis (126,127).

The classic setting of LV remodeling occurs after an acute myocardial infarction. The infarcted territory may exhibit abnormal contraction patterns during systole, and this may ultimately lead to a progressive alteration in the shape of the ventricle. Although many investigators have suggested that LV remodeling represents an adaptive process serving to preserve stroke volume and cardiac output, it is now clear that the enlargement process has very deleterious long-term effects (123). With acute myocardial infarction, the extent of LV remodeling is very dependent on the size of the infarction as well as the location and depth of the acute myocardial injury. Immediately after myocardial infarction, sometimes within hours, there can be “infarct expansion,” which is an important complication and is associated with increased mortality. Infarct expansion is caused by acute dilatation and thinning of the area of infarction that is not explained by additional myocardial necrosis (128). Although the process of infarct expansion is still incompletely understood, it is believed that wall thinning occurs due to slippage between myocyte bundles as well as loss of intracellular space (129). This process can be detected clinically by echocardiogram and is more common in patients experiencing acute transmural infarction of the anterior apical left ventricle (130). In long-term studies, it is the extent of LV end systolic volume that has the most important prognostic power, even more so than the extent of underlying coronary artery disease.

Mechanisms of Progressive Left Ventricular Remodeling

Unlike infarct expansion, LV remodeling is the slowly progressive increment in volume of the heart that occurs over a prolonged period after acute myocardial injury (eFig. 88.2.1) (131). Stroke volume may be preserved by augmenting cavity size, but this occurs at a significant cost. According to the Laplace principle, LV enlargement is accompanied by an increase in wall stress. Wall stress then serves as a stimulus for compensatory myocardial hypertrophy. In addition to mechanical stresses that drive the remodeling process, there are probably also important neuroendocrine signals that act in an autocrine or a paracrine fashion to augment myocardial cellular hypertrophy (132,133,134 and 135). Experimentally, and in human dilated ventricles, it is now clear that cardiac myocytes increase in length shortly after acute myocardial injury (136,137). This increase in the length of the myocyte cell is largely due to so-called eccentric hypertrophy, or an increase in the number of sarcomeres in series. A suggestion has been made that the elongated cell is structurally inadequate and may contribute to the heart failure syndrome (138), although direct proof in support of this hypothesis is still lacking. Factors that contribute to LV remodeling are shown in Table 88.4.



***e*FIGURE 88.2.1** Working hypothesis of heart failure. After an index event, there is neuroendocrine activation leading to a progressive change in the size and the shape of the left ventricle. Further neuroendocrine activation occurs, leading to excessive vasoconstriction and ultimately to reduced organ perfusion. Eventually signs and symptoms of overt heart failure ensue. MI, myocardial infarction.

Neurohormones and cytokines
Increased left ventricular volume and pressure
Myocardial cell elongation
Replacement and reactive collagen deposition (i.e., increased collagen turnover)
Myocyte slippage secondary to dissolution of collagen struts
Apoptosis
Necrosis
Myocardial infarct expansion
Dilation and reshaping of left entricle

TABLE 88.4 FACTORS THAT CONTRIBUTE TO LEFT VENTRICULAR REMODELING

Patency of the infarct-related artery is also important in protecting against LV enlargement (139,140). The presence of antegrade blood flow through the infarct-related artery, either by collaterals or by reperfusion therapy, tends to protect against the development of LV wall motion abnormalities and progressive dilatation of the left ventricle (141,142 and 143).

The fundamental mechanisms that cause the LV remodeling are under intensive study by both basic scientists and clinical investigators. We now know that the increase in heart size is not due to a change in sarcomere length but rather is due to changes in the number of sarcomeres and change in cell size (144,145). Additionally, it is very likely that the process of apoptosis, or programmed cell death, is amplified in the setting of acute myocardial infarction (146). It is not simply loss of cells due to coagulation necrosis, but perhaps also the presumed loss of cells due to apoptosis, that makes an important contribution to the remodeling process. Myocytes may slip away from each other due to dissolution of the collagen struts that normally hold cells in a syncytial pattern. Cells enlarge both concentrically and eccentrically, but it is the increase in length that is most striking. Lastly, and very importantly, there are both replacement fibrosis of necrotic myocardial cells and enhanced growth of the interstitial matrix interstitium (147) during myocardial remodeling. It has long been known that there is a transition from the hypertrophied myocardium to the failing myocardium, but how and when this occurs are still not very clear.

Many of the changes of hypertrophy and remodeling are related not solely to altered mechanical forces, which are clearly important, but also to activation of neurohormones and various cytokines. The renin-angiotensin system is particularly important in this regard (148). It has repeatedly been shown in experimental studies, as well as in clinical trials, that the early use of ACE inhibitors retards LV remodeling after acute myocardial infarction (149,150,151,152 and 153). However, it remains unclear how much of this antiremodeling effect is simply due to betterment of loading conditions, or whether there is an important direct effect via inhibition of the renin-angiotensin system and the incremental increase in local concentrations of bradykinin. ACE inhibitors have multiple pharmacologic actions, including reduction of the sympathetic nervous system, and these actions may also contribute to their antiremodeling properties. Nitroglycerin has also been shown to reduce LV remodeling both experimentally (154) and clinically (155), but as with ACE inhibitors, the antiremodeling effects of nitrates are also not entirely understood. Although nitrates tend to reduce filling pressures and thereby may attenuate LV wall stress, it is also possible that the incremental change in local concentrations of NO associated with nitrates may retard cellular growth and hypertrophy (156). Beta-adrenergic blockers, which do not have immediate effects on loading conditions, also

attenuate progressive LV remodeling (157,158,159,160 and 161) and improve survival (162,163,164 and 165), suggesting that neuroendocrine overactivity is critical in the pathogenesis of heart failure.

What seems clear is that modification of abnormal mechanical forces and excessive neuroendocrine activity can importantly influence LV enlargement. Progressive increases in LV end systolic volume are a very important prognostic marker for a poor outcome, regardless of the cause of heart failure (127). Judicious use of agents such as nitrates and ACE inhibitors, which can favorably alter loading conditions of the left ventricle, may reduce progressive ventricular enlargement and improve survival. The combination of ACE inhibitor therapy, beta-adrenergic blockers, and maintaining patency of the infarct-related artery even beyond the time of myocardial necrosis may powerfully influence the ultimate size and shape of the ventricle. Clinical studies cited above have already led to a very aggressive change in the management of patients in the early stages after acute myocardial infarction. Therapies that limit the size of the infarction, prevent infarct expansion, reduce LV wall stress, and attenuate neuroendocrine activity are likely to favorably alter topographic changes of the ventricle and thus improve prognosis. It is entirely possible that surgical reduction of heart size (the Dor procedure) may some day play a role in the treatment of heart failure. Surgical reduction of marked cavity expansion is currently under intense study as a rational form of therapy (see Chapter 95).

NEUROENDOCRINE ABNORMALITIES

It has been known for many years that heart failure is characterized by activation of a number of neuroendocrine systems (Table 88.5) (12,14). Activation of neurohormones in heart failure has long been considered to be an “adaptive” process, perhaps a response to a fall in cardiac output and an attempt to maintain blood pressure. The perceived threat to circulatory homeostasis is similar to that of volume depletion, even though blood volume is usually increased in patients with heart failure. The sympathetic nervous system is activated, there is activation of the systemic renin-angiotensin-aldosterone system, and in many patients there is a release of AVP. The extent of neuroendocrine activations varies widely from patient to patient, but in general there appears to be a gradual incremental change during the evolution from LV dysfunction to overt heart failure (21) (Fig. 88.3). For many years, and to some extent still today, there has been a serious question as to whether these neuroendocrine changes represent simple markers (epiphenomena) or whether they actually contribute to the pathogenesis of the heart failure syndrome. In all likelihood, neuroendocrine activation makes an important contribution to the pathogenesis of heart failure. This statement is based on the fact that activation occurs very early in the course of the illness, even in the asymptomatic stage (21), and therapies designed to block neuroendocrine activation, such as ACE inhibitors and beta-adrenergic blockers, have had a favorable effect on the natural history of the illness (160).

Norepinephrine	Endothelin
Epinephrine	Beta-endorphins
Renin activity	Calcitonin gene–related peptide
Angiotensin II	Growth hormone
Aldosterone	Cortisol
Arginine vasopressin	Tumor necrosis factor-α
Neuropeptide Y	Neurokinin A
Vasoactive intestinal peptide	Substance P
Prostaglandins	Adrenomedullin
Atrial natriuretic factor	Brain natriuretic peptide

TABLE 88.5 NEUROENDOCRINE FACTORS KNOWN TO BE INCREASED IN PATIENTS WITH HEART ufailure

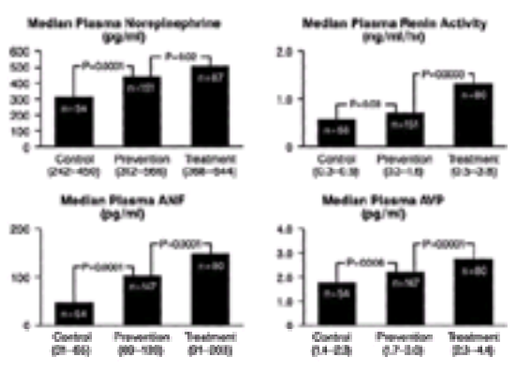


FIGURE 88.3 Data from the Studies of Left Ventricular Dysfunction substudy of baseline neurohormones. There is a progressive incremental rise in neurohormones as patients pass from the asymptomatic left ventricular dysfunction phase (prevention) to overt heart failure (treatment), suggesting that neurohormone activation may precede the onset of symptomatic heart failure. ANF, atrial natriuretic factor; AVP, arginine vasopressin. (From Francis GS, Benedict C, Johnstone DE, et al. Comparison of neuroendocrine activation in patients with left ventricular dysfunction with and without congestive heart failure. *Circulation* 1990;82:1724–1729, and the American Heart Association, with permission.)

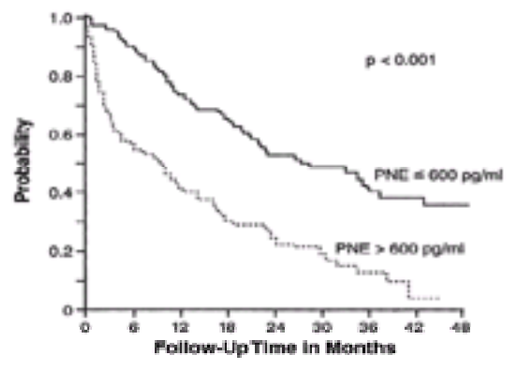
It is generally believed that a number of vasopressor/sodium-retaining peptides or hormones dominate the end stages of heart failure. These include norepinephrine (marked activation of the sympathetic nervous system), angiotensin II and aldosterone, AVP, and endothelin. There are also counterregulatory vasodilators/natriuretic peptides that are released in a presumed attempt to offset excessive peripheral vasoconstriction and salt and water retention. These natriuretic peptides include ANF, BNP, and adrenomedullin. Prostaglandins are also increased, at least locally within the kidney, to maintain homeostasis of renal blood flow and intraglomerular hydraulic pressure. On balance, however, there appears in most cases a dominance of heightened peripheral vascular resistance with sodium and water retention. In all likelihood, the increase in ventricular afterload, coupled with the inability to normally excrete salt and water, contributes importantly to worsening pump failure and circulatory congestion.

The mechanisms responsible for neuroendocrine activation in the syndrome of heart failure have been the subject of numerous studies. It is still unclear how the sympathetic nervous system is activated, although some investigators have suggested that altered reflex control mechanisms are at least partly responsible for excessive sympathetic drive. However, the fundamental signals that are responsible for altered reflex control mechanisms and the incremental change in sympathetic activity remain poorly understood. This lack of insight has impaired, to some extent, our therapeutic attempts to directly block neuroendocrine activation, forcing therapists to rely on drugs that inhibit neuroendocrine responses.

Abnormalities of the Sympathetic Nervous System

There is now direct evidence that increased central sympathetic nerve outflow occurs in patients with heart failure and is associated with an increase in plasma norepinephrine (20). In general, the greater the activation of the sympathetic nervous system, the worse the prognosis (eFig. 88.3.1). A single resting venous blood sample of plasma norepinephrine concentration provides a better guide to prognosis than many of the other commonly measured indexes of cardiac performance (18,166). Because hemodynamic abnormalities do not correlate well with levels of plasma norepinephrine, a direct causal link between heightened sympathetic activity and LV dysfunction has been difficult to substantiate. Moreover, there is a relatively loose correlation between plasma norepinephrine and PRA, suggesting that the two systems are independently activated in heart failure (167). However, it is well known that sympathetic stimulation may be one factor contributing to renin release.



***e*FIGURE 88.3.1** The probability of survival in patients with heart failure who have modest elevation of plasma norepinephrine (PNE) (600 pg per mL or less) and marked elevation of plasma norepinephrine (600 pg per mL or more). In general, elevated plasma norepinephrine has been consistently associated with a poor prognosis. (From Rector TS, Olivari MT, Levine TB, et al. Predicting survival for an individual with congestive heart failure using the plasma norepinephrine concentration. *Am Heart J* 1987;114:148–152, with permission.)

It is now believed that both increased neuronal release of norepinephrine and decreased efficiency of neuronal norepinephrine reuptake contribute to decreased cardiac adrenergic drive in congestive heart failure (168). Diminished norepinephrine stores in the failing heart are likely due to chronically increased norepinephrine turnover and reduced efficiency of norepinephrine reuptake in storage. In the short term, the adrenergic nervous system is important in supporting the failing circulation in patients with heart failure. However, in the long term, excessive sympathetic activity is likely making a major contribution to progressive LV dysfunction. It is well known that high levels of catecholamines are directly toxic to the myocardium (169,170). Cardiac norepinephrine spillover rate is perhaps the single most powerful prognostic neuroendocrine marker for patients destined to do poorly (171). It is the marked increase in norepinephrine spillover from the heart, or excessive sympathetic nerve firing, that is the dominant mechanism of heightened sympathetic activity, rather than faulty neuronal reuptake of norepinephrine (172). Adrenal medullary activity is also increased in patients with heart failure leading to increased plasma epinephrine concentrations, particularly toward the end stages of the disease. The fact that skin sympathetic nerve activity (in contrast to muscle sympathetic nerve activity) is not increased in heart failure supports the concept that altered reflex systems (which have nonuniform effects on muscle and skin sympathetic activity) may underlie much of the sympathoexcitation found in patients with heart failure (173). There is also increased central nervous system turnover of both norepinephrine and epinephrine in patients with heart failure (174), perhaps related to epinephrine neurons in the brain. The fact that norepinephrine kinetics return to normal after heart transplantation would suggest that many of the abnormalities of the sympathetic nervous system in heart failure are functional and to some extent reversible (175).

It is now believed that excessive sympathetic drive to the heart in patients with heart failure is responsible for downregulation of the $beta_1$-receptor and perhaps uncoupling of the $beta_2$-receptor (118). Isolated papillary muscles from pretransplant patients have been demonstrated to be nearly devoid of membrane beta-adrenergic receptors but respond normally to calcium. It has been hypothesized that receptor downregulation of the $beta_1$-receptor and uncoupling of the $beta_2$-receptor is more likely due to excessive local concentrations of norepinephrine and not due to high circulating levels of catecholamines.

The fact that excessive sympathetic stimulation has been repeatedly demonstrated in patients with heart failure and that patients respond to agents that knowingly inhibit excessive neuroendocrine activity would support the contention that neurohormonal activation is a critical factor in the pathogenesis of heart failure. These observations have stimulated a change in thinking away from drugs designed to have direct positive inotropic effects to those that secondarily improve cardiac function via inhibition of the sympathetic nervous system and the renin-angiotensin-aldosterone system.

Renin-Angiotensin-Aldosterone System

As with the sympathetic nervous system, it has been known for many years that the renin-angiotensin-aldosterone system is activated in patients with heart failure (Fig. 88.4) (7,12,14,176). Unlike the sympathetic nervous system, activation of the renin-angiotensin-aldosterone system is less obvious in patients with minimally symptomatic LV dysfunction (21). However, as heart failure progresses, there are profound incremental changes in circulating renin, angiotensin II, and aldosterone (177,178). Moreover, there are now substantial data to support the concept of a tissue renin-angiotensin-aldosterone system, which may play a critical role in both myocardial and vascular remodeling (179,180). A number of factors are responsible for the release of renin (Table 88.6). Decreased perfusion to the kidney with an accompanying reduction in the renal tubular concentrations of sodium and chloride ions in the macula densa can activate the renin-angiotensin-aldosterone system. Increased activity of the sympathetic nervous system is also a potent stimulus for renin-angiotensin-aldosterone system activation. The institution of a low-sodium diet, vasodilator therapy, and diuretics are all known to further activate the renin-angiotensin system.

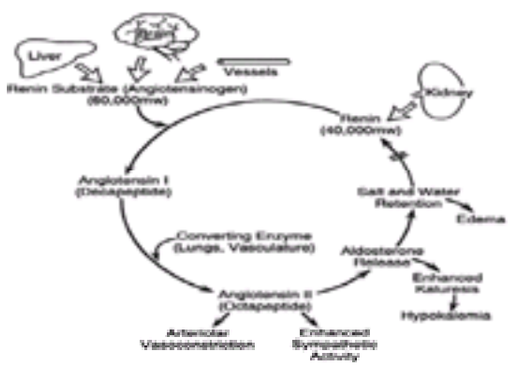


FIGURE 88.4 The circulating renin-angiotensin-aldosterone system. Angiotensinogen and renin produce a small decapeptide, angiotensin I, which is cleaved to angiotensin II by a converting enzyme. Angiotensin II, in turn, causes vasoconstriction, enhanced sympathetic nervous system activity, and aldosterone release. Increased salt and water retention expands circulating volume, which normally reduces renin release.

Renal artery baroreceptor activity
Renal hypoperfusion
Hyponatremic perfusate to the macula densa
Volume contraction secondary to diuretics and salt restriction
Stimulation of beta-adrenergic receptors in the kidney

TABLE 88.6 FACTORS THAT RELEASE RENIN

Angiotensin II is known to be a potent vasoconstrictor substance and also acts on the adrenal cortex to release aldosterone, a mineralocorticoid with potent sodium retentive properties (Fig. 88.5). Hypokalemia and hypomagnesemia often occur in the setting of heart failure, in part induced by the use of powerful diuretics. The combination of excessive adrenergic nervous system drive and hypokalemia is believed to predispose patients to lethal cardiac arrhythmias, from which nearly 30% to 50% of patients with severe heart failure die suddenly. The effectiveness of ACE inhibitors is in part related to their ability to block excessive angiotensin II activity, thus reducing some of the pathoexcitatory drive and diminishing the hypokalemic and hypomagnesemic effects of aldosterone in the kidney. Converting enzyme inhibitor

therapy also increases local concentrations of bradykinin, which in principle may have antiremodeling effects on the heart and contribute to vasodilation. Both excessive adrenergic nervous system activity and an overly active renin-angiotensin-aldosterone system are believed to contribute to progressive remodeling of the left ventricle and may form the underpinnings of the important transition from myocardial hypertrophy to myocardial failure. The precise molecular and cellular abnormalities that are operative in this important transition have yet to be elucidated.

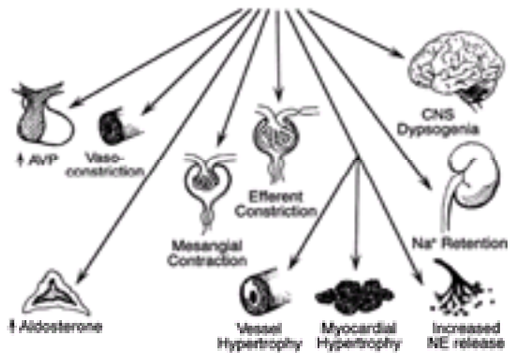

FIGURE 88.5 Angiotensin II has a vast array of biologic activities. These include release of arginine vasopressin (AVP) from the posterior pituitary, peripheral arteriole vasoconstriction, release of aldosterone from the adrenal cortex, mesangial contraction, constriction of the efferent glomerular arterioles, vascular hypertrophy, myocardial hypertrophy, facilitation of norepinephrine (NE) release from sympathetic neurons, sodium retention, and thirst sensation. CNS, central nervous system. (From Francis GS. The relationship of the sympathetic nervous system and the renin-angiotensin system in congestive heart failure. *Am Heart J* 1989;118:642–648, with permission.)

Arginine Vasopressin

Although plasma AVP has been demonstrated to be increased in patients with heart failure (22), these findings have not been highly consistent (178). Nevertheless, there is a trend for a gradual, incremental rise in plasma AVP as patients develop progressive LV dysfunction and overt heart failure (21). Synthesis and release of AVP from the posterior hypothalamus in both normal and pathologic states are regulated by osmotic and nonosmotic stimuli. The primary osmotic stimulus to AVP release is hyponatremia, whereas excessive diuresis, hypotension, and angiotensin II, as well as certain reflex control mechanisms, can act as nonosmotic stimuli. Patients with heart failure primarily have nonosmotic stimuli for AVP release (181,182), although this aspect has not been carefully studied. Although diuretics tend to stimulate AVP release, digitalis may reduce AVP levels by sensitizing cardiac baroreceptors.

AVP may act to constrict peripheral vessels, thus further raising systemic vascular resistance and myocardial afterload. AVP also acts via V_2 receptors in the kidneys to reduce the clearance of free water. V_2 receptors are also found in vascular tissue, where they subserve vasodilation in response to AVP (183,184). The level of AVP does not correlate with serum sodium, plasma norepinephrine, or hemodynamic variables (22). There is a weak correlation between plasma AVP and PRA (22). Patients with high circulating levels of AVP may be responsive to AVP antagonists (185,186), and there currently is an aquaretic AVP antagonist under study in clinical trials for the treatment of heart failure.

Endothelin

Endothelin-1 (ET-1) is a 21–amino acid peptide first reported as a potent vasoconstrictor produced by cultured porcine endothelial cells (187). There are now known to be three isoforms that share common receptors with somewhat different affinities. Only ET-1 is synthesized by vascular endothelial cells. In addition to very potent vasoconstrictive and mitogenic effects on vascular smooth muscle cells, ET-1 acts on endothelial cells in an autocrine fashion to induce the release of NO and prostacyclin. Furthermore, ET-1 has numerous effects on various tissues, including stimulation of the secretion of ANF and aldosterone, as well as inhibition of renin release and potent positive inotropic effects on the heart. Based on these findings, it has been suggested that endothelin has a role in maintaining the homeostasis of the circulatory system and may be important in the pathogenesis of various cardiovascular disorders, such as hypertension, heart failure, vasospasm, and atherosclerosis (188). Mice deficient in ET-1 developed elevated blood pressure and craniofacial abnormalities (189).

Because endothelin is associated with pressure overload hypertrophy (190,191), there is reason to believe that it may be important in the development of progressive LV remodeling. ET_A receptor blockers prevent cardiac hypertrophy in the face of hemodynamic overload (190). Plasma levels of endothelin are known to be increased in experimental heart failure (192) and in patients with dilated cardiomyopathy and heart failure (193,194,195,196 and 197). Evidence now suggests that circulatory endothelin concentrations in the range of 5 to 40 pg per L are vasoactive (198). Consequently, the endothelin concentrations found in patients with heart failure may be of pathophysiologic significance.

In addition to their effects on circulatory homeostasis, endothelins may have important functions in the regulation of contractility when released from the endothelial lining of the heart (199,200). There is growing evidence to support the existence of a dynamic interaction *in vivo* between cardiac myocytes and the adjacent microvascular endothelial cells in the regulation of both cardiac myocyte and possibly endothelial phenotype and function. The endothelium regulates the inotropic response of subadjacent cardiac myofibrils *in vitro* to changes in extracellular calcium. In healthy people, endothelin can induce a rise in blood pressure and in serum potassium concentration. Elevated plasma levels of endothelin are characteristic of severe heart failure and are not usually associated with asymptomatic or mild heart failure. The degree of plasma elevation of endothelin correlates with the magnitude of alterations in cardiac hemodynamics and functional class.

As our understanding of synthesis and release of endothelin in heart failure has expanded, there is great interest in exploring pharmacologic techniques that may alter its plasma concentration. For example, an enzymatic step is responsible for converting proendothelin to the mature peptide. As with angiotensin II, it is conceivable that an enzyme blocker will eventually be developed to inhibit this step. Neutral endopeptidases (NEPs) are known to inactivate endothelin (201,202 and 203), and several NEP inhibitors are now being widely studied as potential therapy for heart failure and hypertension. Perhaps most important, the acute administration of the endothelin receptor antagonist bosentan has been demonstrated to improve hemodynamics in patients with advanced heart failure (204). As with the renin-angiotensin system, it is likely that further research of endothelins will give way to potentially important new forms of therapy designed to block these peptides (205). A single dose of an ET_A blocker given to patients with heart block improves hemodynamics, does not activate other neurohormones, and is well tolerated (206). ET_A blockers may also improve pulmonary hypertension (207) and show promise as antiremodeling agents (208).

Atrial Natriuretic Factor

ANF is a naturally occurring hormone that has been demonstrated to be increased in several pathologic states, including hypertension and heart failure (26). Several different molecular forms of ANF have been isolated, but it is alpha-ANF that represents the major circulating form in humans. Synthesis of ANF occurs predominantly in the atria, where right atrial stretch appears to be an important stimulus for release. The peptide has also been identified in several other tissues, including ventricular myocardium. It is now known that the ANF gene is not expressed fully until late in embryonic life and after birth. However, there is heightened expression of the ANF gene in ventricular myocardium during hypertrophy and cardiomyopathy (209). It is believed that the reemergence of the fetal capacity to synthesize ANF in the setting of ventricular overload in hypertrophy represents an adaptive response to maintain volume homeostasis in response to the failing circulation. As with many other neuropeptides, ANF is progressively released into the circulation during the transition from asymptomatic LV dysfunction to overt heart failure (21). The peptide has vasodilatory properties and can thereby potentially improve cardiac function. It also may inhibit aldosterone secretion in patients with heart failure (210). Although it is a potent natriuretic, the renal effects of ANF appear to be attenuated during progressive heart failure. NEPs, which are highly concentrated in the proximal tubule brush border of the kidney, are responsible for degradation of ANF. This concept has driven the development of NEP inhibitors, some of which are hybrid molecules that include ACE inhibitors, of which omapatrilat is now in clinical trials for treatment of hypertension and heart failure.

In addition to the cardiovascular, renal, and neuroendocrine effects of ANF, the peptide may also have a moderating effect on cell growth (211). Unlike vasoconstrictor peptides, which tend to increase afterload, promote cell growth, and promote retention of salt and water, ANF appears to have important vasodilator properties, may be antigrowth *in vitro*, and has the ability to attenuate neuroendocrine activation and promote natriuresis. It is therefore part of a counterregulatory system that to some extent offsets excessive sympathetic nervous system and renin-angiotensin system activity. Although ANF has not itself become established as a therapeutic drug for heart failure, NEP inhibitors are potentially very important therapy for heart failure and hypertension, particularly when combined with ACE inhibitors (212).

Brain Natriuretic Peptide and C-Type Natriuretic Peptide

BNP was first isolated from the brains of pigs and forms a peptide family with ANF that is involved in the regulation of blood pressure and fluid volume (213). Plasma levels of BNP mainly reflect the degree of LV overload, and the secretion patterns of ANF and BNP vary with underlying cardiac disorders. BNP has been isolated from both brain and heart, whereas C-type natriuretic peptide is purified from porcine brain (214,215). Like ANF, both CNP and BNP can elicit vasorelaxant activity. All three natriuretic peptides share a common structural motif consisting of a 17-amino-acid loop formed by an intermolecular disulfide linkage bridge. When BNP is infused into humans with heart failure, urine volume significantly increases, excretion of sodium is enhanced, and plasma levels of BNP are increased (216). As with ANF, BNP causes a decrease in plasma aldosterone concentrations. Hemodynamic changes with BNP include an increase in heart rate, a decrease in blood pressure, as well as reduction in pulmonary capillary wedge pressure with little or no change in stroke volume index (217). Nesiritide, a human synthetic BNP, is currently approved as an infusion therapy for acute heart failure (218,219). Like ANF, BNP appears to be predominantly synthesized and secreted from the heart. BNP infusion also causes beneficial hemodynamic and neuroendocrine effects during exercise in patients with diastolic heart failure (220). It has been suggested that BNP, when persistently elevated, is a marker for poor long-term prognosis after acute myocardial infarction (184) and may serve as an important marker for ventricular dysfunction and myocardial hypertrophy. Perhaps the most exciting development is the use of BNP as a diagnostic marker for elevated LV filling pressures (31,32 and 33) and the potential to use bedside kits to quantitatively measure the response of circulating BNP to therapy. If successful, this strategy may obviate the need for invasive monitoring in some patients.

Growth Hormone

Patients with untreated heart failure are reported to have serum growth hormone levels more than 10 times the normal values (178). However, because in humans growth hormone secretion occurs mainly at night, random samples taken during the day may be less meaningful. At least one report has suggested that the severity of cardiac failure in patients with dilated cardiomyopathy is correlated with a decrease in circulating growth hormone levels at night (221). Even more intriguing are recent suggestions that recombinant human growth hormone may be useful as therapy for dilated cardiomyopathy. Many of the biologic effects of growth hormone on the heart appear to be mediated by local production of insulin-like growth factor I, which in turn regulates tissue growth by paracrine and autocrine mechanisms. Fazio and colleagues have reported that when administered at a dose of 14 IU per week, recombinant human growth hormone doubled the serum concentration of insulin-like growth factor I, and there were associated increases in LV wall thickness and reduced chamber size (222). In this small uncontrolled study, growth hormone also improved clinical symptoms, exercise capacity, and the quality of life. It has been known for many years that patients with acromegaly may present with cardiomyopathy and myocyte hypertrophy. In rats with acute myocardial infarction due to ligation of the left coronary artery, growth hormone improves cardiac index, stroke volume index, and LV dP/dT (223). The combination of insulin-like growth factor I given with growth hormone to rats with LV failure is associated with diminished vascular resistance and improved cardiac output (224). Severely dysfunctional hearts with evolving myocardial infarction may still be capable of undergoing additional hypertrophy in response to growth factor and may demonstrate evidence of improved function, suggesting a potentially beneficial effect (225). Clearly, this is an area where further basic and clinical studies are needed; however, work in this area has slowed, and there are no clinical trials in progress.

Tumor Necrosis Factor-a

Tumor necrosis factor (TNF)–a is a cytokine produced mainly by macrophages but has also been found in vascular smooth muscle and heart. It is a proinflammatory cytokine that has been consistently identified in virtually all forms of cardiac injury (226,227). It may play an important role in mediating and integrating the myocardial response to stress. As with other neurohormones, TNF-a may have a maladaptive role in long-term LV remodeling and heart failure. It has been suggested that TNF-a may produce inducible NO synthase (iNOS), leading to enhanced local concentrations of NO (229), which is known to exert a negative inotropic effect in the myocardium. TNF-a has also been implicated as a systemic mediator of septic shock and has been isolated from rat myocardium under conditions of acute ischemia and reperfusion (227). TNF is expressed in cardiac tissue of patients with heart failure (226,228). The observation that failing hearts express increased levels of TNF-a suggests that overexpression of the cytokine may have some biologic role in the progressive dysfunction that characterizes the failing heart.

It has been suggested that heart failure is characterized by the progressive loss of cardiac cells. The mechanism of cell dropout is not entirely clear, but apoptosis has been suggested as a potential mechanism. TNF-a is associated with apoptosis (230) and may play a role in the cell dropout associated with ventricular remodeling and heart failure. Ligand family members of the TNF receptor superfamily can induce pleiotropic biologic responses, including differentiation, proliferation, activation of enzymes, and cell death. Levine and colleagues were the first to demonstrate that TNF-a is increased in patients with heart failure (231). In high concentrations, TNF-a can cause pulmonary edema and LV dysfunction. It has also been suggested to stimulate catabolism and cardiac cachexia (232). Soluble TNF-a receptors may be shed from cells and can bind circulating TNF-a, thereby prolonging its half-life and biologic functions (233). In the aggregate, TNF may be an important contributor to the syndrome of progressive heart failure through a vast array of mechanisms, including increased expression of iNOS, deactivation of protooncogenes, and stimulation of apoptosis, and perhaps through as yet not fully identified mechanisms. The development of anti–TNF-a as treatment for heart failure has progressed rapidly, and a large, randomized, controlled trial in patients with heart failure has been conducted with etanercept, a fusion molecule consisting of the p75 receptor linked to the Fc portion of human immunoglobulin G (234). Etanercept and infliximab (a monoclonal antibody to TNF-a) are now being widely used to treat inflammatory conditions such as rheumatoid arthritis and Crohn's disease. Early experience in clinical trials has, however, been disappointing.

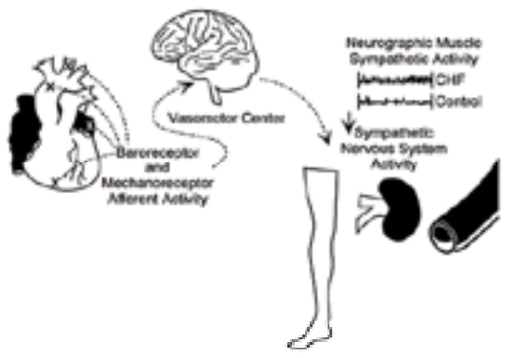
Adrenomedullin

Adrenomedullin is a newly discovered vasodilating and natriuretic peptide that may have some role in the regulation of cardiorenal homeostasis. Plasma concentrations of adrenomedullin are increased in patients with heart failure (235,236), and the peptide is known to be present in the human heart through immunoactive staining. Plasma adrenomedullin levels correlate with pulmonary artery pressure and pulmonary capillary wedge pressure. The precise role, if any, that adrenomedullin plays in the pathogenesis of heart failure has yet to be elucidated.

REFLEX CONTROL ABNORMALITIES IN HEART FAILURE

Human patients and animals with experimental chronic heart failure have abnormal reflex control mechanisms. Both arterial baroreflexes and cardiac reflexes are abnormal and can have profound effects on the patient with low cardiac output (237,238). Eckberg and colleagues first reported in 1971 that patients with heart disease had depressed baroreflex responses when given intravenous phenylephrine (239). Patients with advanced heart failure were subsequently demonstrated to have a blunted baroreceptor response to orthostasis (240).

Abnormal reflex control of the circulation is due to a combination of factors, including changes in end-organ responsiveness, as well as abnormalities in the synthesis, storage, and release of neurotransmitters. Left atrial stretch receptor discharge sensitivity is depressed in animals with heart failure (241). Under normal conditions, increases in atrial and ventricular filling pressures, as well as increased mean arterial pressure or pulse pressure, lead to stimulation of cardiopulmonary and arterial baroreceptors. Baroreceptor activation, in turn, sends inhibitory signals to the medullary vasomotor center in the brain, which in turn suppresses sympathetic efferent activity (*e*Fig. 88.5.1). There is also accompanying increased vagal efferent activity. For reasons that are still not entirely understood, heart failure is characterized by blunting of the normal baroreflex inhibition. This results in increased activation of the sympathetic nervous system and enhanced renin-angiotensin activity. It is as if the normal breaking of inhibitory signals of the medullary cardiovascular control region is lost in heart failure, presumably due to decreases in cardiopulmonary and the aortic baroreceptor sensitivity.



***e*FIGURE 88.5.1** Normal reflex control mechanisms sense changes in heart and vascular fullness and send afferent signals to the vasomotor center of the brain medulla, where they are processed to send out inhibitory efferent traffic that normally reduces sympathetic drive. In heart failure, this inhibitory "breaking" mechanism is defective, leading to enhanced efferent sympathetic activity (as measured by neurographic sympathetic activity to the skeletal muscles), affecting skeletal muscles, the kidney, and peripheral vascular tissue. CHF, congestive heart failure.

Abnormal sensitivity of the reflex control mechanisms can be restored to some extent by pharmacologic interdiction with drugs such as digitalis or ACE inhibitors. Although cardiopulmonary baroreflex control of sympathetic nerve activity is clearly less responsive in heart failure, there is less confidence about abnormalities of baseline arterial baroreflex control of sympathetic nerve activity. However, recent data suggest that reduced inhibitory signals from arterial baroreceptors also contribute to heightened sympathetic activity in heart failure (242). It does seem clear, however, that arterial and cardiac reflex abnormalities are not the sole cause of enhanced sympathetic tone in patients with heart failure. Increases in plasma norepinephrine are similar in baroreceptor-denervated and baroreceptor-intact dogs paced to heart failure (243). It is therefore unlikely that depression of baroreflex sensitivity in heart failure is the only cause of augmented sympathetic tone. It is also unlikely that abnormal baroreflex sensitivity seen in heart failure is due to structural alterations of the baroreceptors (244). Abnormalities of reflex control have been shown to reverse after orthotopic cardiac transplantation (245).

DISTURBANCES OF SALT AND WATER CONTROL

It has been understood by generations of physicians that heart failure is characterized by excessive sodium and water retention, but the mechanisms that underlie this observation continue to be elusive. It is unlikely that any single mechanism accounts for the maintenance of normal sodium balance. Patients with very severe heart failure have glomerular filtration reduced to approximately one-half of normal and renal blood flow reduced to approximately one-fifth of normal, suggesting that there is a considerable diversion of blood away from the kidney. As a result of the lowered filtration rate, a smaller quantity of sodium is probably delivered to the renal tubular cells. However, glomerular filtration rate is not invariably reduced in patients with heart failure, and its preservation is dependent by activation of the renin-angiotensin system (246).

Vasoconstriction and sodium retention are appropriate responses to loss of circulating volume. In heart failure, the kidney is responding to a perceived loss of extracellular fluid and plasma volume. The kidney, therefore, is not the culprit, but the victim. Glomerular filtration may be maintained by the vasoconstrictor effects of angiotensin II on glomerular efferent arterials. In the later stages of heart failure, salt and water retention are enhanced due to the effects of aldosterone and angiotensin II on the kidney. In some cases, vasopressin is released, leading to further reabsorption of free water. Eventually, heightened systemic resistance, circulatory congestion, edema, and hyponatremia become clinically manifested.

The primary signal that the kidney receives to initiate salt and water retention has remained elusive. It is not known what initiates the signal, nor is it understood where the signal is processed. Early studies by Barger observed that sodium excretion alterations are detected even in the mildest forms of experimental heart failure, before venous pressure is even changed (247). Abnormalities of cardiac output may not necessarily precede the increase in salt and water retention. These findings would suggest that sodium excretion abnormalities occur very early in the syndrome of heart failure, perhaps before there is a major reduction in maximal LV performance (248). Clearly, a reduction in cardiac output alone is not sufficient to cause sodium retention.

One of the major determinants of sodium retention is activation of the renin-angiotensin system. But there is only a rough correlation among hemodynamic measurements, the renin-angiotensin system, and urinary sodium excretion in patients with heart failure. Undoubtedly, neural and humoral pathways involve physical adjustments in renal microvascular hemodynamics, tubule fluid composition, flow rate, and tubular ion gradients, but these interactions are highly complex and difficult to precisely characterize (249).

Despite the lack of a penetrating understanding of how the initiation of salt and water retention occurs in heart failure, it does seem rather clear that the kidney perceives, in some way, a threat to the arterial blood pressure. There is a very consistent response to this perceived threat, with activation of baroreceptor reflexes, increases in sympathetic nervous system activity, and enhanced activity of the renin-angiotensin-aldosterone system. Ultimately, the increase in sympathetic nervous system activity may be coupled to reduced renal blood flow, thus leading to the nonosmotic release of vasopressin and other neurohormones. The net effect of these changes is an expansion of the extracellular volume, which helps to maintain blood pressure. Increased blood volume, in turn, acts as a negative feedback message to reduce the renin-angiotensin-aldosterone response, thus accounting for some of the observed heterogeneity in the renin-angiotensin-aldosterone system in patients with early heart failure.

To some extent, the expanded blood volume and intracardiac pressures lead to counterregulatory steps, including the release of ANF and other natriuretic peptides that have important endogenous natriuretic and vasodilator properties. However, the effects of the various natriuretic peptides on the kidney seem to be diminished as the syndrome of heart failure progresses. Ultimately, the effects of the natriuretic peptides are overwhelmed by opposing influences, and the overall effect is one of salt and water retention. It seems fortunate for the patient that our knowledge of how to treat salt and water retention has probably surpassed our understanding of the fundamental mechanisms that cause edema formation (250).

ABNORMALITIES OF THE PERIPHERAL CIRCULATION

It is now recognized that the maladaptive changes in the peripheral vasculature and skeletal muscle of patients with heart failure are largely responsible for symptoms of exercise intolerance. In the peripheral vasculature, impaired vasodilator capacity results from enhanced vessel wall stiffness, endothelial dysfunction, and other structural abnormalities. Blood vessels of patients with heart failure are generally more vasoconstricted. Initially, the vasoconstriction is minimal and somewhat selective as the body strives to redistribute blood flow between organs to maintain circulatory efficiency (Fig. 88.6) (251). However, over time, vasoconstriction becomes excessive in an attempt to protect blood pressure. Only the coronary and cerebral circulations are spared. The vasoconstriction ultimately becomes inappropriate and increases aortic impedance, thus placing a further burden on the already failing heart.

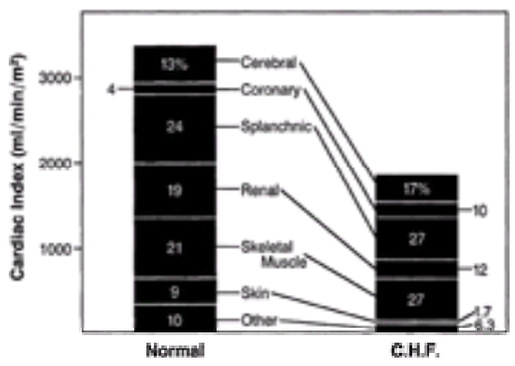


FIGURE 88.6 Cardiac output at rest. The normal distribution of cardiac index and the distribution of flow in heart failure. Renal and skin blood flow are markedly reduced in heart failure, whereas flow to the brain, heart, splanchnic bed, and skeletal muscles is preserved. CHF, congestive heart failure. (From Zelis R, Nellis SH, Longhurst J, et al. Abnormalities in the regional circulations accompanying congestive heart failure.*Prog Cardiovasc Dis* 1975;18:181–199, with permission.)

Although the cause of the heightened vasoconstrictor tone in heart failure is not entirely clear, it appears to be related to increased circulating catecholamines, particularly norepinephrine, as well as to other vasoconstrictors, including angiotensin II, vasopressin, and possibly endothelin. The abnormal redistribution of blood flow that occurs at rest is accentuated by exercise in patients with heart failure (251). Maximum metabolic vasodilation is significantly reduced. The increased sodium content of the vessels accounts for some of the vascular stiffness observed in heart failure. There is also heightened venous tone. Ultimately, the limited arteriolar dilator capacity results in a relative skeletal muscle hypoxia that may, through a reflex arc, lead to further sympathetic tone.

Although the increase in vascular resistance in heart failure is obvious, it is only partially explained by neurogenic and humoral stimuli. More recently, interest has focused on endothelial function, which is well known to be impaired in heart failure (252). Endogenous NO is known to be increased in patients with heart failure (253,254) and correlates with the severity of the syndrome as measured by the New York Heart Association functional class (255). It is believed that increased NO production in heart failure may compensate to some extent for the excessive vasoconstrictor adaptation. Despite an elevated basal release of NO and its role in depressing cardiac function, there is evidence to suggest that the peripheral vasculature has impaired release of NO on stimulation, which may play a role in inadequate vasodilator responses to exercise (256). In support of this hypothesis, there are data to suggest that oral L-arginine, when given in a supplemental fashion to patients with heart failure, has a beneficial effect by increasing forearm blood flow, improving the distances as walked during the 6-minute walk test, and improving quality of life as measured by a questionnaire (257). Dysfunction of the endothelium may persist and worsen as heart failure progresses, as evidenced by diminished vasodilator responses to acetylcholine and attenuated hyperemic responses to exercise and ischemia, both of which are largely endothelium-dependent. Of interest,

heart transplantation results in some reversal of impaired vasodilation, but it is delayed and incomplete (258).

In summary, congestive heart failure is characterized by abnormal peripheral vascular blood flow distribution with diminished hepatic, renal, and limb flow. The changes in peripheral blood flow are proportional and linearly related to the reduction in cardiac output. Vascular resistance is increased and is related to circulating catecholamines, angiotensin II, and AVP. Additionally, there appears to be significant impairment of NO release due to endothelial dysfunction, which probably accounts for some of the exercise intolerance noted in patients with heart failure. A generalized inability to maximally dilate a response to various stimuli characterizes the abnormal circulatory response, which may be corrected to some extent by medical therapy and heart transplantation.

EXERCISE INTOLERANCE IN HEART FAILURE

One of the hallmarks of the syndrome of heart failure is exercise intolerance. Although exercise tolerance is associated with LV systolic dysfunction, numerous studies have suggested that the extent of LV dysfunction bears little correlation to it (259,260,261,262 and 263). Moreover, it has been demonstrated that short-term administration of positive inotropic agents and vasodilators, which acutely improve LV performance, do not improve maximal exercise capacity in patients with heart failure (264). Even agents that are knowingly effective for the long-term therapy of heart failure, such as ACE inhibitors, have failed to consistently demonstrate improvement in exercise tolerance. The reasons for this are not entirely understood but may be related to inadequate methodology. The maximal exercise test may not be very representative of the daily activities of patients suffering from advanced heart failure (264). Maximal exercise testing is also somewhat subjective in that motivational factors and the experience of the operator/investigator can influence the end point. Because of this, the anaerobic threshold may be a more objective end point, but it is sometimes difficult to demonstrate, even with sophisticated gas exchange techniques. The simple 6-minute walk test is highly correlated to overall prognosis and seems to be emerging as an important measurement of exercise tolerance (265).

Maximal oxygen consumption is characterized by a plateau in oxygen uptake despite an increasing work rate (64). It is highly reproducible in normal subjects but can be difficult to determine in patients with advanced heart failure. The regional distribution of cardiac output during exercise is regulated by a complex interaction between the sympathetic nervous system, regional vasoactive factors including metaboreceptors, and endothelial-derived vasoactive substances including NO. The extent of widening of the arteriovenous oxygen difference is determined by increasing oxygen extraction in the exercising skeletal muscles. This in turn is somewhat dependent on capillary density, the number of open capillaries, and the transit time of the red blood cells through the capillaries. These complexities, coupled to the notorious difficulty in making accurate measurements during maximal exercise, have made it difficult to understand the precise mechanism of exercise intolerance in patients with heart failure.

In contrast to normal subjects, patients with heart failure do not achieve a plateau in oxygen uptake at the end of exercise. Rather, a “peak” oxygen uptake is determined in patients with heart failure that can be somewhat less reproducible. Whereas normal subjects distribute close to 90% of their total output to exercising skeletal muscle during maximal exercise, patients with heart failure distribute only 50% to 60% of the total cardiac output to exercising muscle. It has been presumed that the maximum caliber of the resistance arterioles is decreased in patients with heart failure due to changes in structure or perhaps vascular remodeling. When blood flow is chronically reduced, as occurs in advanced heart failure, the maximal vasodilator capacity of the peripheral circulation is markedly diminished through a complex sequence of events. These events include neurohormonal activation, diminished endothelial function related to impaired synthesis of NO, increased synthesis of endothelin, and possibly activation of cytokines and local factors that may further reduce arteriolar diameter. Patients with heart failure compensate for the reduced perfusion by widening their arteriovenous oxygen difference. Complete oxygen extraction can occur in the exercising skeletal muscle beds of patients with heart failure. This compensatory increase in oxygen extraction by skeletal muscles is similar to that observed in highly trained athletes. The mechanism of hyperextraction of oxygen is not understood very well. Unlike in well-trained athletes, increased capillary density has not been observed in patients with heart failure. In fact, there may well be diffuse atrophy of the lower extremities with diminished oxidative skeletal muscle fibers and oxidative enzyme content. This paradox remains poorly explained.

The exercise response in heart failure is very complex. Pump function is poorly related to exercise tolerance. Factors in the peripheral musculature, not the central hemodynamics, largely determine shortness of breath and fatigue. These peripheral factors include endothelial function, vasodilator capacity, distribution of cardiac output, heightened chemoreceptor and ergoreceptor sensitivity, skeletal muscle histology, and oxidative enzyme activity. Minute ventilation is markedly increased. There is a higher ventilation for any given carbon dioxide production (VE/VCO_2 slope), which reflects the severity of heart failure and the prognosis. Enhanced ergoreflexes and chemoreceptor responses drive hyperventilation and heightened sympathetic outflow, leading to increased peripheral resistance and a decrease in muscle perfusion.

Reduced muscle endurance can be improved with chronic exercise training in patients with heart failure (266,267 and 268). Although drugs such as ACE inhibitors may not improve maximal exercise tolerance in patients with heart failure, they can redistribute blood flow to the skeletal muscles during exercise and thereby improve submaximal exercise tolerance. Changes in skeletal muscle structure and function in heart failure may be related in part to deconditioning (266). Therefore, it is reasonable to recommend that all patients with heart failure continue to be physically active, at least with regard to isotonic activity. On the other hand, isometric activities such as work against gravity, are to be discouraged, because such activities impose an immediate afterload stress on the left ventricle. Reduced physical activity alone, however, does not easily explain the genesis of the skeletal muscle changes observed in heart failure (269). Clearly, we still have much to learn regarding the problem of exercise intolerance in heart failure.

TRANSITION FROM ASYMPTOMATIC LEFT VENTRICULAR DYSFUNCTION TO CLINICALLY OVERT HEART FAILURE

There is perhaps no more intriguing concept in the pathophysiology of heart failure than the transition from silent LV dysfunction to overt congestive heart failure. This transition is poorly understood but very important. Available experimental data would suggest that the initial response to an index event, such as acute myocardial infarction, includes a form of adaptive hypertrophy of myocardial cells. Eventually, there is remodeling of the left ventricle with replacement fibrosis, growth of the interstitium, and cell dropout due to apoptosis. Among the host of counterregulatory vasodilator mechanisms set into play is enhanced basal NO production (253,254 and 255). The expression of iNOS is enhanced in the failing human heart (270). iNOS is likely part of a primitive but evolutionary conserved inflammatory response. NO has been shown to have a negative effect on cardiac performance both experimentally (271) and clinically (272). NO may contribute to beta-adrenergic hyporesponsiveness in patients with LV dysfunction (271). Thus, in a purely speculative sense, the overexpression of cardiac NO may contribute to the transition to overt clinical heart failure.

Another mechanism perhaps responsible for the transition from clinically silent dilated cardiomyopathy to overt heart failure is dropout of myocardial cells. Although apoptosis is currently a feature of intense laboratory investigation, its role in the development of heart failure remains somewhat undefined. Nevertheless, there seems to be a commonality of interaction between TNF-a and iNOS. Cytokines such as TNF-a are increased in patients with heart failure (231,232 and 233) and are known to produce apoptosis through a receptor-mediated mechanism (273). TNF-a is also known to stimulate the production of iNOS (270). It is possible that as TNF-a increases over time, it has the dual propensity to induce local myocardial NO release (which in turn hampers LV function) while at the same time mediating cell dropout. In principle, such a mechanism would be a powerful factor in the pathogenesis of transition from clinically silent LV dysfunction to overt heart failure. More study of the complex interaction between TNF-a, iNOS, and progression of heart failure will be required to unravel this potentially very important mechanism.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Heart failure remains a problem of growing magnitude in the Western world. It primarily afflicts the older population and is a major drain on scarce medical resources. Although great strides have been made in the past two decades regarding the management of this complex syndrome, much work remains to be done (274,275,276 and 277).

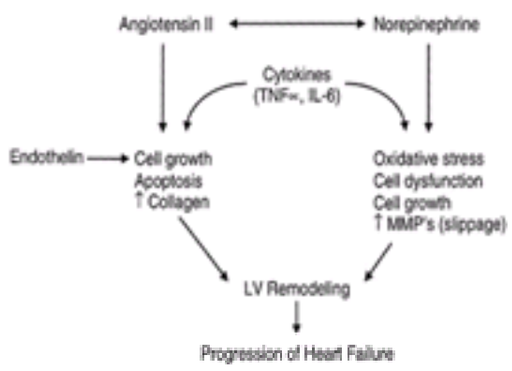
Heart failure is a prime example whereby a clearer understanding of the basic pathophysiology has led to highly specific therapies that are uniformly effective, such as ACE inhibitors and beta-adrenergic blockers. As we delve further into the neuroendocrine and cytokine disturbances in the syndrome, it becomes clear that other potential therapeutic targets are worth developing. Over the years there has been a rather direct course away from drugs designed to stimulate the inotropic state to agents that block excessive neuroendocrine activation pathways. In the future, we can look forward to drugs that are designed to more specifically inhibit the sympathetic nervous system, perhaps through mechanisms other than beta-adrenergic blockade. Drugs designed to block specific ET_A receptors have recently become available in an oral form (278). Preliminary data would suggest that endothelin blockers may have a primary role in the management of patients with heart failure by causing both a reduction in systemic vascular resistance and by stimulating vasodilator counterregulatory mechanisms. Augmentation of these vasodilator counterregulatory mechanisms is also possible through hybrid molecules that contain both NEP inhibitors and ACE inhibitors. Short-term infusion of peptides such as BNP may also find a role.

It will be useful, perhaps, to clinically screen for asymptomatic LV enlargement. Identification of markers in such patients might enable the early introduction of pharmaceutical interdiction. It is also possible that surgical reduction of a markedly expanded LV cavity will prove to be a valuable adjunct form of therapy. If cell dropout via apoptosis is found to be a dominant mechanism in the transition of LV dilation to overt heart failure, research in this arena may allow for the development of agents that block TNF-a receptor activity, thereby reducing iNOS synthase and blocking apoptosis. Until such agents are available, it is perhaps important to recognize that most cases of heart failure are due to coronary artery disease and hypertension. Many of the consequences of long-term high blood pressure can now be prevented with early identification and aggressive treatment. All physicians need to recognize that LV hypertrophy is a powerful risk factor for heart failure and

premature death and should be prevented or controlled when possible. Although the prevention of coronary artery disease is still not fully within our grasp, identification and aggressive control of risk factors are now certainly possible. In the long run, it is through the prevention of heart failure that measurable strides will be made in curbing what is now described as an emerging epidemic. Despite obvious progress, many controversies and uncertainties remain. The role of anticoagulation, especially aspirin, is still debated. The role of myocardial reperfusion on outcome is not entirely clear. The role and costs of polypharmacy remain a challenge. Controversy and uncertainty remain the driving force behind additional study, however, and will continue to serve us well.

CONCLUSIONS

Heart failure is a complex disorder that is still rather poorly understood. An index event occurs, such as acute myocardial infarction or onset of cardiomyopathy, and a host of “adaptations” are staged. Abnormal LV function from any cause appears to stimulate the release of a number of neurohormones and cytokines in an attempt to provide presumed circulatory homeostasis. However, over time neuroendocrine and cytokine activity may become highly maladaptive, contributing to LV remodeling, heightened systemic vascular resistance, and ultimately, worsening heart failure (*e*Fig. 88.6.1). To date, the most impressive long-term effective therapy has been designed to limit excessive neuroendocrine activation, and this is likely where future and more imaginative therapies will also reside.



***e*FIGURE 88.6.1** The neurohumoral hypothesis. Heart failure is characterized by activation of the sympathetic nervous system, the renin-angiotensin-aldosterone system, and specific cytokines, including tumor necrosis factor-a (TNF-a). Endothelin, a potent vasoconstrictor and mitogenic peptide, is also released, and there are counterregulatory natriuretic peptides, which to some extent offset the vasoconstrictor-enhanced growth milieu. Presumably these systems are activated in response to various signals stemming from deranged circulatory homeostasis to provide short-term support to the circulation. However, their long-term or persistent effects are ultimately maladaptive, and their chronic, excessive activity favors a pathway for left ventricular (LV) remodeling, hypertrophy, and progressive heart failure. These changes are facilitated by oxidative stress, apoptosis, increased collagen turnover, and excessive matrix metalloproteinase (MMP) activity. Drugs designed to block the adrenergic nervous system and the renin-angiotensin-aldosterone system are among the most effective therapies we have for the treatment of heart failure. IL, interleukin.

THE FUTURE

Heart failure is a common and highly disabling clinical syndrome. Although advancements have been made in our understanding of the pathogenesis and management of this complex disorder, we are still lacking substantial information regarding fundamental abnormalities, particularly at the cellular level. The mechanisms whereby neurohormones are activated and released are still not explained, but we have the means to abrogate their excessive activity. The underlying myocyte contractile abnormalities that occur on a molecular level are still poorly defined. The precise mechanism leading to exercise intolerance is still debated. Despite these misgivings, it is likely that continued research at both the basic and clinical level will afford clinicians the opportunity to better understand and manage this common clinical syndrome, provided there is sufficient support for basic science as well as clinical investigation. It is likely we will be able to better screen for heart failure via biochemical markers such as BNP, thereby initiating therapy at an earlier stage and thus preventing onset of the full-blown syndrome.

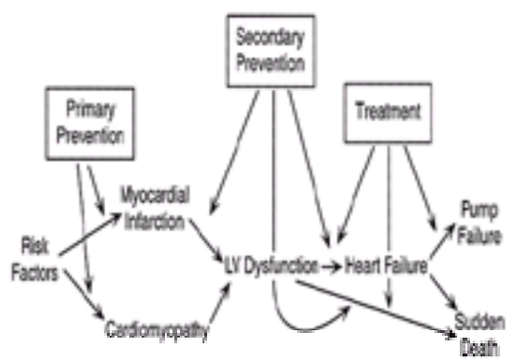
OVERVIEW

Congestive heart failure is an increasing, global epidemic, particularly in the elderly, that results in significant health care expenditure, disability, and mortality. Coronary artery disease, hypertension, and diabetes mellitus are the major etiologic risk factors. Ironically, advances in the treatment of coronary artery disease and acute ischemic syndromes, which have saved lives, have resulted in a growing population of survivors with left ventricular dysfunction destined to develop the heart failure syndrome. Preventive measures that have evolved over the last 25 years, including hypertension management, have not reduced the incidence of heart failure. Congestive heart failure is the leading indication for hospitalization in the United States for patients older than 65 years. The majority of health care dollars spent on heart failure is for inpatient care. Heart failure is a chronic disease amenable to an intensive multidisciplinary care model (disease management program) designed to prevent hospital admissions through patient education, focused outpatient initiatives, and adherence to management guidelines that should enhance cost effectiveness and improve quality of life. Patients with advanced heart failure represent approximately 10% of the total heart failure population, have the highest short-term mortality, and consume the greatest percentage of resources (labor and dollars). Regionalized centers with expertise in the management of advanced heart failure patients (through pharmacotherapy, circulatory support devices, surgical procedures, and transplantation) are necessary to deliver sophisticated care for this expanding population.

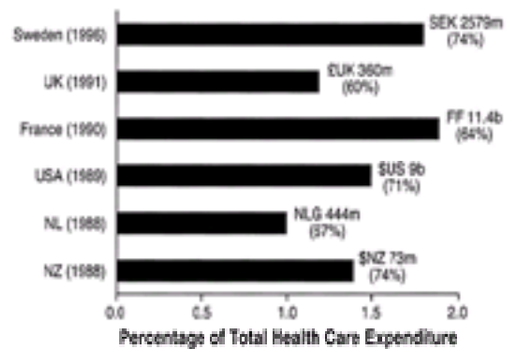
INTRODUCTION

Fifty years ago, chronic heart failure was considered primarily an edematous disorder. Hypertension and valvular heart disease were the most frequent predisposing causes (1). Physicians attempted to control pulmonary and peripheral congestion with diuretic therapy. Heart failure was a slowly progressive disease until patients succumbed with biventricular failure, anasarca, and renal insufficiency. Today, symptomatic heart failure is most often characterized by effort intolerance (dyspnea) and fatigue.

The most common causes of heart failure are coronary artery disease and hypertension. In the United States, incidence is twice as high in hypertensives and five times greater in persons who have had a myocardial infarction (2). Current treatments are judged by their ability to (a) reduce mortality, (b) reduce cardiovascular morbidity, (c) improve functional capacity, (d) improve quality of life, and (e) retard disease progression. As shown in eFigure 89.0.1, the natural history of heart failure has five key stages. The opportunities for medical interventions include primary prevention, secondary prevention, and treatment. An example of primary prevention is the use of pravastatin sodium to retard the progression of coronary artery disease and the incidence of myocardial infarction in a high-risk patient (3). The treatment of hypertension and the reduction in the vectoral transmission of Chagas' disease are also primary prevention efforts (4). A secondary prevention measure would be the use of captopril in a patient after an anterior myocardial infarction to retard left ventricular remodeling and the development of congestive heart failure (5). The mainstay of heart failure therapy today is "treatment" for established and symptomatic disease. Certainly the health care impact of heart failure for our society will continue to grow until effective primary and secondary prevention strategies are adopted and used. Therapeutic strategies can be assessed by determining the expenditure per quality-adjusted life-year (QALY) achieved with the treatment (6,7). A ratio of less than $20,000 per QALY is considered excellent, a ratio of $20,000 to $60,000 acceptable, and a ratio in excess of $100,000 per QALY unattractive (7). Examples for each year of life gained include renal dialysis, $40,000; cardiac transplantation, $25,000 to $44,300; and heart failure treatment with carvedilol, $12,800 to $29,000 (7,8). The cost of treating advanced symptomatic heart failure is high and represents a growing economic burden for industrialized nations. An analysis of six countries revealed that 1% to 2% of total health care expenditures were for treatment of heart failure (eFig. 89.0.2) and approximately 70% of this was consumed by hospital costs (9). The rapidly increasing prevalence of heart failure represents the most important public health problem in cardiovascular medicine (1,9,10).



***e*FIGURE 89.0.1** Stages in the natural history of heart failure, from the presence of risk factors to the syndrome of heart failure and its sequelae. Points for primary and secondary prevention and treatment are shown. LV, left ventricular. (Adapted from the Task Force on Research in Heart Failure, National Heart, Lung, and Blood Institute report Heart Failure. Washington, DC: U.S. Department of Health and Human Services, 1994.)



***e*FIGURE 89.0.2** Costs of chronic heart failure care in relation to the total annual health care expenditure in six industrialized nations. The component for hospital costs, quoted in the local currency, and the percentage of total expenditures on chronic heart failure care consumed by hospital costs are shown to the right of the bars. (Adapted from McMurray JJ, Stewart S. Epidemiology, aetiology, and prognosis of heart failure. *Heart* 2000;83:596–602.)

Heart failure is a chronic disease that may evolve over years and progress from minimal to severe impairment. Successful heart failure management requires lifestyle modifications and impinges on the activities and lives of family members and caregivers as well. Patients may live a limited but reasonable lifestyle for years. Most are disabled, however, and thus are not productive members of society. Aside from the economic burden from a health care resources standpoint, the disability and long-term nature of the condition that limit a patient's ability to be gainfully employed are significant. The components of cost to be considered from a public health perspective include hospitalization costs, outpatient care costs, and disability costs (11). Management of a chronic disease requires a multidisciplinary continuum of care designed to improve quality of life, reduce hospitalizations, and decrease costs (12,13). Thus, heart failure is not an isolated encounter, such as acute pharyngitis or bacterial pneumonia. Rather, it is an "epic of care," and patients, their families, and health care providers must develop relationships. Optimal outcomes can be achieved when physicians have the expertise to care for the patient through the various phases of his or her illness, effect lifestyle changes through education, and use a multidisciplinary team for effective chronic disease management (14).

EPIDEMIOLOGY

Heart failure is a widespread epidemic affecting 2 to 4 million Americans and nearly 15 million people worldwide (10,15,16). The American Heart Association estimated that, in 2001, 4.7 million Americans were alive with congestive heart failure (11). Although mortality rates are declining for cardiovascular disease in the United States, hospitalizations for heart failure have increased substantially (17). In 1990, more than 700,000 hospital discharges had heart failure as the primary diagnosis in the United States (15). This represents a fourfold increase since 1971. Hospital discharges of patients with congestive heart failure in the United States rose from 377,000 in 1979 to 978,000 in 1998, a 155% increase (11). In 1990, there were 708,000 new heart failure patients and 280,000 deaths, which represents a net increase of 428,000 patients or a 12% growth per year (18). Estimates are that approximately one-half of patients with heart failure are age 65 years or older.

A cohort of 2,000 persons aged 25 to 74 years living in Scotland underwent a detailed assessment of cardiac status including echocardiography (9). The overall prevalence of left ventricular systolic dysfunction (ejection fraction of 30% or less) was 2.9%. Concurrent symptoms of heart failure were found in 1.5%, whereas the remaining 1.4% were asymptomatic. Prevalence was greater with increasing age and in men, reaching 6.4% in men aged 65 to 74 years.

The criteria for the diagnosis of the syndrome of congestive heart failure are not standardized. Measures used in population-based studies and cardiovascular drug research rely on a composite of signs, symptoms, and diagnostic findings. Heart failure is a clinical diagnosis, and measures such as ejection fraction do not always identify patients with congestive heart failure (e.g., diastolic dysfunction). Attempts to validate the Framingham clinical heart failure score against a measure of ejection fraction showed that, in patients with a low left ventricular ejection fraction (0.40 or less), 20% met none of the criteria for congestive heart failure (19).

The crude incidence (unadjusted for age) ranges from one to five cases per 1,000 population per year and increases sharply with advancing age to as high as 40 cases per 1,000 population over age 75 years in some studies (20). An indication of the incidence of heart failure in the United States can be obtained from the Framingham study and the Framingham Offspring Study, which represent a population of over 10,000 (15). The incidence of heart failure rises with age in both men and women, as shown in Figure 89.1. In the Framingham study, the annual incidence increased from 3 per 1,000 in men aged 50 to 59 to 27 per 1,000 in men aged 80 to 89 years, and from 2 per 1,000 in women aged 50 to 59 to 22 per 1,000 in women aged 80 to 89 years. The incidence of congestive heart failure after adjustment for age is one-third lower in women than in men. Crude prevalence, unadjusted for age, ranges from 3 to 20 cases per 1,000 and, for those older than 65 years, from 30 to 130 cases per 1,000 population (20). Based on the increasing age of the U.S. population, estimates are that the prevalence of congestive heart failure will nearly double to 5.7 million cases by the year 2030 (21).

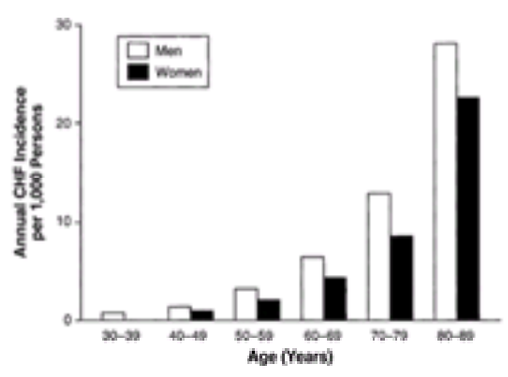


FIGURE 89.1 The annual incidence of congestive heart failure (CHF) among subjects in the Framingham Heart Study, shown by age in decades for men and women. (Adapted from Ho KKL, Pinsky JL, Kannel WB, et al. The epidemiology of heart failure: the Framingham study. *J Am Coll Cardiol* 1993;22[Suppl A]:6A–13A, with permission.)

Etiologic Risk Factors

The prevalence of certain causes of and risk factors for congestive heart failure among Framingham Heart Study subjects is shown in Figure 89.2. The Framingham study documented the relative risk for the development of heart failure in the presence of specific risk factors, including hypertension, hypercholesterolemia, cigarette smoking, electrocardiographically identified left ventricular hypertrophy, and diabetes mellitus, in a population-based cohort study (15). Among 331 men and 321 women in the Framingham study who developed congestive heart failure during follow-up, hypertension and coronary artery disease were the two most common preexisting conditions (15). Only 11% of men and 15% of women had no antecedent history of coronary artery disease or hypertension. Interestingly, in the 40-year period from 1948 to 1988, the age-adjusted prevalence of coronary disease in men with new congestive heart failure increased by 46% per calendar decade (p <.05). However, the age-adjusted prevalence of coronary heart disease among all males in the Framingham Heart Study decreased by 8% per calendar decade (p <.05) (15).

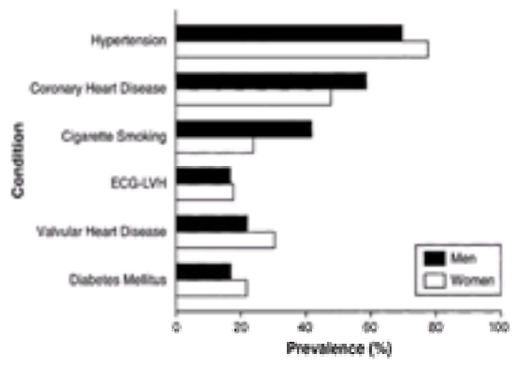

FIGURE 89.2 Prevalence of causes and risk factors for the development of congestive heart failure by gender in the Framingham Heart Study cohort. ECG-LVH, electrocardiographically identified left ventricular hypertrophy. [Adapted from Ho KKL, Pinsky JL, Kannel WB, et al. The epidemiology of heart failure: the Framingham study. *J Am Coll Cardiol* 1993;22(Suppl A):6A–13A, with permission.]

The incidence of heart failure is twice as high in persons with hypertension, and the incidence can be stratified based on severity of hypertension as shown in Figure 89.3 (2). Similarly, when followed prospectively, persons with a history of prior myocardial infarction are found to have a fivefold greater incidence of heart failure over a 5-year period (2) (Fig. 89.4).

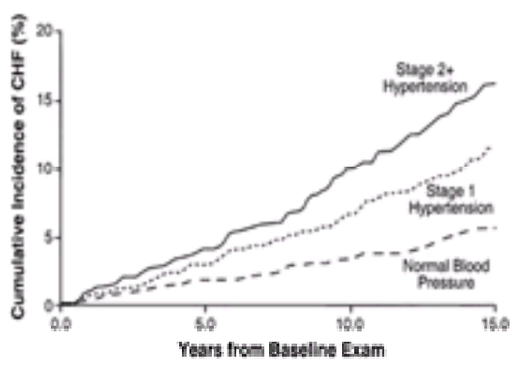

FIGURE 89.3 Incidence of congestive heart failure (CHF) in men and women aged 50 to 79 years by hypertension status. Stage 1 hypertension is defined as systolic blood pressure of 140 to 159 mm Hg or diastolic blood pressure of 90 to 99 mm Hg in people not receiving antihypertensive medication; stage 2 or higher hypertension is defined as systolic blood pressure of 160 or greater, diastolic blood pressure of 100 or greater, or current use of antihypertensive medication. (Adapted from National Heart, Lung and Blood Institute. Congestive heart failure in the United States: a new epidemic. Bethesda, MD: U.S. Department of Health and Human Services, 1996.)

Mortality

Although a significant decline in mortality due to coronary heart disease and hypertension has occurred over the past 40 years, no significant decline was observed in age-adjusted mortality in patients diagnosed with congestive heart failure in the Framingham cohort (15). Heart failure remains a lethal condition, with 5-year survival rates of less than 40% from the time of diagnosis, as shown in Figure 89.5. Data obtained from the National Center for Health Statistics in 1988 show that 267,356 deaths due to heart failure occurred. At all ages, the death rates from heart failure are greater for the African-America population, as shown in Figure 89.6, and the mortality rate from heart failure increases precipitously after age 65 years (15). Since 1968, the incidence of heart failure as the primary cause of death has increased fourfold (15). The most dismal prognosis for patients with severe symptoms [New York Heart Association (NYHA) class IV] and coronary artery disease was a survival rate of 43% and 18% at 1 and 3 years, respectively (22). Patients with dilated, nonischemic cardiomyopathy who are symptomatic with medical therapy have a better prognosis than patients with underlying coronary artery disease (22).

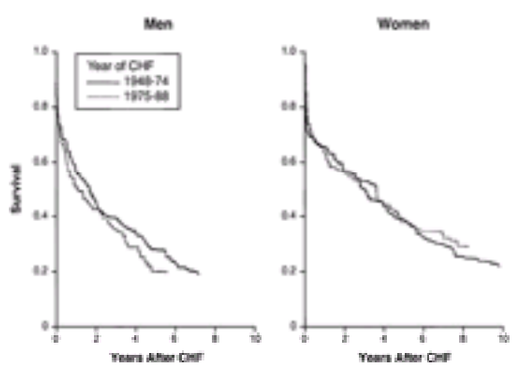

FIGURE 89.5 Age-adjusted survival rates by calendar year after the first diagnosis of congestive heart failure (CHF) for men and women in the Framingham Heart Study. No significant change in survival over 40 years of follow-up was found despite a considerable decline in coronary artery disease mortality. [Adapted from Kannel WG, Ho K, Thom T. Changing epidemiological features of cardiac failure. *Br Heart J* 1994;72(Suppl 2):S3–S9, with permission.]

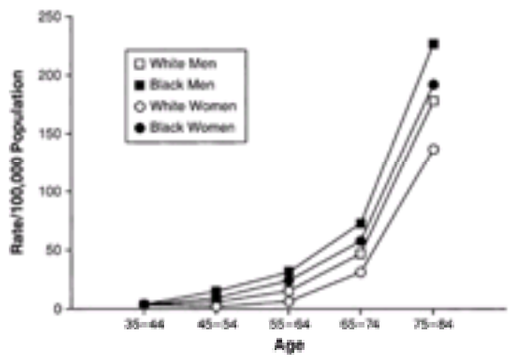

FIGURE 89.6 U.S. heart failure death rate in 1988 by age, gender, and race. Compiled from data from the National Center for Health Statistics. [Adapted from Kannel WG, Ho K, Thom T. Changing epidemiological features of cardiac failure. *Br Heart J* 1994;72(Suppl 2):S3–S9, with permission.]

Although major advances in pharmacologic therapy have occurred in the past decade, cardiac transplantation remains the only therapy that has a major, positive impact (reduced mortality and improved functional class) for patients with class IV symptoms refractory to medical therapy. The primary limitation of heart transplantation is the low availability: only 2,184 heart transplantations were performed in 1999 in the United States (see Chapter 94). Thus, a very small minority of the population at risk is served with this life-sustaining form of therapy. Therefore, most patients with class IV disease, comprising 10% to 15% of the total population with heart failure, remain at highest risk for hospital admission, require frequent outpatient monitoring, and consume a high percentage of the total dollars spent on heart failure care. In 1999, the estimated first-year cost for a heart transplant was $303,400, and the estimated annual follow-up cost was $39,700 (11).

Hospitalization Rates

Congestive heart failure represents America's largest diagnosis-related group, with an annual inpatient volume of more than 600,000, almost double the number of all other cardiovascular disorders (21). As the U.S. population ages, heart failure is a rapidly increasing indication for hospitalization, as depicted in Figure 89.7 (17). A sharp increase in the rates of hospital admission for heart failure in the elderly cohort older than 65 years was observed from 1972 to 1990, with the rate tripling from 55 per 10,000 to more than 150 per 10,000 population (17). The National Hospital Discharge Survey, which analyzed data from 1973 to 1986, identified a dramatic increase in hospital discharges for congestive heart failure in the population older than 74 years (23). Data for persons aged 35 to 54 years showed a significant gender and race differential (nonwhite men and white men have the highest hospitalization rates). With advancing age, however, the gender and race differential for hospitalization attributable to heart failure disappears (23). Overall, since 1971, a fourfold increase has occurred in hospital admissions for which congestive heart failure was the primary diagnosis, rising from 165,000 to 722,000 in 1990 (17). In 1997, 957,000 Americans were discharged from short-stay hospitals with a primary diagnosis of heart failure; of these, 79% were age 65 and older (11).

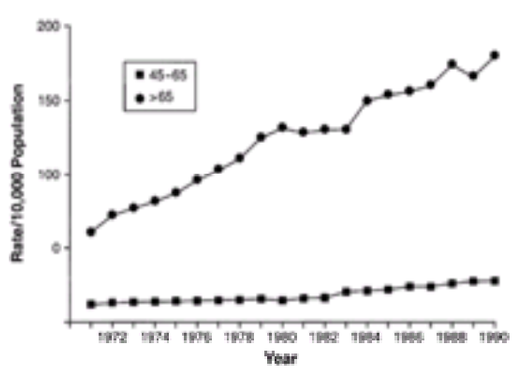

FIGURE 89.7 Hospital admissions per 10,000 population per year for congestive heart failure in the United States. [Adapted from Kannel WG, Ho K, Thom T. Changing epidemiological features of cardiac failure. *Br Heart J* 1994;72(Suppl 2):S3–S9, with permission.]

Reasons for Increasing Prevalence of Heart Failure

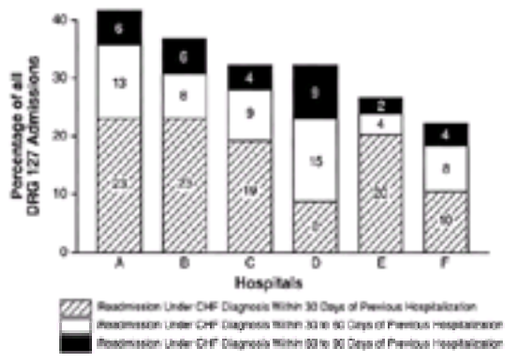
The prevalence of heart failure increases with age. Furthermore, advances in the pharmacologic and surgical management of coronary artery disease, arrhythmias, valvular heart disease, and hypertension have resulted in an ever-enlarging, aging pool of patients who are likely to develop worsening systolic or diastolic function and ventricular remodeling leading to the syndrome of heart failure. Effective medical and surgical interventions have resulted in a reduction in premature deaths. The prevalence of heart failure is rising, however, because predisposing conditions (coronary artery disease and diabetes mellitus) are palliated but not cured. The population of "survivors" with chronic coronary heart disease and left ventricular dysfunction who eventually develop the syndrome of congestive heart failure is growing. Similarly, the advent of implantable cardiac defibrillators has further reduced the incidence of sudden cardiac death. Thus, patients now live longer with left ventricular dysfunction and progressive congestive heart failure. Successful strategies aimed at the primary prevention of coronary artery disease will result in a major decline in the prevalence of congestive heart failure.

ECONOMICS AND THE HEALTH CARE IMPACT OF HEART FAILURE

Medical economics and heart failure are reviewed in Chapter 42. Health care reform in the United States has led to the reexamining, restructuring, and reengineering of all aspects of health care delivery in America. Because congestive heart failure represents the number one public health problem in cardiovascular medicine, its economic impact is tremendous. Projections attempting to estimate the total health care costs of heart failure are performed using indirect measures, extrapolations, and assumptions. Statistics, including those from the National Disease and Therapeutics Index, National Hospital Discharge Survey, and National Ambulatory Medical Care Survey, are used (18,24). Recent estimates of total annual health care expenditures for heart failure in America have ranged from $10.3 billion to $37.8 billion (18,24). The disparity of these figures demonstrates the unavailability of accurate economic data, but the cost to American society per year is at least $10 billion and may be as high as $40 billion. The American Heart Association estimated $21.0 billion for direct and indirect costs of congestive heart failure in the United States in 2001 (11). The breakdown included: $14.3 billion for hospital and nursing home care, $1.5 billion for physician and professional services, $1.6 billion for medications, $1.5 billion for home health care, and $1.6 billion for lost productivity and mortality. Hence, 68% of the total expense is for inpatient care, very similar to the estimates for inpatient care (73% and 62%) in the other two reports cited earlier (18,24). Considering the rates of hospitalization (including readmissions) for heart failure, the fact that 1% to 2% of total health care expenditures is consumed by treatment of heart failure in a number of industrialized countries is not surprising (9) (eFig. 89.0.2). Actual health care expenditures for treatment of heart failure can only be estimated. All estimates assume the accuracy of discharge summaries, death certificates, prescription use, and physician surveys in coding heart failure events.

The frequency of hospitalizations for congestive heart failure accounts for much of the economic burden. A conservative estimate of cumulative care costs during hospitalization ranges from $6,000 to $12,000 per admission. Approximately 35% of the population diagnosed with heart failure become hospitalized on an annual basis (10). Multiple hospitalizations, particularly of elderly patients with multiple comorbid conditions (50% have three or more), are especially common. Indeed, the 3-month readmission rate after an index hospitalization for congestive heart failure was found to be as high as 47% of discharges (25). A demonstration project showed that, in six medical centers, congestive heart failure patients are most likely to require readmission in the first 30 days after hospital discharge, as shown in eFigure 89.7.1, and that 22% to 42% of all patients classified into diagnosis-related group 127 at admission are readmitted within 90 days of a previous hospitalization (21). Many factors are related to the high rates of hospitalization for heart failure patients, including progression of underlying disease, inappropriate treatment plans, lack of patient compliance with prescribed regimens or diet or both, and use of detrimental drug therapy in certain heart failure settings. Many patient- and physician-specific issues that contribute to "heart failure decompensation" are potentially reversible (26). An analysis in Germany of 179 patients admitted to the hospital with acute decompensation of preexisting heart failure concluded that 54% of admissions could be regarded as preventable (27). Noncompliance with drug regimens or diet was the leading cause of acute decompensation and was present in 42%. The importance for practitioners of using pharmacologic agents proven to be effective in multicenter clinical trials (e.g., lisinopril in the Assessment of Treatment with Lisinopril and Survival trial; see Chapter 92) at target doses when managing chronic heart

failure must be reinforced (28).



***e*FIGURE 89.7.1** Rates of readmission under the diagnosis of congestive heart failure (CHF) [diagnosis-related group (DRG) 127] at six hospitals. (Adapted from Field JL. *Beyond four walls: research summary for clinicians and administrators on CHF management.* Washington, DC: Cardiology Preeminence Round Table, Advisory Board Company, 1994, with permission.)

Methods of reducing the high frequency and acuteness of hospitalization, prolonged length of hospital stays, and frequent emergency room visits are essential to reduce costs. Outpatient care is much less expensive. Thus, the costs to intensify the outpatient delivery of care are trivial and are offset by the major reduction in total health care costs if hospital days are reduced. One goal should be to improve the “effectiveness” of inpatient stays so that readmission rate declines. Up to 25% of Medicare expenditures for hospitalizations are for readmissions (29). A demonstration project performed in the United States showed that initiatives to reduce readmissions resulted in a 43% greater reduction in total hospital days than did initiatives to reduce length of stay (21). A study was conducted of 748 patients hospitalized for heart failure in 12 Veterans Administration hospitals. Patients were scored according to ten criteria believed to define readiness for discharge (30). A readiness-for-discharge score below the twenty-fifth percentile was associated with a twofold increase in the risk for readmission. The criteria used are intuitive and simple (stable renal function, compensated congestive heart failure, no change in cardiac medications in 24 hours, patient or family or both understand dietary regimen, etc.). Thus, in heart failure, improving the “quality” of the hospitalization may be the most cost-effective approach. Initiatives to reduce length of stay are important but should not compromise efforts to decrease the risk of hospital readmission.

SEVERITY OF HEART FAILURE AND RESOURCE USE

Patients with advanced heart failure represent approximately 10% of the total heart failure population, experience the highest short-term mortality, and consume tremendous resources (labor and dollars). Because of better pharmacotherapy and management, an increasing number of patients is expected to survive with severe left ventricular dysfunction who will ultimately die from refractory heart failure. Before the era of angiotensin-converting enzyme inhibitors (ACEIs), beta-blockers, and improved treatment for arrhythmias, approximately 50% of patients with left ventricular dysfunction died of presumed arrhythmias. Information now indicates that approximately 20% of patients with compensated heart failure and preserved exercise capacity die from sudden cardiac death (31,32). Despite meticulous management to reduce exacerbations of congestive heart failure, these patients ultimately deteriorate, develop worsening heart failure, and require advanced therapies. Patients with refractory heart failure are the consumers of expensive, technologically sophisticated options, including cardiac transplantation, mechanical circulatory assist devices, automatic implantable cardiac defibrillators, outpatient intravenous inotropic therapy, and frequent high-acuteness admissions (intensive care unit stays and hemodynamic monitoring). A European analysis has shown that treating severe heart failure is more expensive than treating mild heart failure, primarily due to the high rate and costs of hospitalization over the 6- to 12-month period before death (33). An admission for cardiac transplantation and postoperative care averages $303,400. Cost for implantation and care associated with a left ventricular assist device averages $175,000, and implantation of a cardiac defibrillator, $50,000. As discussed in Chapter 42, the cost for 1 year of care for a patient with advanced heart failure is approximately $20,000. Specialized regional heart failure centers will play a critical role in the delivery of cost-effective high-quality care to this group of patients, who consume a high percentage of the total health care dollars spent.

ECONOMIC IMPACT OF PHARMACOTHERAPY

ACEIs reduce mortality, progression of symptomatic disease, and hospitalizations in patients with symptomatic and asymptomatic left ventricular dysfunction (34,35). In the Studies of Left Ventricular Dysfunction (SOLVD) treatment trial, a 26% reduction in risk of death or hospitalizations for heart failure was seen among patients treated with enalapril maleate (34). In the SOLVD prevention trial, which enrolled asymptomatic patients with left ventricular systolic dysfunction, enalapril-treated patients experienced a 36% risk reduction for first hospitalizations and a 44% risk reduction for multiple hospitalizations for heart failure (35). Based on results of published randomized trials with hydralazine hydrochloride/isosorbide dinitrate and enalapril, the incremental cost-effectiveness ratio per year of life saved was calculated (36). The cost per year of life saved is an additional $5,600 for a patient receiving hydralazine and isosorbide and an additional $9,700 for a patient receiving enalapril above the costs for patients receiving no vasodilator therapy (Table 89.1). In comparison, when this modeling technique is used, the cost for a year of life saved by treatment of moderate hypertension is $25,000 and for a year of “useful life saved” by renal dialysis is $35,000 (36). A study in the United Kingdom found that only 17% of patients with heart failure were prescribed ACEIs by their general practitioner (37). In the United States, surveys have indicated that cardiologists are more likely to prescribe ACEIs than are general practitioners and internists (38). Furthermore, “heart failure specialty cardiologists” are more likely to use the documented efficacious dosage of studied drugs and to avoid concomitant use of potentially deleterious medications.

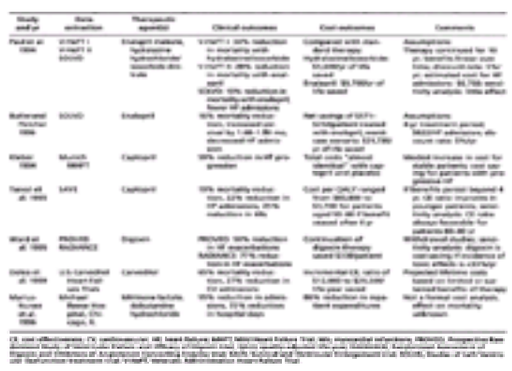


TABLE 89.1 COST EFFECTIVENESS OF PHARMACOLOGIC AGENTS FOR THE TREATMENT OF HEART FAILURE

The use of multiple agents for the treatment of heart failure is becoming state of the art as all randomized trials now include background ACEI therapy (see Chapter 92). In the prospective randomized trial of carvedilol, patients with heart failure receiving background treatment with digoxin, diuretics, and an ACEI were randomly assigned to receive carvedilol or a placebo. Compared with placebo, carvedilol therapy was accompanied by a 27% reduction in the risk of hospitalization for cardiovascular causes (19.6% vs. 14.1%; $p = .036$) as well as a 38% reduction in the combined risk of hospitalization or death (24.6% vs. 15.8%; $p < .001$) (39). Subsequent trials of beta-blocker therapy have consistently shown that the addition of beta-blockers reduces need for hospitalization and can result in considerable reduction in cost of care ($800 per patient over 2 years) (33). The economic outcomes of withdrawal of digoxin therapy for American adults with stable heart failure have been examined (see Chapter 42) (40). When a decision-analytic model is used to estimate the impact of digoxin withdrawal in patients with NYHA class II and III heart failure and a left ventricular ejection fraction of 35% or less, based on hospital Medicare data, an annual savings of over $400 million is anticipated. The proper use of medications thus saves lives, improves quality of life, reduces the need for hospitalizations, and can reduce the cost of treating patients with heart failure.

Heart Failure Guidelines

Clinical practice guidelines have been developed by carefully evaluating the world’s literature, with emphasis on well-controlled randomized clinical trials of solid scientific validity and expert opinion of prominent clinicians. Guideline documents for the evaluation and management of heart failure have been published (41,42,43,44

and 45). Heart failure experts believe that the pharmacologic treatment of patients remains suboptimal, which is explained in part by provider inexperience and the lack of definitive management recommendations. These documents, with acknowledged deficits, represent ambitious efforts to fill the void and communicate state-of-the-art guidelines. The guidelines emphasize the importance of appropriate pharmacologic therapy (target dosages and ACEI use for asymptomatic left ventricular dysfunction) and nonpharmacologic treatment (counseling, education, and lifestyle modifications) in the management of heart failure (42). The economic and quality-of-care ramifications related to the dissemination of and improved adherence to these guidelines are enormous. The publication of guidelines has led to the development of disease care management algorithms that can be implemented within health care systems (14,46).

Cardiac Transplantation and Alternatives

The fiduciary involvement of the U.S. government in the field of heart transplantation began in 1986. Criteria for approval as a Medicare-designated heart transplant center were developed, and reimbursement for treatment of Medicare patients is restricted to centers that have met the stipulated approval criteria (47). Transplant center volume and the experience of key personnel (e.g., transplant cardiologist) may influence a center's results (48,49). With the advent of managed care and capitation, insurance carriers are defining organ-specific transplant centers ("designated centers") based on volume, outcomes, and cost, and are providing coverage for transplantation only at the designated centers. The designated-center approach to the provision of cardiac transplantation tends to favor high-volume, cost-efficient centers with excellent outcomes. The Prudential Institutes of Quality program has reported savings ranging from 9% to 28% and 1-year patient survival rates for patients treated at designated centers that were 4% to 12% higher than average national survival rates (50).

Few accurate data are available detailing the actual cost expended for a heart transplant procedure, and much attention has focused on the total charges ("list price"). The National Cooperative Transplantation Study revealed a wide range of hospital charges, from $8,173 to $1,290,033 (51). The average price (e.g., capitated reimbursement) for a heart transplant procedure reported by national health care provider networks in the United States in 1997 was approximately $98,500. In 1999 in the United States, the estimated first-year cost for a heart transplant was $303,400 and the estimated annual follow-up cost was $39,700 (11). Wide variability exists nationwide. For example, the average hospital charge for a heart transplantation in Pennsylvania in 1991 was $233,276, and the maximum charge approached $1 million (50). In Ohio the breakdown for third-party coverage is 73% covered by a private carrier and 27% by government carriers, including 8% by Medicare and 13% by Medicaid (52).

High-cost procedures are often performed on mortally ill patients with complicated disease, a "no win" practice from a financial viewpoint in an environment of capitation. Thus, transplant professionals must increasingly face the ethical and economic dilemmas posed by high-risk/high-cost patients. Transplant programs are under increasing pressure to be economically efficient. As programs strive to increase their volumes (economy of scale), patient selection policies may actually become more prudent relative to the demands of managed care (50). Transplant professionals must scrutinize and justify the costs and benefits of their patient selection criteria and patient outcomes and must be responsive to the managed care programs with which they contract. Liberal patient selection criteria with regard to high-risk patients will jeopardize a program's competitiveness in an environment of capitation. Current trends suggest that more regionalization of heart transplant centers will occur, driven by managed care contracts and the demands of price and quality considerations. The transplant professional faces complex intertwined ethical and economic challenges and must carefully balance the issues of patient selection, cost containment, patient outcomes, and responsiveness to one's competition in the health care market.

Alternatives to transplantation are discussed in Chapter 94. Mechanical circulatory support, cardiac xenograft transplantation, dynamic cardiomyoplasty, and cardiac reduction surgery are all unproven experimental techniques. Cardiac reduction surgery, highly touted to provide a cost-effective alternative for a discrete subset of patients with dilated cardiomyopathy, has proven largely ineffective (53).

ECONOMIC STRATEGIES FOR TREATMENT OF HEART FAILURE

Principles

Imperative for effective treatment is correctly diagnosing the heart disease and, hence, facilitating definition of the best therapy. Already acknowledged was the fact that heart failure specialists believe that many patients receive suboptimal pharmacotherapy. Perhaps more problematic is the failure to recognize and apply an effective surgical or medical treatment. Regional heart failure centers evaluate many patients referred for consideration of heart transplantation (54). Only approximately 30% of patients referred are listed for transplantation initially. Treatable forms of heart failure must be identified. The expert opinion of a heart failure specialist may often identify an appropriate treatment other than cardiac transplantation. Examples would include the treatment of an arrhythmia that leads to improvement in ventricular function, successful surgical revascularization of a patient with hibernating myocardium, and careful observation of a patient with new-onset dilated cardiomyopathy who ultimately has spontaneous improvement in ventricular function. Transplantation in these situations would be medically inappropriate and expensive and would deprive another patient of a potential donor organ. A positive spin-off of the creation of regional heart failure/transplantation centers has been the exposure of referred patients to heart failure specialists who can make definitive diagnostic and treatment plans (55). These observations are most relevant to patients with advanced heart failure, who have the highest short-term mortality. Patients with stable NYHA class I or II heart failure are generally cared for very appropriately by the primary care physician or general cardiologist. Patients with problematic refractory heart failure may benefit from evaluation by a heart failure specialist (14).

Risk Factors and High-Risk Patients

Elderly patients represent a high-risk population. Readmissions can be reduced in the elderly patient population with a multidisciplinary interventional scheme (25). One study involving a group of geriatric heart failure patients used intensive education on the treatment of heart failure, dietary education, social services evaluation, review of medications and follow-up care by a geriatric cardiologist, intensive outpatient home visits, and telephone contact as interventional techniques. The number of readmissions for heart failure was significantly reduced by 56% in the treatment group (from 39% to 17%) (25). These findings support the tenet of using a nurse-directed multidisciplinary treatment strategy to significantly reduce hospital admissions and improve quality of life in elderly patients with heart failure (25). An analysis of elderly patients (65 years or older) with heart failure in Connecticut identified four predictors of hospital readmission: prior admission within 1 year, prior heart failure, diabetes, and creatinine level higher than 2.5 mg per dL at discharge (56).

Similar conclusions were reached in a study conducted in Israel, in which 42 patients with functional class III or IV heart failure, whose mean age was 78 years, were studied before and after the implementation of a general home care surveillance program (57). Cardiovascular-related hospital admissions decreased 72% from a mean of 2.9 ± 1.5 admissions per patient per year to 0.8 ± 1.1 admission per patient per year (p <.001). The duration of hospitalization for cardiovascular disease fell sharply from 23 ± 13 to 4 ± 4 days, an 83% reduction (p <.001). A significant improvement in the global functional status index was also observed. Resource allocation to fund interventions designed to reduce hospitalizations in high-risk patients (elderly patients and those with NYHA class IV congestive heart failure or a history of frequent hospital admissions for congestive heart failure) is cost effective and improves quality of life. These strategies will play an important role in the management of the expanding elderly population with heart failure (see Chapter 42).

Educational Programs

The heart failure guidelines stress the importance of education in the treatment of heart failure. Education must extend beyond the patient to the family members and care providers who assist in the necessary dietary and lifestyle modifications (42,58). Educational initiatives improve quality of life for the patient and prevent hospitalization. Hence, the cost-savings potential is tremendous. Educational interventions designed to improve dietary compliance and reduce hospital admissions in heart failure patients have been found to be highly successful (59,60). A physician-supervised, nurse-managed, home care program for heart failure management that implemented pharmacologic and dietary therapy with frequent monitoring via telephone contact was conducted in northern California (59). Three generic problems in the outpatient management of heart failure were addressed: cognitive (what to do), executive (who should do it), and organizational (when and where it should be done). Consensus guidelines (of the American College of Cardiology/American Heart Association consensus report and Agency for Health Care Policy and Research) were embedded in the clinical algorithms. The nurse-manager was responsible for obtaining essential information from the patient and laboratory and carrying out the therapeutic program. Fifty-one patients with moderate to severe heart failure were followed for over 4 months, and hospitalization rates for heart failure declined significantly by 87%. Other key findings included a reduction in dietary sodium by 38% and a significant increase in dosages of lisinopril and hydralazine (59). Although this was not a randomized trial, nonetheless it emphasizes the health care impact of adherence to heart failure guidelines and dietary and educational programs in the management of heart failure. Eight studies (Table 89.2) without a pharmacologic component have shown the benefit of multidisciplinary education-based therapy for heart failure (7).

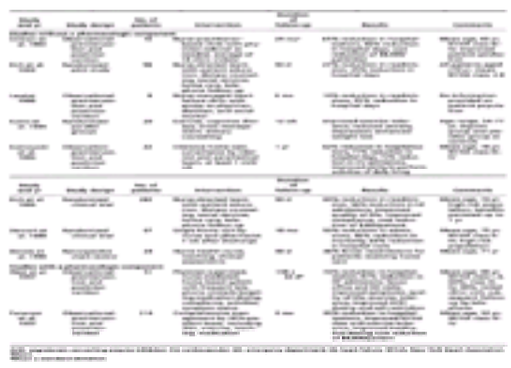

TABLE 89.2 COST EFFECTIVENESS OF NONPHARMACOLOGIC INTERVENTIONS FOR THE TREATMENT OF HEART FAILURE

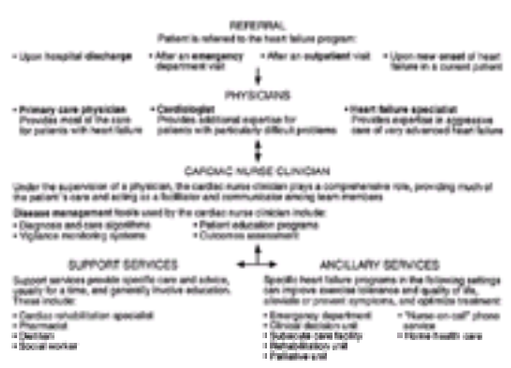
Management of Chronic Disease

Disease management programs are designed to reduce net costs and improve patient outcomes. The primary care model includes a primary care physician as the gatekeeper. Medical care is scheduled and episodic, and the focus is on reducing specialist referrals. In contrast, the chronic care model emphasizes more liberal access to specialized physician and nursing care, disease management, patient monitoring and proactive interventions, and reduction of acute hospital admissions. Disease management is a concept aimed at patient populations with a discrete clinical problem and proposes that tertiary care provided by specialists can be more cost effective and of higher quality than care given in the primary care setting (61). Heart failure is a specific clinical condition that is amenable to treatment by means of a disease management program using specialized physicians and intensive nursing and education programs (14,21,59). A typical heart failure disease management program consists of inpatient consultation and care, treatment at an outpatient heart failure clinic, cardiac home care, and compliance monitoring (62).

A multidisciplinary heart failure disease management program used at The Cleveland Clinic Foundation is shown in eFigure 89.7.2 (14). The cornerstone of a heart failure disease management program is the use of pharmacologic therapy in accordance with evidence-based heart failure guidelines and development of a mechanism to monitor compliance by both patients and physicians. Multidisciplinary heart failure disease management programs have proven efficacy (they are cost effective and improve clinical outcomes) and should be a standard component of routine heart failure care (13). Further research is required to define which patients with heart failure are most likely to benefit from multidisciplinary disease management programs; however, intuitively the elderly, socially deprived, and patients at high risk for readmission appear to require and derive the greatest benefit (56).



***e*FIGURE 89.7.2** Heart failure disease management program used at The Cleveland Clinic.

Heart failure ranks second only to essential hypertension as a cardiovascular reason for an outpatient visit. In 1990, 11.4 million outpatient visits were made, with 3.5 million patients making an average of 3.4 visits per year (18). New algorithms to shift more patient care to the outpatient setting are being implemented at a furious pace. Implementation of cost-effective strategies for the outpatient management of congestive heart failure is mandated. The cornerstone of cost reduction in heart failure care is the reduction of emergency room visits and the frequency and length of hospitalization. The question for the future is how this can be accomplished most effectively. The three components of outpatient care, emergency care, and inpatient care should be addressed. In the chronic care model, the optimal outpatient delivery of care should include (a) a heart failure clinic staffed by heart failure physicians and nurses, (b) home health heart failure nursing specialists, (c) immediate communication between patient and center via telephone or telecommunications, and (d) heart failure–specific cardiac rehabilitation. Insurers do not currently reimburse for cardiac rehabilitation for “heart failure” patients. However, exercise training has been shown to improve exercise tolerance (63). Heart failure centers should provide emergency room–based, 24-hour observation units with algorithms for care designed to reduce hospital admissions. Heart failure–specific subacute care facilities can provide a transition from the hospital to the outpatient setting, reduce the length of hospital stay, and facilitate education and implementation of home health nursing follow-up care (21).

CONTROVERSIES AND PERSONAL PERSPECTIVES

Many heart failure patients are treated suboptimally with pharmacotherapy and receive medical regimens that do not comply with published guidelines for heart failure management (41,44,45). A U.S. survey showed that cardiologists are more likely to prescribe ACEIs than are general practitioners and internists (38). Furthermore, a survey comparing the practice patterns of cardiologists and heart failure specialists showed general conformity but concluded that a portion of heart failure patients may be managed more optimally by heart failure specialists (64). The conclusion was that the improved outcomes observed in heart failure clinics was attributable to the optimal management provided by cardiologists with additional experience in treating heart failure.

These observations indicate that specialist care is cost effective and improves outcomes. Efforts to contain health care costs have attempted to limit patients’ access to specialists, including cardiologists. As discussed previously, the experience of the cardiologist has been shown to be linked to the outcome of patients after cardiac transplantation (48). Few data are currently available to prove that heart failure specialists provide superior care for heart failure patients. An observational study at a single institution showed that hospitalized heart failure patients cared for by a cardiologist were sicker, had a longer length of stay, and underwent more diagnostic studies; however, the incidence of 6-month readmission was lower than that for patients cared for by generalists (65). An analysis of all New York State hospital discharges in heart failure cases (44,296 patients) in 1995 showed that 23% received care from cardiologists, 63% from internists, 11% from family physicians, and 3% from other physicians (66). Care by cardiologists was not associated with longer stay or higher hospital charges, a result that belies the tenet that specialist care is more costly. Conclusions cannot be drawn at present, but the question of who should deliver care to heart failure patients in a manner that is cost effective while maintaining good-quality outcomes requires investigation. Patients with advanced heart failure represent a subpopulation for which specialist treatment seems clearly justified, and the multidisciplinary care model of disease management appears cost effective with superior clinical outcomes.

The a priori end point in most randomized heart failure trials is mortality. Pharmacologic agents that improve quality of life and reduce hospitalizations but increase mortality are unlikely to obtain approval from the U.S. Food and Drug Administration. Initial reports on the use of outpatient dobutamine hydrochloride therapy showed that functional class improved significantly, but mortality was high in this uncontrolled study (67). Outpatient inotropic therapy appears to be cost effective and is reimbursed by many third-party payers despite the lack of randomized trials showing efficacy or a U.S. Food and Drug Administration–approved indication. An uncontrolled study followed 36 patients with intractable heart failure on intermittent inotropic therapy for a mean duration of 294 days (68). The number of emergency room visits, hospital admissions, and days hospitalized all decreased significantly compared to the pretreatment period, and no adverse events were reported. The results of a randomized controlled study evaluating the use of weekly milrinone lactate infusions in treating refractory heart failure over 6 months of follow-up [Randomized Outpatient Assessment of Milrinone Efficacy in Heart Failure (ROME) trial] remain unpublished. No conclusions or projections can be drawn from these uncontrolled studies; nonetheless, many heart failure clinics with outpatient infusion programs have been established throughout the United States. Outpatient inotropic infusions are likely vastly overused in patients who could be readily managed by experienced heart failure specialists with conventional oral medications (69). Outpatient inotropic infusions administered as palliative treatment for refractory heart failure in patients who are not candidates for transplantation may facilitate a return to the home setting with an improved quality of life. In a fatal chronic illness such as heart failure, the quality-of-life benefits of a therapy must be considered, as they may outweigh any mortality effects.

THE FUTURE

Potential economic strategies to face the epidemic of heart failure should include the following initiatives: (a) targeted reduction of inpatient costs, (b) investment in outpatient care and development of chronic disease management programs for heart failure, (c) prevention of admissions (more important than reduction in length of stay), (d) concentration of efforts and resources on high-risk patients (those with a history of frequent readmissions), (e) use of specialized heart failure treatment providers (physicians, nurses, dietitians, rehabilitation specialists), and (f) provisions for extensive patient education. The establishment and implementation of regional specialized heart failure centers should include the following to help achieve these initiatives: (a) detailed patient evaluation to stage disease and ensure appropriate diagnosis and treatment, (b) close patient monitoring at intervals tailored to the individual patient's needs (direct and telephone or electronic contact), (c) immediate access of patients to heart failure team staff and timely responses to patient crises, and (d) comprehensive and continuing patient education concerning heart failure. Regional heart failure centers will provide expertise in the medical and surgical management of heart failure (54,70). Surgical therapy [high-risk standard cardiac surgical procedures, transplantation, connection to mechanical circulatory assist devices, ventricular remodeling procedures (partial left ventriculectomy, Dor procedure, Acorn device, Myosplint), transmyocardial laser revascularization, etc.] has become an essential component and now extends far beyond transplantation. Increasing numbers of high-risk patients will benefit from standard surgical procedures, with a safety net of mechanical support and transplantation available at specialized heart failure centers.

Developing and perfecting a health care delivery system for heart failure should help achieve these goals and result in improved survival, better quality of life, and reduction in cost. Primary prevention is the solution to the challenge. Secondary prevention strategies to alleviate morbidity should be an immediate focus, however, to reduce the economic burden of this devastating epidemic.

The development of health care delivery systems incorporating specialized heart failure centers with systemwide disease management programs will provide the infrastructure to achieve cost-effective improved clinical outcomes for the rapidly expanding heart failure patient population. Efforts and resources will be concentrated on high-risk patients so that overall costs are reduced. Increased emphasis on education of patients and care providers is required. The role of the heart failure nurse-practitioner will expand in heart failure patient management. Emphasis will continue to be on primary prevention as the seminal solution to the increasing cost of heart failure management.

OVERVIEW

The current World Health Organization definition and classification of cardiomyopathy have been revised to reflect the recent insight gained into the pathogenesis of the heart muscle disorders. Cardiomyopathies are categorized into dilated, restrictive, hypertrophic, and unclassified based on the predominant pathophysiologic characteristics. A new category has been added to include right ventricular abnormalities. The disorders that are associated with systemic or certain cardiac diseases are called *specific heart muscle diseases* and include, for example, ischemic cardiomyopathy, diabetic cardiomyopathy, and alcoholic cardiomyopathy. Dilated cardiomyopathy (DCM) is characterized by myocyte hypertrophy and ventricular chamber dilation with diminution of systolic function. This is the most common of the cardiomyopathies. Hypertrophic cardiomyopathy (HCM) is a syndrome that results in heart failure due to left ventricular outflow tract obstruction, diastolic cardiac dysfunction, global cardiac ischemia, dysrhythmias, and sudden cardiac death syndrome in a setting of hyperactive autonomic states. Myocardial hypertrophy and mitral valve abnormalities are gross characteristics of the difficulty with myocardial histology, revealing cellular hypertrophy and disarray with substantive interstitial fibrosis. Inheritance is seemingly in an autosomal dominant fashion, due to mutations in multiple and different contractile protein genes. Restrictive cardiomyopathy is a primarily diastolic disorder, with impairment of ventricular relaxation and filling, usually resulting from an infiltrative or fibrotic process. The myocyte and its surrounding interstitium can be affected. Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a fascinating disorder that primarily involves the right ventricle and may be the result of uncontrolled apoptosis. The unclassified cardiomyopathy category includes disorders such as fibroelastosis, noncompacted myocardium, and systolic dysfunction with minimal dilation. These diseases either have features that overlap the other classifications or do not readily fit any category. Ischemic cardiomyopathy is a common disorder, and one of the most important aspects of its management is identifying areas of viable, but not contracting, myocardium and restoring adequate blood flow if possible. A cardiomyopathy that is associated with infection with the human immunodeficiency virus (HIV) has many possible mechanisms; gaining a better understanding of them will improve treatment of this cardiomyopathy and others. This disorder will certainly be encountered with increasing frequency in the future. Identification of toxins that are associated with left ventricular dysfunction is important because often, if the offending agent is withdrawn, ventricular function returns to near normal levels. Finally, peripartum cardiomyopathy occurs in young women in the last trimester of pregnancy or shortly after delivery. Because its signs and symptoms may resemble some of the normal findings in pregnancy, awareness is key. No reliable methods are available to predict which patients will improve and which will progressively deteriorate. The identification of the etiology of any patient who presents with cardiomyopathy is very important, because specific treatment may reverse cardiac dysfunction. Endomyocardial biopsy is indicated in select situations: to diagnose a specific disease, as part of a clinical trial, to differentiate between restrictive and constrictive disorders, and to monitor anthracycline toxicity. Routine biopsies for idiopathic DCM are of little benefit. Future directions in the diagnosis and management of cardiomyopathies include elucidating genetic and molecular mechanisms and examining the roles of proinflammatory cytokines and apoptosis in the pathogenesis of heart failure.

HISTORICAL PERSPECTIVE

In 1891, one of the earliest descriptions of heart muscle diseases appeared (1). Unfortunately, little more about these "obscure disorders" was gleaned in the six decades that followed. In 1957, Brigden highlighted the ignorance and confusion that existed regarding "noncoronary cardiomyopathies," their terminology, and clinicians' reluctance to diagnose them (2). Since then, medical science has amassed considerable insight regarding the pathophysiology and treatment of these prevalent disorders. Although remarkable progress has been made, there is considerable need for further investigation. Currently, there is tremendous excitement about the field, fueled by clarification of the molecular biodynamic processes and the potential role of apoptosis in cardiomyopathy.

To understand more fully the current nomenclature relating to myocardial failure, it is helpful to review the original working terminology of heart muscle disorders. In 1980, the World Health Organization and International Society and Federation of Cardiology task force met in Paris to clarify this area. They defined the cardiomyopathies as "heart muscle diseases of unknown cause" and divided them into three broad classifications based on characteristic anatomic findings of the heart: dilation, hypertrophy, and restriction (3) (*e*Table 90.0.1). For instance, the dilated and restrictive categories were based on left ventricular dimensions and volume. The reasoning behind creation of these divisions was that they had distinct natural histories, pathophysiologic mechanisms, and medical treatments. A fourth group, "unclassified cardiomyopathies," was also listed to include cases that did not easily fit into one of the other three general categories. Unclassified cardiomyopathies were sometimes referred to as *latent cardiomyopathies*. Completely separate from the cardiomyopathies were specific heart muscle diseases, characterized as diseases of known cause or associated with specific disorders of other systems. They were further divided into infective, metabolic, general system diseases, heredofamilial, hypersensitivity, and toxic reactions categories. Myocardial dysfunction as a result of systemic or pulmonary hypertension, coronary artery disease, valvular heart disease, or congenital anomalies was excluded.

***e*TABLE 90.0.1** ANATOMIC DESCRIPTION OF THE CARDIOMYOPATHIES[a]

Classification	EDV	ESV	EF	Mass	Mass/volume	Primary mechanism of failure
Dilated	↑↑	↑↑	↓↓	↑	–	Systolic
Restrictive	↓, –, ↑	↓	↓, –, ↑	↑↑	↑	Diastolic
Hypertrophic	↓, –, ↑	↓	↓, –, ↑↑	↑↑↑	↑↑	Diastolic
ARV	↑	↑	↓	↓	↓	Systolic

ARV, arrhythmogenic right ventricular; EDV, end diastolic volume; EF, ejection fraction; ESV, end systolic volume; LV, left ventricle; ↑, increased; ↓, decreased; –, no change.
[a]Values reported for the left ventricle except ARV, which corresponds to the right ventricle.

Some debate has taken place regarding which diseases should be included in the category of cardiomyopathy. Etymologically, *cardiomyopathy* refers to a disease that arises from the heart itself (4). When clinical heart failure syndromes are diagnosed, it is the functional integrity of the circulatory network, including the heart, that is important for characterization of heart failure. Many agreed that the term *cardiomyopathy* should refer to a dynamic cardiac muscle process that evolves after myocyte injury of any sort, regardless of whether the injury was rooted in heritable molecular biodynamic aberration or was the result of exogenous muscle injury. Thus, patients with heart failure associated with Duchenne's muscular dystrophy would correctly be labeled as having cardiomyopathy, just as would a patient with ischemic heart disease caused by coronary atherosclerosis. Others have limited use of the term to situations in which the heart itself was the primary problem. Obviously, all cardiomyopathies have some etiologic factor. Many times, the specific reason for the cardiac malfunction and subsequent remodeling cannot be precisely characterized. The term *idiopathic* is used to describe this clinical situation. It is not a specific disease entity but likely represents a wide spectrum of difficulties and is a term that largely reflects our ignorance regarding the etiology of heart failure in many given instances. Over time, the distinction between cardiomyopathy and specific heart muscle disease has became blurred. Furthermore, many previously ill-characterized abnormalities have been better elucidated. As more became known about the individual disorders, it was apparent that new definitions and classifications were needed, and in 1996, a revised categorization was released (5) (*e*Table 90.0.2). Cardiomyopathies were generally more simply defined as diseases of the myocardium associated with cardiac dysfunction. As in the previous scheme, dilated, hypertrophic, restrictive, and unclassified divisions remained. However, ARVC was added. Further, specific heart muscle diseases were referred to as specific cardiomyopathies that included myocardial dysfunction associated with distinct cardiac or systemic disorders.

DILATED CARDIOMYOPATHY

DCM is characterized by ventricular remodeling that produces chamber dilation, with normal or decreased wall thickness, and diminution in systolic function (Fig. 90.1). The impairment of systolic function can involve the left, right, or both ventricles, with the ejection fraction traditionally being defined as less than 40% (6). Although the total mass of the heart is increased, the ratio of left ventricular volume to ventricular wall thickness is much greater than for patients with HCM or diastolic dysfunction due to hypertensive heart disease (7). This eccentric hypertrophy provides a unifying concept for many different disease processes, ultimately resulting in dilation of the heart. It is important to note that remodeling of this sort is caused by diseases that are, for the most part, distinct from those causing hypertrophic and restrictive cardiomyopathy, problems that generally do not result in chamber dilation. Myocardial remodeling is associated with altered hemodynamics characterized by diminished ejection fraction, reduced stroke volume, increased chamber volumes, and, therefore, increased chamber pressures. This triggers the multiple neurohormonal aberrations that are characteristic of the heart failure milieu.

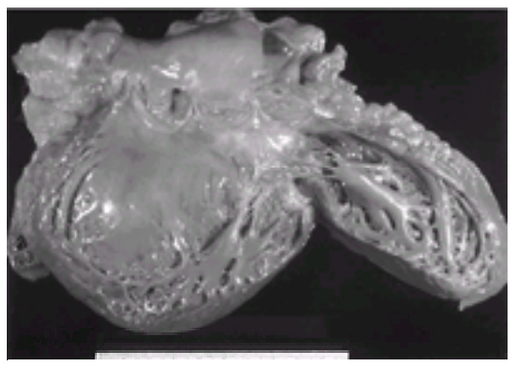

FIGURE 90.1 Dilated cardiomyopathy. The cardiomegaly, globular shape of the heart, dilated ventricular chambers, and flattened trabeculae, which are characteristic of this disease, are all evident in this photograph. No significant endocardial fibrosis is present.

Often, if the toxic or injurious agent can be identified and removed before a cell mortality program is triggered (apoptosis), further detrimental chamber remodeling can be blocked and systolic function returned to a more normal state. However, DCMs generally pass through an early and late evolutionary period. The stages parallel pathophysiologic events triggered by whatever myocardial insult initiated the heart failure process in the first place. At some point, injury produces myocyte and myocardial dysfunction that antedates clinically apparent disease. As progression occurs and decompensation develops, symptoms begin to appear that are characteristic of heart failure in general. Cardiac and extracardiac signs and symptoms that are disease specific may provide insight to the etiology of the heart failure and cardiomyopathy. If the process is not interdicted, later stages will appear and manifest with profound eccentric hypertrophy and, ultimately, marked reduction in systemic flows accompanying elevation of intracardiac pressures. Figure 90.2 conceptually presents the relationship of the heart failure clinical syndrome to molecular and organ-specific physiology.

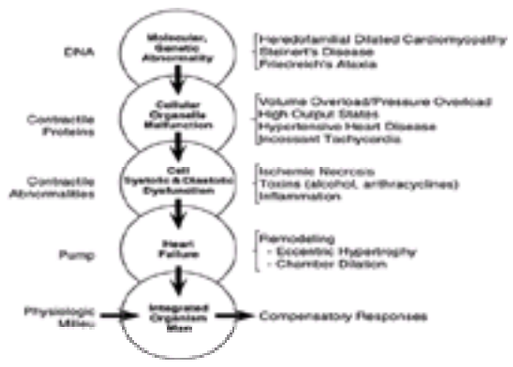

FIGURE 90.2 The milieu of dilated cardiomyopathy from molecular biodynamics to a clinical syndrome.

DCM was previously referred to as *congestive cardiomyopathy*; however, this term is no longer applied because congestion is not consistently present, particularly in the milder and earlier stages or after therapy. DCM is the most common of the cardiomyopathies, comprising more than 90% of all cases that are referred to specialized centers (8), and represents the end result of more than 50 distinct diseases (9,10). When diagnosing DCM, it is important to review the major etiologic and pathophysiologic classes that are responsible for this disorder, as detailed in eTable 90.0.2. By and large, DCMs include those that can be familial or genetic in origin, secondary to infection or inflammation, toxic substance exposure, metabolic derangements, and idiopathic. Examples of genetic disorders that cause cardiomyopathies include Friedreich's ataxia, myotonic dystrophy, Duchenne's muscular dystrophy, and certain mitochondrial dysfunction syndromes. DCM can also be ischemic in origin, particularly when microvascular disease complicating diabetes mellitus is present. A category sometimes referred to as *hyperergopathic* DCM includes heart failure caused by high cardiac output states as noted with certain vitamin deficiencies (beriberi), thyrotoxicosis (particularly Graves' disease), severe anemia, arteriovenous fistulae, osteitis deformans (Paget's disease), chronic liver disease with cirrhosis (intrahepatic arteriovenous shunts), pregnancy, and hypernephroma. Hypertensive heart disease, valvular insufficiency or stenosis, and incessant tachycardia are also examples of DCM due to an "overworked" ventricle (11). Pathogenic factors to consider when evaluating patients with DCM are the potential for substance abuse (alcohol and cocaine in particular), coronary artery disease or atherosclerotic risk factors, family history of DCM, presence of systemic arterial hypertension, history compatible with significant viral illness, presence of diabetes mellitus, cardiotoxin exposure (anthracyclines, for example), malnutrition, and valvular heart disease.

Some progress has been made in characterizing the molecular genetics of DCM (12,13). Perhaps as many as 30% of DCM cases are inherited or familial, with a significant percentage of the remaining being acquired as alluded to above. Inherited forms of DCM may have autosomal dominant, autosomal recessive, X-linked, or mitochondrial transmission, and, to date, genes for X-linked DCM and autosomal dominant DCM have been mapped with genetic heterogeneity documented. The genes for two X-linked cardiomyopathies have been identified, specifically, the dystrophin gene, also responsible for Duchenne's and Becker's muscular dystrophy, and G4.5 in Barth's syndrome, which is X-linked cardioskeletal myopathy with neutropenia and aciduria. Dystrophin is a large cytoskeletal protein that is noted in myocyte sarcolemma. The protein attaches at its N-terminal domain to F-actin in the sarcolemma matrix region and to the dystrophin-associated glycoprotein complex at its C-terminal domain. Although the protein encoded by the G4.5 gene has been identified and referred to as *Tafazzin*, its function is not presently known. Autosomal dominant DCM genes have been noted at six different loci, with "pure" DCM localized to 1q32, 2p31, 9q13, and 10q21–10q23, in contrast to DCM, with conduction defects that have been mapped to 1p1, 1q1, and 3p22–3p25 (12). Mutations in cardiac actin located on chromosome 15q14 have also been identified. Indeed, it has been suggested that DCM is, ultimately, a consequence of defective transmission of force in cardiac myocytes that leads to heart failure.

Idiopathic Dilated Cardiomyopathy

Background and Prevalence

Idiopathic DCM is a primary global myocardial disorder of unknown cause. Because it is the pathophysiologic model for other specific DCMs, this section focuses on the idiopathic type, with distinguishing characteristics of other specific disorders discussed subsequently. Idiopathic DCM alone accounts for 36 cases per 100,000 population, 10,000 deaths in the United States per year (14,15), and approximately 25% of all cases of cardiomyopathy.

Pathophysiology

eTable 90.0.1 compares the anatomic description of the cardiomyopathies, emphasizing that DCM has marked enlargement of left ventricular end diastolic and end systolic volumes, usually with profound reduction of the ejection fraction. This is in contrast to restrictive and hypertrophic cardiomyopathies, which have more normal end diastolic volumes and, sometimes, supernormal ejection fractions. The left ventricular mass-volume ratios (eTable 90.0.1) reflect the fact that muscular hypertrophy is seen in all cardiomyopathies, but to a more significant degree in patients who have HCM. With DCM, the mitral and tricuspid annuli are frequently enlarged from ventricular dilation, with resultant valvular regurgitation. By definition, idiopathic DCM is not caused by coronary artery disease, and therefore the coronary arterial tree is usually normal. It is possible to have some plaque formation; however, the degree of systolic impairment is out of proportion to atherosclerotic involvement. The histology is usually nonspecific, but certain features are present. Under the light microscope, the myocytes are commonly quite hypertrophied, with areas of myocyte necrosis. The nuclei may be very large with bizarre shapes. The areas of interstitial fibrosis are frequently underappreciated. Occasionally, small clusters of lymphocytes in the interstitium or perivasculature can be present. By electron microscopy, the mitochondria may be abnormal, the T tubules dilated, and lipid vacuoles present.

Investigations into the pathogenesis of idiopathic DCM have centered around four potential areas to gain additional insight into this disease: familial and genetic factors, viral myocarditis and cytotoxic damage, abnormal immune responses, and metabolic, energetic, and contractile abnormalities (16). Exogenous injury or internal myocyte perturbation can cause alterations in the cell's genetic program. Reversion to a fetal genotypic program occurs, with resultant cell hypertrophy and malfunction. This ultimately produces ventricular chamber enlargement and dilation. Poisoning the cells with alcohol or doxorubicin can incite cell injury, giving rise to detrimental myocardial remodeling. With idiopathic DCM, the inciting factor is unknown. Patients with idiopathic DCM frequently (5% to 10%) have a positive family history of signs and symptoms that are suggestive of a myocardial disorder, and consequently these individuals have been labeled as having familial idiopathic DCM. Certain gene expressions have been identified as being associated with idiopathic DCM, such as the angiotensin-converting enzyme (ACE) DD genotype (17), human leukocyte antigen (HLA) class II DR4 and Dqw4 antigens (18), and Xp21 locus of the dystrophin gene, which may explain some of these cases (19). The presumption of an underlying viral myocarditis as the cause of idiopathic DCM remains to be proven. Clearly, viral genomic sequences have not been detected in the myocardium to support this theory (20). An abnormal autoimmune response (again possibly inherited), perhaps initiated by a viral infection, may also initiate a cardiomyopathy. Several abnormalities with the immune system have been recognized in idiopathic DCM, including cellular and humoral alterations, decreased natural killer cell and suppressor T-cell activities, and increased levels of many autoantibodies reacting with various cardiac antigens. It is unclear whether these changes are part of the pathogenesis of the disorder or a result of the dysfunction. Finally, as mentioned earlier, neurohormonal activation occurs as a consequence of the disease and may propagate additional injury. Many irregularities occur in cellular energy metabolism (21), calcium interactions and uptake, guanine nucleotide-binding regulatory proteins, and beta-adrenergic receptors, which again may contribute to the heart failure decline or merely be a consequence of it.

Clinical Profile and Management

Most patients initially present with signs and symptoms of fluid overload or low cardiac output. Usually, by the time of diagnosis, they have severe ventricular dysfunction and New York Heart Association (NYHA) class III and IV symptoms (22). Chest pain is surprisingly common and affects up to 35% of patients with normal coronaries (22,23). This angina, in part, may be because of limited coronary vascular reserve (24). The electrocardiogram (ECG) may complicate the picture by having unexplained Q waves, and this has led to the term *pseudoinfarction*. Occasionally, patients present with more right- than left-sided heart failure symptoms, mesenteric congestion more than pulmonary edema, which can be mistaken for a gastrointestinal disorder. Arrhythmias and sudden death are common and may occur at any level of dysfunction and disability. Pulmonary and systemic thromboembolism occur at a variable rate of approximately 1% to 6% per year without anticoagulation (25,26). It is difficult to predict the natural history of idiopathic DCM, and in the past the average 5-year survival rate was approximately 50% (27). With the increasingly aggressive use of ACE inhibitors and other therapies, survival has improved. Predictors of poor outcome are listed in Table 90.1 and parallel prognostic indicators for adverse events in patients with heart failure generally. Various ventricular size and function parameters, laboratory tests, clinical features, and cardiac studies may all be helpful in assessing prognosis. Chapter 91 and Chapter 92 discuss in full detail the treatment of acute and chronic heart failure. Management options include supportive therapy (diet, sodium, toxin and fluid restriction, exercise, etc.), medications (diuretics, digoxin, ACE inhibitors, angiotensin II receptor blockers, inotropes, anticoagulants, antiarrhythmics, and beta-blockers), ventricular assist devices, and novel surgical procedures (cardiomyoplasty, mitral and tricuspid valve repair, and partial left ventriculectomy and cardiac transplantation).

Ventricular size and functioning	
	Increased left ventricular end diastolic volume
	Increased right ventricular end diastolic volume
	Low ejection fraction
	Decreased ventricular mass-volume ratio
	Global rather than segmental wall motion abnormalities
Clinical features	
	New York Heart Association class IV symptoms
	Older age
	Male sex
	History of syncope
	Right-sided heart failure symptoms
	Persistent S_3
	Symptomatic ventricular tachycardia
Laboratory tests	
	Hyponatremia
	Increased norepinephrine levels
	Increased atrial natriuretic factor
	Hyperreninemia
Hemodynamic monitoring	
	Pulmonary capillary wedge pressure >20 mm Hg
	Cardiac index <2.5 L/min/m^2
	Systemic hypotension
	Pulmonary hypertension
	Elevated central venous pressure
Cardiac tests	
	Chest x-ray–increased cardiothoracic ratio
	Electrocardiographic–1- or 2-degree atrioventricular blocks, left bundle branch block
	Stress test–maximal systemic oxygen uptake <10–12 mL/kg
	Endomyocardial biopsy–loss of intracellular myofilaments

TABLE 90.1 PREDICTORS OF POOR OUTCOME IN DILATED CARDIOMYOPATHY

Hyperergasic Dilated Cardiomyopathy

Hyperergasia refers to an increased or excessive functional activity. Hyperergasic or hyperergopathic cardiomyopathy is cardiac remodeling and heart failure that develop secondary to chronically increased myocardial workload. This cardiomyopathy of overwork produces all of the characteristics of DCM. It is this process that is important, additionally, in settings such as acute myocardial infarction whereby well-perfused and remaining healthy myocytes are forced to tote greater workloads to compensate for the loss of neighboring contractile elements and maintain reasonable cardiac output. Situations that produce increased chronic workload with resultant myocardial hypertrophy and dilation include incessant tachycardias, high-output states that accompany anemia, thyrotoxicosis, beriberi, arteriovenous fistulae, cirrhosis of the liver, osteitis deformans, pregnancy, hypernephroma, and hypertensive heart disease. Valvular stenoses that produce significant afterload increase (aortic stenosis and pulmonic stenosis, for example) or valvular insufficiency with volume overload (aortic regurgitation and mitral regurgitation) are examples of hyperergopathic cardiomyopathies. Diagnosis and treatment of these conditions focus on the clinical link between heart failure and each of these specific disease processes. It is important to diagnose this condition because some of the most gratifying treatment responses in heart failure patients are associated with eliminating the primary process that causes the cardiomyopathy and heart failure in the first place. For example, complete normalization of profoundly depressed cardiac contractile activity has been well described after control of tachycardia, resolution of anemia, and repair of arteriovenous fistulae.

HYPERTROPHIC CARDIOMYOPATHY

Prevalence and Background

HCM is addressed in detail in Chapter 29. However, it is important to consider some of the contrasts between hypertrophic, dilated, and restrictive cardiomyopathies (28). The contemporary definition of HCM focuses on the fact that this disorder is characterized by disproportionate and remarkable left, and sometimes right, ventricular hypertrophy. Typically, the septum is more involved than the free left ventricular wall, although on occasion the hypertrophy can be completely concentric in nature (Fig. 90.3). HCM, which may develop at any age, is associated with marked left ventricular volume reduction, and systolic left ventricular outflow tract gradients are common. Up to 70% of cases have a familial pattern of occurrence, with autosomal dominant inheritance.

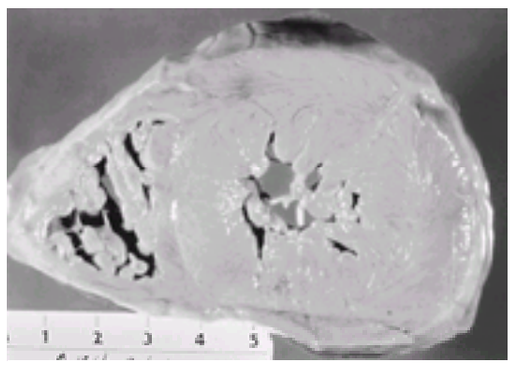

FIGURE 90.3 Severe concentric left ventricular hypertrophy: The left ventricle and interventricular septum are severely and concentrically hypertrophied, with a marked reduction in the size of the ventricular cavity.

Pathophysiology

Some reports have emphasized that variable degrees of myocyte ultrastructural, myofibrillar, and muscle bundle disorganization can be detected, often with substantial degrees of interstitial fibrosis (28,29,30 and 31) (Fig. 90.4). Identification of specific gene mutations associated with HCM has led to the suggestion that the severity of hypertrophy is associated with cardiac troponin t-gene mutations and also mutations at the loci that are responsible for alpha-tropomyosin formation. Intense study of the molecular biodynamics and genetic characteristics of this syndrome is now under way. It is likely that many genetic abnormalities are associated with this pathologic hypertrophy. Indeed, HCM can be a component of many inheritable disease states, such as Noonan's syndrome, Friedreich's ataxia, Fabry's disease, and Hunter's and Hurler's syndromes.

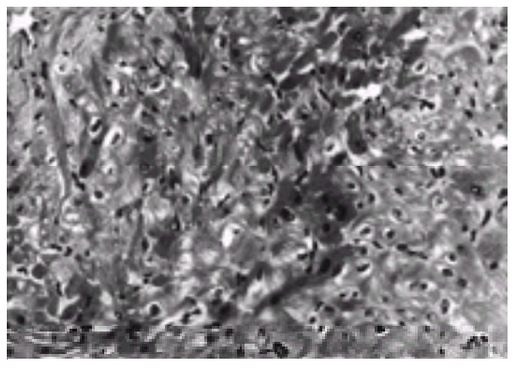

FIGURE 90.4 Hypertrophic cardiomyopathy: In this light micrograph, the myocyte disarray, characteristic of hypertrophic obstructive cardiomyopathy, is evident.

Clinical Profile and Management

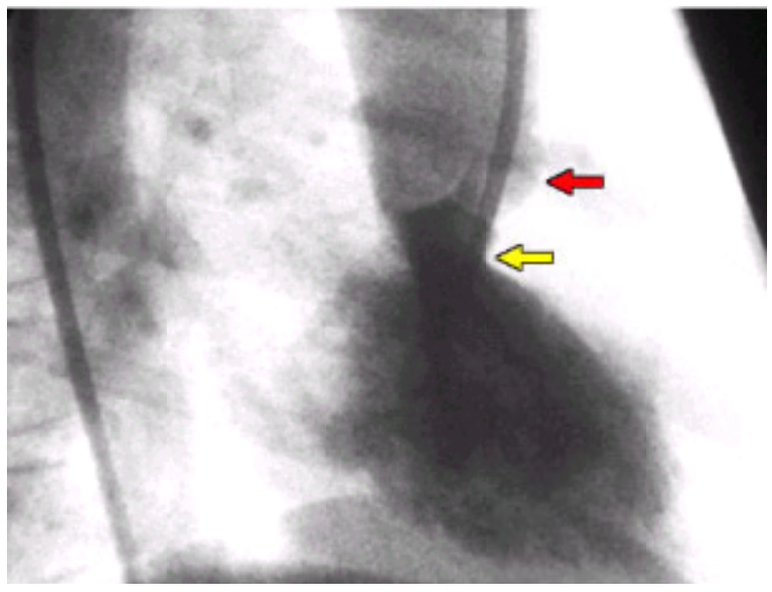
From a hemodynamic standpoint, most patients with HCM have hyperdynamic systolic function with high ejection fraction. This “supernormal” systolic function sets the stage for increased myocardial oxygen consumption, which, in conjunction with a relative myocardial blood flow derangement, can cause ischemia. Diastolic dysfunction is virtually universal in the syndrome and likely arises from factors that decrease the lusitropic properties of the chamber, such as myocyte hypertrophy, interstitial fibrosis, and myocyte disarray. The stiff ventricle requires high filling pressures to operate, and this often translates into pulmonary hypertension and subsequent dyspnea, particularly during exercise. It is the combination of diastolic dysfunction with outflow tract obstruction that likely is responsible for most of the symptoms related to HCM.

VIDEO

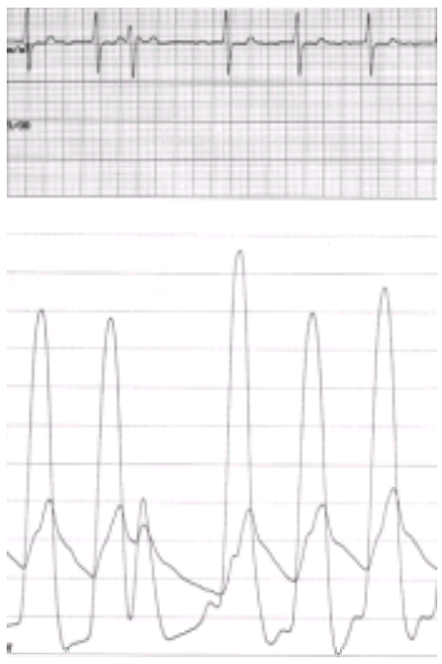
Video 90.3 Intraoperative transesophageal echo of a patient with hypertrophic obstructive cardiomyopathy and left ventricular outflow tract (LVOT) obstruction. The septum is hypertrophied, and the mitral leaflets show some systolic anterior motion of the mitral valve leaflets. An accessory mitral leaflet is located on the left ventricular septum. Note the independent motion of this leaflet in the LVOT. The pressure gradient across the LVOT/AV was greater than 100 mm Hg; however, the aortic valve opens freely. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

VIDEO

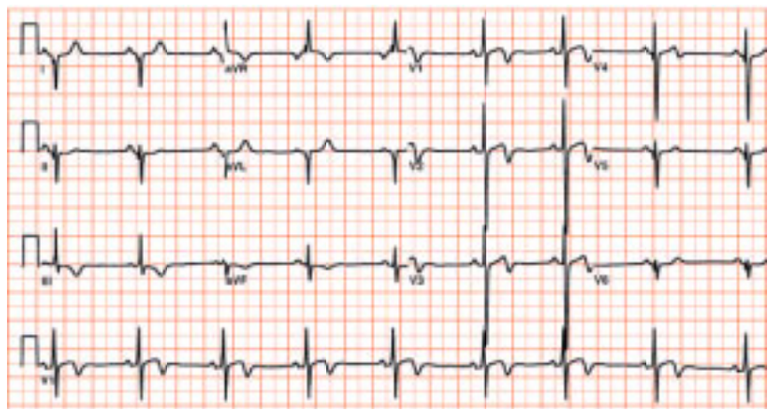
Video 90.4 Subaortic poststenotic flow in hypertrophic cardiomyopathy (long-axis). Asymmetric hypertrophy is noted, resulting in dynamic narrowing of the left ventricular outflow tract with a signal-void jet in the subaortic region. In addition, a signal-void jet in the left atrium is also seen, representing mitral regurgitation due to systolic anterior motion of the anterior leaflet of the mitral valve. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



Subaortic stenosis. This right anterior oblique left ventriculogram demonstrates the presence of a stenosis in the left ventricular outflow tract (*yellow arrow*) just below the level of the aortic valve (*red arrow*).



A 57-year-old female patient with hypertrophic cardiomyopathy. This figure shows the Brockenbrough response after a ventricular premature beat. The Brockenbrough response includes an increase in left ventricular systolic pressure, a decrease in aortic systolic pressure, an increase in left ventricular–to-aortic gradient, and diminished aortic pulse pressure.



A 28-year-old Caucasian male patient with hypertrophic obstructive cardiomyopathy.

Audio 90.5 Hypertrophic cardiomyopathy. Auscultation performed in a 60-year-old male patient. The systolic gradient across the left ventricular outflow tract was 55 mm Hg at rest and increased to 121 mm Hg after amyl nitrate inhalation. The mid-systolic, crescendo-decrescendo ejection murmur is observed. Valsalva maneuver and sudden squatting are helpful in distinguishing this from fixed aortic valvular stenosis. Left upper sternal border. (The heart sounds were digitally acquired courtesy of equipment from Welch Allyn/Meditron and Cardionics Inc.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

RESTRICTIVE CARDIOMYOPATHY

The restrictive cardiomyopathies, sometimes referred to as *nondilated, nonhypertrophic cardiomyopathies*, are described in Chapter 26. Several points deserve reiteration to aid in understanding specific restrictive disorders, as well as to contrast this myopathy with the others. Generally, this is the least common of the major myopathies and is characterized by a normal or only slightly enlarged heart, decreased diastolic volumes, and, early in the disease, normal systolic function. The main pathologic disorder is one of impaired diastolic functioning, resulting from decreased ventricular compliance and filling. This dysfunction may result from a process that involves, primarily, the endocardium, myocardium, or both. The most commonly encountered myocardial disorders are amyloid heart disease and idiopathic myocardial fibrosis, which are fully discussed in the sections Idiopathic Myocardial Fibrosis and Amyloidosis. Other specific myocardial forms include metabolic storage disorders such as Fabry's disease and hemochromatosis, sarcoid heart disease, radiation fibrosis, and various tumor infiltrations, many of which are also addressed under the section Specific Cardiomyopathies. The endocardial disorders, less common in the United States, include entities such as endomyocardial fibrosis, Löffler's endocardial fibrosis (endocarditis parietalis fibroplastica), and, even more rarely, endocardial fibroelastosis. Endocardial fibroelastosis is typically placed in the unclassified cardiomyopathy category. Another restrictive cardiomyopathy is frequently encountered after cardiac transplantation (32). Immediately after transplant and for up to a year, restrictive hemodynamics may exist. Later on, restriction is associated with acute and with chronic rejection (33). Restrictive cardiomyopathy should be considered when patients present with signs and symptoms of myocardial failure but normal cardiac size. Frequently, right-sided findings of increased jugular venous pressure, ascites, and peripheral edema predominate, although left-sided failure does occur. The differential diagnosis includes constrictive pericarditis, which is a more readily treatable condition. Echocardiography and right heart catheterization may help differentiate these disorders. The hemodynamic findings usually demonstrate elevation of left and right ventricular end diastolic pressures, and a characteristic early ventricular diastolic dip and rapid rise to a plateau (square-root sign). Early diastolic pressure typically does not fall to 0 mm Hg, however. Endomyocardial biopsy should also be considered if other historical and physical clues to the diagnosis are not present. The treatment of restrictive cardiomyopathy is also reviewed in Chapter 26 and generally remains quite unsatisfactory.

Idiopathic Myocardial Fibrosis

Idiopathic myocardial fibrosis results in a restrictive physiology; however, no specific histopathologic changes are present to account for the extensive fibrosis (34). Grossly, the heart is increased in weight, with normal ventricular cavity size and wall thickness. By light microscopy, there is patchy endocardial and interstitial fibrosis that ranges from mild to quite severe. The disorder is frequently associated with distal skeletal myopathies, atrioventricular blocks, and possibly an autosomal dominant inheritance. It may occur in children or adults but carries a worse prognosis in children. No specific therapy is present, except that heart blocks frequently necessitate pacemaker insertion. Atrial fibrillation is readily controlled with digoxin. Some have proposed that the etiology of this disorder is related to an abnormality in a calcium-dependent phase of cardiac relaxation. Therefore, calcium antagonists may have a role in therapy, but this has yet to be proven.

Endomyocardial Fibrosis

Endomyocardial fibrosis, also known as *tropical eosinophilic endomyocardial fibrosis*, is common in South and Central America and tropical and subtropical Africa. Surprisingly, it accounts for 15% to 25% of the cardiac deaths in equatorial Africa (35). Endomyocardial fibrosis is characterized by thickening and scarring of the endocardium (Fig. 90.5), which can be so extensive that the ventricular cavity is obliterated. Thrombi may overlie these lesions, increasing the risk of thromboembolism. Frequently, the subendocardial myocardium is also affected. In 50% of cases, the left and the right ventricles are involved, whereas another 40% of cases have lesions isolated to the left ventricle. The mitral and tricuspid valves may become fibrotic as well, leading to valvular regurgitation. Many believe that this disease is a form of, if not the same as, Löffler's endocardial fibrosis, perhaps at a different stage (36,37). Although the overall prognosis is poor, palliative treatment with surgical endocardiectomy and valvular repair/replacement may alleviate some symptoms (38).

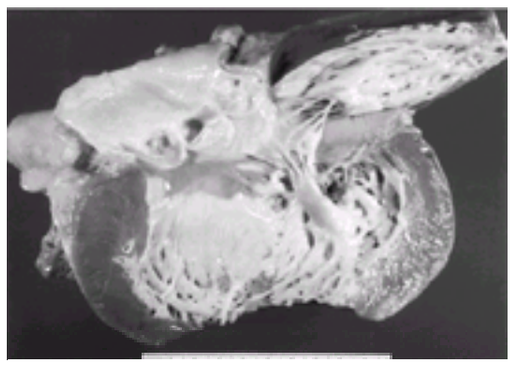


FIGURE 90.5 Endocardial fibrosis. The left ventricle is markedly dilated and hypertrophied. The endocardium, including the papillary muscles, is covered by thick, white, shiny, fibrotic endocardium.

Löffler's Endocardial Fibrosis

Löffler's endocardial fibrosis is also associated with eosinophilia, giving it its other names: eosinophilic cardiomyopathy and nontropical eosinophilic endomyocardial fibrosis. The severity of cardiac dysfunction seems to parallel the degree and duration of the eosinophilia, leading to the belief that the eosinophil itself is responsible for the dysfunction. Compared to normal eosinophils, the cells in endocardial fibrosis have fewer granules and contain vacuoles and may represent an abnormal cell line producing a type of autoimmune disorder (39). The contents of the intracytoplasmic granules of the eosinophils can cause direct myocardial necrosis. It has also been observed that the eosinophils bind immunoglobulin G and increase peroxidase, which can have further direct toxic effects. The cardiac manifestations of this eosinophilic disorder are similar, if not identical to, those produced by eosinophilic leukemia and the eosinophilia-myalgia syndrome, which has been associated with tryptophan. Treatment with corticosteroids and cytotoxic agents (hydroxyurea) can improve symptoms and survival (40).

RIGHT VENTRICULAR CARDIOMYOPATHY

Arrhythmogenic Right Ventricular Cardiomyopathy

Prevalence and Background

ARVC, also known as *arrhythmogenic right ventricular dysplasia*, is a rare disorder that occurs in adolescence and young adulthood. It has a male-female ratio of approximately 2 to 3:1 (41). Interestingly, similar to HCM, the disorder was initially described anatomically, but it has been discovered to have a genetic basis. The true incidence of ARVC remains unknown, partly because of difficulties with its diagnosis, as described below.

Video 90.6 Arrhythmogenic right ventricular dysplasia (transaxial). Thinning the right ventricular wall with dyskinesia of the right ventricular free wall during systole is due to fibrous replacement of the myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Pathophysiology

The abnormalities of ARVC are limited to the right ventricle, although in rare instances, the left ventricle is involved (42,43 and 44). Grossly, the ventricle is mildly dilated and thinned. The characteristic feature is the segmental, progressive, noninflammatory loss of myocytes and their replacement by nonhyalinized collagen and adipose tissue (39,45). This fibrofatty infiltration is transmural in nature and can be confirmed either at autopsy or with surgical biopsy. Transvenous endomyocardial biopsies are sometimes helpful but have limitations (46). First, full-thickness specimens are not obtained, preventing a definitive diagnosis. Second, ARVC is focal and segmental in nature; therefore, the likelihood of false-negative tests increases. Also, the septum, the usual area of endomyocardial biopsy sampling, is rarely, if ever, involved. Finally, adipose tissue in the right ventricle can be a normal finding. Despite this, finding extensive fibrofatty replacement of myocytes in the right ventricle is concerning. Cine–magnetic resonance imaging has the potential to aid diagnosis by being able to differentiate normal myocardium from adipose tissue, assess morphologic alterations, and detect areas of regional and global ventricular dysfunction (47,48 and 49). Because so much remains unknown about the exact pathogenesis of ARVC, a possibility is that the fibrofatty infiltrate may represent the end result of several different diseases rather than one specific process (see Uhl's Anomaly).

Evidence has been found for a familial pattern of autosomal dominant inheritance, with variable penetration (50). At least three different gene loci have been identified (51,52 and 53). It is unclear at this time, however, how abnormalities in each of these genes affect the disease process and phenotype. Apoptosis has been described in ARVC and may be the cause of the degenerative process (54). Apoptosis is a highly regulated and active process that leads to programmed cell death. It differs significantly from cell necrosis, which is normally considered the mechanism for myocyte loss. Most notably, the apoptotic cells are quickly phagocytosed by adjacent cells or macrophages, without releasing toxic substances and causing an inflammatory reaction (55). In a study by Mallat and colleagues, not only was apoptosis demonstrated in ARVC, but high levels of expression of CPP-32, a cysteine protease that is required for the initiation of apoptotic cell death (56), were also present (52). Further, apoptotic cells were seen in areas with little fibrofatty replacement, suggesting that the myocyte loss preceded the infiltration. Possibly, the triggering events and pathways that led to the cell death can be identified and favorably manipulated in the future. It is possible that the three genes that have been recognized to be associated with ARVC control various steps in myocyte apoptosis.

Clinical Profile and Management

Because of the difficulties and risks of obtaining tissue to confirm the diagnosis of ARVC, as well as inaccuracies in assessing right ventricular structure and function with many of the noninvasive tests, a task force from the European Society of Cardiology and the International Society and Federation of Cardiology met and released criteria to assist in this process. The diagnosis can be made by meeting any of the following: two major criteria, one major plus two minor, or four minor criteria (57) (Table 90.2). These criteria are based on the clinical manifestations of the disease, family history, endomyocardial biopsy, and electrophysiologic abnormalities. Other diagnoses can mimic ARVC: atrial septal defects, abnormal pulmonary venous return, congenital absence of the left pericardium, Ebstein's anomaly, right ventricular outflow tract tachycardia, and pulmonic insufficiency.

Category	Major criteria	Minor criteria
Global and/or regional dysfunction and structural alterations	Severe dilatation and reduction of RV ejection fraction	Mild global RV dilatation and/or EF reduction with normal LV
	Localized RV aneurysms (akinetic or dyskinetic areas with diastolic bulging)	Mild segmental dilatation of the RV
	Severe segmental dilatation of the RV	Regional RV hypokinesia
Tissue characterization of walls	Fibrofatty replacement of myocardium on endomyocardial biopsy	—
Repolarization abnormalities	—	Inverted T waves in right precordial leads (V_2 and V_3)[a]
Depolarization/conduction abnormalities	Epsilon waves or localized prolongation (>110 ms) of the QRS complex in right precordial leads (V_1–V_3)	Late potentials on signal-averaged ECG
Arrhythmias	—	LBBB-type ventricular tachycardia (sustained and nonsustained)
		Frequent ventricular extrasystoles (>1,000/24 h)
Family history	Familial disease confirmed at autopsy or surgery	Family history of premature sudden death (<35) due to suspected RV dysplasia
		Family history (clinical diagnosis based on present criteria)

ECG, electrocardiogram; EF, ejection fraction; LBBB, left bundle branch block; LV, left ventricle; RV, right ventricle.
[a]The diagnosis of arrhythmogenic right ventricular myocardium is based on meeting two major, one major plus two minor, or four minor criteria as outlined in the table. These criteria are based on the known structural and functional abnormalities of the right ventricle, family history, and repolarization/depolarization and electrical conduction disturbances.
[b]Patient must be ≤17 yr old, in the absence of right bundle branch block.
From Wichterle H, Thiene G, Basso C, et al. Diagnosis of arrhythmogenic right ventricular dysplasia/cardiomyopathy. Br Heart J 1994;71:215–218.

TABLE 90.2 CRITERIA FOR THE DIAGNOSIS OF ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY[a]

Severe ventricular dysrhythmias and, less frequently, supraventricular dysrhythmias are a common presentation for ARVC. Patients may also present with right heart failure, asymptomatic cardiomegaly, syncope, or sudden death syndrome. Polymorphic ventricular tachycardia originating from the right ventricle, with a left bundle branch morphology, is often associated with exertion. In patients who have ventricular tachycardia, the signal-averaged ECG is almost always abnormal, with a very long duration of the low-amplitude signals (58). Premature death results from right-sided congestive heart failure or sudden death. In fact, ARVC is one of the most common causes of juvenile sudden death.

The clinical course of ARVC is unknown, and patients may live to be quite old, whereas others die in early childhood. Treatment of ARVC is aimed at the specific manifestations of the disease. The ventricular dysrhythmias can be treated with antiarrhythmics such as amiodarone and sotalol but may be quite refractory. Radiofrequency ablation of severe refractory tachycardias may be successful, although it is possible to have recurrence of the dysrhythmias but from a different area within the right ventricle. Not uncommonly, automatic cardioverter defibrillators are necessary. Because of conduction abnormalities, pacemakers may be required. Right-sided heart failure should be treated with sodium restriction, diuretics, digoxin, and afterload reducers. Cardiac transplantation also has been successfully performed for this syndrome. In the future, the identification of ARVC carriers by linkage analysis in affected families (50) may allow for earlier treatment with more standard therapies such as automatic defibrillators or even with the administration of agents that can prevent further apoptosis.

Uhl's Anomaly

Prevalence and Background

Uhl's anomaly, first described in 1952, is similar to ARVC (59). It is rare, tends to occur in infancy and early childhood, and has a more equal male-female sex distribution. Primarily, it affects the right ventricle but has much more extensive loss of the myocytes, with severe dilatation. Unlike ARVC, which tends to be focal and episodic in nature, Uhl's anomaly is an incessant disease that frequently results in complete destruction of the entire ventricle.

Pathophysiology

In Uhl's anomaly, the entire right ventricular wall can be paper thin, with apposition of the endocardium to the epicardium, explaining its other moniker: parchment heart. Apoptosis has been described in Uhl's anomaly (60,61). At birth, when the pressure in the right ventricle decreases with pulmonary flow, appropriate apoptosis may occur as fewer myocytes are needed. Uhl's anomaly may represent a case in which the triggering signals for apoptosis do not stop or for some other reason escape appropriate regulation. Indeed, massive apoptosis has been reported in other systems, including the central nervous system and bone marrow (62,63).

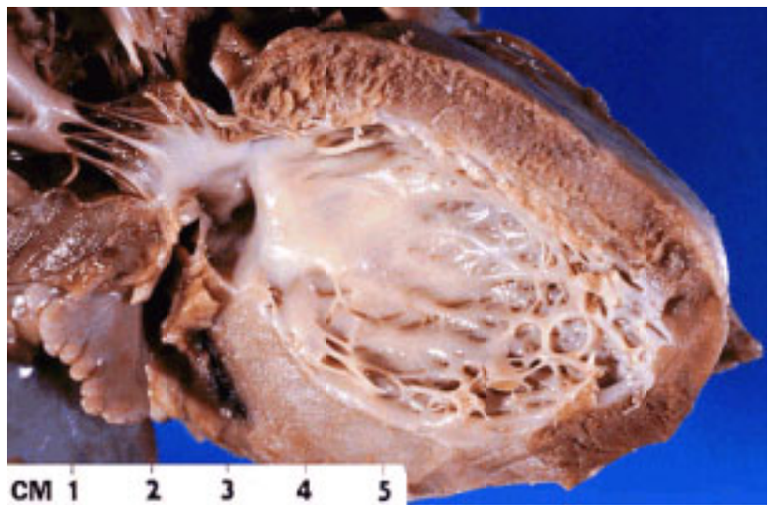
Clinical Profile and Management

The manifestations of Uhl's anomaly are quite similar to those of ARVC and include right heart failure, supraventricular and ventricular dysrhythmias, and conduction abnormalities. The right-sided failure tends to be more common and severe. The treatment of Uhl's anomaly is the same as for ARVC. Unfortunately, because of the progressive, more extensive nature of this disease, patients tend to be refractory to treatment. Cardiac transplantation has been successfully performed in these cases, but the timing of listing for transplant can be exceedingly difficult because there is a high risk of sudden cardiac death on the one hand and patients who live for several years with ventricular dysrhythmias on the other. Many investigators have contemplated whether Uhl's anomaly and ARVC are the same or different entities (64,65 and 66). It is best explained, at this time, that they share the common pathogenesis of apoptosis, but they remain separate clinical diseases.

UNCLASSIFIED CARDIOMYOPATHIES

Endocardial Fibroelastosis

Endocardial fibroelastosis is an abnormal thickening of the endocardium of the left ventricle and aortic and mitral valves. It occurs in infancy and early childhood. The fibrosis leads to decreased compliance of the myocardium and diastolic dysfunction. Typically, a DCM occurs frequently with significant mitral regurgitation, but a restrictive cardiomyopathy can also occur. The exact genetic defect has not been identified; autosomal recessive, autosomal dominant, and X-linked recessive patterns of inheritance have been reported. The X-linked forms demonstrate mitochondrial abnormalities that are similar to those of Barth's syndrome. Endocardial fibroelastosis has also been associated with tissue carnitine deficiency (67), and there is evidence that it may be related to a defect in the plasma membrane carnitine transporter (68). Other theories of its pathogenesis include inadequate subendocardial blood flow, pre- or postnatal inflammation, and infections. The diagnosis is one of exclusion, with diseases such as hypertrophic obstructive cardiomyopathy, myocarditis, anomalous pulmonary origin of the left coronary artery, and glycogen storage diseases needing to be ruled out. The ECG frequently shows features of left ventricular hypertrophy, with occasional pseudoinfarction patterns and atrioventricular block. The echocardiogram is remarkable for dense echoes along the left ventricular endocardium. The treatment consists of prolonged administration of digoxin. In one study, up to 74% of children were cured, with the remainder having either persistent ventricular dysfunction or dying. Prolonged treatment with high doses of digoxin seemed to be a determining prognostic factor, with relapses demonstrated with cessation of therapy (69). Cardiac transplantation has been successful in select cases.



Fibroelastosis and hypertrophy of the left ventricle. This specimen was obtained from a 3 month old child with incomplete closure of the foramen ovale.

Endofibroelastosis. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

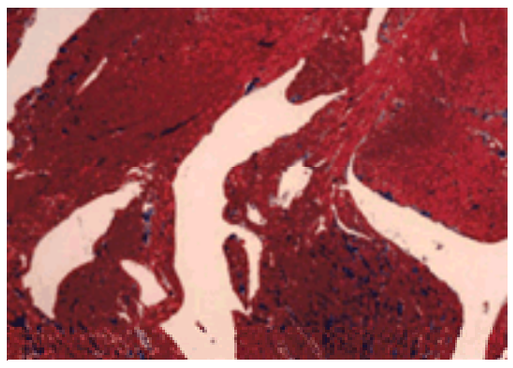
Noncompacted Myocardium

Noncompaction of the myocardium, also known as *spongy myocardium* or *persisting myocardial sinusoids*, is a relatively rare disorder that is encountered mainly in pediatric patients and young adults. This disorder is characterized by numerous, excessively prominent ventricular trabeculations and deep intertrabecular recesses and is readily diagnosed by echocardiography (70,71). The intertrabecular recesses extend approximately two-thirds of the way through the walls of the involved ventricles and may be lined by thickened, fibrotic endocardium. The deep intertrabecular recesses and prominent trabeculae are features of embryonic or "spongy" myocardium, which normally develops into the compact myocardium that is characteristic of the mature mammalian heart (eFig. 90.5.1). Presumably, this entity is from an arrest in endomyocardial morphogenesis (72) and may involve either both ventricles or the left ventricle alone. It has never been reported as involving only the right ventricle. Noncompaction is almost always associated with other cardiac congenital defects, such as anomalous origin of the left coronary artery, and a characteristic facial dysmorphism. Isolated noncompaction of the myocardium is a similar disorder except that it is even rarer and is not associated with other congenital abnormalities (73). Both diseases have an increased incidence of familial cardiomyopathies, but no specific genetic locus has been identified. In pediatric and adult patients, embolic events occur because of the deep intertrabecular recesses. Ventricular dysrhythmias have been the most common presenting complaint. Left ventricular systolic dysfunction also occurs, although the etiology is uncertain. Restrictive physiology and endocardial fibrosis have also been noted (74). No definitive therapy is available, and many patients die from dysrhythmias.

Video 90.7 Apical two-chamber view of a patient with noncompaction with the inferior wall to the left of the screen and the anterior wall to the right. Again, note the thickened, heavily trabeculated myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 90.8 Apical four-chamber view of a patient with noncompaction with the right ventricle to the left of the field and the left ventricle to the right. Note the thickened, heavily trabeculated myocardium. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Video 90.9 Apical long-axis view of a patient with noncompaction. Isolated ventricular noncompaction is a rare idiopathic cardiomyopathy characterized by abnormal structure of the myocardium caused by intrauterine arrest of compaction of the myocardial fibers without any coexisting congenital lesions. The typical echocardiographic appearance includes segmental thickening of the myocardium consisting of two layers: a thin compacted epicardial and an extremely thickened endocardial layer with prominent trabeculations and deep recesses. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*



***e*FIGURE 90.5.1** Noncompacted myocardium. This is a typical example of the microscopic appearance of noncompaction of the myocardium. This section, taken from the left ventricle and stained with Masson's trichrome, could just as easily have come from the right ventricle or interventricular septum. The characteristic feature of this congenital abnormality is the deep, endocardial-lined invaginations in the myocardium, reminiscent of the sinusoidal lining of reptilian ventricles.

The largest series to date of noncompaction cardiomyopathy was reported by Oechslin et al. (75,76). Thirty-four adults, all aged greater than 16 years (25 men) demonstrated echocardiographic criteria for noncompaction cardiomyopathy that included, in the absence of significant heart lesions, segmental thickening of the left ventricular myocardial wall consisting of two layers, a thin compacted epicardial and an extremely thickened endocardial layer with prominent trabeculations and deep recesses. The mean age of the cohort was 42 ± 17 years, and 35% of the patients were in NYHA class III or IV. The left ventricular end diastolic diameter was 65 ± 12 mm and ejection fraction was 33% ± 13%. The apex or midventricular segments, or both, of the inferior and the lateral wall were involved in more than 80% of the patients. Mean follow-up was 44 ± 40 months with major complications noted during follow-up, including worsening heart failure in 53%, thromboembolic events in 24%, and ventricular tachycardia in 41%. Twelve deaths occurred; six were sudden, and four were related to worsening congestive heart failure. Four patients underwent heart transplantation, and automatic implantable cardioverter-defibrillator devices were implanted in four other individuals. This large case series emphasizes the mortality and morbidity of noncompaction cardiomyopathy and points out the risks of worsening heart failure, thromboembolic events, and ventricular arrhythmias. This group suggested that patients receive "heart failure therapy," oral anticoagulation, and consideration for heart transplant or automatic implantable cardioverter-defibrillator implantation. It should be pointed out, however, that no specific recommendations can be made regarding these tactics.

Mitochondrial Cardiomyopathy

Mitochondrial cardiomyopathy is defined as ventricular dysfunction caused by mitochondrial DNA mutations, which are maternally inherited. These mutations are not limited to the heart mitochondria and may also be demonstrated throughout the liver, kidney, pancreas, central nervous system, skeletal muscles, and thyroid gland. The mitochondria are typically irregular, vary in size, and have a very abnormal cristae structure (Fig. 90.6). Within the myocardium, there may be focal fibrosis and myofibrillar disarray, closely resembling idiopathic HCM. Mitochondrial cardiomyopathy may also present with signs, symptoms, and features of DCM. Progressive hypertrophy and dilation of the heart with cardiac dysrhythmias are characteristics of these mitochondrial abnormalities. DNA defects frequently result in cytochrome c oxidase deficiency and abnormalities in the mitochondrial respiratory chain. Research is active in identifying these mutations by endomyocardial biopsy (77). Several systemic diseases are associated with mitochondrial dysfunction. For example, the MELAS syndrome (*m*itochondrial *e*ncephalopathy, *l*actic *a*cidosis, and *s*troke-like episodes) is complicated by cardiomyopathy and generalized microangiopathic occlusive disease.

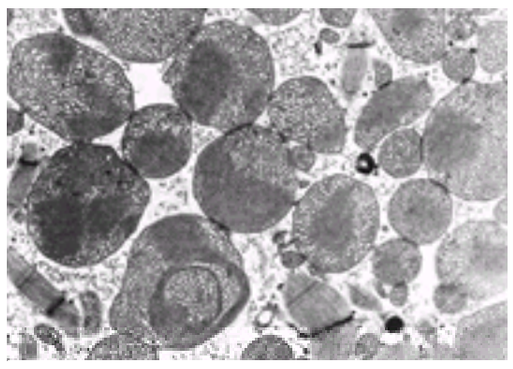


FIGURE 90.6 Mitochondrial myopathy. In this electron micrograph, the bizarre mitochondria, which are characteristic of a mitochondrial myopathy, are evident. All of the mitochondria illustrated here are abnormal. The normal mitochondria in a myocyte are filamentous and branching with regular cristae. The mitochondria in this myopathy are predominantly spherical. The extreme variation in size and structure of the cristae is distinctly abnormal. Within individual mitochondria, two distinct conformations of cristae can be seen. One of the mitochondria has ring-shaped cristae. Other abnormalities, too numerous to illustrate, were noted in this patient.

Systolic Dysfunction with Minimal Dilatation

Patients with DCM have ventricular dysfunction with enlarged ventricles. However, there is an entity in which ventricular dysfunction that is similar to DMC occurs but with minimal or no dilation (78). Furthermore, there are no signs of restrictive physiology to suggest that it is a restrictive or early HCM. This variant of DCM is termed *mildly dilated congestive cardiomyopathy* (MDCM) or *systolic dysfunction with minimal dilatation cardiomyopathy*. MDCM is defined as end-stage heart failure of unknown etiology (NYHA class IV), with an ejection fraction of less than 30%, without significant ventricular dilation (<15% above the normal range of ventricular size

for body surface area) (79). Additionally, the ventricular hemodynamic waveforms should not suggest restriction, such as with an early diastolic dip and plateau. MDCM can be differentiated from early stages of DCM, because early DCM does not have severe dysfunction clinically by echocardiogram or with right heart catheterization. On endomyocardial biopsy, the light microscopic findings demonstrate myocyte hypertrophy, bizarre-shaped nuclei, and interstitial fibrosis. Little to no myofibrillar loss occurs by electron microscopy, despite severe ventricular impairment. This preservation of myofibrils may explain the lack of dilation. Vitamin and nutritional element deficiencies must be ruled out before this diagnosis can be made, because these processes can cause profound reduction in systolic performance with preserved heart size as well. The etiology of this disorder is unknown; however, a positive family history of DCM can frequently be elicited. The prognosis overall is similar to that of DCM, but it appears more related to the hemodynamic impairment than to ventricular size. This is in contrast to DCM, in which increasing ventricular size denotes a poorer survival. For this reason, cardiac transplant should be considered if congestive symptoms persist after medical therapy.

SPECIFIC CARDIOMYOPATHIES

Ischemic

Ischemic cardiomyopathy, defined as an ejection fraction of less than 40%, with multifocal wall motion abnormalities due to coronary artery diseases, is the most common DCM in the United States (Fig. 90.7 and Fig. 90.8). It carries with it significant disability and mortality. In the past, a 5-year survival rate of only approximately 40% has been reported (80). Adequate perfusion of the myocardium is essential for appropriate cellular aerobic respiration, and heart failure due to ischemic cardiomyopathy is caused by at least four distinct mechanisms. The predominant mechanism is ischemic necrosis, owing to myocardial infarction (81). It is vital to determine the amount of stunned myocardium in these ischemic cardiomyopathy patients, particularly in the periinfarction phase, as well as the extent of hibernating tissue, because they may play significant roles in contractile dysfunction (82). Stunned and hibernating myocardial tissue are viable, with potential for improvement in functioning with better perfusion. Differentiation of ischemia, scar, and hibernating myocardial tissue is discussed fully in Chapter 50 and Chapter 55 and includes methods such as positron emission tomography, dobutamine and myocardial contrast echocardiography, and rest-redistribution thallium-201 scintigraphy (83). The final mechanism of ischemia that causes cardiomyopathy is related to pathologic remodeling after acute myocardial infarction. Nonischemic myocytes are subjected to increased workloads as infarcted cardiac tissue drops out of the contractile scene. Pathologic hypertrophy is induced in these remaining myocytes, as well as other molecular biodynamic characteristics of remodeling. Additional important factors include the development of ventricular aneurysm, dysrhythmias, and mitral regurgitation from papillary muscle ischemia and dysfunction. It is the combination of these factors that contributes to progression from normal cardiac function to cardiac dilation and heart failure.

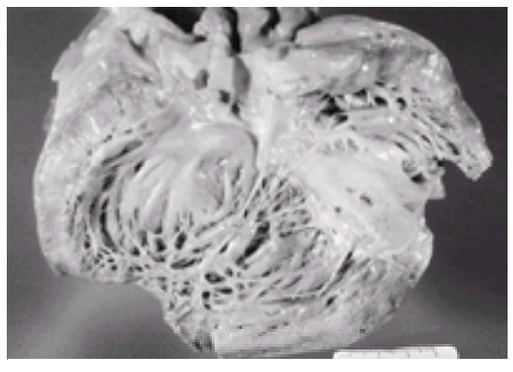

FIGURE 90.7 Ischemic cardiomyopathy. Photograph shows a heart that has been sectioned through the mitral and aortic valves, exposing the left ventricle. The heart is dilated, round, and globular, with an overall appearance much like that of an idiopathic dilated cardiomyopathy. However, in the cut surfaces of the left ventricle, visible here, the extensive white scar tissue of remote myocardial infarcts can be appreciated.

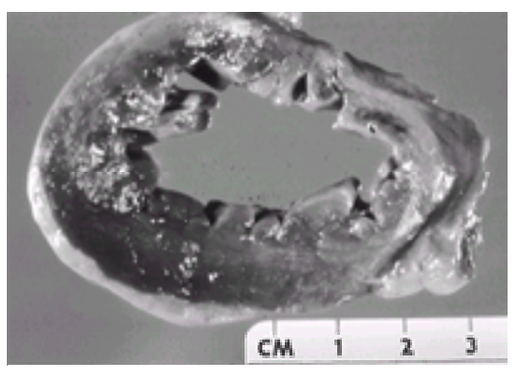

FIGURE 90.8 Ischemic cardiomyopathy. In this cross section from a heart with a remote myocardial infarct, many of the features of ischemic cardiomyopathy are demonstrated. A remote infarct is at the top of the picture. The portion of the left ventricular wall involved by this transmural infarct is notably thinner than the remainder of the ventricle, reflecting stretching and distention of the infarcted area. The left ventricular cavity is substantially enlarged, a reflection of the overall dilatation of the left ventricle.

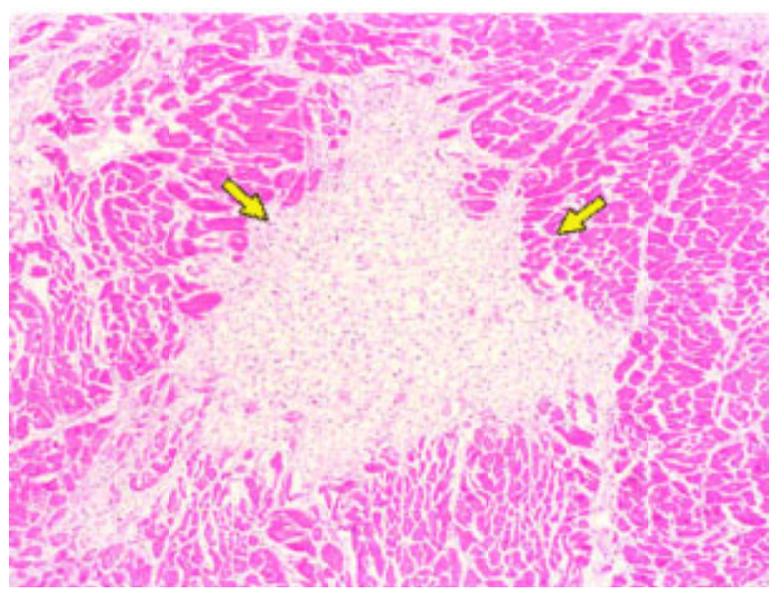

Histology showing the early stages of healing following myocardial infarction. These changes are typical in the second week after the acute event. This is a hematoxylin-eosin stain showing removal of the necrotic myocytes and early ingrowth of vascular tissue and fibroblasts, particularly evident at the edges of the lesion (*yellow arrows*).

This characterization of ischemic cardiomyopathy is more generally related to the traditional large-vessel epicardial coronary artery disease that is seen in most patients with atherosclerotic heart disease. However, diffuse small-vessel atherosclerosis can also produce ischemic-related malfunction of the cardiac myocyte. Indeed, the cardiomyopathy of diabetes mellitus may be due, in part, to epicardial vessel disease as well as diffuse, small-vessel subendocardial atherosclerosis. Syndrome X, systemic lupus erythematosus, and other autoimmune chronic inflammatory disease states produce, on occasion, similar findings. The allograft arteriopathy noted in patients after cardiac transplantation is also an example of diffuse small-vessel coronary artery disease that can produce myocyte contractile dysfunction that leads to cardiac remodeling and heart failure. These diseases are difficult to address because of the limited ability to restore adequate myocardial perfusion.

Differentiation of ischemic cardiomyopathy from nonischemic processes is extraordinarily important. Patients with ischemic cardiomyopathy frequently, but not

always, have histories of chest discomfort, myocardial infarctions, or abnormal ECGs, suggesting previous infarction. Restoring adequate perfusion of the heart is key to reversing the progression of a clinical heart failure state. Coronary angiography is key, although often lesions are seen that are not producing ischemia, and, on the other hand, diffuse small-vessel disease may not be well appreciated. Coupling angiographic findings to perfusion, viability, and functional studies of the heart differentiates contributions of ischemia, scar, hibernation, and periinfarction stunning to the pathologic remodeling process of heart failure.

Valvular

Valvular cardiomyopathy is a hyperergopathic DCM produced by valvular defects of numerous etiologies, discussed in Chapter 21, Chapter 22, Chapter 23, and Chapter 24. Typically, defects that produce volume-overloaded states (regurgitation) are more likely to cause cardiomyopathy than are lesions associated with pressure overload (valvular stenosis). The etiologies of valvular cardiomyopathy have changed considerably over the past several decades. The aggressive treatment of rheumatic fever and the earlier and more successful valvular repairs and replacements being performed are leading to a decreased incidence of more common causes. Further, the identification of nonrheumatic disorders are increasing the documented frequency of other problems. The clinical presentation of valvular cardiomyopathy is similar to that of any of the other dilated cardiomyopathies. The prominent signs and symptoms of failure depend on what valve or valves are dysfunctional and on what side of the heart they are located. It may be difficult to evaluate fully the severity of some disorders when myocardial dysfunction is present. For example, the degree of aortic stenosis can be underestimated by echocardiography, because the ventricle may be too weak to generate a large gradient across the valve. The use of dobutamine may help to clarify this. Another area in which physicians frequently struggle is mitral regurgitation in the setting of a very dilated ventricle. Unless a good history is available, it may be difficult to ascertain whether the insufficiency caused the dilation and dysfunction or whether the regurgitation is a result of ventricular dilation with stretching of the annulus. Medical treatment is the same as with the other DCMs. Frequently, the issue of corrective valvular surgery in the setting of severe myocardial dysfunction is raised, with the hope of promoting myocardial recovery if the lesion is fixed. For instance, attempts at reducing mitral regurgitation have been performed in patients with severe cardiomyopathy, either as an isolated surgery or in conjunction with partial left ventriculectomy, with some symptomatic success and at least early improvement in certain cases (84,85).

Hypertensive

Hypertensive cardiomyopathy is discussed in detail in Chapter 5.

Obesity

Obesity is recognized as a specific separate disorder that can result in a cardiomyopathy. This is a condition distinct from other entities that can cause heart failure and are also associated with obesity, such as hypertension, coronary atherosclerosis, sleep apnea, and diabetes. It is believed that the severity of the cardiomyopathy is associated with the duration and the severity of the obesity and initially is a type of high-output failure. Obesity cardiomyopathy results in systolic and diastolic dysfunction, left ventricular hypertrophy, and elevations in left ventricular filling pressure. Substantial weight loss has been correlated with improvement in the ventricular function.

Inflammatory

Inflammatory cardiomyopathies are addressed specifically in Chapter 93. They are generally divided into idiopathic, autoimmune, and infectious categories and are listed in Table 90.3. The cardiomyopathies that are associated with systemic autoimmune disorders include the collagen-vascular disease syndromes and many of the mixed connective tissue diseases. Numerous viral infections are associated with DCM, including viral (enterovirus, adenovirus and cytomegalovirus, Coxsackie), rickettsial, bacterial (diphtheria), mycobacterial, fungal, parasitic (toxoplasmosis, trichinosis, Chagas' disease), and spirochetal (see Chapter 39). One particular cardiomyopathy, associated with HIV, warrants further mention here because it will, unfortunately, be encountered more and more frequently in clinical practice.

Idiopathic
Autoimmune
Collagen-vascular and mixed connective tissue diseases
Churg-Strauss syndrome
Systemic lupus erythematosus
Polyarteritis nodosa
Progressive systemic sclerosis
Infectious
Bacterial
Fungal
Parasitic
Schistosomiasis
Trichinosis
Toxoplasmosis
Trypanosoma cruzi
Rickettsial
Leptospirosis
Spirochetal
Viral
Adenovirus
Coxsackie virus
Cytomegalovirus
Echovirus
Human immunodeficiency virus

TABLE 90.3 CAUSES OF INFLAMMATORY CARDIOMYOPATHY

Human Immunodeficiency Virus

Background and Prevalence

The first mention of a cardiac manifestation of the acquired immunodeficiency syndrome (AIDS) occurred in 1983, when a woman with cardiac Kaposi's sarcoma and heart failure was described (86). Since then, several cardiac pathologies associated with HIV infection have been identified, including pericardial diseases, valvular lesions with or without endocarditis, lymphocytic myocarditis and myocardial necrosis, neoplasms, right ventricular failure, and DCM (87,88 and 89) (see also Chapter 39). The actual incidence of cardiac abnormalities in HIV-infected patients remains unknown; however, it has been estimated to be approximately 50% in cases when confirmed at autopsy (90,91 and 92). About 20% of these had DCM, although many were not clinically apparent. The presence of a cardiomyopathy is strongly associated with CD4 cell counts of less than 100 H 10^6 per L (93). Cardiac complications may be the cause of death in approximately 5% of all AIDS cases (94), with patients who manifest signs and symptoms of heart failure having a 6-month mortality that approaches 50%. With the currently increasing number of HIV-infected individuals worldwide, HIV cardiomyopathy will clearly become a more commonly seen clinical entity.

Pathophysiology

Many theories have been advanced proposing possible etiologies of HIV cardiomyopathy. No single mechanism has been accepted as the cause, and probably several different factors contribute to the dysfunction. First, the presence of an underlying mononuclear cell infiltrate/myocarditis is frequently present and may chronically lead to myocyte necrosis with resultant myocardial failure (88). Many of the opportunistic organisms that are common in HIV-infected patients, including bacterial, fungal, viral, and protozoal infections, are already known to cause myocarditis in otherwise healthy individuals. The mononuclear infiltrate may also be the result of an autoimmune process. In one study, immunoglobulin G antibodies directed against myosin and cardiac mitochondrial adenine nucleotide translocators were identified in HIV-positive patients with cardiomyopathy (95).

Several substances that are present in HIV patients may be directly or indirectly toxic to the myocardium. Catecholamines, found in higher levels in this group, can induce myocyte death. Further, it has been postulated that there may be focal areas of catecholamine-induced microvascular spasm, leading to areas of chronic ischemia or even infarction. Many of the drugs that are commonly used to treat AIDS or one of its associated problems have been implicated in the cardiomyopathy, including zidovudine (AZT), interferon-a, and doxorubicin. For instance, a correlation between antiretroviral therapy, such as with AZT, and the degree of cardiomyopathy has been identified (96). Additionally, AZT has been shown to cause myocyte mitochondrial DNA chain replication termination *in vitro*. This may eventually lead to impaired cellular energy production and myocyte death. It has been demonstrated that tumor necrosis factor-a (TNF-a), present in increased amounts in HIV-positive patients, can directly induce significant myocardial depression (97,98). It also promotes the release of other harmful substances, such as nitric oxide and oxygen-free radicals, which can in turn cause additional depression of function (99,100). The AIDS virus itself can directly infect myocytes and may be directly toxic by a cytolytic effect (101,102). Additionally, when the virus replicates in interstitial lymphocytes and macrophages, destructive enzymes can be released (103). It has been suggested that nutritional deficiencies can lead to heart failure (104,105). For example, low selenium levels are common in HIV-positive patients, especially in more severe cases. Glutathione peroxidase activity is diminished with selenium deficiency, which may lead to the accumulation of myocardial toxins.

Other factors that can contribute to cardiomyopathy in AIDS are the same causes of cardiac failure in non-HIV–positive patients (106,107). It is always possible that

underlying coronary artery disease can lead to ischemic cardiomyopathy, hypertension resulting in hypertensive cardiomyopathy, or a secondary viral infection, such as Coxsackie B virus, with subsequent viral cardiomyopathy. Similarly, patients with a history of drug abuse may have a higher incidence of alcoholic cardiomyopathy or cocaine-induced failure that is unrelated to their HIV status.

Clinical Profile and Management

The clinical presentation of heart failure is frequently misinterpreted to be one of the other more common illnesses in HIV-positive patients. For example, shortness of breath and dyspnea with exertion immediately raise the suspicion of an opportunistic pulmonary infection. It is important to consider also the possibility of heart failure when these patients present with new complaints. The chest x-ray is insensitive, but it may be helpful by demonstrating cardiomegaly or pulmonary edema. ECGs are usually nonspecific with HIV cardiomyopathy, although they could exclude other possibilities such as ischemia or infarction. The most helpful diagnostic test is an echocardiogram, which assesses ventricular size and contractility and valvular function and detects pericardial effusions.

In addition to the conventional treatment of heart failure with digoxin, diuretics, and ACE inhibitors, several other therapies have been suggested. Selenium supplementation has been documented to improve left ventricular function in a few cases (108). If AZT or another drug is suspected of causing or contributing to the ventricular dysfunction, the risk-benefit ratio of discontinuing therapy warrants examination. Some clinicians have supported the use of immunosuppressive agents, such as corticosteroids with or without azathioprine, especially if an inflammatory or autoimmune mechanism is responsible (85,109). No randomized trials have validated this approach, however, and the use of immunosuppressants in an already compromised host requires careful consideration. In the future, as more is understood about TNF-a and similar compounds, antioxidants and oxygen-free radical scavengers may play a pivotal role.

Tachycardia Induced

One of the more important cardiomyopathies is that related to chronic tachyarrhythmia. In many senses this form of cardiomyopathy is a classic hyperergasic cardiomyopathy. If substantive ventricular dysfunction and heart failure are due to this difficulty, response to treatment can be gratifying. Severe dropsical states can resolve quickly, for example, by simply slowing the ventricular heart-rate response in patients with heart failure due to rapid atrial fibrillation. In fact, William Withering's (110) description of patients who are likely to respond to his foxglove herbal tea therapy were characterized as having pale countenances with weak, thready, and irregular pulses accompanying their dropsical state. It is very likely, in retrospect, that these individuals had atrial fibrillation with rapid ventricular response rates. Although ventricular and atrial tachycardias are very common in patients with heart failure, whether or not they are the primary etiology of the difficulty or simply an added complication that contributes to decompensation varies from patient to patient. This is of little consequence, however, because control of dysrhythmia, with slowing of the heart rate, is mandatory in either circumstance. Further, it is often difficult to know whether tachyarrhythmias that are seen in heart failure patients caused or are the result of ventricular chamber dilatation, hypertrophy, and heart failure. Indeed, in 1913, Gossage and Braxton Hicks (111) first suggested that atrial fibrillation might have been the etiology of left ventricular dilation and hypertrophy. This report did not, however, document reversal of the cardiac remodeling with control of the "auricular fibrillation." Many reports in the 1930s and 1940s did, however, describe resolution of congestive heart failure syndromes after termination of atrial fibrillation and cardioversion to normal sinus rhythm (112,113 and 114). Because atrial fibrillation frequently complicates hypertension and coronary heart disease, with both difficulties also contributing to ventricular dysfunction and possibly precipitating heart failure, it is difficult to determine precisely the degree of contribution that the dysrhythmia is making to the cardiomyopathy in some patients. On the other hand, descriptions of heart failure syndromes associated with reentrant atrial tachyarrhythmias with resolution of the syndrome after control of the arrhythmia are convincing that heart rate alone contributes to contractile dysfunction (115,116 and 117). As electrophysiologic techniques became more sophisticated and pathophysiologic clarification of atrial tachycardias emerged, it became even more apparent that rapid heart rates alone could cause heart failure and cardiomyopathy. Restoration of systolic function, manifest by normalization of ejection fraction, has been reported for accessory pathway–reciprocating tachycardias (118,119) and atrial ventricular nodal reentry tachyarrhythmia (120,121). In children, control of incessant ventricular tachycardia has also been noted to reverse dilated myopathic ventricles (122,123).

In an attempt to mimic tachycardia-induced heart failure clinically, an experimental model was proposed by Whipple et al. (124) in 1962 that demonstrated that cardiomyopathy could be produced in large mammals if the heart was stimulated to incessantly beat very fast. Furthermore, this model of low-output biventricular failure demonstrated that termination of the pacing stimulation with slowing of the heart rate reversed the heart failure syndrome. Tachycardia-pacing animal models of heart failure have been invaluable during characterization of heart failure syndromes in general. Overall, they have served to stress the importance of controlling tachycardia in managing clinical heart failure (125). The reasons for the development of ergopathic myocyte contractile impairment in patients with incessant tachyarrhythmias or rapid pacing–induced cardiomyopathy are complicated. Decompensation of cardiac performance may be due to myocardial energy depletion or impaired energy use, regional ischemia (usually subendocardial), abnormalities of myocyte organelle calcium flux, and acute leading to chronic cardiac myocyte and interstitial matrix remodeling. Chronic tachypacing in animals has been demonstrated in some studies to reduce creatine, phosphocreatine, and adenosine trisphosphate (126). Furthermore, mitochondrial structural injury and functional abnormalities have been noted. Particularly intriguing is the observation that altered subendocardial-subepicardial blood flow ratios impair coronary flow reserve states when tachycardia is induced in animals and might contribute to myocyte dysfunction by promoting a relative ischemic setting. This is an important observation because many patients have concomitant coronary heart disease or substantive hypertension-induced left ventricular hypertrophy and could be quite susceptible to myocardial flow changes. A considerable amount of attention has focused on abnormalities of calcium channel activity and sarcoplasmic reticulum calcium transport in paced heart failure models. The downregulation of calcium cycling, which ultimately decreases availability of this ion to the myocyte contractile machinery, may be a unifying hypothesis to explain the failure that develops in this syndrome. Observations of myocyte hypertrophy and extracellular matrix deposition with resultant stiffening could explain the more chronic abnormalities noted in paced cardiac models. Collectively, these pathophysiologic effects translate into low cardiac output and, ultimately, high cardiac filling pressures with dilatation and hypertrophy of the heart. Concomitant aberration in neurohumoral characteristics of the clinical heart failure syndrome subsequently occurs.

Controlling rapid ventricular responses is, therefore, paramount in attempting to ameliorate heart failure states that are associated with tachycardia. Because atrial fibrillation is so common in patients with heart failure, control of the ventricular rate needs to be emphasized. Focus should first be on attempts to convert the patient, either with pharmacologic therapy or direct current cardioversion, to sinus rhythm. Should this not be possible, consideration of pharmacologic strategies to control ventricular rate is important, as might be atrioventricular junction nodal ablation with permanent ventricular pacemaker insertion. Other types of supraventricular tachycardias might respond to more focused electrophysiologic arrhythmia-track ablation techniques or insertion of electronic arrhythmia-termination pacing devices. Likewise, incessant, but not necessarily sustained, ventricular arrhythmias need to be addressed in similar fashion with consideration of pharmacologic treatment strategies, ablation therapeutics, or use of electronic arrhythmia-termination and control devices. Finally, the Maze operation is a surgical alternative that might assist in controlling the dysrhythmia and ameliorate heart failure. The procedure involves making several intertwining incisions in the atria to interrupt the fibrillation circuits.

Metabolic

Many metabolic disorders are known to induce myocardial dysfunction and can be categorized into endocrine, familial storage disease and infiltrations, deficiency states and nutritional disorders, and amyloidosis. Endocrine diseases, such as adrenocortical insufficiency, thyrotoxicosis, hypothyroidism, acromegaly, and pheochromocytoma, are covered in detail in the endocrine section of Chapter 35. Because diabetes mellitus and diabetic heart disease are so frequently encountered, they are further explored here. Additionally, amyloidosis and its unique nature deserve additional description.

Diabetic

Heart failure in the setting of diabetes is multifactorial and can be due to epicardial atherosclerotic coronary artery disease, small-vessel subendocardial disease, or the diabetes itself (127). Patients with diabetes mellitus are well known to be prone to silent myocardial ischemia and infarction. Furthermore, hypertension often complicates diabetes and can also contribute to the detrimental remodeling of the heart. It is disturbing to note that almost half of asymptomatic diabetics experience a reduction in left ventricular ejection fraction during stress.

The hearts of diabetic patients at autopsy demonstrate the characteristic findings of DCM, with widespread regions of myocardial fibrosis, intimal proliferation of small myocardial arterioles, and accumulation of interstitial glycoprotein and collagen, all leading to decreased ventricular compliance and contractility (128). In laboratory animals, alterations in myocytes occurred before any damage to the intramural arteries, suggesting other derangements in cellular metabolism (129). It has been presumed that some of the resultant dysfunction may be related to abnormal processing of lipids and decreased lysosomal activity (130). Many additional theories have been postulated and explored to explain the ventricular failure, including the possible role of increased circulating catecholamines (131). It has also been observed that the concentration of collagen increases when diabetes is poorly controlled (132), and other studies have documented improvement in left ventricular functioning and reversal of biochemical abnormalities with the administration of insulin (133). In addition to the more standard treatments for DCM, tighter control of glucose levels may be beneficial to cardiac functioning in diabetics. Finally, the chronic addition of propionyl-L-carnitine to the diets of diabetic rats in one study overcame the induced myocardial dysfunction (134), raising the potential of testing this treatment in humans.

Familial Storage Disease and Infiltrations

Many of the familial storage diseases and infiltrations cause various substances to be deposited within the myocardium, either intracellularly (frequently interfering with cellular metabolism and functioning) or extracellularly (resulting in a restrictive cardiomyopathy). Many of these disorders, such as Hurler's syndrome, Niemann-Pick

disease, Hand-Schüller-Christian disease, and Morquio-Ullrich disease, are more fully reviewed in the neurology section of Chapter 35. A few of the more understood and common disorders are further discussed here.

Hemochromatosis

Hemochromatosis is a metabolic storage disorder, associated with HLA-A3 and HLA-B14 autosomal recessive inheritance, leading to iron deposition in the sarcoplasmic reticulum of many organs (Fig. 90.9). It results clinically in the classic description of the bronzed diabetic with heart failure due to skin, pancreatic, and cardiac iron deposition. The cardiac deposits tend to be in the subepicardial and subendocardial regions and in the papillary muscles. Cardiac hemochromatosis may present as either a restrictive cardiomyopathy early on or, more commonly, a dilated one, with impressively enlarged ventricles. In addition to the iron deposition, an interstitial fibrosis that is unrelated to the degree of iron overload may occur independently. Endomyocardial biopsy is useful in demonstrating the iron deposits and important in establishing the diagnosis because the most common form of death in hemochromatosis is cardiac. Treatment consists of repeated phlebotomy or possibly chelation therapy, with the cardiomyopathy often reversible when the iron load is decreased.

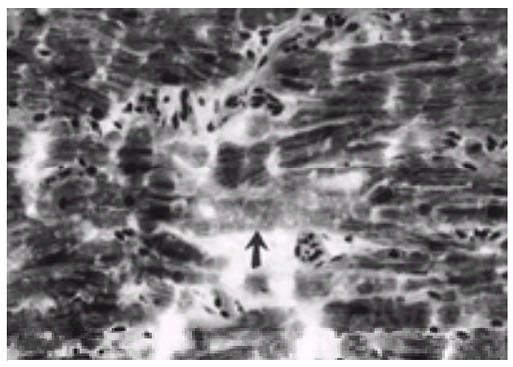

FIGURE 90.9 Cardiac hemochromatosis. This longitudinal light microscopic section of myocardium has been stained for iron. It has been specially stained blue for iron, but in black and white print all of the dark material seen within the myocytes is iron, with one large aggregate of iron in the center (*arrow*). This particular area does not have any overlying cardiac structures and appears lighter than other iron-laden areas in this picture. In the normal heart, there should be virtually no stainable iron.

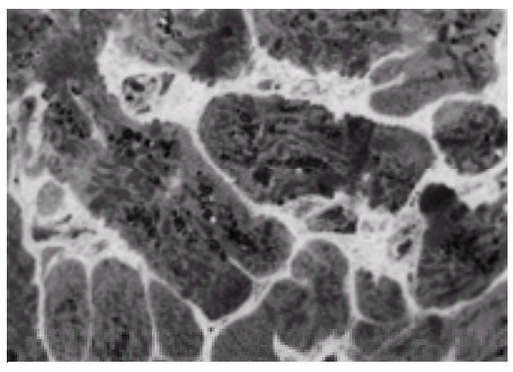
Refsum's Syndrome

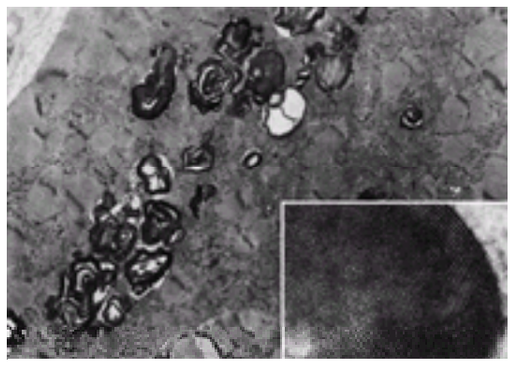
Refsum's syndrome is an autosomal recessive disorder caused by the absence of the enzyme alpha-hydroxylase, which metabolizes dietary phytol and phytanic acid. This results in an accumulation of intracellular phytanic acid. The syndrome is characterized by cerebellar ataxia, peripheral neuropathies, retinitis pigmentosa, and cardiac disorders. A cardiomyopathy may result and can be either dilated or hypertrophic, depending on the stage of the disease. Wide-ranging conduction disturbances may occur, as well as dysrhythmias and sudden cardiac death. Current treatment consists of dietary modifications. Plasmapheresis has been shown to remove the accumulated phytanic acid.

Anderson-Fabry's Disease

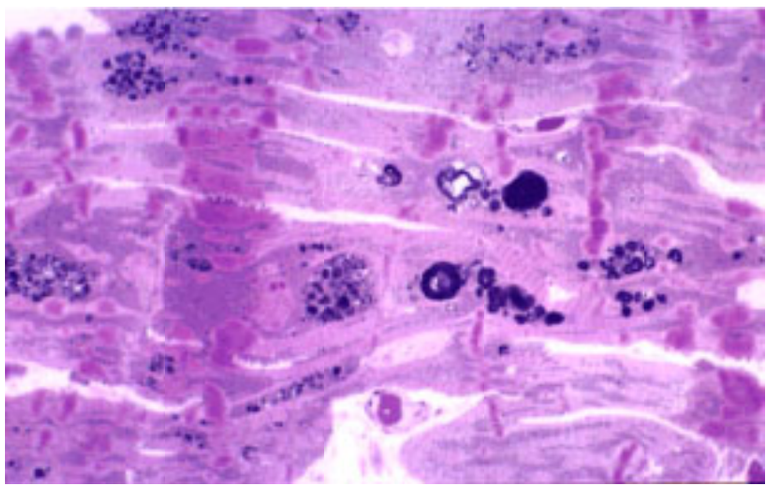
Fabry's disease, formally known as *angiokeratoma corporis diffusum universale*, is an X-linked disorder of glycosphingolipid metabolism and is present in 1 in 40,000 live births. It is due to a deficiency of the lysosomal enzyme alpha-galactosidase A, which normally degrades the neutral glycolipid ceramide trihexoside. The disorder is characterized by the intracellular lysosomal accumulation of this glycolipid, with prominent involvement of the skin, glomerular, and tubular cells of the kidneys, and the heart (eFig. 90.9.1 and eFig. 90.9.2). Within the heart, the myocytes, vascular endothelium, conducting system, and valves can all be affected (135). Storage of the lipid in the blood vessels, with eventual occlusion on the small arterioles, leads to most of the clinical manifestations. Mostly males are affected, whereas the female carriers are usually asymptomatic or have only mild symptoms. Patients are generally diagnosed in childhood, when they present with burning pains, fevers, multiple angiokeratomas, corneal opacifications, and strokes; however, they do not present with renal and cardiac failure until their third or fourth decade of life. An atypical form of Fabry's disease exists, in which there is retention of some residual alpha-galactosidase activity, probably from partial gene deletions and point mutations (136,137 and 138). These patients present late with a cardiomyopathy but no other systemic complaints.



***e*FIGURE 90.9.1** Fabry's disease. High-magnification light micrograph of a semithin plastic section. With dual fixation in glutaraldehyde and osmium tetroxide, the globular dark-staining glycolipids within the cytoplasm of the myocytes, which are characteristic of Fabry's disease, have been preserved. When biopsies from Fabry's disease are processed by standard light microscopic methods with paraffin sections, the appearance is that of a vacuolar myopathy.



***e*FIGURE 90.9.2** Fabry's disease. Electron micrograph illustrating the accumulation of dark, electron-dense membrane profiles of accumulated glycolipids within myocytes. **Inset:** High-magnification electron micrograph revealing the characteristic "fingerprint" of the membrane accumulations within the cytoplasm of the myocytes.



Fabry's syndrome exemplified in cardiac muscle. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Cardiovascular manifestations include renovascular and systemic hypertension, aortic root dilatation, mitral valve prolapse, and congestive heart failure. Patients may additionally have severe vasospastic angina and myocardial infarctions, perhaps from endothelial cell damage (139). The ECG may show left ventricular hypertrophy, P-wave abnormalities, conduction defects, and ventricular dysrhythmias. The echocardiogram typically shows marked increases in wall thickness and ventricular dilatation later in the disease process. The diagnoses may be confused with other disorders, such as HCM, hypertensive cardiomyopathy, and amyloidosis (140). Magnetic resonance imaging may help differentiate this from amyloid (141). Endomyocardial biopsy is remarkable, showing the lipid vacuoles creating a lacework (fingerprint) appearance, with increased levels of ceramide trihexosidase. The muscle fibers demonstrate an irregular degree of hypertrophy. Definitive diagnosis requires showing decreased alpha-galactosidase activity in leukocytes. No specific therapy exists for Fabry's disease. Unfortunately, renal transplantation, by attempting to replace the missing enzyme, does not prevent further cardiac deterioration (142). Lately, encouraging preclinical studies have been performed in corrective gene transfer for enzyme replacement. By using high-titer recombinant retroviral vectors to transduce and correct target cells, a continuous source of alpha-galactosidase may ultimately be available for uptake by unmodified patient cells (143).

Selenium Deficiency

Selenium deficiency is a form of DCM that has been primarily reported in northeast China, where it is known as Keshan disease. It has, however, been demonstrated in HIV-positive patients with cardiomyopathy and in individuals who are receiving chronic parenteral nutrition. Selenium is an essential mineral, and deficiency results in the decreased activity of glutathione peroxidase. This causes an increase in free radicals that can be directly toxic to myocytes. Selenium replacement can reverse the ventricular dysfunction.

Thiamine Deficiency (Beriberi)

The Sinhalese word *beriberi* translates into "I cannot," meaning the patient is too ill to do anything. Thiamine (vitamin B_1) is a necessary coenzyme for carbohydrate metabolism, and patients with this deficiency can present with edema, polyneuritis, and cardiac pathologies for at least 3 months. *Dry beriberi* refers to the constellation of flaccid paralysis, muscular atrophy, areflexia, and cardiac enlargement with tachycardia. Wet beriberi is similar in terms of the cardiac failure, except it has extensive edema. The extensive nervous system involvement is not present. Patients with beriberi have high-output failure, with a cardiac presentation similar to that of the other dilated cardiomyopathies. The mechanism of this failure is uncertain. Lesions in sympathetic nuclei have been observed (144) and may lead to decreased peripheral resistance with compensatory increases in cardiac workload, eventually resulting in ventricular failure. The cardiac dysfunction can rapidly return to near normal with thiamine replacement, although if the deficiency has been long-standing the dysfunction may be irreversible.

Carnitine Deficiency

In carnitine deficiency, the oxidation and mitochondrial transport of fatty acids are impaired, leading to lipid accumulation in the cytoplasm. The deficiency may be familial (145). Carnitine deficiency may result in a dilated or occasionally restrictive cardiomyopathy or a worsening of a preexisting cardiomyopathy of another cause. The cardiac lesions are often associated with endocardial fibroelastosis. Oral therapy with L-carnitine can be quite effective (146).

Amyloidosis

Background and Prevalence

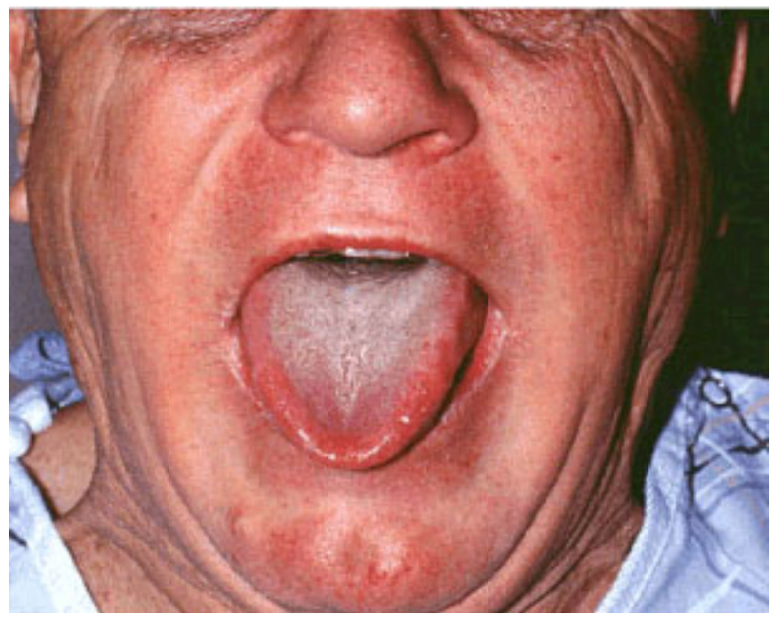
Amyloid restrictive cardiomyopathy is caused by the abnormal deposition of various proteins into the interstitium of the myocardium. The four general categories of amyloid heart disease are primary systemic, secondary, familial or hereditary, and senile. These are summarized in Table 90.4. Primary systemic amyloidosis is also known as *myeloma-associated* or *amyloid AL*. It is caused by the uncontrolled production of an amyloid protein subunit, the ammonia terminal portion of an immunoglobulin light chain (kappa or lambda), from a monoclonal population of plasma cells. It is usually, but not always, the consequence of multiple myeloma, is more common in men, and rarely presents before age 30. Secondary amyloidosis results from the production of a nonimmunoglobulin protein, termed *AA*. It is frequently encountered with chronic inflammatory disorders, such as rheumatoid arthritis, tuberculosis, and Crohn's disease, and in familial Mediterranean fever. Familial and hereditary cardiac amyloidosis consists of six different forms. They result from the production of amyloid AF, a prealbumin protein component known as transthyretin. They are autosomally dominant disorders, unlike familial Mediterranean fever, which is autosomal recessive. Senile cardiac amyloid, also known as *amyloid SSA*, is also due to the production of an abnormal transthyretin and is seen in older individuals (147). The three forms of this disorder are amyloid IAA, which only affects the atria; senile systemic amyloidosis, which may involve other organs; and a third form that is limited to the aorta. Each of the four main categories of amyloid heart disease has varying degrees of cardiac involvement, clinical significance, and survival rates. For instance, cardiac failure is the most common cause of death in primary amyloidosis. At autopsy, nearly 100% of systemic amyloid cases have demonstrable cardiac infiltration, although only 25% to 33% have clinically apparent disease (148,149). In contrast, fewer than 10% of secondary amyloid cases are associated with clinically significant cardiac derangement. Even when present, the deposits are typically small and perivascular in location and do not result in considerable ventricular dysfunction. Familial amyloidosis rarely has cardiac involvement, and then only very late in the disease. Senile amyloidosis is much more variable than the other types. Almost all individuals over the age of 60 have scattered deposits of amyloid in locations such as the aorta, and one-fourth have some cardiac infiltration (150). This ranges from small atrial deposits to extensive ventricular involvement with severe congestive failure. The survival with senile amyloidosis is much longer than with primary amyloid. In one study, the median survival was 60.0 months and 5.5 months, respectively, from the time of diagnosis (151).

Name	Designation	Other names	Amyloid deposit
Primary	AL	Myeloma-associated, idiopathic*	Immunoglobulin light chain, kappa or lambda
Secondary	AA	Associated with other inflammatory disorders, familial Mediterranean fever	Nonimmunoglobulin protein A
Familial	AF	Hereditary	Transthyretin
Senile	SSA	Senile systemic amyloid	Transthyretin

*This term is outdated and should no longer be used.

TABLE 90.4 CLASSIFICATION OF AMYLOIDOSIS

Amyloidosis. Infiltration of the skin results in raised waxy papules or plaques that are usually in clusters.



Amyloidosis. Infiltration of the tongue occasionally leads to macroglossia. Cardiac manifestations include cardiomegaly, congestive heart failure, and arrhythmias.

Pathophysiology

The myocardium in amyloidosis is usually firm, thickened, and noncompliant, with the amyloid being present extracellularly. The deposits occur in the interstitium in a pericellular or focal nodular pattern and can result in systolic and diastolic impairment (Fig. 90.10 and Fig. 90.11). Nodular deposits and thick perimyocyte layers of amyloid are associated with shorter survival (152). Mild atrial enlargement is generally present, usually without significant ventricular dilatation. Besides the myocardial infiltration, there can also be deposition in the papillary muscles, the sinoatrial and atrioventricular nodes, the bundle branches, and the endocardium. Amyloidosis can incite focal thickening of all four valves, especially the mitral; however, it rarely interferes with overall valve function and competence. Finally, the intramural arteries and veins can contain deposits in the media and adventitia, occasionally compromising blood flow. Rarely, deposits can also occur directly in the lumen of the vessels. The different types of amyloid vary in their vascular encroachment. Only 4% of senile amyloidosis has vascular involvement, whereas it is found in up to 90% of primary amyloid cases (153).

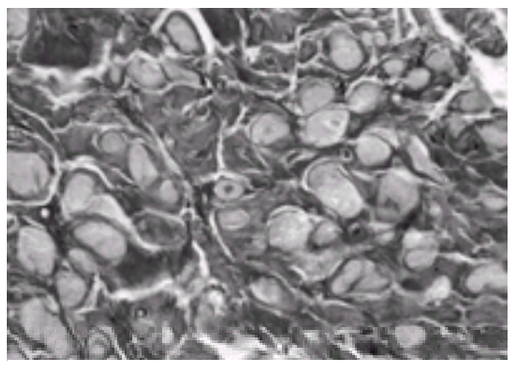


FIGURE 90.10 Cardiac amyloid. Light microscopic section from an endomyocardial biopsy stained with sulfonated alcian blue. Although the color cannot be appreciated, the myocytes are the lighter-shaded cells. The darker-colored amyloid closely surrounds each myocyte and isolates it.

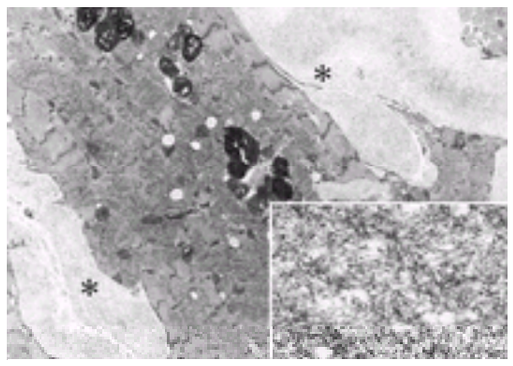

FIGURE 90.11 Amyloid. Electron micrograph showing a dense accumulation on amyloid fibrils (*asterisks*) hugging the myocyte. **Inset:** At high magnification, 10-nm nonbranching straight filaments, which are characteristic of amyloid, are revealed.

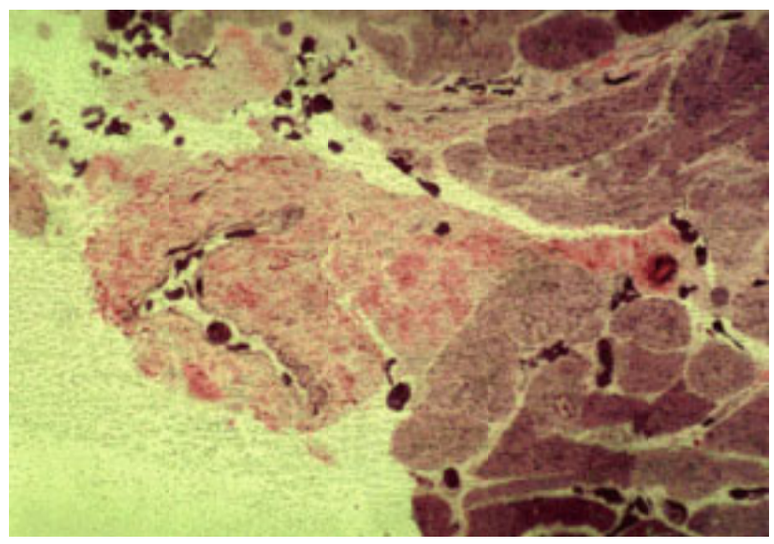
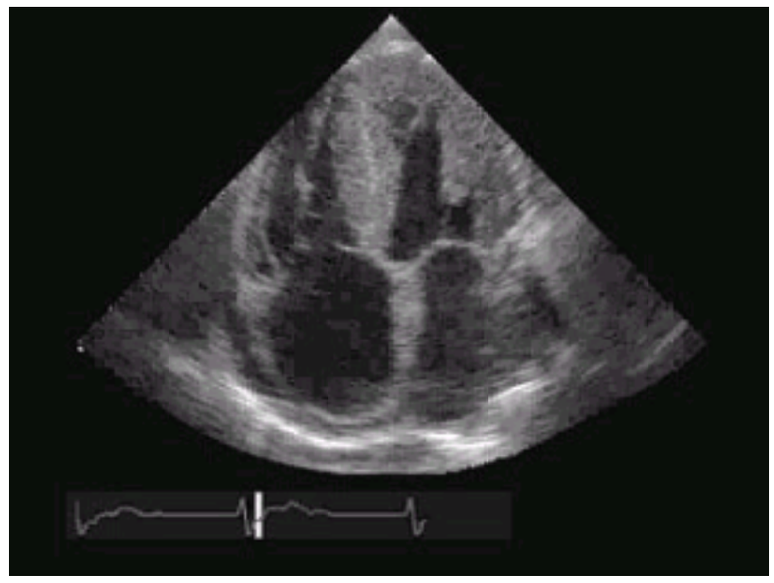
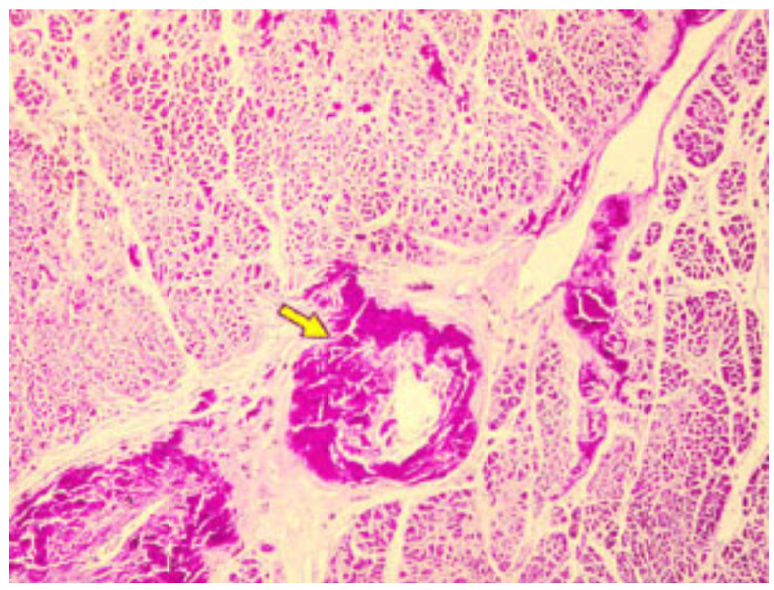


Amyloid deposition. (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)



Apical four-chamber view of amyloid heart disease. Note the significant thickening of the left ventricle and right ventricle walls due to infiltration. There is also characteristic thickening of the valves and biatrial enlargement. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.)



Amyloidosis of the heart. This is cresyl violet stain of the left ventricular myocardium. The yellow arrow indicates a metachromatic red-violet homogenous deposit around an intramyocardial arteriole with similar interstitial deposits.

Pulsed wave Doppler of the mitral valve inflow in a patient with amyloidosis demonstrating a short deceleration time (134 ms) consistent with restrictive physiology.

Video 90.10 Transthoracic apical four-chamber view of a patient with amyloidosis. Note the thickened “sparkling” walls of the right and left ventricles. Both the mitral and tricuspid valves are mildly thickened and there is biatrial enlargement and a trivial pericardial effusion. *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

Clinical Profile and Management

Cardiac amyloidosis can manifest itself in one of four general ways; however, it is important to realize that by the time symptoms appear there is generally quite extensive myocardial infiltration. The first presentation is that of a restrictive cardiomyopathy, with primarily diastolic dysfunction and right-sided heart failure findings. These include peripheral edema, jugular venous distention, and hepatic congestion. A fourth heart sound is uncommon, because atrial infiltration can decrease pumping ability. Right-heart catheterization can demonstrate a restrictive physiology, including the characteristic diastolic dip and plateau in the ventricular pressure waveform. The second presentation is one of more typical congestive heart failure symptoms from systolic dysfunction. In this case, hemodynamic restriction may not be as prominent. Systolic ventricular impairment, when present, is an ominous sign, with a generally poor response to treatment and a progressive decline. Patients may have angina, either from involvement of the coronaries with amyloid deposition or from unrelated coronary atherosclerosis (154). Third, orthostatic hypotension may be the initial presenting complaint in approximately 10% of patients. Amyloid infiltration of the autonomic nervous system, blood vessels, or the adrenal glands may be partially responsible. Finally, because there may be amyloid deposits within the conduction system, various abnormalities of impulse formation and conduction may occur. Patients may have bradycardia and varying degrees of blocks, including complete heart block and atrial and ventricular dysrhythmias. In such patients with conduction system involvement, sudden death, unfortunately, is relatively common.

Cardiac studies range in usefulness for the diagnosis of amyloidosis. The chest x-ray is nonspecific and can show cardiomegaly, pulmonary congestion, and pleural effusions. The classic description of amyloid heart disease seen on the ECG is diffuse low voltage in all leads, which is present in approximately 50% of patients. Pericardial effusions, chronic obstructive lung disease, and obesity can also cause low voltage. Other findings on the ECG include left-axis deviation, ventricular dysrhythmias, and atrioventricular conduction delays and blocks. The echocardiogram can display small cardiac chambers with symmetric thickening of the left ventricle, dilated atria, thickened valves, pericardial effusions, and impaired left ventricular contractility. A characteristic finding is a granular sparkling appearance of increased echogenicity of the myocardium. Increasing myocardial wall thickness is a predictor of poor survival. Diastolic dysfunction, with impaired relaxation, is manifested by a reduction in the rate and volume of the rapid diastolic filling phase. A Doppler-derived index of combined systolic and diastolic myocardial performance has been described. This index is the sum of isovolumetric contraction and relaxation times divided by the ejection time and was found to be another independent predictor of survival (155). Amyloid infiltration can cause the technetium-99m (Tc-99m)–pyrophosphate and gadolinium-diethylenetriaminepentaacetic acid–enhanced magnetic resonance imaging scans to be strongly positive (156,157 and 158). Finally, endomyocardial biopsy can demonstrate amyloid if other laboratory tests and areas of biopsy are negative or equivocal. Special stains, including immunoperoxidase stains for kappa and lambda immunoglobulin chains and prealbumin, may help to distinguish subtypes of the amyloid infiltrate, guiding management decisions and prognosis.

The management of amyloid cardiomyopathy is exceedingly difficult and typically ineffective. Low doses of diuretics and vasodilators are the most useful of the drug options but require careful supervision. Patients with nephrotic syndrome from the amyloid, for example, may have a considerable amount of extravascular fluid, but they may be intravascularly depleted. Vasodilators can easily cause orthostatic symptoms, especially in patients who already have amyloid-induced autonomic dysfunction. ACE inhibitors have been reported to be of benefit, although no controlled trials have confirmed this. Unfortunately, calcium channel blockers, which have been of benefit in other disorders that cause diastolic dysfunction, have been disappointing in the treatment of amyloid cardiomyopathy. Nifedipine is bound by the amyloid fibrils and its use, as well as that of other calcium channel blockers, and may exacerbate congestive heart failure symptoms by a local, enhanced, negative inotropic mechanism (159,160 and 161). Digoxin, which controls supraventricular dysrhythmias, is similarly relatively contraindicated because the drug may also be selectively bound to the fibrils, resulting in increased sensitivity and toxicity (162,163). It is unknown whether other antiarrhythmics share this same potential for toxicity. Beta-blockers can be detrimental by promoting heart blocks. Pacemakers are helpful for the treatment of severe and symptomatic conduction disease. Various drugs, including colchicine, dimethyl sulfoxide, and prednisone, have anecdotal reports of improving amyloidosis, but these have not been validated with prospective randomized trials. Early studies with interferon-a and TNF antagonists have been encouraging. Dose-intensive intravenous melphalan followed by autologous growth factor–mobilized stem cells for primary amyloidosis may result in improvement, with reversal of the cardiomyopathy symptoms and reductions in ventricular wall thickness (164). Finally, cardiac transplantation is generally believed to be contraindicated in most cases of amyloidosis because of the propensity for recurrence of the disease in the transplanted heart and progression of systemic problems (165).

General System Diseases

The connective tissue and collagen-vascular disorders, such as systemic lupus erythematosus, polyarteritis nodosa, and rheumatoid arthritis, are covered in Chapter 35E. A few entities warrant additional description.

Sarcoidosis

Sarcoidosis is a systemic disease that is typified by noncaseating granulomas infiltrating the lungs, skin, and reticuloendothelial system. Cardiac sarcoidosis results in a restrictive cardiomyopathy, although rarely it more closely resembles a DCM. Interstitial lymphocytic inflammation and fibrosis may be present, in addition to the myocardial granulomas, which early on cause diastolic dysfunction but preserve systolic function. Later on, further fibrosis and infiltration can lead to systolic impairment as well. Cardiac sarcoid is often present with systemic sarcoidosis but clinically remains silent approximately 95% of the time (166). The initial cardiac presentation may be with high-degree atrioventricular blocks, syncope, or sudden cardiac death. Gallium-67, thallium-201, and Tc-99m–pyrophosphate myocardial imaging have been useful in localizing segmental myocardial involvement (167,168). Endomyocardial sampling can be helpful in confirming the diagnosis; however, the false-negative rate is high, even when numerous pieces are obtained. One explanation for this is that the granulomas have a predilection for the basal and free wall portions of the myocardium, areas where sampling does not usually occur. The cardiac granulomas occasionally respond to treatment with steroids. Pacemakers may help with symptomatic conduction disturbances.

Iridocyclitis in a patient with sarcoidosis. There is inflammation of the iris and there may be associated lacrimal gland enlargement (not shown here).

Scleroderma

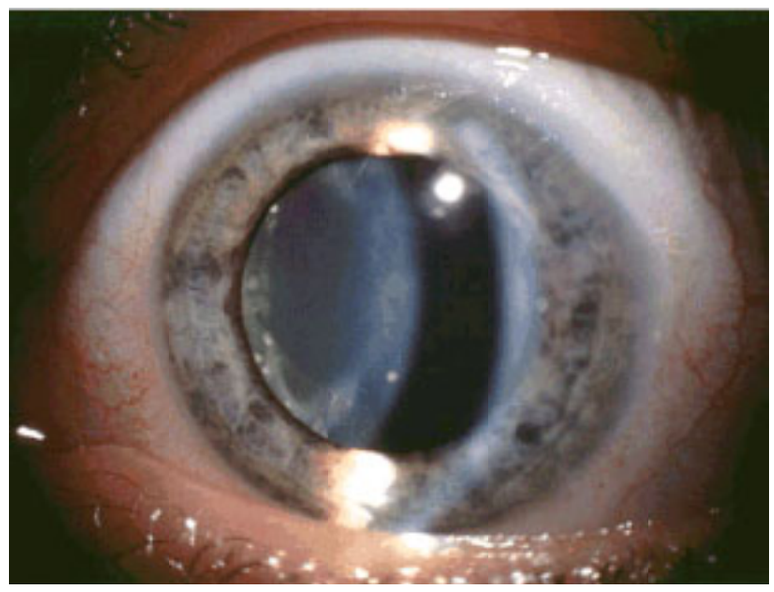
The cardiac manifestations of scleroderma include a slowly progressive fibrosis that involves the pericardium, myocardial interstitium, and conduction system. Small-vessel coronary artery disease may also occur. These patients can present with either dilated or restrictive cardiomyopathies.

Scleroderma. In scleroderma, there is swelling of the fingers and hands, later becoming firm, thick, and tight with flexion contractures. On the second panel, digital ulcers are shown (*arrows*). Cardiac manifestations include cardiac fibrosis, abnormality of the conduction system, and pericarditis.

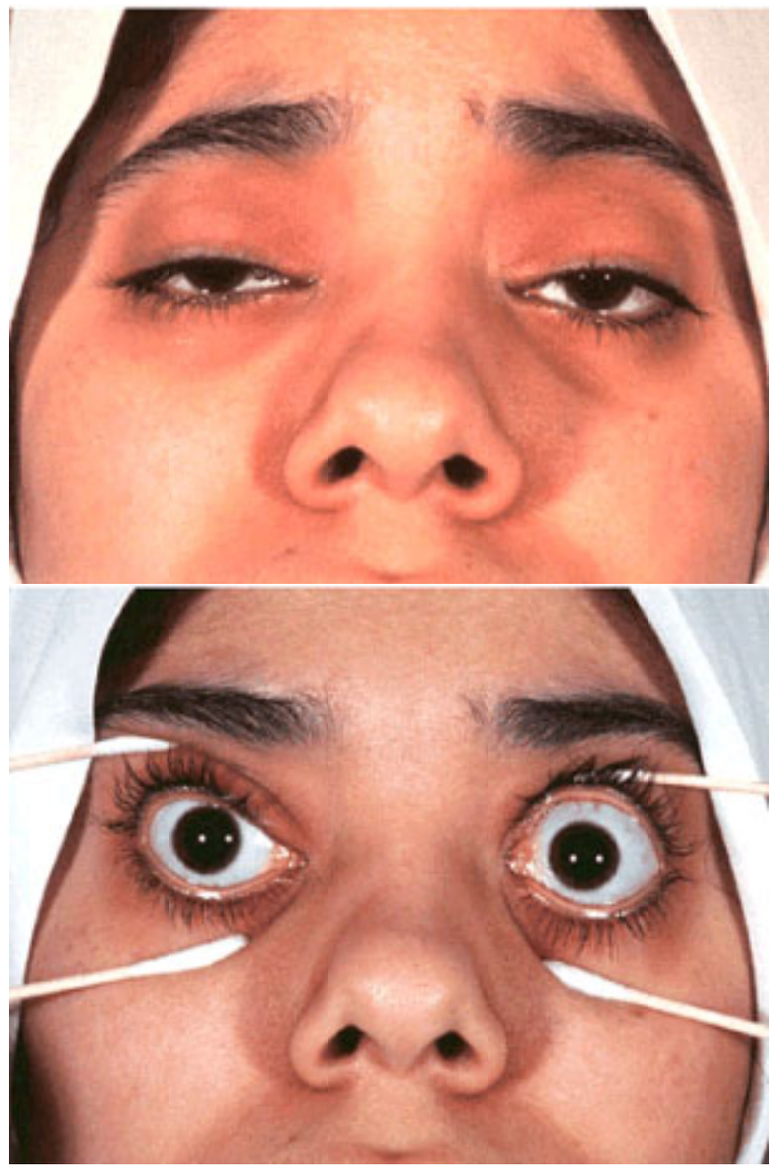
Scleroderma. Calcific deposit in subcutaneous tissue in the olecranon bursa (*arrows*).

Muscular Dystrophies

Many cases of DCM are familial (169). Pedigree analysis of families with suspected heredofamilial cardiomyopathy suggest a polygenic inheritance pattern, which in turn suggests that environmental factors such as infections or other toxins play a role in precipitating the detrimental remodeling process. A variety of neuromuscular diseases are associated with cardiomyopathy as part of their syndrome complex. Disorders of oxidative phosphorylation have been identified that are associated with these neuromuscular disorders (170), and linkage analysis has demonstrated that these difficulties are related to DNA mutations of mitochondrial protein function. Many of the muscular dystrophies and neuromuscular disorders are covered in Chapter 35D.



Premature cataract in myotonic muscular dystrophy.



Ocular findings in the Kearns-Sayre syndrome (A,B). There is ptosis and external ophthalmoplegia (not shown) secondary to muscular dystrophia.

Duchenne's Muscular Dystrophy

Duchenne's muscular dystrophy, also known as *pseudohypertrophic muscular dystrophy*, is an X-linked, proximal muscle dystrophic disease that is frequently associated with cardiac involvement manifesting as DCM (166). Indeed, death usually results either from respiratory infection due to cardiorespiratory failure or from the development of congestive heart failure with sudden cardiac death syndrome. Specific point mutations have been identified for this particular muscular dystrophy, and sometimes a DCM may be the only manifestation of the dystrophin gene mutation (171). Becker-type muscular dystrophy, similar to Duchenne's, is also X-linked recessive in inheritance. Its onset is later in life, but it is slowly progressive once it manifests signs and symptoms.

Erb's Limb-Girdle Dystrophy

Limb-girdle muscular dystrophy, Erb's disease, is an autosomal recessive condition, with DCM as a potential complicating factor (172). Like myotonic dystrophy it appears toward the middle years. It is a slowly progressive disorder that can affect either sex.

Myotonic Dystrophy

Myotonic dystrophy, also known as *Steinert's disease*, is an autosomal dominant disorder that demonstrates incomplete penetrance and variable expressiveness. The defect has been located to chromosome 19, with the production of a protein kinase that may be associated with receptor signal transduction. Myotonic dystrophy is the most common inherited dystrophy in adults. This slowly progressive and insidious dystrophic process frequently manifests symptoms between the ages of 20 and 50 years. Patients present with ptosis, cataracts, hypogonadism, and a mask-like expression from atrophy of the face and neck muscles. Cardiac involvement occurs in up to 90% of patients, and it typically presents as a DCM or with conduction disturbances. Replacement of the myocytes and Purkinje system with fibrofatty tissue occurs. Indeed, these patients are at extremely high risk of sudden cardiac death syndrome due to either a malignant ventricular arrhythmia or sudden-onset high-degree atrioventricular heart block. Cardiac transplantation is generally not an option because of the systemic nature of the disease. Often the respiratory muscles are involved, and general anesthesia should be avoided if at all possible.

Neuromuscular Disorders

X-Linked Cardioskeletal Myopathy

Barth's syndrome is an X-linked recessive condition characterized by cardiomyopathy, accompanied by a variety of neuromuscular abnormalities (proportionate short stature) and recurrent neutropenia (173). Some patients exhibit carnitine deficiency, although this is an inconsistent finding. Contrary to most cardiomyopathies, this syndrome tends to improve with age. It is proposed that the primary defect in this disorder rests in the mitochondrial electron transport chain (174).

Friedreich's Ataxia

Friedreich's ataxia is a spinocerebellar degenerative disorder that has an autosomal recessive form of inheritance, with the genetic defect located to chromosome 9. It is characterized by a broad-based gait, impaired vibration, position and joint sense, dysarthria, pes cavus, and incoordination. Childhood onset has a high likelihood of also developing diabetes, although the reasons for this are unclear (175). Interestingly, Friedreich's ataxia is commonly associated with HCM, either with concentric or

asymmetric left ventricular hypertrophy (176). More rarely, this neuromuscular syndrome can present as a DCM, with myocardial fibrosis, at times apparently transformed from an initially hypertrophic ventricle. Death from cardiac origin occurs in 5% of cases. Histologic findings include diffuse interstitial fibrosis, myocellular hypertrophy, and necrosis. Abnormalities of large and small coronary arteries can also occur. One theory of the etiology of the dysfunction suggests that myocardial calcium overload may have a role. Verapamil treatment, effective with other forms of HCM, has had no effect on patients with established hypertrophy (177).

Sensitivity and Toxic Reactions

A variety of toxins can cause myocyte injury, with subsequent dysfunction leading to actual cell death with fibrotic replacement or, simply, more transient contractile dysfunction. *e*Table 90.4.1 lists many cardiotoxic agents that have been reported to cause heart muscle disease. Discontinuing some of these drugs has led to substantive improvement in cardiac function on occasion. Specific examples of this include lithium, phenothiazines, and tricyclic antidepressants. One should always be particularly sensitive to the possibility that these drugs are producing cardiomyopathy in patients who receive them for psychiatric conditions. Some other specific toxins are discussed in the following sections.

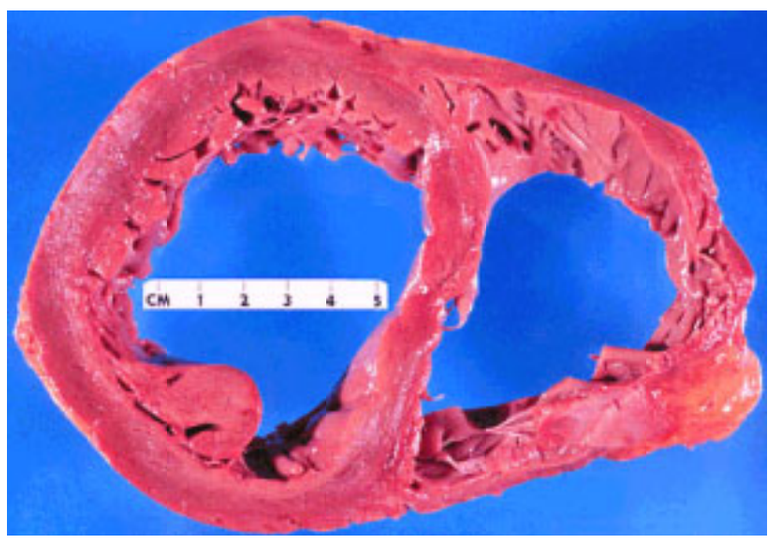
Alcoholic Cardiomyopathy

Background and Prevalence

An association between alcohol and cardiac dysfunction was first reported in Wood's treatise of 1855 (178). However, it was not until the 1950s that clinicians began to realize that alcohol and its major metabolite, acetaldehyde, could cause direct toxicity to the myocardium (179,180 and 181). Until that time, the cardiomyopathy had been presumed to be due solely to nutritional deficiencies. Currently, alcohol consumption is increasing, and, therefore, the incidence of alcohol-related cardiomyopathy is increasing as well. It is estimated that at least 15 million people in the United States alone are at risk for development of cardiac trouble from excessive alcohol use (182). Interestingly, it is a cardiomyopathy that is quite difficult to produce in animals, and substantive DCM develops in only a small proportion of ethanol drinkers who meet diagnostic criteria for alcoholism. On the other hand, 60% to 80% of patients with "idiopathic" dilated congestive cardiomyopathy report a history of substantive alcohol intake. Furthermore, individuals with DCM who continue to imbibe to excess have continued and progressive ventricular function deterioration. Currently, alcoholic cardiomyopathy accounts for approximately one-third of all nonischemic dilated cardiomyopathies (183). If alcohol consumption continues, 40% to 50% of patients will die within 3 to 6 years (184). The effects of alcohol on the cardiovascular system are fully explored in Chapter 9.



Dilated congestive cardiomyopathy. Both the left and right ventricles are significantly enlarged. In this example, the left ventricular wall thickness falls within normal limits.

Pathology

The pathologic findings of alcoholic cardiomyopathy are nonspecific and similar to, if not indistinguishable from, idiopathic DCM. The electron microscopic study of endomyocardial biopsies suggest that an accumulation of intracellular lipid droplets within the cardiac myocytes, too small to be seen with the light microscope, is a common finding in patients with alcoholic cardiomyopathy (185). Additionally, edema of the vascular wall and perivascular fibrosis of intramyocardial coronaries have been seen. Three basic mechanisms may explain the cardiac dysfunction that results from alcohol exposure. The first, and most important, is the direct toxicity that alcohol and its metabolites can have on the heart (186). Second, various additives in alcohol may produce dysfunction. The most widely recognized was the cobalt additive in beer in Quebec and Milwaukee that was used to stabilize the foam before its identification as a cardiac toxin. Finally, alcohol may lead to select deficiencies in magnesium, potassium, and thiamine, which may further exacerbate existing dysfunction. When the cardiovascular system is exposed to ethanol, there are acute and chronic changes, with the most significant being a depression in contractility.

Ethanol has been shown to depress the force of contraction acutely through inhibition of the calcium-myofilament interaction (187). Compensatory mechanisms such as vasodilation or sympathetic stimulation (catecholamines) may mask this direct depression. Experimentally, the electromechanical alteration can be reversed by increasing the amount of calcium available to the myofilament or by removing the ethanol. Because catecholamines can modulate intracellular calcium transport, this may explain why the acute negative inotropic effects of alcohol can be reversed by catecholamine administration. Alcohol and acetaldehyde have also been shown to interfere with a number of other membrane and cellular functions that involve mitochondrial respiration, myocardial lipid metabolism, and myocardial protein synthesis.

Clinical Profile and Management

The stereotyped profile of a patient with alcoholic cardiomyopathy is a man, aged 30 to 55, who has consumed whiskey, wine, or beer for more than 10 years. In reality, however, it has been virtually impossible to quantitate the amount of alcohol consumption that is required to produce cardiomyopathic effects. The diagnosis of alcoholic cardiomyopathy is likely best made in the setting of an idiopathic DCM accompanied by the traditional psychosocial characteristics of a chronic alcoholic (blackouts, marital discord, excessive work absenteeism, business failures, misdemeanor driving citations, and high blood-alcohol concentrations while appearing not to be intoxicated). Besides the more common presentation of congestive heart failure with right- and left-sided findings, atrial fibrillation and other supraventricular dysrhythmias may be the initial manifestation of the disorder. On physical examination, a narrow pulse pressure may be present, signifying the elevated diastolic pressure from excessive compensatory vasoconstriction. The ECG findings are nonspecific and numerous, including first-degree atrioventricular block, bundle branch block, left ventricular hypertrophy, repolarization abnormalities, and prolongation of the QT interval. Frequently, there will be rapid normalization of the ST-T changes after alcohol cessation. Complete abstinence may stop the progression or even allow for reversal of the failure (188,189) in early stages (usually in the first 2 to 6 months); however, severe heart failure may have little improvement. Continued consumption leads to further damage and fibrosis. It may also be prudent to give thiamine in case of underlying beriberi. The risk of anticoagulation is tremendously increased in alcoholic patients for several reasons and warrants use in only very select individuals and situations. For instance, the risk of bleeding in the alcoholic is elevated due to noncompliance, high likelihood of significant trauma, and overanticoagulation due to concomitant hepatic dysfunction.

Anthracycline-Induced Cardiomyopathy

Chronic anthracycline toxic cardiomyopathy is a dose-dependent DCM that is seen after therapy with agents such as doxorubicin (190). It is believed that anthracyclines cause myocyte cell death by increasing oxygen-derived free radical molecules, activating platelets, increasing histamine secretion, and producing C-13 hydroxymetabolites. This ultimately inhibits enzymatic activity within the sarcoplastic reticulum, mitochondria, and sarcolemma such that energy production by adenosine triphosphate cleavage is altered. Doxorubicin can cause the release of TNF-a and interleukin-2, which may create further toxicity. Myocyte destruction is associated with characteristic histopathologic findings, and this is one of the cardiomyopathies that is readily diagnosed by specific electron microscopic changes noted at the time of endomyocardial biopsy sample analysis (191) (Fig. 90.12 and Fig. 90.13). Evaluation of anthracycline cardiotoxicity requires semithin (1 to 2 μ) plastic sections with electron microscopy to ensure an adequate evaluation of the severity of cardiotoxicity. Therefore, it is essential that this information be conveyed to the pathologist before the endomyocardial biopsy specimens reach the histology laboratory. Doxorubicin has been associated with this cardiomyopathy, with cumulative doses under 400 mg per m^2 having a trivial incidence, but dose levels over 700 mg per m^2 have resulted in a nearly 20% incidence of cardiomyopathy. Why some patients who receive very low doses of doxorubicin still get cardiomyopathy and others who receive extraordinarily high doses do not remains unclear. Some of the risk factors identified for the development of toxicity include higher rates of administration and a history of previous cardiac irradiation. Patients can present either acutely or several years after exposure to this chemotherapeutic agent. Most patients who are exposed to this drug have a determination of the baseline ejection fraction with serial studies performed to follow ventricular performance indexes during treatment. Some data suggest that using continuous infusion of doxorubicin rather than bolus dosing, coadministering antioxidants or free radical scavengers, or treating patients with concomitant beta-adrenergic or calcium channel blocking drugs reduces the incidence of anthracycline cardiotoxicity. Unfortunately, this form of DCM does not usually improve with time.

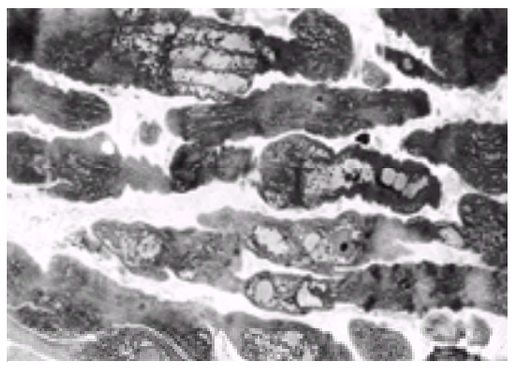


FIGURE 90.12 Severe doxorubicin cardiotoxicity. This light micrograph of a semithin plastic section illustrates the swollen sarcoplasmic reticulum, appearing as cytoplasmic vacuoles by light microscopy, and the loss of contractile elements.

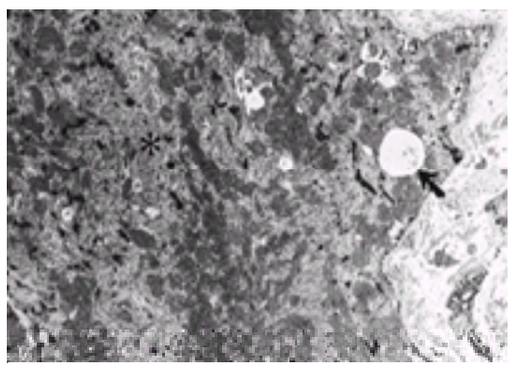

FIGURE 90.13 Doxorubicin cardiotoxicity. This electron micrograph illustrates the dilation of the sarcoplasmic reticulum (*arrow*) and the loss of contractile elements (*asterisk*), which are characteristic of doxorubicin cardiotoxicity.

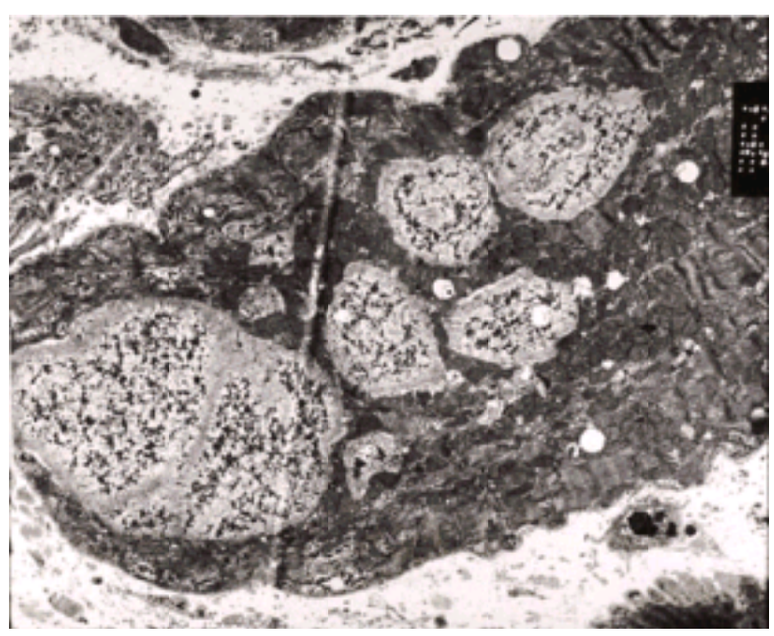
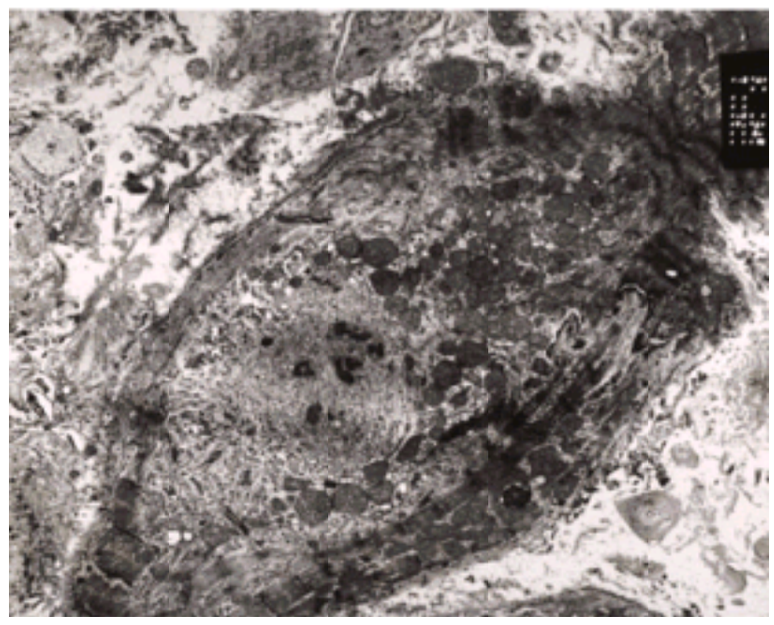
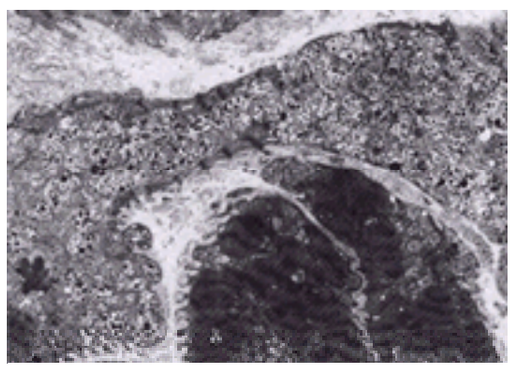




Electron microgram of 3+ doxorubicin (Adriamycin) toxicity (A,B). (Courtesy of Norman Ratliff, M.D., Cardiac Pathologist at The Cleveland Clinic Foundation.)

Cocaine

Cocaine-related heart disease is increasing in frequency, with myocardial infarction sometimes noted after acute cocaine intoxication (192,193). An acute DCM has been described, as well as DCM occurring after long-term use of this drug (*e*Fig. 90.13.1). Cocaine produces central and peripheral nervous system adrenergic stimulation by inhibiting the presynaptic uptake of catecholamine. Therefore, this cardiomyopathy is likely due to excessive or excessively long myocyte exposure to adrenergic stimulation. In addition, cocaine can have direct effects on myocardial contractility and coronary resistance. Finally, vasospasm may cause chronic focal ischemia, leading to segmental wall motion abnormalities.



***e*FIGURE 90.13.1** Cocaine cardiomyopathy. This electron micrograph shows a myocyte in which the contractile elements have been virtually replaced by accumulations of large, dark-staining secondary lysosomes. The accumulation of these lysosomes seems to be characteristic of certain forms of drug toxicity. Compare this with chloroquine cardiomyopathy. This image could represent other drug toxicities as well, and the diagnosis rests on the history of cocaine abuse in this patient.

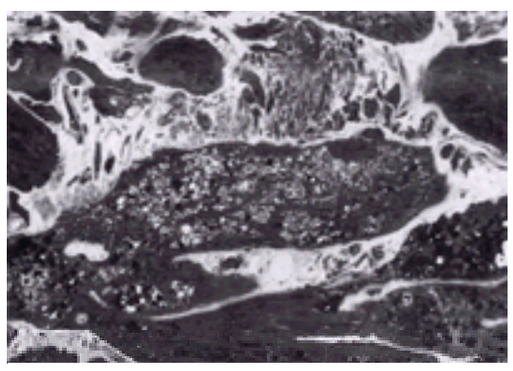
Irradiation

Radiation therapy, especially when used to treat Hodgkin's disease, may induce acute and chronic ventricular dysfunction and is an increasingly common entity as more and more patients are receiving radiation. Acutely, radiation may cause a pancarditis and arteritis, producing a transient decrease in ventricular function, which usually resolves over 48 hours (194). Chronically, radiation may induce several cardiac disorders, each of which can lead to ventricular failure (195,196). First, endocardial and myocardial fibrosis, sometimes massive in nature, result causing a restrictive cardiomyopathy (197). The fibrosis is usually more prominent in the right ventricle, because it is more anterior and therefore receives a higher dose of radiation. The fibrosis is typically very dense, nearly acellular, and primarily perivascular in location. Second, the vascular endothelium is particularly sensitive to the effects of radiation. Loss of endothelial alkaline phosphatase activity has been demonstrated and may be another factor in the pathogenesis of the myocardial dysfunction (198). Third, the clinical picture may be confused by concomitant radiation-induced constrictive pericarditis, which may also be present years after the therapy was administered. Next, radiation may also cause valvular fibrosis, resulting in either regurgitant or stenotic lesions (199). Finally, accelerated atherosclerosis usually manifests 6 to 12 years after exposure and may cause more of a DCM picture (200). If endomyocardial biopsy is performed to evaluate chemotherapeutic cardiac toxicity, radiation heart disease may complicate the interpretation. Further, radiation injury to the heart may be compounded by certain chemotherapeutic agents, especially the anthracyclines and cyclophosphamide (201). Additionally, some drugs, particularly doxorubicin, may "recall" the radiation effects even years after the administration of radiation. Risks for cardiac mortality from irradiation therapy increase with higher mediastinal doses, minimal protective cardiac blocking, and younger age at irradiation (202). No specific therapy is available.

Chloroquine Cardiomyopathy

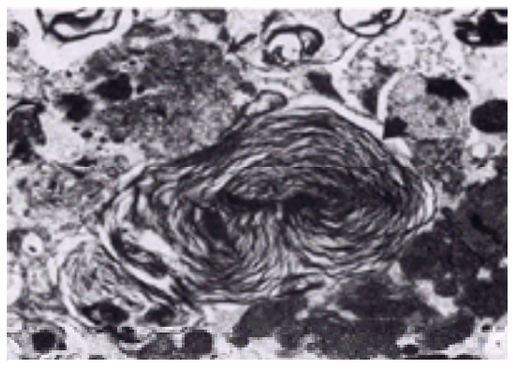
Chloroquine is a 4-aminoquinoline compound, which was widely used during World War II as an antimalarial drug. It was subsequently found to be useful in the treatment of a variety of collagen-vascular diseases, including rheumatoid arthritis, systemic lupus erythematosus, and certain dermatologic disorders. Hydroxychloroquine was found to be less toxic than chloroquine and equally effective for the treatment of rheumatoid arthritis and systemic lupus erythematosus. Hydroxychloroquine contains a single hydroxyl group at the end of the side chain—its only difference from chloroquine.

It has been known for some time that the long-term administration of chloroquine could result in a vacuolar myopathy of skeletal muscle. More recently, it has been recognized that hydroxychloroquine can produce a similar myopathy and that both drugs can also induce a severe toxic cardiomyopathy (203) (*e*Fig. 90.13.2 and *e*Fig. 90.13.3). Biventricular hypertrophy, congestive heart failure, and heart block have all been reported with chloroquine cardiomyopathy. Some, but not all, of the patients with chloroquine cardiomyopathy have a concomitant skeletal muscle myopathy. Biopsy findings in cardiac muscle are similar to those in skeletal muscle and are diagnostic of the disease (204). The light microscopic findings in semithin plastic sections are highly suggestive, with striking accumulation of large lysosomes and membrane profiles within the myocytes. The diagnostic changes of curvilinear bodies can only be visualized in biopsies that have been fixed according to an electron microscopy protocol and embedded in plastic. On cessation of the drug, patients begin a slow but progressive recovery over months from the skeletal and cardiac myopathies.



***e*FIGURE 90.13.2** Chloroquine cardiomyopathy. This is a high-magnification light micrograph of a semithin plastic section, which has been fixed with glutaraldehyde

and osmium tetroxide by an electron micrograph protocol. This preserves the secondary lysosomes that are filling the cytoplasm of the myocytes. The large, complex secondary lysosomes vary in size, shape, and staining intensity, from pale gray to black. By standard light microscopy, this would appear as a vacuolar myopathy, with the center of the myocytes appearing largely empty.



***e*FIGURE 90.13.3** Chloroquine cardiomyopathy. This higher-magnification electron micrograph reveals, side by side, a curvilinear body (*thin arrow*), characteristic of chloroquine cardiomyopathy, and a large myelin figure (*thick arrow*), a common feature of this disease but one that is not diagnostic. Chloroquine cardiomyopathy may be the prototype of the toxic myopathies. Note the resemblance to cocaine cardiomyopathy.

Peripartum Cardiomyopathy

Background and Prevalence

Peripartum DCM is defined as left ventricular systolic dysfunction without other apparent causes or underlying heart disease, occurring in the peripartum period. The onset must occur during the last month of pregnancy or within the first 5 months after delivery, although it is most common (75%) during the first 2 months postpartum (205). Because of differences in precisely defining this cardiomyopathy and aggressiveness in searching out other causes, the incidence has been reported to be anywhere between 1 in 1,300 to 1 in 15,000 pregnancies (206,207 and 208). Several risk factors have been identified, including twin pregnancy, age greater than 30, multiparity, a family history of peripartum cardiomyopathy, African descent, and prolonged therapy with tocolytic agents. The natural history differs from other forms of DCM. If recovery is going to occur, there is usually some sign of improvement within the first 6 weeks. Approximately 50% of patients spontaneously recover, usually in the first 6 months, with improvement after that time unlikely. The initial severity of heart failure or ventricular dysfunction is not predictive of long-term outcome (209). Death or deterioration to the point of requiring transplantation occurs in 25% to 50% of patients (210). Progressive congestive heart failure, dysrhythmias, and embolic events are the usual immediate causes of death. However, identifying patients who are likely to improve is not usually possible. A notable exception: In one small report, women who appeared to have peripartum cardiomyopathy associated with prolonged b-sympathomimetic tocolysis had full recovery (211).

Pathophysiology

The actual mechanism that causes ventricular dysfunction remains unknown, although several explanations have been offered. Numerous series have reported a higher incidence of myocarditis diagnosed by endomyocardial biopsy compared to idiopathic DCM (212,213,214 and 215). The cases of confirmed myocarditis may represent one of two distinct possibilities. It may be that these patients should not be labeled as having peripartum cardiomyopathy at all but rather an inflammatory cardiomyopathy. Indeed, in one study, the incidence of myocarditis by biopsy with “peripartum cardiomyopathy” did not differ from age- and sex-controlled matches that had idiopathic DCM (216). Alternatively, cases in which myocarditis is not confirmed by biopsy may represent a false-negative test. Diagnostic tissue may not have been obtained either because of insufficient tissue sampling or because the timing of the biopsy was not during the acute phase when inflammation was present. To some extent, perhaps all peripartum cardiomyopathies represent a pregnancy-induced, abnormal, immune-mediated response with myocarditis. It is known that T-cell suppressor activity is decreased during pregnancy. This may make patients more susceptible to certain viral infections such as Coxsackie virus, or perhaps maternal exposure to fetal or placental antigens may result in the production of antibodies that cross-react with the myocardium.

Clinical Profile and Management

The diagnosis of heart failure in the last month of pregnancy may be difficult to make, because many of the early signs and symptoms of ventricular dysfunction mimic those of normal pregnancy. These include fatigue, dyspnea on exertion, pretibial edema, and an increase in baseline heart rate. Orthopnea, chest discomfort, cough, gallops, and rales are also suggestive of heart failure. After delivery, these findings should quickly resolve, and failure to do so may indicate an underlying cardiomyopathy. Other diseases can have a presentation similar to that of heart failure and should therefore be considered in the differential diagnosis. Some of these disorders are listed in *e*Table 90.4.2. Echocardiography, the most helpful study, typically shows four-chamber enlargement, biventricular hypokinesia, and a small, hemodynamically insignificant pericardial effusion. Strong opposing views have been presented regarding the necessity of performing endomyocardial biopsies. Some have suggested that the biopsy may give prognostic information, because individuals with mild interstitial changes have a better prognosis than patients with dense fibrosis (217). This may encourage more aggressive treatment and earlier referral for transplantation. Biopsy may also identify active myocarditis, for which some have advocated immunosuppressive therapy. This has never been shown to be effective therapy, and it is our recommendation that biopsy not be performed unless the patient is enrolled in a specific trial addressing this issue or if one is concerned that a different diagnosis would have an impact on the treatment strategy.

Sepsis
Thyrotoxicosis
Toxemia of pregnancy

The treatment of peripartum cardiomyopathy is different from that of the more traditional DCMs in several aspects. First, ACE inhibitors are contraindicated during pregnancy because of the risks of fetal anuria and death. They are also relatively contraindicated in nursing women. Hydralazine can be safely used in place of ACE inhibitors if afterload reduction is required. It should be recalled that during pregnancy the systemic vascular resistance is already low because of the placenta, and further afterload reduction may not be necessary or may not be well tolerated. Digoxin is a U.S. Food and Drug Administration (FDA) class C drug, and its risks and benefits should be considered. Digoxin can pass into the placenta and is secreted in breast milk. Similarly, diuretics are also FDA class C drugs. Frequently, strict sodium restriction diminishes fluid overload and can avert the need for diuretics. Beta-blockers may be helpful if the patient is not volume overloaded. Strong consideration for anticoagulation is important because of the marked increased incidence of thromboembolic events, which has been reported to be as high as 53% (218,219). As reviewed in Chapter 32, pregnancy is a hypercoagulable state, with demonstrated increases in coagulation factors II, VII, VIII, and X and plasma fibrinogen. Coagulation slowly returns to normal by approximately 6 weeks postpartum (220), and after this time anticoagulation becomes less critical. Warfarin is contraindicated (FDA class D) and should not be used prenatally because of severe teratogenic effects. Short-term unfractionated or low-molecular-weight heparin use is easily stopped just before delivery. If symptoms and ventricular function do not improve or if the clinical condition deteriorates, referral for cardiac transplantation should be contemplated. Some of these patients may even require a left ventricular assist device for stabilization while awaiting a suitable donor (221,222). A compatible donor may be more difficult to identify, because postpartum women tend to have higher panels of reactive antibodies from fetal antigen exposure. Some have advocated the use of immunosuppressants or intravenous immunoglobulin (223) for the treatment of peripartum cardiomyopathy based on small, retrospective, nonrandomized trials and observations. No large, prospective, randomized controlled trials have demonstrated a benefit for any of these therapies.

If full recovery of left ventricular function does not occur, the mother should be warned to avoid future pregnancies, because the rate of maternal and fetal morbidity and mortality is unacceptably high. The recommendation to the patient who is clinically completely recovered and contemplating another pregnancy is controversial. In general, the woman should be advised that recurrence is certainly possible, is usually more severe the second time, and is fatal approximately 10% of the time (224). One group has suggested performing dobutamine stress testing on apparently recovered hearts. Evidence of impaired contractile reserve may identify a subset of patients who have inducible abnormalities, which may become significant with the increased hemodynamic load of pregnancy (225). Finally, it has been demonstrated that there is increased activity of calcium-independent inducible nitric oxide synthetases (iNOS) in peripartum cardiomyopathy (226). The generation of nitric oxide by iNOS may be responsible for some of the dilation and impaired contractility of the heart. In the future, nitric oxide or iNOS antagonists may play a critical role in the early treatment of peripartum as well as some of the other dilated cardiomyopathies.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Even with the most recent revisions in the World Health Organization classification scheme of cardiomyopathy, it remains difficult to categorize certain disease states. At times there can be overlap because of changing ventricle characteristics. For example, hypertensive cardiomyopathy may initially best fit classification as an HCM, but when end-stage dilation occurs, it may be better defined as a DCM. Similarly, a patient may present with numerous risk factors that, alone or in combination, could be responsible for the ventricular dysfunction. Consider, for instance, how a gentleman who had diabetes, coronary artery disease, and hypertension would be classified if he were found to have an ejection fraction of 30% and a mildly dilated ventricle. Further complicating the issue would be a history of a flu-like illness with fever developing 2 months before presentation with a low ejection fraction.

When such a patient presents with signs and symptoms that are suggestive of ventricular dysfunction, one of the first steps in devising a management plan is obtaining an accurate diagnosis. With the desire to provide exemplary care, while at the same time maintaining cost effectiveness, the provider must choose tests carefully. One should not overlook the importance of a detailed history and physical examination, which can often provide insight into the disease process. Specifically important is looking for onset and duration history, a positive family history of heart failure, evidence of systemic diseases, and a history of other illnesses or toxin exposure. If a specific cardiomyopathy is suggested, the evaluation usually proceeds along a fairly demarcated path. However, when an illness appears obscure, idiopathic in origin, or due to a number of different possibilities, one must decide critically which of the multiple tests will lead one to a more definite diagnosis. A rational approach is imperative. Echocardiography is extremely helpful and can, for example, determine which chambers are involved (and to what degree), differentiate a focal from a global process, determine if the major dysfunction is systolic or diastolic, and detect valvular abnormalities. It is the single most important test to obtain, because it is necessary to determine a cardiomyopathy etiology that might respond to medical or surgical therapies or elimination of toxins. These patients with heart failure usually have a gratifying response, with, at times, dramatic reversal of their failure syndrome. Stopping ethanol consumption in the face of alcoholic cardiomyopathy, for example, can effect substantial improvement in ventricular function in more than 50% of patients. If a DCM is present, often a viral myocarditis is suspected. It is tempting to order large panels of acute and convalescent viral titers; however, the clinician should refrain from doing so because it is extremely expensive and the tests' conclusiveness is questionable. (Consider the current general public incidence of cytomegalovirus or Epstein-Barr virus seroconversion evidence.) Further, patient management would not generally change. The question of whether to perform right ventricular endomyocardial biopsy for a diagnosis frequently arises. Currently, if a specific disease process is strongly suggested and cannot be diagnosed by a less invasive manner, a biopsy is reasonable. *e*Table 90.4.3 lists some specific cardiomyopathies that can be diagnosed by biopsy. A second reason for biopsy is to monitor the effects of anthracycline cardiotoxicity, guiding further chemotherapy. Third, if a patient will be participating in a randomized trial to evaluate a specific therapeutic intervention, a biopsy might be useful to document entry criteria. The Intervention in Myocarditis and Acute Cardiomyopathy with Intravenous Immunoglobulin (IMAC) multicenter trial is such a study (see below). Fourth, in patients in whom it is unclear, after other noninvasive studies, that a restrictive process (as opposed to constrictive pathology) is responsible for the syndrome, the prognosis and treatment can be considerably different. Routine endomyocardial biopsy in patients with idiopathic DCM serves little purpose.

Sarcoidosis
Wilson's disease

The treatment of cardiomyopathy is covered in Chapter 91 and Chapter 92; however, one area that remains unsettled regards diseases for which transplantation may not be indicated because of an increased likelihood of primary disease recurrence in the transplanted heart. Although early- and intermediate-term follow-up reports of patients with cardiac amyloid indicated that transplantation could be successfully performed (227,228 and 229), long-term results suggest a high incidence of failure due to recurrent amyloid (230,231). Transplantation in sarcoidosis, when other end-organ involvement is present, is also unwise. When the only manifestation of sarcoid is cardiac infiltration, transplantation has been performed and can be successful (232). It is, however, possible to have recurrence of noncaseating granulomas in the heart in as short a time as 6 months (233). Inflammatory cardiac conditions, such as lymphocytic myocarditis, may have an increased incidence of rejection after heart transplant as compared with control groups, and they may have a significantly higher mortality. Although this diagnosis does not represent an absolute contraindication to transplant, this therapy should be considered with caution.

Importantly, in a controlled trial of intravenous immunoglobulin in recent-onset DCM (234), 62 patients with recent onset (less than 6 months of symptoms) of DCM and left ventricular ejection fraction of less than 40% were randomized to receive 2 g per kg intravenous immunoglobulin or placebo. The mean age of the group was 43.0 ± 12.3 years, with 37 men and 25 women participating. All underwent an endomyocardial biopsy before randomization, which revealed cellular inflammation (lymphocytic myocarditis) in 16%. The primary outcome was change in left ventricular ejection fraction at 6 and 12 months after randomization, with the ejection fraction improving from 25% to 41% at 6 months (p <.001) and 42% (p <.001 vs. baseline) at 12 months. The increase was the same for patients who received intravenous

immunoglobulin and placebo. Overall, 56% of patients at 1 year had an increase in ejection fraction of greater than 10% from study entry, and 36% normalized their ejection fraction (greater than 50%). The transplant-free survival rate was 92% at 1 year and 88% at 2 years. Thus, the IMAC trial suggests that for patients with recent-onset DCM, intravenous immunoglobulin does not augment the improvement in left ventricular ejection fraction and, as an overall cohort, ejection fraction is likely to improve significantly during follow-up, with short-term prognosis remaining favorable in patients who meet this trial's entry criteria. The debate about treating these patients will likely continue.

Further highlighting the issues is the European Study of Epidemiology and Treatment of Cardiac Inflammatory Diseases (ESETCID) (235). Initial epidemiologic results have been published from this registry. By adding immunohistochemical parameters, the World Heart Federation Task Force for the Definition of Acute and Chronic Myocarditis expanded the light microscopy "Dallas" criteria of myocarditis, referred to in previous sections. Polymerase chain reaction molecular biologic techniques and *in situ* hybridization have improved our understanding of the underlying etiologic and pathophysiologic mechanisms in inflammatory heart disease. Because of this, patients in ESETCID are screened not only for infiltrating cells but for the presence of persisting viral genomes and, specifically, footprints of enterovirus, cytomegalovirus, and adenovirus. ESETCID investigated endomyocardial biopsies from 3,055 patients but could find an ongoing inflammatory process in the heart in only approximately 17%. Of these patients, only 182 showed a reduced ejection fraction below 45%, fulfilling the entrance criteria for the ESETCID trial. The observations suggest that in symptomatic patients, inflammatory heart disease muscle has to be considered regardless of left ventricular function and that endomyocardial biopsy can in fact be an important tool for diagnosis. However, virus could be detected in only approximately 12% of patients (enterovirus in 2%, cytomegalovirus in 5%, and adenovirus in 4%). This exercise was the first epidemiologic study to demonstrate that viral persistence may contribute to the pathogenesis of inflammatory heart muscle disease and that in chronic myocarditis, viral persistence occurs in a small percentage of patients compared to previous studies that were performed on highly selected individuals. The implications of this study are that, perhaps, more specific viral treatment therapeutics will be useful in the future to attenuate ventricular function deterioration.

THE FUTURE

Every day, new insight is gained in all areas of basic research addressing the pathophysiology of cardiomyopathy. Clarification and elucidation of genetic and molecular biodynamic mechanisms that are important to the development of cardiomyopathy are anticipated. The time when recognition of genetic markers that can identify susceptible or asymptomatic patients, thereby allowing preventive and early-treatment strategies to be instituted, is rapidly approaching. Clinical trials are under way that examine the role of various humors, including proinflammatory cytokines (TNF-a, interleukin-1, interleukin-6) and nitric oxide, in the cardiomyopathic process and may allow identification of new, specific treatment modalities such as anticytokine agents and antioxidants. Likewise, the use of cell transplants and gene-vector therapy is actively being pursued. Finally, we are entering a new era of examining mechanisms that mediate apoptosis. Inappropriate apoptosis has been associated with arrhythmogenic right ventricular cardiomyopathy, and already more than 30 inducers of programmed cell death have been discovered. Apoptosis in end-stage heart failure, for example, has been suggested to be the result of TNF-a exposure, amyloidosis, incessant tachycardia syndromes, pressure overload states, ischemia-reperfusion injuries, hypertension, situations with increased mechanical stretch, and chemotherapeutic and radiation injuries (236,237,238,239,240,241,242 and 243).

OVERVIEW

Acute heart failure is a complex syndrome that is often a direct result of myocardial systolic dysfunction caused by underlying ischemia or infarction. Although atherosclerotic heart disease is the most common cause of acute heart failure in Western societies, a broad spectrum of other potential causes exists, including such diverse conditions as acute valvular abnormalities, pericardial disease, acute myocarditis, and pulmonary embolism. The management of acute heart failure requires rapid identification of the underlying mechanism, with specific treatment directed at reversing the associated abnormal pathophysiologic state. The support of patients while the diagnostic evaluation is pursued can range from therapy with intravenous nitrates and diuretics to full pharmacologic support with combinations of inotropic, vasodilator, and vasopressor agents. In complicated situations, hemodynamic monitoring is essential. In circumstances in which a reparable lesion has been identified or in which cardiac transplantation is considered an option, mechanical circulatory support may be required until definitive treatment can be instituted. Because of the complexity and diverse nature of the acute heart failure syndrome, treatment must be individualized.

The ultimate success of acute heart failure management depends heavily on the rapid institution of effective pharmacologic support to relieve symptoms and reverse hemodynamic derangement with simultaneous pursuit of definitive diagnostic studies. The inability to identify or correct an underlying lesion or condition is associated with significant short-term mortality.

INTRODUCTION

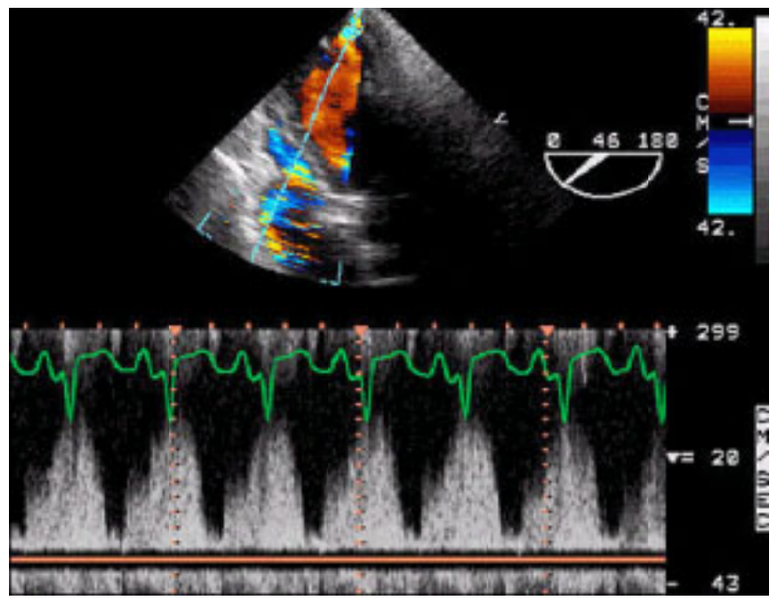
The syndrome of acute heart failure represents a true medical emergency that warrants an expedient diagnostic and therapeutic approach by the clinician. If appropriate treatment is not instituted within a reasonable period of time, irreversible cardiac decompensation may ensue, leading to a progressive syndrome of shock, multiorgan failure, and death. The complexity of acute heart failure and the diversity of its potential causes make a precise definition difficult. But in clinical practice, it is generally recognized when symptoms develop within hours to days in patients without a history of cardiac decompensation (1). A history of previous treatment for heart disease may be elicited, however, because many patients will have experienced symptoms (i.e., angina, exertional dyspnea) related to myocardial ischemia. In fact, atherosclerotic heart disease and the complications of myocardial ischemia and infarction are the most common causes of acute heart failure in Western societies. A multitude of other potential causes must also be considered, however, including acute valvular dysfunction, pericardial disease, acute myocarditis with left ventricular dysfunction, uncontrolled severe hypertension, and pulmonary embolism (Table 91.1). Many of the conditions resulting in acute heart failure may be definitively treated, which results in a favorable impact on the patient's short- and long-term course. Although the majority of patients presenting with acute heart failure suffer from some degree of myocardial systolic dysfunction, diastolic heart failure with preserved systolic function may also occur in those with underlying restrictive or hypertrophic myocardial diseases. When acute pulmonary edema is the presenting problem, consideration must also be given to possible noncardiac causes. A brief history and directed physical examination, electrocardiogram, and possibly echocardiography usually suffice to differentiate cardiogenic from noncardiogenic pulmonary edema.

Myocardial ischemia or infarction
Complications of myocardial infarction
Acute mitral regurgitation (papillary muscle rupture)
Ventricular septal rupture
Cardiac free wall rupture and pericardial tamponade
Acute valvular catastrophe (mitral or aortic)
Severe, poorly controlled hypertension
Myocarditis
Sustained cardiac arrhythmias
Acute pulmonary embolism
Decompensation of chronic heart failure or cardiomyopathy
Acute aortic dissection with myocardial ischemia or infarction

TABLE 91.1 MAJOR CAUSES OF ACUTE HEART FAILURE

Guidelines published by a task force of the American College of Cardiology and American Heart Association have categorized presentations of acute heart failure into three major clinical groups: acute cardiogenic pulmonary edema, cardiogenic shock, and acute decompensation of chronic left heart failure (2). Treatment strategies differ for these groups, but in general, rapid evaluation, diagnosis, and therapy are imperative. The 1-year mortality rate for patients presenting with acute pulmonary edema may exceed 50% when an underlying lesion or condition is not defined and treated (3). In certain life-threatening conditions, such as acute ischemic myocardial injury or complications thereof (i.e., acute valvular regurgitation, ventricular septal defect, cardiac tamponade), immediate evaluation and specific, directed therapy are indicated for stabilization and treatment of the acute heart failure syndrome. In these emergency situations, definitive therapy should not be delayed by prolonged efforts to achieve a stabler clinical situation. Without correction of the underlying lesion, such efforts are often unsuccessful and commonly result in further clinical deterioration with the development of irreversible myocardial dysfunction. When the disorder precipitating acute heart failure does not appear to be one requiring urgent therapy, definitive diagnostic studies and consideration for specific forms of therapy can be delayed until clinical and hemodynamic stabilization have been achieved. In patients with decompensated chronic heart failure, an urgent diagnostic evaluation is often unnecessary because the underlying cause of myocardial dysfunction is

usually known.



Doppler recording of flow through an ischemic ventricular septal defect before surgical repair.

This chapter focuses on patients presenting with predominantly acute systolic heart failure. Because management strategies differ for different clinical groups across the spectrum of acute heart failure (e.g., acute myocardial infarction is managed differently from acute valvular insufficiency or right ventricular infarction), specific therapeutic principles for the treatment of patients presenting within the major clinical subsets of acute cardiogenic pulmonary edema, cardiogenic shock, and decompensated chronic heart failure are addressed. Individualization of the therapeutic strategy is always necessary. The standard intravenous pharmacologic agents used to manage acute heart failure are discussed in detail, as are some of the more promising investigational drugs currently being evaluated in clinical trials. For those situations in which pharmacologic stabilization of the patient is not achieved, selection criteria for mechanical support are reviewed. The initial assessment of the patient with acute heart failure is reviewed with an emphasis toward disease-specific treatment. One must recognize that the evaluation process (determination of cause) and the initial management and stabilization of the patient occur nearly simultaneously.

HISTORICAL PERSPECTIVE

Significant advances in the pharmacologic support of acute heart failure have been made over the past four decades. In the 1960s, only digitalis and diuretics were available for heart failure management, and furosemide was the mainstay of drug therapy for acute heart failure. The intravenous inotropic, vasopressor, and vasodilator therapies introduced in the 1970s proved to be effective in the stabilization of many patients presenting with acute cardiac decompensation. The development of dobutamine by Tuttle and Mills was an important step in the refinement of inotropic support for acute heart failure and cardiogenic shock, and this drug has largely replaced agents with unacceptable toxicity such as isoproterenol and epinephrine (4). The use of hemodynamic monitoring in intensive care units now allows for the appropriate titration of inotropic and vasodilator medications and provides a means for more effective assessment and correction of hemodynamic abnormalities. This methodology also provides a means for investigating the effectiveness of new and perhaps novel experimental agents that may be beneficial for treating acute heart failure. In those situations in which significant hemodynamic instability unresponsive to pharmacologic intervention is present, circulatory support with intraaortic balloon counterpulsation or extracorporeal membrane oxygenation serves as a temporary measure to allow for completion of the diagnostic work-up and institution of the appropriate therapeutic intervention (5). More recently, the development of ventricular assist devices has provided a means for prolonged support until definitive treatment, such as cardiac transplantation, can be offered (see Chapter 95).

PATHOPHYSIOLOGY AND CLINICAL PRESENTATION OF ACUTE HEART FAILURE

Acute left ventricular failure usually occurs as a result or complication of coronary artery disease, valvular disease, or, less commonly, primary myocardial disease such as myocarditis. An acute exacerbation of chronic heart failure or cardiomyopathy may also manifest as pulmonary edema and cardiogenic shock. The majority of patients presenting with acute heart failure has suffered significant injury to or ischemia of the myocardium, producing a substantial degree of regional and global myocardial systolic and diastolic dysfunction. This leads to a progressive deterioration in central hemodynamics that usually results in elevated left ventricular filling pressures and a variable reduction in stroke volume and cardiac output with subsequent circulatory failure. Often concomitant valvular dysfunction secondary to increased ventricular volumes and annular distention is found, which further exacerbates the hemodynamic abnormality (6). If immediate intervention with the goal of stabilizing the patient and definitively treating the underlying condition is not pursued, progressive left ventricular dysfunction and hemodynamic compromise may ensue.

Acute Cardiogenic Pulmonary Edema

The accumulation of extravascular fluid in the pulmonary interstitium or alveolar space resulting in pulmonary edema is caused by an imbalance in the equilibrium that normally exists between the opposing hydrostatic and oncotic forces of the pulmonary capillaries and the pulmonary interstitium (Starling forces). Under normal conditions, the balance of forces favors a continuous transudation of fluid from the capillaries to the interstitial space of approximately 500 mL per day, which is removed by the lymphatics (7). If the pulmonary capillary wedge pressure (PCWP) acutely exceeds 20 to 25 mm Hg, as may occur in acute left ventricular dysfunction, the increase in capillary hydrostatic pressure results in increased filtration of fluid and protein across the vascular endothelium, which leads to interstitial or alveolar pulmonary edema (7). As a result, the patient experiences breathlessness and increased work of breathing due to a drop in pulmonary compliance and hypoxia.

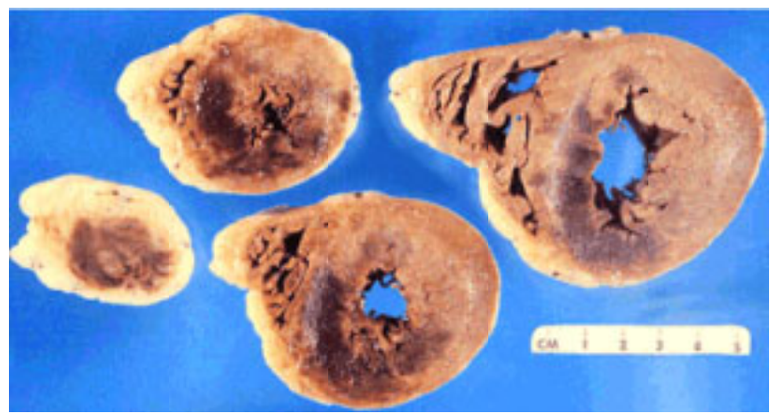
Few conditions in clinical practice generate the degree of alarm and sense of urgency for both the patient and clinician that acute pulmonary edema does. Patients present in acute distress with extreme breathlessness and increased respiratory effort. They may have a cough with hemoptysis and are often diaphoretic and demonstrate a variable reduction in peripheral perfusion manifest as cool extremities and poor capillary refill (8). This results not only from a possible diminution in cardiac output but also from a markedly elevated sympathetic tone and redistribution of blood flow away from the skin. Unlike in the patient with chronic heart failure and cardiomyopathy, the pulmonary examination usually demonstrates course rales and diffuse rhonchi. Conducting the cardiac examination in this setting may be difficult because of patient distress, but specific findings (or the absence thereof) can provide important clues to the cause of heart failure.

Pulmonary edema may occur in the setting of high, normal, or low cardiac output. Treatment initially is directed toward “unloading” the ventricle with the goal of reducing pulmonary capillary hydrostatic pressure, pulmonary edema, and dyspnea. In treating this condition, one should be aware that correction of the hemodynamic abnormality precedes the clearance of excess pulmonary fluid as assessed by either physical examination or chest radiography (7,9,10). Therefore, the detection of pulmonary rales on physical examination would not necessarily warrant further diuretic administration if the hemodynamic abnormality has been reversed. Failure to recognize this phase lag could result in inappropriate diuretic use, intravascular volume depletion, and hypotension in the patient with acute myocardial infarction.

When evaluating acute pulmonary edema, one must always be aware of noncardiac causes that are seen in the clinical setting of normal to low PCWP and most often result from injury to the alveolar-capillary membrane due to any of a number of reasons (7,11). Edema formation by this mechanism often occurs more rapidly and to a greater degree than cardiogenic pulmonary edema.

Cardiogenic Shock

The often catastrophic condition of cardiogenic shock (see Chapter 19) is usually the result of myocardial damage resulting either from a single acute event or as the culmination of multiple events resulting in extensive (greater than 40%) ischemic myocardial injury. Cardiogenic shock most commonly occurs as a consequence of left ventricular dysfunction resulting from coronary occlusion. Data from the SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock?) Trial Registry identified predominant left ventricular failure as the cause of shock in 78.5% of all cases (12). Complications of myocardial infarction, including severe mitral regurgitation and ventricular septal rupture, were identified as the primary cause of shock in 6.9% and 3.9% of cases, respectively (12).



Massive acute transmural anteroseptal myocardial infarction. Cross sections from multiple levels are shown in this chemical fixed preparation. The dark brown area represents the zone of infarction. In this example, approximately 50% of the myocardium is involved.

Several additional cardiovascular causes may also produce cardiogenic shock, including acute myocarditis, primary valvular catastrophe, and acute decompensation of end-stage cardiomyopathy (13). The shock syndrome may also result from predominant right ventricular infarction, which generally has a better prognosis than shock due to left ventricular failure and is treated primarily with volume resuscitation and inotropic support.

Right ventricular infarction. ST-segment elevation in leads V_{4R} and V_{5R} reveals right ventricular involvement complicating the inferior infarct.

The incidence of cardiogenic shock in patients suffering acute myocardial infarction is approximately 7.5% (14,15). The cardiogenic shock syndrome is often accompanied by severe hypotension with diminished pulse pressure and tachycardia, low cardiac output, and signs and symptoms of reduced tissue and organ perfusion, including renal dysfunction, cool and clammy extremities, lethargy and confusion due to cerebral hypoperfusion, and metabolic acidosis resulting from elevated blood lactate levels. In the absence of prompt reperfusion and pharmacologic or mechanical support to correct the profound hemodynamic derangement associated with shock, progressive deterioration will occur, resulting in a high probability of continued cardiac dysfunction and circulatory failure (Fig. 91.1) (13). Although significant progress has been made in the short-term support of the cardiovascular system in shock, if the ischemic myocardium is not reperfused, the mortality rate remains high and in excess of 70% (14,16). In the SHOCK Trial Registry, in-hospital mortality was approximately 60% in patients with shock after myocardial infarction (12).

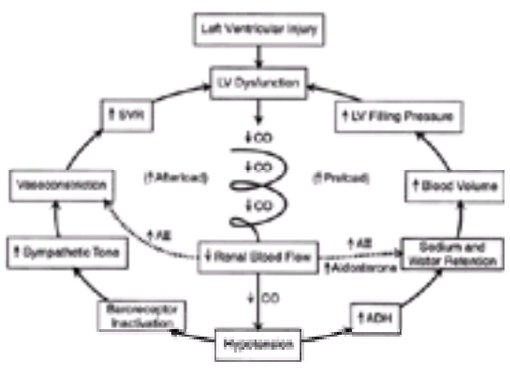


FIGURE 91.1 Depicted are the factors in cardiogenic shock perpetuating continued left ventricular (LV) dysfunction and progressive deterioration in cardiac output (CO). As CO falls, renal blood flow is reduced, which thus activates the renin-angiotensin-aldosterone system. Angiotensin II (AII) directly results in vasoconstriction and indirectly increases blood volume by enhancing aldosterone release. Hypotension resulting from a further fall in CO activates the central nervous system release of antidiuretic hormone (ADH). Inactivation of baroreceptors enhances sympathetic tone and vasoconstriction. As CO, renal blood flow, and hypotension remain reduced, preload and afterload continue to increase, which leads to further LV dysfunction. ↑, increased; ↓, decreased; SVR, systemic vascular resistance.

The neurohormonal compensatory mechanisms activated to acutely support the cardiovascular system in shock are similar to those activated in chronic heart failure (see Chapter 88). As shown in Figure 91.1, a dramatic and often acute reduction in cardiac output leads to the perception that intravascular volume is reduced. Baroreceptor inactivation results in increased sympathetic tone with consequent vasoconstriction and increased heart rate and myocardial contractility. Diminished renal perfusion causes activation of the renin-angiotensin-aldosterone axis, which causes further vasoconstriction (mediated by angiotensin II) and sodium and water reabsorption mediated by elevated aldosterone levels. Hypotension induces the central release of antidiuretic hormone, which serves to further increase renal water resorption and intravascular volume. Peripheral autoregulation and local production of vasoactive metabolites cause redistribution of blood flow away from skin, intestines, and skeletal muscle in favor of the brain, heart, and kidneys (13). These compensatory mechanisms may support the cardiovascular system for a brief period of time, but without appropriate intervention, they are soon overwhelmed, which results in continued hypoperfusion and myocardial dysfunction. Pharmacologic intervention is directed toward supporting the blood pressure and systemic perfusion with inotropic and possibly vasopressor therapy. If an adequate systemic blood pressure can be sustained, vasodilators may also be considered in an attempt to lower filling pressures and decrease pulmonary congestion and valvular regurgitation. Mechanical support will likely be necessary to allow for definitive diagnostic studies and therapeutic interventions.

Acute Decompensation of Chronic Heart Failure

Acute decompensation and clinical deterioration in a patient with previously documented chronic heart failure represent a different pathophysiologic state than the acute heart failure syndrome in patients without prior left ventricular dysfunction. These patients have a marked reduction in left ventricular systolic function at baseline due to a previous substantial injury to the myocardium. In approximately 50% of cases, the underlying disease is ischemic in etiology. In the remainder, a variety of causes may be identified, such as valvular disease or long-standing hypertension. The majority of cases of nonischemic chronic heart failure, however, is idiopathic (17). The typical patient with chronic heart failure is likely receiving some rational combination of oral therapy (angiotensin-converting enzyme inhibitors, beta-blockers, aldosterone antagonists, vasodilators, diuretics, digoxin) in an attempt to maintain stability and adequate functional capacity. Despite this treatment, however, these patients generally have mild to moderate symptoms of heart failure and exhibit some degree of total volume overload even in the compensated state. Left ventricular wall stress, because of left ventricular dilatation, is usually elevated, and compensatory neurohormonal mechanisms are activated (see Chapter 88). When acute decompensation occurs, these baseline abnormalities become further deranged. This is in contrast to the patient without significant myocardial dysfunction who suffers an acute insult to the myocardium leading to acute heart failure. Before the precipitating event, these patients generally have normal heart size and total body volume and do not exhibit baseline neurohormonal perturbation.

Table 91.2 outlines some of the important clinical and pathophysiologic characteristics of acute and chronic heart failure (18). Patients with decompensated chronic heart failure usually present with low output and congestive symptoms. They may describe worsening exertional dyspnea or dyspnea at rest, orthopnea, paroxysmal

nocturnal dyspnea, and fatigue. Findings of the physical examination often reflect volume overload with peripheral edema and jugular venous distention. Pulmonary rales may be present but are certainly not as impressive as in the patient with acute myocardial injury and pulmonary edema. In fact, pulmonary findings may be relatively unremarkable in cases of decompensated chronic heart failure even when cardiac filling pressure is markedly elevated. A gallop rhythm and murmur of mitral regurgitation are typically audible, and the cardiac impulse is enlarged, sustained, and laterally displaced (8). Again, this is in contrast to the findings in acute pulmonary edema, in which cardiac size is usually normal and mitral regurgitation is less audible due to rapid equilibration of pressures between the left ventricle and normal left atrium.

Feature	Acute heart failure	Decompensated chronic heart failure	Stable chronic heart failure
Symptom severity	Marked	Marked	Mild to moderate
Pulmonary edema	Frequent	Frequent	Rare
Peripheral edema	Rare	Frequent	Frequent
Weight gain	None to mild	Marked	Frequent
Total body volume	No change or mildly increased	Markedly increased	Increased
Cardiomegaly	Uncommon	Usual	Common
Left ventricular systolic function	Hypo-, normo-, or hypercontractile	Reduced	Markedly reduced
Wall stress	Elevated	Markedly elevated	Elevated
Activation of sympathetic nervous system	Marked	Marked	Mild to marked
Activation of RAAS	Acutely abnormal	Marked	Mild to marked
Acute ischemia	Common	Occasional	Rare
Hypertensive crisis	Common	Occasional	Rare
Reparable, remediable causative lesions[a]	Common	Occasional	Occasional

RAAS, renin-angiotensin-aldosterone system.
[a]Coronary thrombosis, acute mitral regurgitation, etc.

TABLE 91.2 COMPARISON OF ACUTE AND CHRONIC HEART FAILURE

A broad range of variability exists, however, and specific physical findings are often dependent on the underlying lesion and duration of cardiac dysfunction. The factors leading to acute decompensation in chronic heart failure may be obvious or subtle and include such diverse conditions as myocardial ischemia, hypertension, new-onset atrial fibrillation, poorly controlled diabetes, hyper-or hypothyroidism, dietary sodium indiscretion, and medication noncompliance. In many cases, however, the cause is not as obvious clinically as are the events causing acute cardiogenic pulmonary edema (see Chapter 92). In both conditions, a concerted effort must be made to identify the precipitating factor, but a reparable lesion amenable to definitive treatment is less likely to be discovered in those with decompensated chronic heart failure.

PHARMACOTHERAPEUTICS OF ACUTE HEART FAILURE

Goal of Acute Pharmacologic Therapy

The objectives of the pharmacologic management of acute heart failure are to relieve disabling symptoms and discomfort rapidly, to reverse hemodynamic derangement, to preserve myocardial blood flow and energetics, and to stabilize the patient while further definitive diagnostic evaluation and therapy are pursued. Acute intravenous therapy is directed toward improving overall ventricular performance by favorably affecting the major determinants of ventricular function, including ventricular preload, afterload, and myocardial contractility. Acute intravenous pharmacologic support merely serves as a bridge to a more definitive treatment (i.e., myocardial revascularization, valve replacement) in most situations of acute heart failure and therefore should be viewed as a temporary means of support. The medications commonly used to stabilize the patient presenting with acute heart failure are usually administered intravenously, exhibit pharmacokinetic properties that allow for rapid titration to hemodynamic effect, and have a short plasma half-life so that any untoward effect can be quickly terminated. The medications commonly used to initially support the patient with acute heart failure are discussed in detail.

Acute Vasodilator Therapy

Nitroglycerin

Nitroglycerin is often effective in the early management of acute heart failure. The major hemodynamic effect of nitrates is to evoke a reduction in ventricular filling pressure and volume by increasing venous capacitance through venodilation (19,20,21,22,23,24,25,26,27,28 and 29). This shifts central blood volume to the venous capacitance vessels, which causes a decrease in pulmonary congestion and often a dramatic improvement in the symptoms of breathlessness associated with acute heart failure and elevated ventricular filling pressures. This vasodilating action is mediated through relaxation of vascular smooth muscle resulting primarily from a nitrate-induced production of *S*-nitrosothiols, which cause an increase in intracellular cyclic guanosine monophosphate (30,31). Nitrates may also elicit vasodilation by other mechanisms, including stimulation of the endothelial production and release of prostacyclin or prostaglandin E (32,33 and 34). Although these agents are predominantly considered for venodilation, higher doses of nitrates produce arterial dilatation and therefore reduce systemic vascular resistance (SVR) and ventricular impedance (35).

This effect is variable, however, and is not nearly comparable to the potent afterload-reducing properties of sodium nitroprusside (see the following section, Nitroprusside). For this reason, nitrates are less effective in reducing and treating acute mitral or aortic regurgitation, which require aggressive afterload reduction to augment forward stroke volume. If nitrates are to improve valvular regurgitant volume, they must be given in dosages that not only lower ventricular filling pressure but, most important, also reduce SVR (36).

Nitrate therapy may also favorably affect myocardial blood flow and energetics. Although not studied extensively in acute heart failure, this benefit is secondary to significant reductions in ventricular filling pressures and volume that reduce wall stress, a major determinant of myocardial oxygen consumption (MVO_2). Nitrates reduce coronary vascular resistance and lengthen diastolic perfusion time (by lowering heart rate in heart failure), and thus favorably affect subendocardial perfusion and oxygenation (37,38). An improvement in diastolic function has also been described, particularly in patients with ischemic heart disease and subendocardial ischemia (38,39,40 and 41).

Nitrates are effective therapy in the urgent treatment of acute heart failure, acute cardiogenic pulmonary edema, and acute decompensation of chronic heart failure (21,42,43,44,45,46 and 47). Nitroglycerin therapy can generally be instituted rapidly when it is evident that pulmonary congestion is present and therefore preload reduction is desired. Intravenous nitroglycerin is the preparation most commonly used. However, sublingual tablets and lingual-buccal spray may occasionally be used until an intravenous preparation is available to be infused (48,49). Sublingual nitrates have rapid onset of action (3 to 6 minutes) and can be administered in 0.4- to 0.8-mg doses every 5 to 10 minutes as necessary to reduce the severe dyspnea and elevated ventricular filling pressures commonly associated with acute heart failure, particularly if myocardial dysfunction is secondary to ischemia or infarction. A 0.4-mg sublingual tablet given every 4 to 5 minutes is approximately equivalent to a 1.5-µg-per-kg-per-minute continuous infusion (50). The sublingual preparation is often used at the authors' institution to reverse high pulmonary artery pressures in patients with chronic heart failure who are undergoing transplant evaluation (51). Therefore, its potency should not be underestimated.

Intravenous nitroglycerin (typically starting at a dosage of 0.2 µg per kg per minute) may be rapidly titrated upward in increments of 0.1 to 0.2 µg per kg per minute to improve symptoms and reduce pulmonary and systemic venous pressures and resistance, ventricular filling pressures, and, to a variable degree, SVR. As noted previously, however, the ability of nitrates to augment stroke volume and cardiac output by decreasing left ventricular afterload is often dose dependent and usually requires an initial intravenous dosage of at least 0.4 µg per kg per minute (21). One must also consider the propensity for the development of pharmacodynamic tolerance during continuous intravenous infusions, which necessitates an intermittent increase in dose to maintain the desired hemodynamic effect (52).

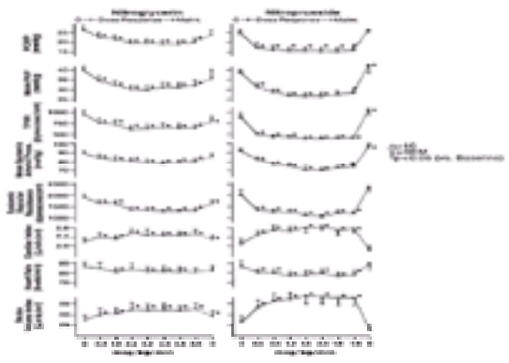
Careful attention should also be given to intravascular volume and the need for diuretic therapy because this may also affect pharmacodynamic tolerance (21,53). Resistance to the hemodynamic effects of nitrates has also been described in patients with elevated right atrial pressures (53). Institution of diuretic therapy may reverse nitrate resistance. Patients already on long-term nitrate therapy may require a higher initial dose of intravenous nitroglycerin. If the desired clinical response has not been achieved after reaching a dosage of 5 to 6 µg per kg per minute, use of an alternative or additional vasodilating agent is generally required. In this setting, further intravenous therapy is often most optimally tailored with the guidance of hemodynamic monitoring. An added advantage of intravenous nitroglycerin administration in the unstable patient is that its hemodynamic effects resolve rapidly once the infusion is stopped.

Nitroprusside

Sodium nitroprusside is a powerful venous and arterial vasodilator with potent afterload-reducing properties (54). It is the agent most frequently used early in the treatment of acute heart failure, particularly when a rapid and substantial reduction in SVR is necessary. Common clinical conditions for which it is used include

complications of myocardial infarction such as acute mitral regurgitation secondary to papillary muscle dysfunction or rupture, ventricular septal defect, and acute aortic regurgitation. Nitroprusside relaxes arterial and venous smooth muscle via the production of nitric oxide and nitrosothiols, which leads to an increase in cyclic guanosine monophosphate and smooth muscle relaxation (23). As with nitroglycerin, nitroprusside causes preload reduction by diminishing heightened venous tone and increasing venous capacitance with a concomitant shift in central blood volume to the periphery (24). This causes a reduction in right ventricular pressure and volume. Unique to nitroprusside is its rapid and powerful effect on afterload. This agent reduces the major components of aortic impedance (mean and hydraulic vascular load), which results in an improved and often dramatic increase in forward stroke volume and cardiac output with reductions in left ventricular filling pressure, volume, and valvular regurgitation (19,21,24,55,56,57 and 58). Fortunately, this decrease in afterload occurs without major changes in aortic pressure (56).

In most patients with heart failure, judicious titration of nitroprusside can result in decreased aortic impedance, increased cardiac output, and reduced ventricular filling pressures without the undesirable effects of a decrease in systemic blood pressure or rise in heart rate. The combined balanced vasodilator effect of nitroprusside can therefore rapidly improve the hemodynamic abnormalities associated with acute heart failure when preload and afterload reduction is desired. eFigure 91.1.1 compares the hemodynamic response to intravenous nitroglycerin and nitroprusside in chronic heart failure. Although both medications produce desirable effects on cardiac filling pressures and cardiac output, the magnitude of the response to nitroprusside appears to be significantly greater, particularly with respect to afterload reduction (21).



***e*FIGURE 91.1.1** The hemodynamic responses to intravenous nitroglycerin and sodium nitroprusside are depicted in ten patients with moderately severe congestive heart failure. The baseline control period (C) is followed in sequence by a dose response, a 90-minute constant maintenance dose (Maint), and a discontinuation point. The changes in hemodynamic parameters evoked by nitroglycerin and nitroprusside are directionally similar, but the magnitude of change is greater with nitroprusside. Note the dramatic rebound effect after discontinuation of nitroprusside. PAP, pulmonary artery pressure; PCWP, pulmonary capillary wedge pressure; SEM, standard error of the mean; TPVR, total pulmonary vascular resistance. (Adapted from Leier CV, Bambach D, Thompson MJ, et al. Central and regional hemodynamic effects of intravenous isosorbide dinitrate, nitroglycerin, and nitroprusside in patients with congestive heart failure. *Am J Cardiol* 1981;48:1115–1123, with permission.)

Generally, by improving ventricular wall stress and reducing MVO_2, nitroprusside has a favorable effect on myocardial energetics (59,60). Nitroprusside may also improve coronary blood flow and myocardial perfusion by directly reducing coronary vascular resistance and by increasing coronary perfusion pressure (61). The latter will occur as long as the reduction in ventricular diastolic pressure is greater than aortic coronary diastolic pressure. In patients with occlusive coronary artery disease, care must be taken to avoid excessive reductions in systemic pressure or elevations in heart rate that would reduce coronary perfusion and increase myocardial oxygen demand. Unlike nitroglycerin, nitroprusside may cause “coronary steal” whereby arteriolar dilatation in nonischemic zones diverts coronary flow away from areas of ischemia (60,62). The frequency with which this occurs in heart failure is not well documented.

Nitroprusside is administered intravenously with an infusion pump and is usually initiated at a dosage of 0.10 to 0.20 µg per kg per minute. Its effects are evident within 60 to 90 seconds after initiation of the infusion, and, should an adverse effect such as symptomatic hypotension occur, the vasodilating properties usually abate within 20 to 30 minutes after discontinuation (19). Continuous monitoring of central hemodynamics with an indwelling flow-directed thermodilution pulmonary artery catheter is mandatory to safely and effectively achieve the optimal dosage. In acute heart failure, insertion of an arterial catheter for continuous systemic blood pressure recording and monitoring and frequent blood gas determinations is also recommended. One should recognize, however, that during nitroprusside infusion, the pressure measured in a peripheral artery (i.e., radial artery) may not reflect a reduction in central aortic pressure because of nitroprusside-induced changes in the amplitude and timing of reflected waves within the central aorta (63). One must remain cognizant of this when the clinical findings are consistent with systemic hypoperfusion despite a seemingly acceptable peripheral arterial pressure.

Nitroprusside can be rapidly titrated to achieve the desired clinical and hemodynamic end points, including a reduction in PCWP to 18 to 20 mm Hg, a decrease in SVR to 1,000 to 1,200 dynes per second per cm^5, a reduction in valvular regurgitation, and an improvement in stroke volume, cardiac output, and systemic perfusion, while avoiding significant hypotension and tachycardia. Although the target blood pressure is variable depending on the individual patient, a systolic blood pressure of 80 mm Hg or greater is usually acceptable. A higher systolic blood pressure may be required in the elderly or in patients with a recent history of hypertension or cerebrovascular disease. The target PCWP is usually higher in patients with acute heart failure than in patients with decompensated chronic heart failure. In the latter condition, the stroke volume of the dilated ventricle is not preload dependent, and therefore relatively normal left ventricular filling pressures can be targeted. In acute heart failure, particularly when myocardial ischemia is present, attention to Starling mechanisms with respect to preload and augmentation of stroke volume remains important. Although nitroprusside is titrated to achieve hemodynamic goals, rarely are dosages greater than 4 to 5 µg per kg per minute required to maintain adequate vasodilation in the acute heart failure setting, and dosing this high for prolonged periods (greater than 72 hours) should generally be avoided due to the risk of thiocyanate and cyanide toxicity (64,65).

The most common serious adverse effect of nitroprusside administration in acute heart failure is systemic hypotension (54,62,66). One should be particularly cautious when initiating nitroprusside therapy in a patient with ischemia or infarction and a systolic arterial pressure of less than 100 mm Hg. An increase in heart rate during the infusion is an ominous finding and usually presages hypotension. This typically occurs when stroke volume has not increased appropriately, often because of ongoing or worsening ischemia, valvular regurgitation, and inadequate cardiac reserve. A reduction or cessation of the nitroprusside infusion is usually warranted. Alternatively, the addition of a positive inotropic agent such as dobutamine hydrochloride is often advantageous and may allow for the continuation of nitroprusside. Such a combination is commonly used to stabilize particularly severe, low-output heart failure until more definitive therapy can be instituted (see the section Combination Pharmacologic Therapy later in this chapter). When systemic hypotension and poor peripheral perfusion are present at the outset, nitroprusside should generally be avoided as initial treatment.

As noted earlier, thiocyanate toxicity is a potentially serious side effect of prolonged nitroprusside infusion and is manifest clinically by nausea, disorientation, psychosis, muscle spasm, and hyperreflexia when plasma thiocyanate concentrations exceed 6 mg% (64,65). Such toxicity is uncommon in the management of acute heart failure in which nitroprusside therapy is usually a temporary means of support while the patient awaits definitive therapy. Cyanide toxicity is extremely rare in heart failure management and occurs only during prolonged high-dose infusion, usually in the setting of significant hepatic dysfunction.

The rationale for intravenous vasodilator therapy in acute heart failure is based on correction of hemodynamic derangement and stabilization of the patient while a therapeutic plan is devised. The necessity for prolonged treatment (longer than 72 hours) often portends a poor prognosis, particularly in the absence of a reversible underlying disorder.

Positive Inotropic Therapy

Dobutamine

Dobutamine hydrochloride is a synthetic catecholamine and positive inotropic agent that is useful in the acute management of systolic heart failure associated with systemic hypoperfusion. Along with intravenous diuretics, it is used commonly in patients with acute decompensation of chronic heart failure or myocardial infarction presenting with pulmonary congestion and low cardiac output symptoms. Dobutamine exists as a racemic mixture of dextro-and levoisomers, which are potent beta- and alpha-adrenergic agonists, respectively (67). Therefore, dobutamine produces its positive inotropic effect via stimulation of myocardial $beta_1$ and probably $alpha_1$ receptors (68). Theoretically, the opposing forces of $alpha_1$ and $beta_2$ stimulation on the peripheral vasculature should result in a negligible change in vascular resistance. Binkley and colleagues have shown, however, that in a total-artificial-heart model, dobutamine improves ventricular performance through direct modulation of arterial and venous tone (69). Dobutamine also has a favorable effect on aortic impedance, which allows for more efficient transfer of ventricular work and energy into stroke volume, cardiac output, and systemic perfusion. This maximizes the blood volume ejected by the ventricle for any augmentation in myocardial contractility (70,71). This is in contrast to the inotropic/vasopressor agent dopamine hydrochloride, which does not decrease aortic impedance and therefore limits the amount of

blood ejected for any given increase in contractility (70,71) (Table 91.3). These differences in ventricular-vascular coupling explain why dobutamine augments cardiac output and improves ventricular performance whereas dopamine, at moderate to high doses, is a vasopressor and ultimately worsens cardiac function in heart failure (71,72 and 73) (Fig. 91.2, eFig. 91.2.1). Thus, these inotropic and vascular effects of dobutamine account for its favorable hemodynamic profile in acute heart failure. Dobutamine increases stroke volume and cardiac output, reduces ventricular volume and mitral regurgitant fraction, and lowers left ventricular diastolic pressure without producing a significant increase in heart rate (72,74). This cardiocirculatory response to dobutamine results from its potent inotropic and substantial vasodilator effects, which are linearly related to dose and plasma concentration (74,75).

TABLE 91.3 SYSTEMIC VASCULAR PROFILES OF DOBUTAMINE AND DOPAMINE IN HEART FAILURE

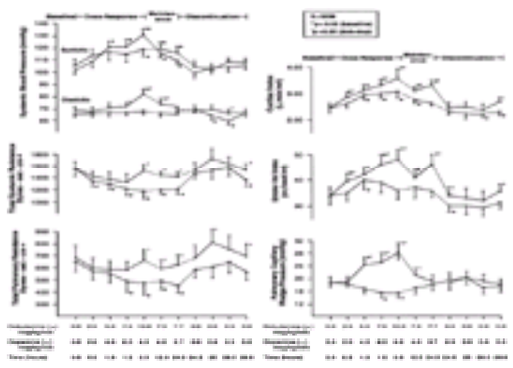

FIGURE 91.2 Comparison of dopamine hydrochloride (*filled circles*) and dobutamine hydrochloride (*open triangles*) on central hemodynamics in patients with low-output congestive heart failure. Infusions for both medications followed a baseline period, with titration of each drug to peak effect. The maximal dosage of dobutamine was 10 µg per kg per minute and of dopamine was 8 µg per kg per minute. The data illustrate that dopamine given at infusion rates that exceed 2 to 4 µg per kg per minute does not have a favorable effect on total systemic vascular resistance. This results in a reduction in stroke volume and cardiac index compared to those of dobutamine. Dopamine at moderate dosages also increases pulmonary capillary wedge pressure. Dobutamine produces a mild increase in systemic blood pressure, with reduction in total systemic resistance and improvement in cardiac filling pressure and cardiac index. SEM, standard error of the mean. (From Leier CV, Heban PT, Huss P, et al. Comparative systemic and regional hemodynamic effects of dopamine and dobutamine in patients with cardiomyopathic heart failure. *Circulation* 1978;58:466–475, with permission.)

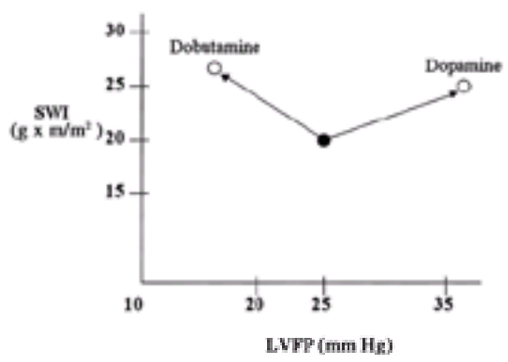

***e*FIGURE 91.2.1** Comparison of effects of dopamine hydrochloride and dobutamine hydrochloride on left ventricular filling pressure (LVFP). Doses of dopamine and dobutamine that produce a similar augmentation in stroke work index (SWI) have opposite effects on LVFPs in patients with heart failure. (From Loeb HS, Bredakis J, Gunnar RM. Superiority of dobutamine over dopamine for augmentation of cardiac output in patients with chronic low output cardiac failure. *Circulation* 1977;55:375–381, with permission.)

The safety of inotropic therapy in patients with occlusive coronary artery disease and active myocardial ischemia is often questioned in clinical practice. Often dobutamine therapy is withheld from patients with low cardiac output and coronary artery disease for fear of aggravating ischemia or precipitating arrhythmias. Although the positive inotropic effect of dobutamine increases MVO_2, which could be detrimental in acute ischemia or infarction, this is balanced by other factors that decrease MVO_2 and improve coronary blood flow and myocardial perfusion (76). Dobutamine, when carefully administered to the patient with heart failure, systemic hypoperfusion, and elevated filling pressures, reduces MVO_2 by decreasing ventricular volume and wall tension. Dobutamine may increase coronary blood flow by increasing coronary perfusion pressure (increase in arterial diastolic pressure and decrease in ventricular diastolic pressure) and coronary perfusion time, and possibly by causing mild coronary vasodilation (76,77,78 and 79). These factors tend to offset any increase in MVO_2 evoked by positive inotropy. In fact, standard dosages of dobutamine have been shown to improve cardiac function in patients with heart failure and significant coronary obstruction without undue risk of worsening ischemia or infarction (76,80,81). In a controlled study of patients with myocardial infarction, dobutamine use did not increase infarct size or the frequency of arrhythmia (82). Avoiding significant increases in heart rate during dobutamine infusion is imperative, however, because this would serve to increase MVO_2 and reduce coronary perfusion time (76). Also, dobutamine administration should be avoided when ventricular filling pressures are not significantly elevated. Therefore, the titration of dobutamine dosage in the patient with occlusive coronary artery disease mandates careful attention to multiple parameters, including heart rate, systolic and diastolic blood pressures, central hemodynamics, presence of arrhythmias, acid–base balance, and clinical signs of improved systemic perfusion. Failure to follow these parameters closely may result in an adverse response to dobutamine therapy, particularly when occlusive coronary artery disease is present.

In acute heart failure, dobutamine therapy is usually initiated when an augmentation in cardiac output and systemic perfusion is desired in patients with elevated filling pressures. The infusion is started at 2.5 to 5.0 µg per kg per minute and is titrated in increments of 1 to 2 µg per kg per minute at 20- to 30-minute intervals until the desired clinical and hemodynamic response is attained. Rarely is it necessary to exceed a dosage of 15 µg per kg per minute in treating acute heart failure, although dosages this high are sometimes necessary for a brief time while more definitive therapy is pursued. Sustained dosing at this level or greater may be detrimental, however, because of a higher MVO_2 and reduced myocardial perfusion, primarily related to the increased chronotropic response to dosages greater than 15 to 20 µg per kg per minute. In addition, the ideal body weight of the patient should be considered when initiating therapy.

The pharmacokinetic profile of dobutamine makes this agent ideal for the critical care setting. It has an extremely short half-life (less than 5 minutes), and a full pharmacodynamic response to a particular dose and its steady-state phase is attained within 10 to 15 minutes (71). Importantly, any adverse effect of dobutamine is also eliminated within only 10 to 15 minutes of stopping the infusion. Additional side effects that may occur during dobutamine infusion include headache, anxiety, and tremor. Dobutamine must also be used cautiously in patients with atrial arrhythmia such as atrial fibrillation or atrial flutter. Dobutamine has been reported to increase atrioventricular conduction in atrial fibrillation (83). Due to the excessive dosing required to achieve hemodynamic benefit in patients who are receiving long-term

beta-blocker therapy, dobutamine should generally not be used for inotropic support in these patients (see the next section, Milrinone) (*e*Table 91.3.1).

Milrinone

Milrinone lactate, a bipyridine analog of amrinone, is a second-generation phosphodiesterase inhibitor that exhibits both direct inotropic and vasodilator properties (71,76,84). Milrinone is approved by the U.S. Food and Drug Administration (FDA) for parenteral use in the treatment of congestive heart failure. The parent compound, amrinone, is also available parenterally but because of its substantial side-effect profile and weak inotropic properties, it has largely been supplanted by milrinone.

Through inhibition of the phosphodiesterase III isoenzyme located primarily in cardiomyocytes and vascular smooth muscle, milrinone increases the concentration of cyclic adenosine monophosphate (cAMP) in these tissues. Elevated cAMP levels, via phosphorylation of several cellular proteins, increase intracellular calcium, which is the final common pathway to enhanced inotropy and vasodilatation. Although dobutamine and milrinone exert their effects through the cAMP-dependent pathway, important differences are found. Dobutamine actually increases cAMP production via beta receptor activation, whereas milrinone raises cAMP levels by preventing its degradation. This mechanistic difference is important with respect to the potential for both drugs to act synergistically to enhance myocardial contractility in patients with heart failure (see the section Combination Pharmacologic Therapy) (81).

The acute hemodynamic effects of milrinone in patients with chronic heart failure have been well described (85,86,87,88 and 89). The hemodynamic profile is one that would be expected from a drug with potent inotropic and balanced vasodilator properties. Once therapeutic plasma levels are achieved, milrinone elicits a reduction in right and left ventricular filling pressures and increases cardiac output without producing significant changes in the heart rate–blood pressure product. Because of its potent vasodilator properties, however, milrinone has the potential to worsen preexisting systemic hypotension. A reduction in pulmonary vascular resistance is usually observed and is primarily secondary to the reduction in left ventricular filling pressure rather than a direct pulmonary vasodilator effect. Even though milrinone may be expected to increase MVO_2 via its direct positive inotropic effect, its substantial vasodilator properties usually offset any detrimental increase in MVO_2 (87). This favorable effect is further enhanced by mild coronary vasodilatation (90). Compared with dobutamine, milrinone tends to evoke a greater reduction in left ventricular filling pressure and SVR while producing an equivalent increase in cardiac output (88) (Fig. 91.3). For the same reduction in SVR, milrinone produces a greater increase in stroke work index than nitroprusside, which reflects its additional inotropic properties (88,89).

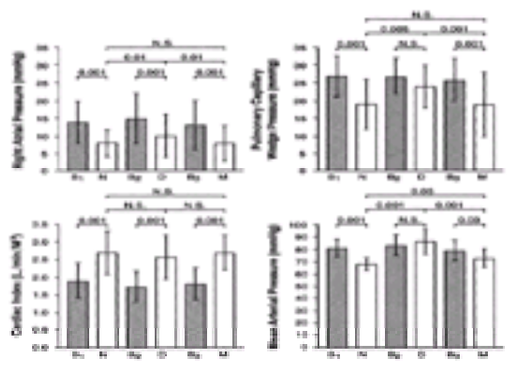

FIGURE 91.3 Effects of sodium nitroprusside (N), dobutamine hydrochloride (D), and milrinone lactate (M) on cardiac index, mean arterial pressure, right atrial pressure, and pulmonary capillary wedge pressure in patients with severe heart failure (B_1, B_2, and B_3 = baseline measurements). At dosages evoking a similar increase in cardiac index, all agents significantly reduced right atrial pressure, with nitroprusside and milrinone also producing a significant reduction in mean arterial pressure compared to baseline. The effect of milrinone and nitroprusside on pulmonary capillary wedge pressure was greater than that observed with dobutamine. N.S., not significant. (Adapted from Monrad ES, Baim DS, Smith HS, et al. Milrinone, dobutamine, and nitroprusside: comparative effects on hemodynamics and myocardial energetics in patients with severe congestive heart failure. *Circulation* 1986;73[Suppl III]:168–174.)

Based on its hemodynamic profile in heart failure, milrinone would appear to be advantageous in the treatment of the patient with acute pulmonary congestion and low cardiac output. Unfortunately, the pharmacokinetic properties of milrinone may make it less desirable as an acute, first-line therapy in some patients. Milrinone has a long half-life (20 to 45 minutes) compared to nitroglycerin, nitroprusside, and dobutamine (50,71,76). To rapidly achieve a therapeutic plasma level, a bolus administration of 50 µg per kg is given over a 10-minute period followed by a constant infusion at a rate of 0.375 to 0.750 µg per kg per minute. This requirement for an initial bolus or high infusion rate to elicit a significant inotropic response places the unstable patient at greater risk for hypotension. The elimination half-life of 1.7 hours is also much longer than that of dobutamine or nitroprusside, and more time would be required to eliminate the drug should an undesirable side effect occur (76). Therefore, milrinone should generally not be used as first-line therapy in the management of acute heart failure but should be reserved for situations in which hemodynamic instability continues despite maximal support with dobutamine, nitroprusside, or nitroglycerin. These drugs are favorable first-line agents because of their short half-lives and ease of titration to inotropic and vasodilator effects. Milrinone may be more appropriate for treating chronic decompensated heart failure or during combination therapy with dobutamine or beta-blockers.

The choice of inotropic agent for treating decompensated heart failure will likely be affected by the growing numbers of patients receiving long-term beta-blocker therapy. Beta-blockers have now been shown to dramatically improve survival in chronic heart failure and play an integral role in the pharmacotherapy of this condition. Therefore, patients presenting with acute decompensation are increasingly likely to be receiving some form of long-term beta-blocker treatment. If inotropic support is necessary, milrinone is currently the agent of choice given that it acts beyond the level of the beta receptor and its inotropic effect is not altered by beta-receptor blockade (91,92) (*e*Table 91.3.1 and *e*Table 91.3.2). Depending on the degree of decompensation and hemodynamic compromise, the dose of beta-blocker should generally remain unchanged or gradually reduced during institution of inotropic support. If prolonged inotropic support is likely to be necessary or an inadequate hemodynamic response is observed, then the beta-blocker should be stopped.

Vasopressor Therapy

Dopamine

Dopamine hydrochloride is a drug that exhibits complex pharmacologic properties. This agent mediates its effects through either direct activation or indirect activation (via norepinephrine release) of multiple pre- and postsynaptic receptors (93,94). Receptors that are activated are extremely sensitive to dopamine concentration, and this contributes further to the complexity of drug administration (94). The positive inotropic and chronotropic effect of dopamine is mediated through activation of postsynaptic myocardial $beta_1$ receptors. This effect is most evident clinically at dosages greater than 5 µg per kg per minute. At low doses, the primary effect of dopamine is one of vascular relaxation and sodium excretion by stimulation of specific dopaminergic receptors located postsynaptically on vascular smooth muscle cells (primarily in renal and mesenteric vascular beds) and renal tubular cells (95,96). Dopamine receptors may also be found in cerebral, coronary, skeletal muscle, and cutaneous vessels (93). Low-dose dopamine (0.5 to 2.0 µg per kg per minute) is often used to treat patients with heart failure and renal insufficiency to selectively activate renal dopaminergic receptors, induce renal vasodilatation and improve renal blood flow, and provoke natriuresis (97). As the dopamine dosage is progressively increased above 5 µg per kg per minute, postsynaptic $alpha_1$ and $alpha_2$ receptors are activated, and this mediates vasoconstriction and produces blood pressure elevation.

Dopamine does not stimulate postsynaptic $beta_2$ receptors, so the predominant effect of higher dosing is one of vasoconstriction. On the presynaptic membrane, dopamine activates $alpha_2$ and $dopaminergic_2$ receptors, both of which inhibit the release of norepinephrine (98). By another mechanism, however, dopamine directly increases the release of norepinephrine, which further enhances peripheral vasoconstriction via alpha-adrenergic receptor activation (94,96).

Because dopamine selectively affects multiple receptors in a dose-dependent manner, a variety of hemodynamic effects can be achieved with careful titration (72). In the setting of acute heart failure, its primary use is to elevate systemic blood pressure and improve renal perfusion through activation of $beta_1$, alpha, and dopaminergic receptors. In patients with cardiogenic shock and significant hypotension, dopamine is usually the drug of choice and may be used either alone or in combination with dobutamine to elevate blood pressure and improve systemic and renal perfusion (99,100).

Prolonged use at high dosages, however, will ultimately cause worsening of myocardial function because of the increase in aortic impedance and the negative influence of dopamine on ventricular-vascular coupling (Table 91.3) (70). This is reflected in significant increases in PCWP and systemic blood pressure when dopamine is administered at dosages of 5 µg per kg per minute and greater (72). As the dopamine dosage is progressively increased, peripheral vasoconstriction is the predominant clinical feature similar to that seen with norepinephrine infusion. Upward titration of dopamine is usually limited by tachycardia, ischemia, and arrhythmia, particularly in the presence of occlusive coronary artery disease. At low to moderate dosages, coronary blood flow increases in parallel with increased myocardial work and a mild dopamine-induced coronary vasodilator effect (93,101,102). At high dosages, dopamine further increases MVO_2; however, coronary vascular resistance also increases because of alpha-mediated vasoconstriction (102).

To summarize, dopamine is the drug of choice in acute heart failure when significant hypotension is present despite adequate intravascular volume and ventricular filling pressures. In addition to evoking peripheral vasoconstriction and elevating blood pressure, it also has the unique property of enhancing renal blood flow through dopaminergic receptor activation, although this effect is probably negligible at doses in excess of 10.0 to 12.5 µg per kg per minute. Because of undesirable effects on myocardial function and hemodynamics, dopamine at high doses should be used only until more effective and definitive treatment is available.

Norepinephrine and Epinephrine

Norepinephrine is a potent alpha-adrenergic agonist that also possesses mild $beta_1$-agonist properties. It elicits a cardiovascular vasopressor response through dose-related vasoconstriction (76,103,104). This drug is not used for positive inotropic therapy because any increase in myocardial contractility is offset by increased afterload. During norepinephrine infusion, the combination of high preload and afterload markedly increases MVO_2 to the point at which the myocardial oxygen demand to supply ratio is threatened (76). Its primary indication in acute heart failure is to improve blood pressure and coronary perfusion in the setting of shock and persistent hypotension when dopamine and dobutamine are ineffective.

Norepinephrine can be infused starting at a rate of 0.02 to 0.04 µg per kg per minute and the dose can be advanced every 10 to 15 minutes until the desired blood pressure response is achieved (76). The target blood pressure should be that which is considered minimally acceptable in the individual patient to maintain adequate coronary perfusion and avoid serious side effects. Dopamine or dobutamine may be used in combination with norepinephrine to allow for lower dosing.

Epinephrine, like norepinephrine, is a catecholamine with potent alpha- and beta-agonist properties. Unlike norepinephrine, epinephrine also exhibits mild $beta_2$-agonist properties, which offsets some of the alpha effect and thereby mildly reduces its pressor response in comparison to norepinephrine (105). Epinephrine may be used in intensive care units for hemodynamic support in patients with severe heart failure and shock. It may be used in conjunction with other catecholamine inotropic and pressor drugs. Infusions of 0.1 to 1.0 µg per minute are commonly used.

The adverse effects seen during norepinephrine and epinephrine infusions are those usually observed with catecholamine administration, including ischemia and serious arrhythmia. Prolonged use may result in problems associated with reduced organ and tissue perfusion. The plasma half-life of these agents is short (less than 10 minutes), so undesirable pharmacologic effects generally resolve by 10 to 20 minutes after discontinuation of the infusion (76,105). As with high-dose dopamine therapy, the duration of treatment with any potent vasopressor should be as brief as possible, because prolonged use leads to continued myocardial dysfunction, decreased organ perfusion, and metabolic derangement. The need for prolonged catecholamine vasopressor infusions to maintain an acceptable systemic blood pressure would warrant proceeding to mechanical assistance such as intraaortic balloon counterpulsation in the appropriate patient.

Vasopressin

In the critical care setting, some centers advocate the use of vasopressin (antidiuretic hormone) for systemic pressure support when catecholamine infusions have failed to improve hemodynamics or when serious adverse responses to catecholamine infusions have occurred (105). Vasopressin, by activation of vascular smooth muscle V1 receptors, is a potent vasoconstrictor of skeletal muscle vascular beds at high dosages, but importantly, it produces less intense vasoconstriction of the renal and coronary vasculature (105).

Interestingly, vasopressin seems to produce vasodilation of the cerebral vasculature, which results in an improvement in cerebral blood flow during infusions (105,106 and 107). This selective vasodilatory response may be mediated by nitric oxide (107). In the absence of direct myocardial stimulation through beta-receptor activation, vasopressin may result in lower MVO_2 compared to catecholamines. Also, unlike catecholamines, the pressor response to vasopressin remains intact during severe metabolic acidosis.

Diuretic Therapy

Intravenous furosemide is the loop diuretic most commonly used to treat the patient presenting with acute heart failure and pulmonary congestion. The major objective of diuretic therapy in this circumstance is to decrease excessive lung water through natriuresis and diuresis with a reduction in intravascular volume. Intravenous administration is necessary to rapidly achieve adequate furosemide levels at its site of action, the renal tubules.

The most important effect of furosemide in the acute management of heart failure probably relates to its substantial hemodynamic effects. Although both vasodilator and vasoconstrictor properties have been attributed to intravenous furosemide (108,109,110 and 111), most data support the view that furosemide evokes a reduction in cardiac filling pressures, and this likely results from an early vasodilator effect. A vasoconstrictor effect with reduction in cardiac output has also been reported, however, and may be a consequence of diuretic-induced neurohormonal activation (110,111). Furosemide, by decreasing systemic and pulmonary venoconstriction, has been shown to reduce left ventricular filling pressure in acute heart failure associated with myocardial infarction (112,113).

Diuretic therapy must be used judiciously in acute heart failure secondary to myocardial infarction because intravascular and total body volume is usually normal (Table 91.2). Excessive diuresis can result in hypotension with progression of myocardial ischemia by further compromise of coronary perfusion. In fact, subgroup analysis of data from two large post–myocardial infarction treatment trials suggests that diuretic therapy may be detrimental in this patient population (114,115).

The effective dosage of intravenous furosemide is variable but is usually in the range of 20 to 40 mg in the patient not previously receiving diuretic therapy and exhibiting normal renal function. On the other hand, patients with acute decompensation of chronic heart failure often present with substantial volume overload and

usually require much larger dosages to achieve an adequate diuresis. This is because of prior chronic oral diuretic use and activation of renal compensatory mechanisms to counteract natriuresis in the chronic heart failure milieu. In patients exhibiting volume overload and diuretic resistance, a continuous infusion of furosemide (5 to 20 mg per hour) may prove advantageous (50,116). An attempt to enhance renal perfusion by increasing cardiac output (with dobutamine or nitroprusside) or by reducing renal vascular resistance (with low-dose dopamine) should also be considered. In patients with massive volume overload unresponsive to these therapeutic maneuvers, ultrafiltration may be effective (117).

Combination Pharmacologic Therapy

The use of multiple agents to support the failing circulation may provide certain advantages over treatment with a single agent (76,118). This is because acute heart failure or acute decompensation of chronic heart failure is associated with several hemodynamic abnormalities that cannot be entirely addressed by a single drug. The administration of an inotrope treats systolic dysfunction by improving contractility and stroke volume, but cardiac filling pressures and SVR (and associated valvular regurgitation) may not be substantively altered. A pure vasodilator alone may not be sufficient to support the circulation, and in fact may be detrimental when myocardial contractility is severely diminished and systemic blood pressure is unacceptably low. Using only a vasopressor drug to raise blood pressure in a patient with hypotension would increase afterload, ventricular wall stress, and filling pressures, which would inhibit the desired increase in cardiac output and potentially worsen ischemia.

Several combinations of intravenous drugs are theoretically appealing in the setting of severe acute heart failure. The simultaneous administration of dobutamine and a vasodilator such as nitroglycerin or nitroprusside augments stroke volume and lowers cardiac filling pressures more effectively than either agent alone (119,120). This combination is particularly useful in treating patients with cardiogenic shock resulting from a complication of myocardial infarction such as ventricular septal or papillary muscle rupture. As noted previously, the phosphodiesterase inhibitors also offer the advantage of potent vasodilation and positive inotropy; unfortunately, their pharmacokinetics and long half-life make these agents less than ideal in managing acute, unstable heart failure (71,76).

Using dobutamine (a beta-agonist), and milrinone (a phosphodiesterase inhibitor) simultaneously also offers possible advantages (85,118,121,122). The rationale behind this approach is based on the different mechanisms by which these drugs increase inotropy. Both agents, by different and complementary mechanisms, increase inotropy by elevating cAMP levels in cardiomyocytes (71,76,89). Studies in patients with stable heart failure have shown an added effect of combination therapy on major hemodynamic parameters (122) (Fig. 91.4).

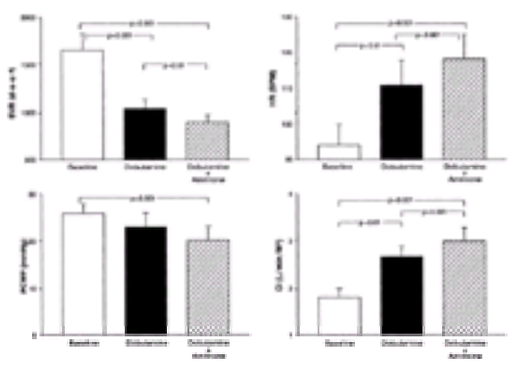

FIGURE 91.4 Effects of dobutamine hydrochloride and amrinone in ten patients with severe congestive heart failure. Dobutamine at peak dose increases cardiac index and reduces pulmonary wedge pressure (PCWP) and systemic vascular resistance (SVR). Dobutamine also increases heart rate (HR) above baseline. The addition of amrinone to dobutamine results in further augmentation in cardiac index (CI) and reduction in pulmonary wedge and SVR. Amrinone added to dobutamine further elevates the HR. (Modified from Uretsky BF, Lawless CE, Verbalis JG, et al. Combined therapy with dobutamine and amrinone in severe heart failure. *Chest* 1987;92:657–662.)

Dobutamine plus low-dose dopamine is one of the most commonly used combinations. The goal of this therapy is to achieve the inotropic effect of dobutamine with the concomitant renal vasodilator effect of low-dose dopamine (72,84,118). This combination is usually considered for the patient exhibiting marginal urine output and poor responsiveness to diuretics despite seemingly adequate central hemodynamics and systemic blood pressure.

Combination pharmacologic therapy is usually reserved for conditions associated with severe hemodynamic derangement, such as cardiogenic shock or severely decompensated chronic heart failure. It is rarely indicated in acute pulmonary congestion alone, for which a diuretic and vasodilator (or inotrope) often suffice. Combination therapy would be indicated for conditions in which its use would allow more immediate and prolonged stabilization of the circulation while definitive therapy is pursued. Another potential advantage of combination therapy is to enable the use of lower dosages of drugs so that significant untoward effects can be avoided. Again, the success of this therapy, as with any treatment of acute heart failure, is highly dependent on the cause and potential for myocardial recovery (118). In the patient in whom combination therapy is deemed potentially useful, hemodynamic monitoring should be used to guide treatment.

Investigational Agents for Acute Heart Failure

The current management of stable, chronic heart failure is guided by data from numerous large clinical trials, and several sets of guidelines have been published. Unfortunately, similar guidelines for the management of acute heart failure or acutely decompensated chronic heart failure do not exist. All of the therapies previously discussed may play a role in treating a particular patient with decompensated chronic heart failure; however, no consensus exists regarding the relative role of each therapeutic class. This uncertainty in selecting the appropriate treatment strategy is compounded by the fact that more than a decade has passed since the introduction of a new drug (milrinone) for acute heart failure. Thus, interest is now growing in several promising acute heart failure therapies.

Positive Inotropic Drugs

Levosimendan (levo-OR-1259) and toborinone (OPC 18790) are two compounds that are presently undergoing evaluation in clinical trials and are nearing final review by the FDA. Both agents have positive inotropic properties and other unique features that set them apart from dobutamine and milrinone. Their role in clinical practice, if they are approved by the FDA, remains to be determined.

Levosimendan evokes a positive inotropic response primarily by increasing the sensitivity of myofilaments (specifically troponin C) to intracellular calcium (123,124). This action is independent of cAMP mechanisms and thus elicits inotropy while avoiding many of the adverse effects commonly associated with cAMP-dependent agents (125,126). Levosimendan also exhibits vasodilator properties through its mild inhibition of phosphodiesterase III and by activation of potassium-dependent adenosine triphosphate channels (126,127). *In vitro*, it does not impair myocardial relaxation and, in fact, has lusitropic actions in the failing myocardium (123). These multiple mechanisms of action result in the expected hemodynamic changes during short-term intravenous administration to patients with severe heart failure. Investigators have reported a significant improvement in cardiac index (primarily as a result of increased stroke volume), reduction in systemic and pulmonary vascular resistance, and reduced filling pressures with only a small increase (approximately 8%) in heart rate (126).

As with most cardiotonic medications, increased heart rates and ventricular arrhythmia were more likely to be evident at the higher infusion rates. Preliminary studies suggest that this favorable hemodynamic response may translate into a survival benefit in those with severe heart failure (128). Large clinical trials are currently under way to better define the value of this agent in the management of decompensated heart failure.

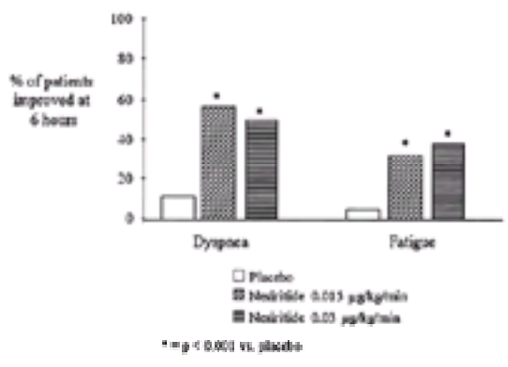
Toborinone exerts positive inotropic activity and balanced vasodilation primarily through phosphodiesterase III inhibition (129,130). Clinical evaluations of this compound have identified favorable hemodynamic benefits in heart failure during short-term intravenous administration, including improvements in cardiac output and reductions in ventricular filling pressure and vascular resistances coincident with reductions in MVO_2 (129,130 and 131). Unlike most other cardiotonic medications, toborinone does not appear to increase heart rate at hemodynamically effective doses.

Toborinone seems to act primarily as a venodilator at low dosages (similar to nitrates), whereas at higher infusion rates, conductance vessels are dilated, which produces a balanced vasodilator effect (132). As with other phosphodiesterase III inhibitors, the inotropic and vasodilating properties of toborinone are cAMP dependent and thus may be associated with similar adverse effects.

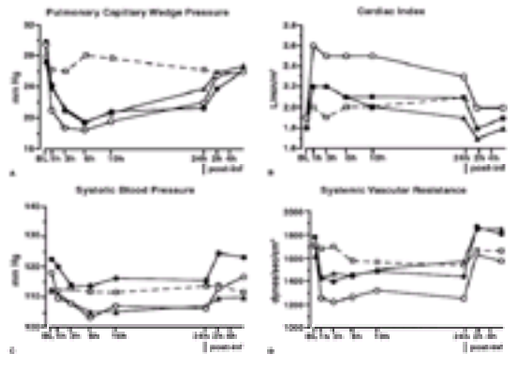
Natriuretic Peptides

The concentrations of circulating endogenous natriuretic peptides are known to be increased in patients with heart failure. These peptides are produced by the myocardium in response to increased myocyte stretch and wall tension resulting from an elevation in ventricular pressure. Elevated circulating levels appear to correlate with disease severity (133). The physiologic actions of endogenous natriuretic peptides only partially counteract the harmful effects of other neurohormones that are elevated in heart failure, specifically renin, aldosterone, and norepinephrine. By targeting various biologic sites, natriuretic peptides act as balanced vasodilators while also producing a mild degree of natriuresis and lusitropy.

Because of these beneficial hemodynamic effects, the postulation has been that the intravenous administration of natriuretic peptides may be beneficial in managing patients with decompensated heart failure. Nesiritide, a recombinant human brain natriuretic peptide, is currently being evaluated in clinical trials of acute and decompensated heart failure. The intravenous administration of this agent has been shown to produce favorable hemodynamic effects, including balanced vasodilation associated with a rapid improvement in heart failure clinical symptoms (*e*Fig. 91.4.1). Several trials have identified a dose-related reduction in ventricular filling pressures and augmentation in left ventricular stroke volume after both bolus administration and continuous infusion of nesiritide (134,135). These effects appear to be sustained during continuous administration over 24 hours (136) (*e*Fig. 91.4.2). Nesiritide compares favorably to standard inotropic and vasodilator therapy for heart failure with a trend toward fewer side effects (137). Clinical trials have identified the following adverse reactions to nesiritide:



***e*FIGURE 91.4.1** Effect of nesiritide and placebo on dyspnea and fatigue. Compared to placebo, nesiritide evoked a dose-related improvement in the symptoms of dyspnea and fatigue after 6 hours of infusion in hospitalized patients with decompensated heart failure. (From Colucci WS, Elkayam U, Horton DP, et al., for the Nesiritide Study Group. Intravenous nesiritide, a natriuretic peptide, in the treatment of decompensated congestive heart failure*. N Engl J Med* 2000;343:246–253.)



***e*FIGURE 91.4.2** Mean observed hemodynamic values from baseline (BL) through 24 hours and 4 hours postinfusion (post-inf) of nesiritide in patients with symptomatic heart failure. As early as 1 hour after initiation of nesiritide infusion, the pulmonary capillary wedge pressure **(A)** was significantly reduced below baseline. A dose-related decrease in cardiac index **(B)**, systolic blood pressure **(C)**, and systemic vascular resistance **(D)** was also observed. Importantly, no evidence was seen of a rebound effect after infusion in any of the treatment groups. Open squares: placebo; filled circles: 0.015 µg per kg per minute; filled triangles: 0.03 µg per kg per minute; open circles: 0.06 µg per kg per minute. [From Mills RM, LeJemtel TH, Horton DP, et al., on behalf of the Natrecor Study Group. Sustained hemodynamic effects of an infusion of nesiritide (human b-type natriuretic peptide) in heart failure. *J Am Coll Cardiol* 1999;34:155–162, with permission.]

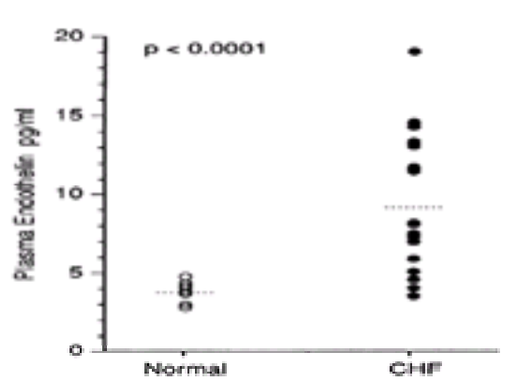
- Hypotension (symptomatic or asymptomatic)
- Nausea
- Bradycardia
- Nervousness
- Confusion
- Headache

The most common of these are dose-related hypotension, which is usually asymptomatic, and nausea. Significant proarrhythmia, a common concern during positive inotropic therapy, has not been observed during nesiritide infusion.

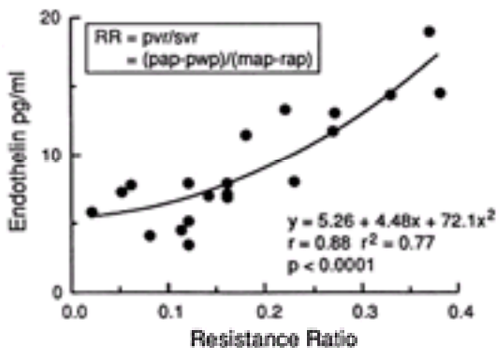
The Vasodilation in the Management of Acute Congestive Heart Failure (VMAC) trial has been completed and the preliminary results have been presented. This trial was conducted in response to the FDA's request for additional clinical data concerning the efficacy of nesiritide compared with standard vasodilator therapy using intravenous nitroglycerin. The VMAC trial was a multicenter, randomized, double-blind comparison of the hemodynamic and clinical effects of nesiritide, intravenous nitroglycerin, and placebo when added to standard therapy (including dobutamine, dopamine, and diuretics) in patients with acutely decompensated congestive heart failure. Preliminary results indicate that nesiritide achieved a greater hemodynamic and clinical benefit than did intravenous nitroglycerin with fewer adverse effects.

Endothelin Receptor Antagonists

Endothelin (ET-1) is a potent vasoconstrictor, the level of which is elevated in patients with congestive heart failure (138,139) (*e*Fig 91.4.3). This endogenous peptide, which activates endothelin type A and B receptors (located on vascular smooth muscle and vascular endothelium, respectively), is yet another neuropeptide that is likely a significant contributor to the pathophysiology of heart failure (see Chapter 88). ET-1 levels have been shown to correlate strongly with pulmonary vascular resistance in severe congestive heart failure, which suggests that ET-1 mediates the reactive pulmonary hypertension seen in this condition (138) (*e*Fig. 91.4.4). Therefore, clinical trials are under way to evaluate the potential benefit of endothelin receptor antagonists in treating both acute and chronic heart failure as well as pulmonary hypertension.

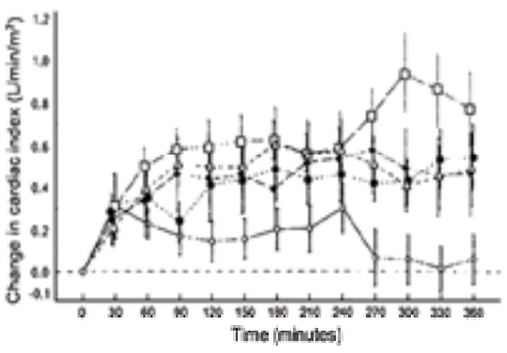


***e*FIGURE 91.4.3** Comparison of levels of plasma immunoreactive endothelin-1 in healthy subjects and patients with congestive heart failure (CHF). A threefold increase in mean levels of endothelin-1 was seen in the patients with heart failure compared with healthy subjects. (From Cody RJ, Haas GJ, Binkley PF, et al. Increased plasma endothelin correlates with the extent of pulmonary hypertension in patients with chronic congestive heart failure. *Circulation* 1992;85:504–509, with permission.)

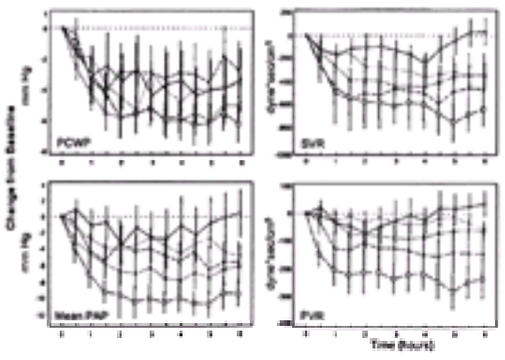


***e*FIGURE 91.4.4** Correlation of the resistance ratio (RR) with plasma endothelin level in patients with heart failure. A strong relationship is seen between endothelin plasma activity in heart failure and the degree of secondary pulmonary hypertension. map, mean arterial pressure; pap, pulmonary artery pressure; pvr, pulmonary vascular resistance; pwp, pulmonary wedge pressure; rap, right atrial pressure; svr, systemic vascular resistance. (From Cody RJ, Haas GJ, Binkley PF, et al. Increased plasma endothelin correlates with the extent of pulmonary hypertension in patients with chronic congestive heart failure. *Circulation* 1992;85:504–509.)

Tezosentan is a short-acting, parenteral dual endothelin receptor antagonist. This drug, because of its water solubility and short plasma half-life, seems particularly promising and is undergoing phase III clinical trials targeting the acute heart failure population (140). A study comparing tezosentan to placebo in the treatment of severe heart failure identified a dose-dependent increase in cardiac index during tezosentan administration (141) (*e*Fig. 91.4.5). A significant reduction in PCWP and systemic and pulmonary vascular resistances also resulted from endothelin receptor blockade (*e*Fig. 91.4.6). Importantly, heart rate remained unchanged. Tezosentan did not produce significant hypotension or proarrhythmia (141). These findings support a potential role for tezosentan in the treatment of acute heart failure; however, further studies may be necessary before final FDA consideration.



***e*FIGURE 91.4.5** Effect of endothelin receptor blockade with tezosentan on cardiac index in patients with severe heart failure. Depicted are the changes in cardiac index over the course of treatment with placebo (*open circles*) or tezosentan at 5 mg per hour (*filled circles*), 20 mg per hour (*open triangles*), 50 mg per hour (*filled diamonds*), and 100 mg per hour (*open squares*). Dose-trend analysis of the change from baseline to the end of treatment (hour 6) in cardiac index with the four tezosentan dosages showed a significant dose relationship (*p* = .038). (From Torre-Amione G, Young JB, Durand JB, et al. Hemodynamic effects of tezosentan, an intravenous dual endothelin receptor antagonist, in patients with class III to IV congestive heart failure*. Circulation* 2001;103:973–980, with permission.)



***e*FIGURE 91.4.6** Acute hemodynamic changes during tezosentan infusion. Change from baseline in pulmonary capillary wedge pressure (PCWP), mean pulmonary artery pressure (mean PAP), systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR) over the treatment period with placebo (*open circles*) or tezosentan at 5 mg per hour (*filled circles*), 20 mg per hour (*open triangles*), 50 mg per hour (*filled diamonds*), and 100 mg per hour (*open squares*). Tezosentan produces favorable acute hemodynamic changes during short-term infusion in patients with severe heart failure. (From Torre-Amione G, Young JB, Durand JB, et al. Hemodynamic effects of tezosentan, an intravenous dual endothelin receptor antagonist, in patients with class III to IV congestive heart failure*. Circulation* 2001;103:973–980, with permission.)

HEMODYNAMIC MONITORING IN ACUTE HEART FAILURE

Catheterization with a flow-directed thermodilution pulmonary artery catheter (Swan-Ganz catheter) is often indicated for optimal management of acute heart failure. Although hemodynamic monitoring is rarely necessary in uncomplicated cases of acute pulmonary edema, it is often helpful in the patient who does not respond initially to standard therapy (usually nitroglycerin and diuretics) and is vital in managing those with persistent hypotension and preshock or shock syndromes (2) (Table 91.4). These patients have evidence of hypoperfusion on examination, including a narrow pulse pressure, cool skin, reduced urine output, and mental obtundation. Continuous assessment of cardiac output and ventricular filling pressure is essential to appropriately guide and determine the effectiveness of pharmacologic therapy or assess the need for mechanical support. Other indications for hemodynamic monitoring include acute heart failure in which volume status is in question and pulmonary edema in which a cardiac cause has not been definitely determined (2,142,143). As discussed previously, some patients presenting with acute cardiogenic pulmonary edema may have only mild elevation of PCWP. This is typically a result of reduced plasma volume from extravasation of water outside of the pulmonary capillaries further complicated by diuretic therapy. Hemodynamic monitoring may also be diagnostically helpful in further defining the severity of hemodynamic compromise due to specific lesions or conditions such as pericardial tamponade, right ventricular infarction, ventricular septal rupture, or circulatory collapse secondary to various shock syndromes (Table 91.5) (143).

Acute pulmonary edema
- After poor response to initial treatment
- To exclude noncardiogenic pulmonary edema

Cardiogenic shock or preshock syndrome not responsive to initial fluid challenge

Acute decompensation of chronic heart failure (to allow tailored therapy)

Questionable volume status

TABLE 91.4 INDICATIONS FOR PULMONARY ARTERY CATHETERIZATION AND HEMODYNAMIC MONITORING IN ACUTE HEART FAILURE

	CO	RAP	PAP	PCWP	SVR	SvO_2
Acute pulmonary edema	Variable	→	Variable	Variable	Variable	Variable
Cardiogenic shock	↓	↑	↑ or →	↑ or →	↑↑	↓↓
Decompensated heart failure	↓	↑	↑↑	↑↑	↑	↓
Acute right ventricular failure	↑	↑↑	→ or ↓	→ or ↓	↑	↓
Massive pulmonary embolism	↓	↑	↑	→	↑	↓
Acute aortic/mitral valve insufficiency	↓	→	↑	↑↑	↑	↓
Tamponade	↓	↑*	↑*	↑*	↑	↓
Hypovolemic shock	↓	↓	↓	↓	↑	↓

↑, increased; →, normal; ↓, decreased; ↑↑, markedly increased; ↓↓, markedly decreased; CO, cardiac output; PAP, pulmonary artery pressure; PCWP, pulmonary capillary wedge pressure; RAP, right atrial pressure; SvO_2, mixed venous oxygen saturation; SVR, systemic vascular resistance
*Equalization of pressure is characteristic.

TABLE 91.5 COMMON HEMODYNAMIC PATTERNS IN LOW CARDIAC OUTPUT STATES

The major parameters measured during hemodynamic monitoring are cardiac output, PCWP, systemic arterial pressure (usually measured with an indwelling arterial catheter), heart rate, and the calculated SVR (mean arterial pressure minus mean right atrial pressure, divided by cardiac output). The measurement of mixed venous oxygen saturation is also important (143,144), particularly when the thermodilution cardiac output may not be reliable (i.e., in cases of tricuspid regurgitation). By repeated assessment of these parameters, pharmacologic therapy using the agents previously discussed can be more effectively tailored to achieve the optimal hemodynamics for the individual patient (145). The therapeutic approach must take into account not only the presenting hemodynamics but also the cause of the underlying condition. For example, the optimal PCWP for patients with acute myocardial injury is higher (18 to 20 mm Hg) (9,146) than that for patients with acutely decompensated chronic heart failure in which a normal PCWP (10 to 12 mm Hg) is often the goal (147). Even when the underlying condition is known and general hemodynamic goals have been defined, individualization of therapy is important. Metabolic demand may be significantly different among individuals, and often significant variability exists in individual peripheral oxygen extraction ratios and oxygen use. Because of these differences, some patients tolerate a much lower cardiac output than others. Therefore, parameters in addition to hemodynamics must be considered when treating severe heart failure, and assessment should include a physical examination with attention to peripheral perfusion, urine output, and mentation. The blood lactate level is an important prognostic indicator in shock and is also useful in guiding therapy (148,149).

The use of hemodynamic monitoring in the management of critically ill heart-failure patients has come under scrutiny since the publication of data from the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (150). In this study, patients undergoing right heart catheterization had a significantly lower survival at 30 days than did those not undergoing this invasive monitoring approach. Drawing conclusions from this trial is difficult, however, because only 11% of patients had heart failure as the primary reason for admission to the intensive care unit and multisystem failure was present in the majority (150). Greater insight into the utility of invasive hemodynamic monitoring in the management of decompensated heart failure should be available after completion of an ongoing randomized, controlled trial [Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE)] sponsored by the National Institutes of Health.

GENERAL APPROACH TO THE MANAGEMENT OF ACUTE HEART FAILURE

Acute Cardiogenic Pulmonary Edema

The patient presenting with acute pulmonary edema is often in great distress, and the diagnosis is usually not in question because of the dramatic nature of the clinical presentation. Although the ultimate management strategy is dictated by the precipitating factor or factors causing pulmonary edema, initial therapy must be guided by the early clinical findings until a definitive diagnostic evaluation can be completed. As mentioned previously, the evaluation for precipitating factors and the initial therapeutic intervention usually occur simultaneously.

The management strategy for the patient with acute cardiogenic pulmonary edema is outlined in Table 91.6. Nitroglycerin, administered by the sublingual route, is a rational first step in the treatment of most patients (2). This preload-reducing agent, which can be administered every 5 minutes, often relieves a significant amount of the sensation of breathlessness and can provide a bridge for preparation of the patient for further treatment and diagnostic procedures. Sublingual nitroglycerin is an effective means of immediately reducing preload and afterload until the intravenous preparation can be infused (49,51). If afterload reduction is the most important objective, as in a patient with pulmonary edema, acute valvular insufficiency, or hypertension, or if the response to nitroglycerin is suboptimal, nitroprusside should be substituted or added for its balanced vasodilator effect. An indwelling arterial catheter for continuous monitoring of systemic blood pressure is optimal but not mandatory for initiation of treatment. Intravenous furosemide should also be administered early in the clinical course but with care to avoid overdiuresis. In acute heart failure, intravascular volume is often normal or low; judicious diuretic therapy is useful primarily for its early vasodilator effect (108,109 and 110). The patient's failure to respond within a reasonable period to these measures should warrant strong consideration of hemodynamic monitoring and the addition of inotropic therapy (Table 91.4; also see the section Cardiogenic Shock and Decompensated Heart Failure).

Sublingual nitroglycerin
- 0.4 mg every 5 min

Intravenous nitroglycerin
- Start at 0.2 to 0.4 μg/kg/min

Intravenous furosemide
- 20 to 40 mg i.v.
- Follow volume status closely

Sodium nitroprusside if further afterload reduction required

Supplemental oxygen/mechanical ventilation as guided by arterial blood gas analysis

Consider intravenous morphine sulfate (2 to 6 mg) if no pulmonary contraindication

Electrocardiogram
- Exclude myocardial infarction

Echocardiography
- Evaluate ventricular function, valvular status

Proceed with urgent coronary angiography if reperfusion therapy indicated

TABLE 91.6 INITIAL MANAGEMENT OF ACUTE CARDIOGENIC PULMONARY EDEMA

In the acute setting, patients with pulmonary edema may also benefit from morphine sulfate 2 to 6 mg given intravenously (50). This medication may have an immediate hemodynamic effect through its preload-reducing properties. It may also alleviate anxiety and blunt the catecholamine response to the acute illness. Caution must be used, however, in patients with evidence of respiratory or metabolic acidosis or in those with significant underlying obstructive lung disease.

Supplemental oxygen is traditionally administered to patients with acute pulmonary edema regardless of arterial oxygen saturation. This is essential in the patient with hypoxemia; however, its utility in those with normal oxygen saturation is questionable, and typically therapy is empiric. Although patients may receive a subjective benefit, supplemental oxygen administration may have an adverse effect on central hemodynamics in patients with chronic heart failure (151). Optimally, one should obtain information from arterial blood gas analysis before administering supplemental oxygen. When severe respiratory distress or acidosis is present, the threshold for proceeding to mechanical ventilatory support should be low. This not only corrects hypoxemia but also may reduce metabolic demands and therefore favorably affect the relationship between oxygen delivery and utilization (144).

Early in the treatment of the patient with acute heart failure, a directed history and physical examination, electrocardiography, and usually transthoracic two-dimensional echocardiography should be performed to determine the presence of myocardial injury and assess the severity of cardiac dysfunction (2). Evidence of acute myocardial infarction would warrant proceeding to cardiac catheterization with consideration of urgent reperfusion therapy. A diligent effort must be made to identify the cause of acute heart failure, because without correction of a reversible lesion, the long-term prognosis is poor (3).

Cardiogenic Shock and Decompensated Heart Failure

Patients with acute unstable heart failure (preshock or shock syndromes) require an expedient diagnostic evaluation and therapeutic plan. They usually exhibit severe cardiac dysfunction and hemodynamic compromise, and often present with symptoms and signs of organ hypoperfusion (cyanosis, cool extremities, altered mentation) (13). If the high mortality associated with this syndrome is to be avoided, a rapid diagnostic evaluation and institution of supportive therapy (pharmacologic and mechanical) is necessary.

In patients with acute decompensation of chronic heart failure, the underlying heart disease is often known. In this setting, the therapeutic strategy incorporates a search for factors precipitating acute decompensation. Patients are usually receiving standard medical therapy for chronic heart failure, and a reparable lesion is less likely to be identified. Nevertheless, one must always consider the possibility of correctable ischemic myocardial dysfunction if a prior assessment for coronary artery disease has not been performed.

When cardiogenic shock occurs or when standard therapy fails to stabilize decompensated chronic heart failure, hemodynamic monitoring to guide pharmacologic support is essential (142,143,145). In addition, hemodynamic evaluation, along with the physical examination and echocardiography, can assist in the identification of common shock syndromes requiring specific forms of therapy (e.g., right ventricular infarction) (143,152) (Table 91.5).

Figure 91.5 provides a general approach to the selection of specific intravenous pharmacologic agents based on hemodynamic profile. The initial therapeutic decision is influenced primarily by systemic arterial pressure. Although the optimal systolic or mean arterial pressure for the individual patient is variable, a systolic arterial pressure of less than 80 to 85 mm Hg would be classified as significant hypotension when accompanied by evidence of organ hypoperfusion, such as renal dysfunction and altered central nervous system activity. When this clinical situation presents, arterial pressure must be rapidly augmented to the level at which myocardial perfusion is not jeopardized. General hemodynamic goals would include increasing the cardiac index above 2.2 L per minute per m^2, reducing the PCWP below 20 mm Hg (15 mm Hg or less in chronic heart failure), maintaining SVR at 1,000 to 1,200 dynes per second per cm^5, and reducing right atrial pressure to 7 mm Hg or less (Table 91.7) (153). For the individual patient, these goals will vary depending on the nature and acuteness of the cardiac dysfunction. The optimal PCWP would be the lowest pressure that can be maintained without a preload-related decline in systolic arterial pressure or cardiac index. In dilated cardiomyopathy and severe systolic dysfunction, stroke volume is primarily afterload-dependent and is affected minimally by manipulation of preload (19,154). Therefore, relatively normal PCWP can be targeted (147). The optimal SVR would be the lowest that one could achieve while maintaining adequate systemic perfusion.

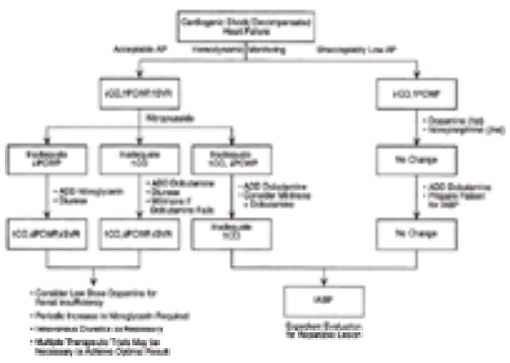


FIGURE 91.5 Algorithm for hemodynamics-directed pharmacologic support of cardiogenic shock and decompensated heart failure.↑, increased; ↓, decreased; AP, arterial pressure; CO, cardiac output; IABP, intraaortic balloon pump; PCWP, pulmonary capillary wedge pressure; SVR, systemic vascular resistance.

TABLE 91.7 HEMODYNAMICS-DIRECTED PROTOCOL FOR TREATMENT OF DECOMPENSATED HEART FAILURE

When significant systemic hypotension is present, therapy with vasopressor doses of dopamine (more than 5 µg per kg per minute) should be used (99,100). Failure to achieve an acceptable blood pressure response with high-dose dopamine would warrant consideration of switching to another vasopressor, such as norepinephrine or vasopressin, or adding dobutamine (71,76). In either case, preparations should be made for proceeding to mechanical assistance if appropriate (see the section Circulatory Support Devices). In refractory hypotension and shock, the mortality is extremely high if a surgically correctable lesion is not identified or if mechanical support (as a bridge to transplantation) is not an option (2).

Unstable or decompensated heart failure with low cardiac output but acceptable arterial pressure may initially be treated with nitroprusside to augment stroke volume and reduce the quantity of valvular regurgitation (19,21). A failure to augment cardiac output with this approach would warrant consideration of dobutamine or milrinone to enhance inotropy and vasodilation (71,74,79,86,87,89,118). If cardiac output increases appropriately with nitroprusside but left ventricular filling pressure remains elevated, then nitroglycerin can be added for further preload reduction (21,26,28,29). If both cardiac output and PCWP remain unacceptable, the option of changing to or adding milrinone should be considered (86,88,118,121). Other therapeutic considerations would include the addition of low-dose dopamine to augment renal blood flow, frequent assessment of volume status and appropriate intravenous diuretic administration, and upward titration of intravenous nitroglycerin when hemodynamic tolerance develops (52,95,96 and 97,108,110,116).

The approach to the pharmacologic support of the patient with cardiogenic shock or severely decompensated heart failure must be individualized. Evaluation of multiple clinical variables is often necessary for appropriate drug selection. Even then, several therapeutic trials may be required. When pharmacologic support obviously will not be sufficient to avoid progressive circulatory failure, then mechanical assistance must be considered.

CIRCULATORY SUPPORT DEVICES

Overview of Available Devices

In cardiology, few situations are as dramatic as observing the successful use of circulatory-support-device technology in an individual about to succumb to acute heart failure with cardiogenic shock and devastating hemodynamic profiles. A wide spectrum of mechanical circulatory assistance devices is now available and can provide extended hemodynamic support for patients showing acute deterioration while awaiting definitive therapy (see Chapter 95). Implantable ventricular assist devices successfully provide extended support for patients hemodynamically deteriorating to the degree that they are unlikely to survive until transplantation. This observation served as a major impetus for the successful development of many circulatory support systems (155,156 and 157). Many types of ventricular assist devices have also been used as a bridge to recovery. In select individuals suffering shock after acute myocardial infarction or myocarditis, timely insertion of mechanical support can allow for recovery of the injured heart so that primary responsibility for hemodynamic support can ultimately once again be carried by the heart. Indeed, relieving pressure and stress-load burdens from the injured myocardium might be therapeutic in and of itself.

Many devices are available that can provide one degree or another of circulatory support. These range from the intraaortic balloon counterpulsation pump (IABP), extracorporeal membrane oxygenation (ECMO) systems, and univentricular and biventricular nonpulsatile and pulsatile devices to the total artificial heart. *e*Table 91.7.1 lists the various options currently available. Many of these devices are commercially available for routine use (the IABP, nonpulsatile extracorporeal centrifugal pump, ECMO, extracorporeal pulsatile devices, and the pneumatic intracorporeal pulsatile HeartMate device). Others must be used according to FDA-monitored research protocols.

Ventricular-assist-device implantation today is playing a greater role in heart transplantation (158). At some centers as many as 30% to 50% of patients undergoing cardiac transplantation are being bridged to that procedure with a ventricular assist device. Posttransplant outcome in these patients is now excellent, with survival rates at some centers exceeding 90% for patients successfully bridged to transplantation. Approximately three-fourths of patients undergoing ventricular-assist-device insertion with this intention survive.

Patient Selection

Table 91.8 summarizes many considerations that come into play when ventricular assist devices or other circulatory-support machinery is considered for the individual patient. Devices capable of being used as a short-term bridge to cardiac transplantation can be singled out. Devices used to “bail out” a patient from acute shock (such as might occur after myocardial infarction) or used for a more subacute insertion in a patient with “preterminal” heart failure and hemodynamics are in this category. Furthermore, some patients undergo device insertion with the idea of bridging to recovery. These patients are those likely to be suffering acute inflammatory conditions of the heart or shock syndromes rooted in difficulties with stunned or hibernating myocardium. The reality and implications of using ventricular-assist-device insertion long term as an alternative to cardiac transplantation are just beginning to be explored. Obviously, mechanical circulatory support and, more specifically, ventricular-assist-device insertion, attenuates the multifactorial difficulties apparent in circulatory decompensation. Pump dynamics are important, as is flow. That ventricular-assist-device insertion can dramatically reverse the neurohumoral perturbation characteristic of heart failure states has been elegantly demonstrated. These devices are capable of returning catecholamine levels, for example, to near normal (159).

Patient selection
Short-term bridge to heart transplantation
Acute insertion: bailout from acute shock (after myocardial infarction)
Subacute insertion: insertion in patients with "preterminal" heart failure
Short-term bridge to recovery
Long-term alternative to transplantation
Ventricular-assist device interdiction of circulatory decompensation
Pump dynamics
Flow dynamics
Impact on neural-humoral perturbation
Troublesome circumstances
Small patient size
Cachexia
Infection (particularly sepsis)
Fixed pulmonary hypertension
Substantive right heart failure
Significant hepatic or renal dysfunction
Malignant tachyarrhythmias (atrial and ventricular)
Hypercoagulable states
Consumption coagulopathy
Acute/chronic pulmonary emboli
Challenging acute clinical situations
Myocardial infarction with shock
Cardiac arrest with ongoing cardiopulmonary resuscitation
Failure to wean from cardiopulmonary bypass after open heart surgery

TABLE 91.8 CONSIDERATIONS FOR VENTRICULAR-ASSIST DEVICE INSERTION IN CASES OF ADVANCED HEART FAILURE

Indications for emergency mechanical support vary. Patients with long-standing heart failure deteriorate more slowly than those with the recent onset of ventricular dysfunction, but patients with both acute and chronic heart failure can be saved with this technology. One must remember that exacerbation of chronic heart failure frequently reverses after aggressive adjustment of tailored medication and resolution of concomitant difficulties such as acute ischemia or infection (145). Such patients do not require mechanical circulatory support. In general, the indication for the use of circulatory-support devices is evidence of critical organ hypoperfusion despite aggressive and adequate medication therapies, including infusion of inotropic drugs such as milrinone and dobutamine, as previously discussed.

Hemodynamic parameters that characterize severe end-stage heart failure vary from patient to patient, and these indicators should be analyzed over long periods of time rather than at any one given moment. Generally, an inability to maintain a systolic blood pressure greater than 75 to 80 mm Hg, cardiac index greater than 1.5 to 2.0 L per minute per m^2, and mixed pulmonary venous saturation of more than 50% on aggressive oral and parenteral pharmacotherapeutic support defines a patient who might benefit from use of a support device. When analyzing hemodynamics, one should ensure that adequate ventricular filling pressures are present but not inordinately elevated. Invariably, reduction of left ventricular filling pressures below 25 to 30 mm Hg leads to improvement in cardiac output, because high ventricular filling pressures are frequently causing significant mitral regurgitation (160). Persistently elevated high right atrial pressures (mean pressure greater than 20 mm Hg) despite reduction in PCWP identifies a patient population not likely to be easily stabilized with long-term drug therapy. Unfortunately, this characteristic hemodynamic pattern also identifies individuals who might be at risk for right ventricular failure after support-device implantation. A goal should be to attempt to lower pulmonary vascular resistance below 5 Wood units and to maintain SVR at 1,000 to 1,200 dynes per second per cm^5. Deterioration during pharmacologic bridge to cardiac transplantation is generally manifest by an insidious drop in urine output, rising creatinine levels, and tachycardia (161).

Contraindications to circulatory-support-device insertion relate largely to device choice and therapeutic goal. For implantable left ventricular assist devices, technical contraindications include a body surface area less than 1.5 m^2 or greater than 2.5 m^2 or a weight greater than 150% of the patient’s ideal body weight. Currently, most implantable devices are large and will not fit into very small patients. Obese patients can have problems with percutaneous access sites and are at higher risk for comorbid events such as pulmonary embolism. A highly calcified aorta, particularly at the proposed site of outflow conduit anastomoses, can be problematic, as can substantive aortic insufficiency. Presence of a prosthetic aortic valve is considered to be a contraindication to ventricular-assist-device insertion because frequently the aortic valve closes permanently as blood is pumped during diastole into the ventricular assist device. This sets the stage for thromboembolism. Some device controllers that regulate the circulatory pressure/electrocardiography/device interphase react adversely in electrical fields in which pacemakers or defibrillating units are present. Therefore, pacemaker dependence or presence of an implanted defibrillating device may be a contraindication to the use of certain ventricular assist devices. Certainly, the inability to deliver long-term anticoagulation therapy to a patient is also cause for great concern. As suggested, hemodynamic contraindications to device insertion

might include significant right heart failure as reflected by right atrial pressures higher than 20 mm Hg despite aggressive medical therapy. Likewise, patients with a PCWP below 15 mm Hg and a cardiac index of more than 2 L per minute per m^2 without the use of parenteral inotropes represent a population that might, although very sick, do reasonably well without insertion of a circulatory support device.

Pulmonary contraindications to device insertion might include long-term ventilator dependency, recent pulmonary embolism, or the presence of markedly impaired pulmonary function, particularly that characteristic of chronic obstructive pulmonary disease (forced expiratory volume in 1 second less than 50% of predicted, for example). As mentioned, fixed pulmonary hypertension can lead to right heart failure and set the stage for low systemic flows during left ventricular-assist-device insertion. Generally, those patients with systolic pulmonary artery pressures greater than 70 mm Hg, transpulmonary gradient greater than 17 mm Hg, and pulmonary vascular resistance greater than 5 Wood units while on intensive vasodilator therapy are poor candidates for ventricular-assist-device insertion or the use of circulatory-support devices in general. Peripheral vascular disease can produce complications after device insertion as well. Significant abdominal aortic aneurysm (larger than 4.5 cm) carries the risk for rupture at the higher pulsatile flows generated by these devices. Peripheral vascular disease in general, with significant limb claudication or limb risk due to low flow states, can arise from device insertion. Cerebrovascular disease can also be a contraindication to ventricular-assist-device insertion, and, in particular, a prior stroke or transient ischemic episode in the presence of internal carotid artery plaque or lesion is considered a contraindication. Active infection is a great concern, because these devices are susceptible to microbial organism seeding and may give rise to chronic endocarditis. Often, the organisms cannot be eliminated with antimicrobial therapy with the device still in place. Irreversible end-organ dysfunction is also associated with high mortality after device insertion. Hepatic cirrhosis must be ruled out, and a liver biopsy should be performed when questions arise. Liver enzyme levels greater than three times the upper limit of normal or a bilirubin level greater than 3 mg per dL should be of great concern and prompt serious consideration of postponing device insertion. Patients with platelet counts of less than 50,000, primary coagulopathy, prothrombin time with an international normalized ratio greater than 1.8, or activated partial thromboplastin time greater than twice the control value in patients not on an anticoagulant do not make good candidates for mechanical circulatory support. Likewise, a serum creatinine level of more than 3 mg per dL or creatinine clearance of less than 30 mg per hour predicts poor outcome. Finally, psychosocial issues that might impair compliance with prescribed regimens after device insertion represent contraindications. Alcohol dependency or abuse, major psychiatric illness, and inadequate social support matrixes will likely be associated with failure to survive device implantation (*e*Table 91.8.1). The choice of a particular circulatory-support device (*e*Table 91.7.1) is based on patient presentation characteristics. Potentially reversible difficulties requiring only short-term support would be best treated by an IABP or extracorporeal pulsatile device. Sometimes the IABP is used as a “bridge to a bridge,” that is, this device is inserted to stabilize a patient long enough to make definitive decisions regarding ventricular-assist device insertion. Patients not likely to improve solely with this limited form of support might be considered candidates for insertion of intracorporeal pulsatile devices that can be used over the long term. Sometimes patients receiving left ventricular assist devices require temporary right ventricular assistance with a separate pump that can be subsequently removed.

***e*TABLE 91.8.1** FACTORS TO CONSIDER WHEN EVALUATING PATIENTS FOR VENTRICULAR-ASSIST DEVICE INSERTION
Technical contraindications
Body surface area <1.5 m^2 or >2.5 m^2
Weight greater than 150% of ideal
Highly calcified aorta (particularly at proposed site of outflow conduit anastomosis)
Moderate to severe aortic insufficiency
Prosthetic aortic valve
Pacemaker dependence or presence of an implantable defibrillating device
Contraindication to anticoagulation
Hemodynamic contraindications
Right atrial pressure >20 mm Hg despite aggressive diuresis and vasodilator therapy
Pulmonary capillary wedge pressure generally <15 mm Hg when treated
Cardiac index generally >2.0 L/min/m^2 without use of parenteral inotropes
Pulmonary contraindications
Long-term ventilator dependency
Recent pulmonary embolism
Substantively impaired pulmonary function (forced expiratory volume in 1 sec <50% predicted)
Fixed pulmonary hypertension (systolic pulmonary artery pressure >60 mm Hg, transpulmonary gradient >17 mm Hg, pulmonary vascular resistance >5 Wood units while on intensive pulmonary vasodilator therapy)
Peripheral vascular contraindications
Significant abdominal aortic aneurysm (>4.5 cm)
Peripheral vascular disease with limb claudication
Cerebrovascular disease (prior stroke or transient ischemic episode in the presence of internal carotid artery plaque/lesion)
Active systemic infection (fever >38°C)
Irreversible end-organ dysfunction
Hepatic cirrhosis
Liver enzymes >3× upper limit of normal or bilirubin >3.0 mL/dL
Platelet count <50,000
Primary coagulopathy
Prothrombin time with international normalized ratio >1.8 or activated partial thromboplastin time more than twice control value in patients not on anticoagulant therapy
Serum creatinine >3.0 mg/dL or creatinine clearance <30 mL/h
Psychosocial issues that might impair compliance
Alcohol dependence or abuse
Major psychiatric illness
Inadequate social support systems

CONTROVERSIES AND PERSONAL PERSPECTIVES

The complexity and significant mortality associated with the acute heart failure syndrome have served to generate a broad spectrum of potential therapeutic modalities, as has been discussed. Potent intravenous vasodilator and inotropic drugs, designed to correct specific hemodynamic abnormalities, are now available for use alone, or in combination, to support patients with acute pulmonary edema as well as those with severe cardiac dysfunction and cardiogenic shock. New drug therapies targeting more specific hemodynamic and neurohormonal perturbations are promising. Advancements in medical technology have improved the ability to monitor and evaluate continuously the patient with severe hemodynamic compromise so that medical therapy can be appropriately tailored. For those not responding to aggressive pharmacologic management, short- and long-term mechanical assist devices can now be used to support the sickest of patients until further therapeutic options are explored. These advances in the ability to treat and support the patient with acute heart failure allow for a more thorough and aggressive diagnostic evaluation in many instances. As emphasized throughout this chapter, the finding of a treatable condition has important prognostic implications, and the ability to uncover a reparable lesion in an individual with heart failure continues to improve. The continued advancements in reperfusion strategies (thrombolysis, angioplasty, antithrombotic therapy) as well as improved outcome after high-risk coronary bypass surgery provides a means potentially to avoid irreversible myocardial injury and its sequela of severe heart failure. These therapeutic options also offer some encouragement that the high mortality of cardiogenic shock may be favorably altered in the future. Various reperfusion strategies continue to undergo clinical investigation.

The advances in technological support and treatment options for acute heart failure, however, have not simplified its management. The significance of the initial clinical assessment and treatment plan cannot be overemphasized. Due to the complexity and diverse nature of the acute heart failure syndrome, diagnostic and therapeutic strategies must be individualized and a “cookbook” approach to pharmacologic therapy or other modes of support cannot be advocated. Certainly, the patient presenting with acute pulmonary edema and hypertension is treated differently from the patient with a large anterior myocardial infarction presenting with congestion and hypotension. Within these two extremes lies a great diversity of acute heart failure presentations, each with subtle differences requiring a different diagnostic and therapeutic approach. Therefore, the basics of patient care cannot be ignored but must be used in conjunction with advanced monitoring capabilities.

The algorithm for the pharmacologic management of heart failure presented in this chapter should be viewed as a generalized approach to therapy in which various treatment trials may be necessary. Even when one uses specific drugs with known hemodynamic profiles, close observation and monitoring are essential because the response of a given patient is not always predictable. For example, dobutamine administration is often avoided in the setting of myocardial ischemia and marginal cardiac output because of the perceived potential for inducing worsening ischemia and myocardial dysfunction or arrhythmia, or both. As has been discussed, dobutamine may also evoke hemodynamic effects that are favorable, even in the setting of ongoing ischemia. Some individuals, however, experience untoward effects if the drug is not judiciously administered. (For instance, one should not administer dobutamine to those with normal or low left ventricular filling pressures, and rapid titration or initiation at a dosage greater than 5 µg per kg per minute should also generally be avoided.) The identification of an excessive heart-rate response during dobutamine titration would also identify the patient with marginal cardiac reserve and potential for adverse effects. Therefore, repeated clinical evaluation in conjunction with appropriate medication adjustment is necessary.

Hemodynamic monitoring should be used in concert with, but should not replace, the overall clinical assessment. Unfortunately, major alterations in therapy based solely on hemodynamic parameters are often seen in intensive care settings. For example, a cardiac index of 2.2 L per minute per m^2 might lead to an increase in

inotropic therapy even though no evidence of organ hypoperfusion otherwise exists. This pharmacologic manipulation based only on hemodynamics without account taken of other important clinical variables is often not necessary and potentially detrimental.

At the other end of the spectrum are patients who continue to exhibit clinical deterioration despite maximal pharmacologic support. In this scenario an early decision to proceed with mechanical assistance is imperative. Failure to recognize this and proceed to mechanical assistance in an expedient manner, unfortunately, is common. Often, excessive delays are incurred in an attempt to stabilize a condition that is clearly unstable and nonresponsive to medical therapy. The greater the delay when significant organ hypoperfusion is evident, the less effective mechanical support will be, and this translates into fewer definitive therapeutic options. At the present time, options primarily include surgical approaches such as coronary bypass surgery, valvular repair or replacement, and cardiac transplantation.

A tremendous amount of progress has occurred in the management of acute heart failure over recent years, particularly with respect to mechanical circulatory support systems that can bridge patients from devastating hemodynamic decompensation to more clinically acceptable stages. The beginning of the century is an exciting time in which smaller and more reliable devices with fewer complications will become available for implantation. Even then, individualization of therapy and careful, repeated clinical assessment will be important.

THE FUTURE

Although a decade has passed since the introduction of a new pharmacologic treatment for the management of acute heart failure, important progress has been made recently toward the development of novel, more directed, and perhaps safer therapies. As with the pharmacologic approach for treating chronic heart failure, the treatment of acute hemodynamic compromise may also follow the neurohormonal paradigm. One or more drugs directed toward specific neurohormonal abnormalities of acute heart failure likely will be approved in the near future. Certainly, the continued development of aggressive myocardial reperfusion strategies will be important for the majority who present with acute ischemia and infarction to minimize ventricular remodeling and left ventricular dysfunction. Advances toward smaller, totally implantable mechanical devices will also continue.

OVERVIEW

Treatment of heart failure is a challenging task that depends on making the proper diagnosis, staging the syndrome severity, and choosing interventions that are likely to diminish suffering while decreasing an exceptionally high mortality. Contemporary insight into the pathophysiology of heart failure has set the stage for designing and implementing a large number of clinical trials, whose results give guidance when planning medical therapies and surgical adventures. No longer is treatment of heart failure the simple dispensation of a diuretic and digitalis preparation. Therapies are now very complicated, and an appreciation of the sometimes subtle nuances of the heart failure syndrome is mandatory if greater strides are to be made with treatment paradigms. Medications for heart failure have evolved from diuretics to digoxin to vasodilators to angiotensin-converting enzyme (ACE) inhibitors to angiotensin II receptor blockers to beta-adrenergic receptor blockers, and they have included a vast variety of drug combinations. A greater focus has more recently been placed on surgical treatment of heart failure. Implantable arrhythmia management devices and biventricular cardiac resynchronizing pacemakers are presently undergoing intense study. Equally important has been clarification of therapeutic strategies that have proved detrimental in heart failure patients, such as use of certain inotropic and antiarrhythmic agents. Much can be done today to ameliorate heart failure's devastating natural course, and familiarity with treatment options is essential. We are now seeing another paradigm shift occurring in heart failure treatment: the early diagnosis of cardiac failure such that "preventive" strategies can be implemented in an attempt to forestall ventricular function deterioration and manifest congestive heart failure. Furthermore, it is now well established that use of agents capable of countermanding the complicated neurohumoral cascade characteristic of heart failure (ACE inhibitors and beta-blockers) is the primary focus when considering therapeutic options. Greater understanding of the molecular dynamics, humoral perturbation, and circulatory insufficiency characteristic of heart failure will lead to even newer and more radical heart failure treatments.

HISTORICAL PERSPECTIVES ON THE TREATMENT OF HEART FAILURE

Evolution of Heart Failure Therapies Related to Pathophysiologic Insight

Treating patients with heart failure is no longer the simple matter of prescribing concoctions of digitalis and primitive diuretics. Largely because of insight gained from well-designed and meticulously performed clinical trials undertaken to define better strategies with new drugs, therapeutic schemes have become very complicated. Substantive evolution of treatment paradigms has occurred (Table 92.1). Therapies have moved from crude attempts to relieve dropsy toward the amelioration of hemodynamic and, subsequently, neurohormonal perturbation characteristic of the syndrome (1,2 and 3). Today, strategies that block or ameliorate adverse remodeling seem most important (4,5 and 6). Future treatment paradigms will shift toward attenuation of inflammatory processes important in the pathophysiology of heart failure and toward blocking, at the molecular signaling level, necrotic or apoptotic events that lead to cell death. A wide array of surgical, electrophysiologic, and pharmacologic treatment options are now available, and prescribing safe and effective therapies requires a sophisticated understanding of the etiology and pathophysiology of the syndrome as well as drug effects, arrhythmia management, and anticipated surgical results.

Heart failure is a dropsical condition.
Lymphatic drainage tubes
Primitive diuretic therapies
Foxglove tea
Heart failure is central cardiac pump inadequacy.
Cardiac glycoside preparations
Alternative inotropic therapies
Cardiac transplantation
Mechanical ventricular assist devices and total artificial hearts
Heart failure is caused by decompensated ventricular hypertrophy.
Antihypertensive therapy
Surgical repair of valvular defects
Heart failure is circulatory dysfunction.
Vasodilator therapy
Heart failure is an endocrinopathy.
Angiotensin-converting enzyme inhibitor therapy
Angiotensin II receptor blockade
Beta-blocker use
Heart failure is a fever.
Development of cytokine-modulating agents
Heart failure is a complicated milieu of pump dysfunction, myocardial remodeling, humoral perturbation, and subsequent circulatory insufficiency.
Angiotensin-converting enzyme inhibitor therapy
Digoxin therapy
Diuretic therapy
Beta-blocker therapy
Surgical therapies (revascularization, remodeling, valve repair, transplantation)

TABLE 92.1 PROGRESS OF UNDERSTANDING OF HEART FAILURE RELATED TO THERAPIES

Today's spectrum of options should be placed in the perspective of the limited strategies previously available. Before the seminal publication of William Withering's marvelously accurate monograph on the Shropshire maid's remedy for dropsy, *An Account of the Foxglove*, in 1785 (7), Thomas Sydenham (in 1683) suggested bleeding, purges, vomiting, blistering, garlic, and wine or good ale as therapies (8). Although there had been a tenuous intellectual link between the heart and certain dropsical conditions at the time of Withering's publication, it would be many decades before clear-cut relationships would be described. Withering, however, knew the implications of giving foxglove preparations to the wrong patients or in improper dosages (7). He cautioned against treating dropsical patients who had robust and regular pulses, indicating that these individuals simply became toxic with the potion and, seemingly, did not achieve effective diuresis. Excessive or excessively concentrated foxglove tea would, Withering pointed out, precipitate a spectrum of nausea, vomiting, visual disturbances, and cardiovascular collapse. In responders to his therapy, it is likely that the prescient Withering was observing dropsical states with atrial fibrillation; the weak and thready pulse, coupled with pale countenance, characterized patients he thought would likely respond to the herb. Dropsical patients with nephrotic syndrome, tuberculosis, peritonitis, myxedema, or cirrhosis of the liver (conditions common in Withering's day) would be more likely to have robust and regular pulses with ruddy complexion and not be expected to diurese with a foxglove preparation. These observations hold true today and follow more contemporaneous and important tenets of heart failure therapeutics, which emphasize the necessity of ensuring that a given patient's symptomatology and physical findings, are, in fact, due to heart failure and not some other disease that produces edematous states.

Treatment paradigms for dropsical conditions due to heart failure shifted slowly. In 1812, Corvisart, in *Essay on the Organic Diseases and Lesions of the Heart and Great Vessels* (9), continued to suggest purges, bleeding, leaches, squill (a glycoside preparation), physical removal of ascites and pleural effusions, puncture of

edematous legs, and nitrated drinks for dropsy. The mid-nineteenth century saw more aggressive use of diuretics, although the agents were rather primitive and weak, being primarily mercurial preparations (calomel) and potassium bitartrate. Subcutaneous morphine sulfate injections came into use in the late 1860s. The Karrell diet, which was primarily skimmed milk (relatively low in sodium), was proposed in 1866. In Austin Flint's 1873 edition of *A Treatise on the Principles and Practice of Medicine* (10), dropsy due to decompensated ventricular hypertrophy was said to respond to digitalis, ether, dry cupping, opiates, cathartics, incisions, and organ-cavity space puncture. Southey tubes inserted into leg lymphatics were introduced in 1877, and bromides for sedation were also urged at that time. Diuretics used in that period included theophylline, theobromine, and urea salts. Catharsis and venesection were still much practiced in the late 1800s. Supplemental oxygen therapy was urged in the early 1900s, and in James MacKenzie's 1910 edition of *Diseases of the Heart* (11), amyl nitrate was suggested as therapy as well as digitalis, oxygen, purgatives, and venesection. Mercurial diuretics were used with increasing frequency in the 1920s and 1930s, as was thyroidectomy in severe cases. The cardiac chair was introduced about this time, and diet therapies began to focus seriously on water and salt restriction. Bed rest was virtually always a component of therapies, culminating in the late 1950s and early 1960s with recommendations of Birch and colleagues for complete and compulsive long-term bed rest for patients with cardiomyopathy (12). In Arthur Fishberg's 1937 *Heart Disease* (13), recommendations can be found to treat atrial fibrillation and flutter with quinidine and digitalis. Fishberg also proposed thyroidectomy as an alternative, albeit aggressive, therapy. The carbonic anhydrase inhibitor acetazolamide (Diamox) was introduced in 1950 and hexamethonium in 1956. Ligation of the inferior vena cava was a treatment used in 1952. Friedberg continued to suggest thyroidectomy and radioactive iodine ablation of the thyroid gland for severe heart failure in his second edition of *Diseases of the Heart* (1956) (14). Intraaortic balloon counterpulsation for hemodynamic collapse secondary to severe heart failure was proposed in 1961 (15), and Lillehei and coworkers introduced left ventricular aneurysmectomy as a surgical treatment of heart failure in 1962 (16). Lown and colleagues promoted electrical cardioversion for atrial fibrillation complicating heart failure in 1962 (17), and the era of cardiac valvular surgery as therapy for heart failure due to valvular stenosis or insufficiency began in earnest. Thiazide diuretics were introduced in 1962, furosemide in 1965, and ethacrynic acid (Edecrin) in 1966. The first human-to-human cardiac transplant was performed in 1967 (18). The 1970s were characterized by use of vasodilator therapies (19), in general, and new inotropic preparations were pursued in earnest as the Holy Grail of heart failure therapeutics (20). Dopamine was introduced by Goldberg in 1972, nitroprusside by Guiaha in 1974, dobutamine by Tuttle in 1975, and hydralazine in 1977. J. Willis Hurst and colleagues' 1978 textbook, *The Heart* (21), recommended decreasing physical and emotional stress, low-salt diet, digitalis, diuretics (including thiazide, furosemide, ethacrynic acid, spironolactone, and mercurials), and vasodilators (including nitroprusside, isosorbide dinitrate, and hydralazine) in certain heart failure states. Captopril was introduced in 1980 and enalapril in 1984. Indeed, the decade of the 1980s can best be characterized as the era of the ACE I inhibitor in heart failure (4,5,22,23 and 24). Many landmark clinical trials were performed beginning in the late 1970s (extending through today) that promoted better definitions and modern therapies for the syndrome. These trials focused on pharmaceutical strategies as well as operative intervention. The 1980s and 1990s also were decades characterizing heart failure treatment practices that, although intuitive, ended up actually increasing mortality. Several inotropic agents with varying degrees of vasodilating properties seemingly improved heart failure symptoms, but at the cost of higher death rates (20,25,26). Certain antiarrhythmic agents were found detrimental in the face of left ventricular dysfunction, even though heart failure patients frequently die of malignant ventricular arrhythmias, and it seemed logical to eliminate the arrhythmias (27,28). Trials suggested that calcium channel blockers, despite being potent arteriolar dilators, as a group seemed to produce more problems than benefits in heart failure cohorts.

The 1990s have been marked by continued paradigm shift with better, but still incomplete, clarification of the role of digitalis (29,30 and 31) and beta-blockers (4,32,33) and with heart failure assuming a more prominent profile. Professional and public awareness of the heart failure pandemic increased, and it became clear that strategies should focus more on the asymptomatic patient with left ventricular dysfunction. An awareness that heart failure was not solely a "congestive" state, but, rather, a complicated spectrum of cardiac dysfunction seen in patients entirely asymptomatic as well as those with fulminant pulmonary edema or shock. Although beta-blockers were first given to heart failure patients in the 1970s, two decades of drug package inserts have warned of their use in patients with heart failure. The 1990s appeared to be an the era of clarifying the importance of this strategy. Indeed, as we enter the twenty-first century, the treatment paradigm shift continues, with a focus now on interdiction of the alpha- and beta-adrenergic cascades known to be important in heart failure (32,33,34 and 35) and more recently identified inflammatory components of the syndrome (36,37,38,39 and 40). More complete blockade of the renin-angiotensin-aldosterone pathway has been attempted with specific angiotensin II receptor antagonists. The past decade has also seen mechanical left ventricular assist devices emerging as lifesaving options in seriously ill patients with cardiogenic shock, and they have become frequently used tools to "bridge" patients to recovery or cardiac transplantation (41). Programs began to evaluate use of these machines as long-term heart failure treatment options as well (42).

Prescription Practice in Heart Failure

To set the stage for contemporary heart failure treatment recommendations, it is important to mark more recent practice patterns (43,44,45,46,47 and 48). Studies of Left Ventricular Dysfunction (SOLVD) and the Studies of Patients Intolerant to Converting Enzyme inhibitors (SPICE) trial registries were two of the most extensive evaluations of patterns of medication use in patients with heart failure (44,47) undertaken to date. They are important data sets to review because they document the change in prescription practice with regard to heart failure over the last decade. In SOLVD, drug use was analyzed in almost 6,000 patients participating in a registry running concurrently with the two SOLVD clinical trials from 1986 through 1989. The SOLVD Registry comprised a broad spectrum of patients with heart failure, including some with predominantly diastolic dysfunction. Drug use was determined in a population cross-section manner at the time patients were identified as having "heart failure." Almost three-fourths of the patients were evaluated during a hospitalization. The median number of cardiovascular drugs used per patient was four (Fig. 92.1), with diuretics taken by 62%, digitalis by 45%, ACE inhibitors by 32%, calcium channel blockers by 36%, antiarrhythmics (nonamiodarone) by 22%, and beta-blockers by 18%. At that time (data were compiled between January 1988 and February 1989), only 18% were on the combination of ACE inhibitor, diuretic, and digitalis. Stratification for diagnosis, heart failure symptoms, and ejection fraction demonstrated that triple-drug therapy (digitalis, diuretic, and ACE inhibitor) was common only in patients with ejection fraction less than 20% and several concomitant signs or symptoms of heart failure. "Preventive" strategies in individuals with a few symptoms did not appear to be common practice. Older patients were taking diuretics frequently (73% of patients older than 70 years).

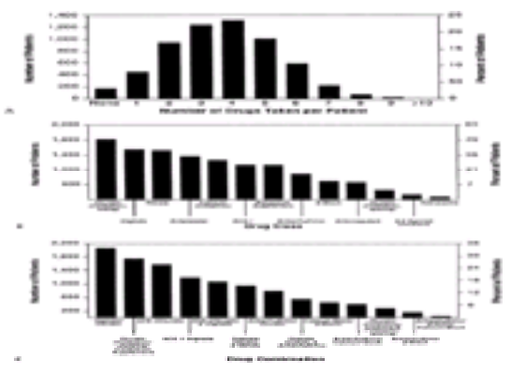

FIGURE 92.1 Data from 5,999 patients in the Studies of Left Ventricular Dysfunction (SOLVD) Registry indicated that the median number of cardiac drugs taken per patient with heart failure was four **(A)**. The rank-order histographic plot of drugs most commonly used by registry participants **(B)** and the most common drug combinations **(C)**. These data were compiled in 1988 and, therefore, represent the prescription practice to which we should compare contemporaneous habits. In 1988, more calcium antagonists were used than angiotensin-converting enzyme (ACE-I) inhibitors in patients with heart failure, and antiarrhythmic therapies (generally Vaughn Williams class I agents) were noted in approximately one-fifth of patients. Triple therapy (i.e., ACE inhibitor, diuretic, and digitalis) were used in less than 20% of patients with heart failure at that time. [Modified from Young JB, Weiner DH, Yusuf S, et al. Patterns of medication use in patients with heart failure: a report from the registry of Studies of Left Ventricular Dysfunction (SOLVD). *South Med J* 1994;88:514–523.]

The SPICE Trial Registry was designed to evaluate heart failure treatment practices, and, more specifically, determine the incidence of ACE inhibitor intolerance in an "optimal" practice situation (48). Between 1996 and 1997, study centers located in eight American and European countries retrospectively reviewed the medical records of 100 consecutive patients with heart failure and an ejection fraction less than or equal to 35%. There were 9,580 subjects studied, and the mean age was 66 years with 26% women and a median ejection fraction of 27%. Ischemic heart disease was the primary cause of the heart failure in 63% of the population. ACE inhibitors were used in 80% of the patients, and this likely represents an ideal circumstance because the study was conducted at largely academic medical centers with education and interests in this issue. The most common reason for not using ACE inhibitors was intolerance, and of these patients, 80% were said to be intolerant because of cough. Figure 92.2 compares the use of medications, generally, in the SPICE and SOLVD Registries, giving insight into the changing prescription practices in heart failure evolving over the last decade. The difference in the prevalence of ACE inhibitors was the most obvious difference, with 30% of the SOLVD Registry population on these agents compared with 80% in SPICE. This likely reflects the acceptance of clinical trial results into day-to-day clinical practice. Other descriptive differences between the groups merit commentary as well. The higher use of diuretics among SPICE Registry patients may reflect more advanced heart failure symptoms as the prevalence of New York Heart Association (NYHA) class III or IV in the SPICE Registry was 43% compared with 32% in the SOLVD Treatment Trial and 17% in the SOLVD Registry. The increase in the use of beta-blockers in SPICE may be related to the growing acceptance of the important role these agents play in ameliorating perturbed neurohormonal activation in patients with heart failure. Of course, today, it is known that these agents are essential. The increase in the use of digoxin and warfarin in the SPICE Registry probably relates to the higher prevalence of atrial fibrillation (27% vs. 14% in the SOLVD Registry). Interestingly, the use of calcium channel antagonists and antiarrhythmic drugs in SPICE was less than that noted in SOLVD. This is not surprising given the results of several clinical trials that were published in the intervening period that showed increased mortality in post–myocardial infarction patients with left ventricular dysfunction treated with class I antiarrhythmic agents (49). As well, several intervening studies suggested that calcium channel antagonists (particularly short-acting dihydropyridines) may increase mortality in patients with heart failure (50,51). Perhaps the differences in the use of certain cardiovascular medications as noted in the SOLVD-SPICE Registry

comparison indicate that so-called evidence-based medicine has had an effect on routine clinical practice (52).

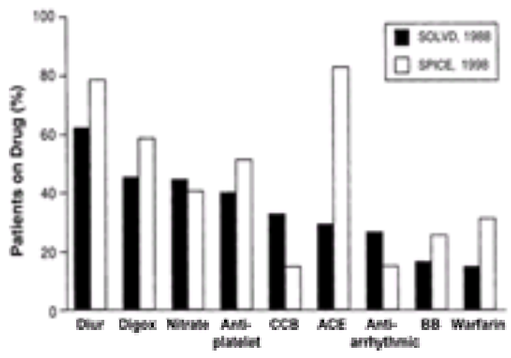

FIGURE 92.2 Comparison of Studies of Left Ventricular Dysfunction (SOLVD) Registry medication use (1988) to the Studies of Patients Intolerant to Converting Enzyme Inhibitors (SPICE) Registry (1998). More angiotensin-converting enzyme (ACE) inhibitors and beta-blockers (BB) are used today, with fewer calcium channel blocker (CCB) and class I antiarrhythmic medications prescribed. Nonetheless, optimal treatment prescription practices have not generally been met. Digox, digoxin; Diur, diuretics.

It is accepted today that congestive heart failure patients should be treated with combinations of ACE inhibitors, diuretics, and digoxin (22,53,54,55,56,57,58 and 59). This should be compared with patterns of practice identified by the Clinical Quality Improvement Network Investigators (45). Perhaps giving a more real world assessment of ACE inhibitor use in heart failure, this audit of 4,606 consecutive hospitalized patient charts between 1992 and 1993 demonstrated that diuretics were used in 86% of heart failure patients, ACE inhibitors in 53%, long-acting nitrates in 49%, digoxin in 46%, potassium supplements in 40%, aspirin in 36%, calcium channel antagonists in 20%, warfarin in 17%, beta-adrenergic blockers in 15%, and magnesium supplements in 10%. Hospital mortality was high in this cohort (19%), with 30% of the deaths due to noncardiovascular causes. More data accumulated in 1994 and 1995 in Ohio also suggest that ACE inhibitors are underused in at-risk heart failure patients (46). The Ohio Peer Review Project analyzed the records of 760 patients in 21 hospitals admitted with a principal diagnosis of congestive heart failure. In those having objective measurements of left ventricular ejection fraction less than 40%, with serum creatinine less than 3.0 mg per dL, serum potassium less than 5.5 mEq per L, and systolic blood pressure greater than 90 mm Hg (n = 381), an assessment of admission and discharge medications was made with respect to ACE inhibitor use. Patients in both rural (n = 280) and urban (n = 480) hospitals were evaluated. Mean patient age was approximately 75 years, and 55% were men. In cases eligible for ACE inhibitors at hospital discharge, 16% were said to have contraindications to ACE inhibitors at hospital admission. No difference with respect to hospital type or location was noted with respect to ACE inhibitor use. Although only 37.7% of patients with documented systolic dysfunction were on ACE inhibitors at admission, 73% were prescribed this drug class at discharge.

Now that beta-blockers are also considered important adjuncts to a heart failure patient's polypharmacy protocol, new approaches to educating care givers and patients about the importance of compliance with consensus statement recommendations are needed. Perhaps implementation of heart failure disease management protocols will be helpful (58,59). Although the observations regarding the increasing number of heart failure patients being treated with ACE inhibitors is reassuring in some senses, it is obvious that a large cohort of patients who would likely benefit from this class of drugs is not being so treated. Also troublesome is the fact that patients were often noted to be on medication doses lower than those generally used in the ACE inhibitor heart failure trials. What dose of beta-blocker and ACE inhibitor to prescribe to patients with heart failure has become contentious, with some suggesting that aggressive dosing of these drugs is best, whereas others are content to see patients simply on, at the least, the combination of any dose of the agents (60,61).

CREATING A CHRONIC HEART FAILURE MANAGEMENT STRATEGY

Therapeutic Philosophy

*e*Table 92.1.1 addresses the contemporary definition of heart failure and summarizes important considerations during patient evaluation that emphasize treatment strategies (1,2 and 3,61,63). A variety of injurious processes can cause acute or chronic myocardial dysfunction (diastolic or systolic and right-sided or left-sided heart dysfunction). Injured myocytes, because of inotropic and lusitropic dysfunction, are exposed to passive tension and workload demand changes that translate, ultimately, into increased preload and afterload. This sets the stage for detrimental cardiac remodeling (2,64,65,66 and 67). Therapies designed to normalize these hemodynamic perturbations seem logical. Less easy to address is myocyte interstitial matrix deposition, which occurs in heart failure and causes stiffening of the myocardium, with all its diastolic dysfunction implications (67,68 and 69). Strategies (not yet clearly defined) that prevent inflammation and fibrosis may become important with respect to this issue. The aforementioned mechanical alterations produce peripheral vascular bed flow decrement in either subtle or more obvious fashion (70,71). Therein lies the attraction of using agents that increase stroke volume (vasodilators or inotropic agents, for example). The combination of mechanical cardiovascular and peripheral vascular blood flow changes triggers a variety of humoral, neurohormonal, and inflammatory responses, which initially appear to create systemic organ flow compensation. Ultimately, these factors intertwine to precipitate detrimental remodeling of the heart (cardiac hypertrophy and chamber dilation) and provide targets for therapies that can block molecular factors leading to this remodeling. Because these processes vary in degree from patient to patient, individuals may present without symptoms or suffer from a variety of fatigue, dyspnea, or fluid retention states that fluctuate based on treatment protocols, diet, physical conditioning, and diseases that caused the problem in the first place. Obviously, findings such as valvular heart disease, coronary artery occlusions, cardiac conduction disturbances, and ventricular or atrial arrhythmias important in the pathophysiology of heart failure need to be surgically or electrophysiologically addressed as well.

***e*TABLE 92.1.1** A CONTEMPORARY DEFINITION OF HEART FAILURE RELATED TO THERAPIES
Myocardial injury causes acute or chronic myocyte dysfunction (systolic or diastolic or both).
Prevent injury to the heart
Myocyte passive tension and workloads change.
Preload and afterload reduction
Myocyte interstitial matrix stiffens.
Prevent inflammation and fibrosis
Peripheral vascular bed blood flow is altered (generally decreased in subtle fashion).
Increase cardiac output and organ perfusion
Subsequent mechanical, humoral, neurohumoral, and inflammatory responses appear in an attempt to create systemic organ flow compensation.
Block adverse humoral factors
Compensatory mechanisms ultimately produce a maladaptive circulatory state.
Reverse remodeling of the heart and vascular network
Patients may present without symptoms or suffer from a variety of fatigue, dyspnea, or dropsical states that fluctuate in severity based on treatment protocols, diet, physical conditioning, and diseases that precipitate the heart failure syndrome.
Design therapies based on syndrome stage
In addition to ameliorating symptoms with tailored treatment strategies, early identification of patients with insidious hemodynamic and hormonal perturbation is critical so that therapy can attenuate heart failure morbidity and decrease mortality.

Figure 92.3 links an overview of heart failure therapy to prevention and treatment strategies. Besides ameliorating symptoms with tailored therapeutic programs, identifying individuals with insidious hemodynamic and hormonal perturbation early on is critical so that therapy can be given early in the syndrome's course to prevent development of symptomatic heart failure. It is imperative that treatment of asymptomatic ventricular dysfunction begin early to interdict harmful remodeling. Obviously, treatment strategies are designed to ameliorate symptoms when present, maintain functional capacity at maximal levels, keep patients out of the hospital, reduce mortality, and reverse remodeling.

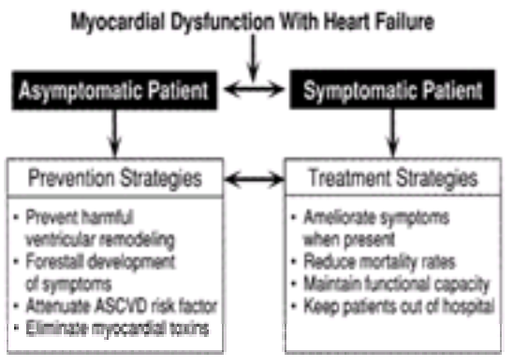

FIGURE 92.3 This diagram emphasizes the importance of a philosophy of heart failure therapy that focuses on practices revolving around *prevention* strategies for the asymptomatic patient and *treatment* strategies for the symptomatic patient. Obviously, one would like to identify myocardial dysfunction in asymptomatic or minimally symptomatic individuals early on so that intervention has the greatest likelihood of preventing ventricular function deterioration and subsequent symptoms. When symptoms are present, treatment protocols should move patients into an asymptomatic position. ASCVD, arteriosclerotic cardiovascular disease.

Table 92.2 summarizes important questions to ask when designing protocols for patients with chronic heart failure (62,63). Does the patient actually suffer from heart failure and are symptoms or physical findings related to this difficulty? Many patients with weakness, fatigue, dyspnea, and dropsical states do not have heart failure. Furthermore, patients with heart failure may present with these symptoms and physical findings, but the symptoms are related to ancillary comorbidities rather than cardiac dysfunction. What is the etiology of the syndrome? This question forces consideration of diseases that can be treated and eliminated or, at the least, ameliorated, such that progression of the heart failure milieu is halted. Following this is questioning what evaluation is needed to confirm the diagnosis and stage the syndrome severity. Indeed, it is important to note what precipitated the patient's deterioration. Frequently, medication noncompliance, excessive sodium or fluid consumption, worsening ischemic syndromes, atrial and ventricular arrhythmias, intercurrent infection, uncontrolled chronic obstructive pulmonary disease, diabetes mellitus, and hypertension plunge patients into the realm of symptomatic congestive heart failure. Staging the syndrome severity is critical to answering the question of what a patient's short- and long-term prognosis might be. A question that often goes unasked is whether the patient takes medications that can be detrimental in the heart failure setting, such as nonsteroidal antiinflammatory agents, certain calcium channel blockers, and Vaughn Williams class I antiarrhythmic drugs. Obviously, designing a treatment protocol is intimately linked to the question of how the patient should be treated acutely as well as chronically (22,53,57,72,73,74,75 and 76). Often, we neglect social factors that play a significant role in morbidity, and we should always ask what social support mechanisms that can be considered adjunctive nonpharmacologic treatments are available to the patient (73). Again, it is critical to remember that patients with heart failure have varied clinical presentations as they move from asymptomatic cardiac dysfunction to symptomatic heart failure. Complicating this issue further is the fact that patients make this transition over highly variable time intervals.

Does the patient actually suffer from heart failure, and are presenting symptoms or physical findings related to this difficulty?
What is the etiology of the syndrome?
What evaluation is needed to confirm diagnosis, clarify etiology, and stage syndrome severity?
What precipitated the patient's deterioration?
How severe is the heart failure syndrome, and what are the patient's short- and long-term prognoses?
Is the patient on medications that are potentially detrimental in the heart failure milieu?
How should the patient be treated acutely?
How should the patient be treated chronically?
Can the precipitating disease process be cured, or can the state of heart failure be ameliorated?
What social factors played a role in morbidity, and what social support mechanisms should be considered as adjunctive therapeutic measures?

TABLE 92.2 INTEGRATION OF DIAGNOSTIC EVALUATION INTO A MANAGEMENT STRATEGY: QUESTIONS TO ASK WHEN DESIGNING THERAPEUTIC PROTOCOLS FOR CHRONIC HEART FAILURE PATIENTS

Guidelines for Heart Failure Patient Evaluation and Management

The Agency for Health Care Policy and Research (AHCPR) published the first guidelines for evaluating and treating heart failure patients in 1994 (72,73,74,75 and 76). Subsequently, guidelines have emerged from several groups as our knowledge base increased (see Table 92.3 for a listing). Diagnosis and treatment algorithms subsequently have been based largely on experience gained during the performance of carefully controlled clinical trials evaluating a variety of strategies. These trials are subsequently reviewed. In general, a well-constructed practice guideline specifies the types of professionals involved in developing the guideline, defines the methods of primary evidence analysis, and provides a grading of one sort or another to characterize the strength of data the recommendations are based on. There are several problems with clinical practice guidelines, however. Generally, the guidelines do not emphasize the importance of risk stratification with regard to syndrome severity (particularly in asymptomatic or minimally symptomatic patients and more advanced, decompensated patients), and, therefore, largely ignore the issue of tailoring therapies to patients in the mildly or severely ill categories. Furthermore, guidelines cannot possibly address all relevant clinical situations (76). Often, consensus cannot be reached because evidence is not always available regarding certain therapeutic strategies. Guideline development can be a slow, politically charged, and ponderous process with guidelines being slow to respond to new knowledge and therapies. It is also difficult to educate clinicians regarding guidelines, and many practitioners perceive guidelines as being intrusive and excessively regulatory. Nonetheless, practice guidelines are, arguably, the best method of defining treatment practices that continuing quality improvement programs can use to grade any health care provider's practice.

Guidelines	Year published
U.S. Department of Health and Human Services, Agency for Health Care Policy and Research (Clinical Practice Guideline no. 11, publication 94-0612)	1994
American College of Cardiology/American Heart Association Guidelines for the Evaluation and Management of Heart Failure (*Circulation* 1995;92:2764)	1995
World Health Organization Heart Failure Guidelines (*J Card Fail* 1996;2:153)	1996
European Society of Cardiology Heart Failure Guidelines (*Eur Heart J* 1997;18:736)	1997
ACTION Heart Failure Treatment Guidelines [*Am J Cardiol* 1999;83(2A):1]	1999
Heart Failure Society of America Guidelines for the Management of Heart Failure (*J Card Fail* 1999;5:358)	1999

TABLE 92.3 CLINICAL HEART FAILURE GUIDELINES

The commonest themes of all of these guidelines are summarized in Table 92.4. All guidelines support an aggressive approach to diagnosing and treating patients with active ischemia and left ventricular dysfunction. The guidelines are unanimous in recommending ACE inhibitors in all patients with left ventricular systolic dysfunction. The more recent guidelines address use of beta-blockers in stable patients with mild to moderate heart failure symptoms and no significant congestion. All guidelines suggest avoiding agents with incomplete benefit-risk profiles and reminding clinicians about diagnosing and treating underlying and precipitating difficulties. Furthermore, most of the guidelines emphasize the importance of prescribing nonpharmacologic therapy such as exercise and salt and fluid restriction while addressing patient education about heart failure. Largely ignored in present guidelines are patients with congestive heart failure but preserved left ventricular systolic function and management of advanced heart failure (particularly the acutely decompensated chronic heart failure patient who requires hospitalization and the terminal "hospice-type" patient with heart failure).

Identify and aggressively treat ischemia in patients with heart failure (revascularization)
Use angiotensin-converting enzyme inhibitors in all tolerant patients with left ventricular systolic dysfunction
Use beta-blockers in stable patients with mild to moderate symptoms and no significant congestion
Avoid agents with incomplete benefit-risk profiles
Diagnose and address underlying and precipitating disorders
Prescribe nonpharmacologic therapies
Exercise
Salt and fluid restriction
Educate patient, family, and care givers

TABLE 92.4 MOST COMMON THEMES OF HEART FAILURE GUIDELINES

The AHCPR algorithm (72) specifically suggests evaluation of all patients with symptoms suggestive of heart failure, such as paroxysmal nocturnal dyspnea, orthopnea, dyspnea on exertion, lower-extremity edema, decreased exercise tolerance, unexplained confusion, altered mental status or fatigue in an elderly patient, and abdominal complaints associated with ascites and hepatic engorgement (nausea or abdominal pain). The algorithm stresses the importance of a physical examination to elicit findings supportive of congestive heart failure, such as elevated jugular venous pressure or positive abdominal jugular reflex, a third heart sound, a laterally displaced apical cardiac impulse, pulmonary rales not clearing with cough, and peripheral edema not due to simple venous insufficiency. In individuals with symptoms and physical findings suggestive of heart failure, determination of left ventricular function is mandated. Echocardiographic and radionuclide ventriculographic studies are important to quantify the degree of systolic left ventricular dysfunction. Echocardiography was thought to be more advantageous because it permitted concomitant assessment of valvular heart disease, left ventricular hypertrophy, chamber dimension, and left atrial size. Furthermore, this technique is generally less expensive and more readily available than radionuclide ventriculography. Ancillary tests suggested included electrocardiography, a complete blood cell count, urine analysis, serum creatinine, serum albumin, and thyroid function tests. To broaden the scope of catchment populations and assist in characterization of patient-specific therapies, AHCPR and other guidelines should be amended to include a category that refers patients at high risk of having occult left ventricular systolic dysfunction for an estimation of left ventricular ejection fraction. It is probably prudent to perform echocardiography, for example, in every patient suffering an acute myocardial infarction, particularly if more than one has occurred in the past. Additionally, elderly patients having had chronic hypertension, prior coronary artery bypass graft surgery, or percutaneous coronary interventions (particularly in the setting of comorbid conditions, such as diabetes mellitus, cerebrovascular accidents, or peripheral vascular disease) should have echocardiography performed at some intermittent screening interval that has yet to be optimally characterized.

CLINICAL TRIAL INSIGHTS

Certainly, clinical trials cannot answer all questions about heart failure therapeutics. Anecdotal experience as well as more detailed, but small, uncontrolled experimental paradigms can offer guidance. Clinical trials performed in heart failure cohorts are limited by certain design difficulties. There is a tremendous winnowing of patients screened for these studies, for example, and it is not unusual to see a 10:1 or 20:1 ratio of patient screening to trial entry. Figure 92.4 and Figure 92.5 depict mortality end points in a variety of clinical heart failure trials and emphasize, by reviewing placebo group death rates, the tremendous heterogeneity of populations included in the trials. To be successful, clinical trials require that specific questions be asked in well-characterized and relatively homogeneous patient populations; therefore, the most challenging patient to manage (the aged patient, female in particular, with multiple comorbidities) is often not allowed into clinical trials. Unfortunately, there is a large underrepresentation of women, minority races, the elderly, and youth in clinical trials. Furthermore, end points used to evaluate potentially beneficial or detrimental treatment strategies are sometimes imprecise or not necessarily clinically relevant. Another difficulty is that the studies are performed on varying “background” pharmacotherapeutic strategies. It is extremely important to assess clinical trials with respect to their analyzed end points and the power with which the study was designed to answer the questions asked. It must be emphasized that the success of a clinical trial is not rooted solely in demonstration of a positive result. Trials that do not support a priori hypotheses are sometimes more important than those that do because they can clarify what should be done in these populations as well as strategies that should not be pursued.

FIGURE 92.4 An algorithm for diagnosis and pharmacologic management of heart failure (HF) patients that focuses largely on symptomatic out-of-hospital patients with suspected congestive HF. In these patients, initiating diuretic, angiotensin-converting enzyme (ACE) inhibitor therapy, and beta-blockers is initially recommended, with addition of digoxin and other vasodilating agents suggested for cases with persistent symptomatology. BMI, body mass index; CAD, coronary artery disease; CPK-MB, creatine phosphokinase-MB; ECG, electrocardiography; ED, emergency department; ETOH, ethanol; NSAIDs, nonsteroidal antiinflammatory drugs; NYHA, New York Heart Association; Tx, treatment.

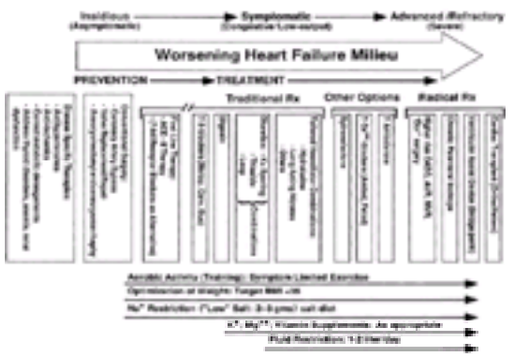

FIGURE 92.5 This figure graphically plots a scheme for tailoring therapies to individual heart failure patients. It is based on the fact that treatments change as the heart failure milieu worsens. Preventive strategies are recommended for individuals with insidious and asymptomatic or minimally symptomatic heart failure, with treatment strategies accelerating in intensity as congestive or low-output states worsen. At the root of all treatment protocols, however, is disease-specific therapy. Also important is a variety of lifestyle changes, including aerobic activity training, optimization of weight, and dietary restriction of salt use. ACE, angiotensin-converting enzyme inhibitor; AVR, aortic valve replacement; BMI, body mass index; CABG, coronary artery bypass grafting; MVR, mitral valve replacement.

Despite these issues, the clinical trial remains an excellent method for fashioning rational protocols and identifying their cost effectiveness by exploring schemes that are effective, neutral, or detrimental with respect to endpoint impact. Because of the multiple drugs heart failure patients take and the complicated interrelationship of comorbidities, it is important to create algorithms that include only advantageous strategies. Those that are neutral or disadvantageous should be avoided.

*e*Table 92.4.1 lists select clinical trials that provide important insight into treatment of patients with a wide range of heart failure. Highlighting a few specific trials allows the stage to be set for proffering contemporary heart failure treatment recommendations. The first Veterans Administration Cooperative Vasodilator Heart Failure Trial (V-HeFT-I) (77) was made up of men with moderate congestive heart failure and was a landmark study because it was the first to suggest that vasodilators beneficially affected mortality in patients with congestive heart failure. At the time it was performed, the trial was controversial because conventional wisdom dictated that diuretics and inotropic agents were the most logical approach to congestive heart failure. Insight into detrimental ventricular remodeling in heart failure was not great at that time, but the beneficial effects of direct-acting vasodilators, such as hydralazine and isosorbide dinitrate, on cardiac output and ventricular filling pressures gave rise to the so-called hemodynamic hypothesis of heart failure therapy and led to the design of V-HeFT-I. Specifically, this hypothesis speculated that drugs that lowered impedance to ventricular ejection, with subsequent reduction of diastolic pressures and augmentation of forward flow (or reduction of venous blood return after venodilation with nitrates), was beneficial and decreased mortality and morbidity. This study was also important because it demonstrated disparity among vasodilating drugs. Although the combination of hydralazine and isosorbide dinitrate, prescribed in addition to digoxin and a diuretic, arguably improved morbidity and mortality (the study was relatively small, and its statistical analysis has been criticized), V-HeFT-I showed that the peripherally acting alpha-adrenergic blocking agent prazosin, known to effectively reduce both preload and afterload in heart failure, was no better than placebo. Thus, the conclusion was reached that all vasodilators may not be alike with respect to long-term morbidity and mortality effects. Since V-HeFT-I, we have seen drugs that improve heart failure hemodynamics significantly but produce higher mortality in clinical trials (67,68,69,70,71,72,73,74,75,76,77,78,79,80,81 and 82) (*e*Table 92.4.1).

***e*TABLE 92.4.1** SELECT CLINICAL TRIALS, REGISTRIES, AND EXPERIENCES RELEVANT TO HEART FAILURE

Acronym	Full title	Study design	Findings	Therapeutic implication
AIRE	Acute Infarction Ramipril Evaluation	Effect of ramipril on morbidity and mortality of survivors of acute MI with clinical evidence of heart failure.	Significant reduction in mortality noted with ramipril; findings complement SAVE, SMILE, TRACE, GISSI-III, ISSIS-IV.	ACE inhibitor therapy should be routinely started postinfarct when CHF or left ventricular systolic dysfunction present.
AIREX	Acute Infarction Ramipril Evaluation—Extension Study	Long-term (mean, 59 mo) follow-up of AIRE study patients.	Average duration of “masked” trial drug 12 mo but even poststudy differences in mortality were 39% for placebo vs. 28% for ramipril groups (RR = 36%; 95% CI, 0.15–0.52; *p* = .002).	Ramipril post-MI with heart failure has large and sustained benefit.
ALLHAT	Anti-Hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial	Randomized, double-blind, active drug controlled clinical trial of chlorthalidone, doxazosin, amlodipine, or lisinopril with composite end point of fatal CAD event or nonfatal MI (prevention of CHF) secondary end point (n = 24,335).	Doxazosin arm discontinued early because the diuretic produced equal mortality to the alpha-blocker, but there were fewer strokes and combined CVD events with the risk of CHF doubled with doxazosin at 4 yr (RR = 2.04; 95% CI, 1.79–2.32; *p* <.001).	Doxazosin appears inferior to at least a thiazide diuretic for hypertension for the prevention of CVD events, particularly heart failure (chlorthalidone, amlodipine, and lisinopril arms still running).
APRES	Angiotensin-Converting Enzyme Inhibition Post Revascularization Study	After revascularization, angina patients with EF 0.30–0.50 (asymptomatic) were randomized (double-blind) to ramipril or placebo for mean of 33 mo (n = 159).	ACE inhibitor reduced composite end point of cardiac death, acute MI, CHF, or recurrent angina (RR = .58; 95% CI, 0.07–0.80; *p* = .031).	More evidence for benefits of ACE inhibitor for broad spectrum of LVD/heart failure patients.
ATLAS	Assessment of Treatment with Lisinopril and Survival	Survival study of high- (approximately 35 mg) vs. low-dose (approximately 5 mg) lisinopril in moderate to severe CHF (n = 3,164).	No mortality benefit with high ACE inhibitor dose, but hospitalizations and morbidity diminished.	High target ACE inhibitor dose likely wise.

AVID	Antiarrhythmics Versus Implantable Defibrillators Trial	Randomized comparison in resuscitated (near fatal ventricular fibrillation or symptomatic ventricular tachycardia) patients with EF <0.40 of AICD vs. antiarrhythmics (amiodarone or sotalol) (n = 1,016).	Survival greater in AICD group (75.4% vs. 64.1% at 3 yr; *p* <.02; a 39% ± 20% reduction in mortality).	In survivors of ventricular fibrillation or symptomatic ventricular tachycardia with low EF, AICDs appeared superior to antiarrhythmic drugs for improving survival.
BASIS	Basel Antiarrhythmic Study of Infarct Survival	Randomized, open, clinical trial of antiarrhythmic (amiodarone) therapy in post-MI patients with asymptomatic complex arrhythmias (frequent multiform or repetitive ventricular arrhythmias); control group, “individualized” antiarrhythmic treatment (drug titrated to eliminate arrhythmia), routine low-dose amiodarone (200 mg daily) (n = 312).	Probability of “survival” (combined end point of mortality and sudden death, sustained ventricular tachycardia/fibrillation) increased with routine amiodarone prescription (10 group 1 vs. 5 group 2 vs. 15 control deaths).	Low-dose amiodarone appears to decrease mortality the first yr after MI when certain asymptomatic ventricular arrhythmias are present; although not a “heart failure” trial, mean EF was 0.43 ± 0.16.
BEST	Beta-Blocker Evaluation Survival	Patients receiving standard treatment randomized to placebo or bucindolol to determine a mortality benefit in moderate to severe heart failure.	No benefit noted in class III and IV CHF patients with bucindolol.	Either bucindolol is a beta-blocker not associated with benefit in heart failure or population studied was resistant to benefit.
CABG-Patch	Coronary Artery Bypass Graft Patch Trial	CAD patients undergoing CABG with EF <0.36 and abnormal SAECG randomized to patch-ICD vs. control with mortality primary end point (n = 1,055).	At mean follow-up of 32 ± 16 mo, the hazard ratio for death was 1.07 (95% CI, 0.81–1.42; *p* = .64); no significant interaction between ICD and baseline variables).	Survival not improved with ICD during CABG in patients with depressed EF and abnormal SAECG.
CAMIAT	Canadian Myocardial Infarction Amiodarone Trial	Patients (n = 120) 6–45 d postinfarction without EF entry criteria but electrocardiographic ventricular arrhythmia followed for combined end point of arrhythmic death or resuscitated ventricular fibrillation; all-cause mortality and cardiac mortality secondary end point.	Primary end point benefitted with amiodarone but toxicity great (42.3% of treatment group stopped amiodarone by 2 yr), all-cause mortality not reduced.	Although not a heart failure trial per se, some patients obviously had LVD; amiodarone may benefit select post-MI patients, but difficult to tolerate.
CAPPP	Captopril Prevention Project	Prospective, randomized, open label trial of captopril vs. conventional (diuretics/beta-blockers) antihypertensive therapies with composite end point of fatal/nonfatal MI, stroke, other CVD deaths (n = 10,985).	No difference in events was observed (RR = 1.05; 95% CI, 0.90–1.22; *p* = .52).	Captopril and conventional therapy did not differ in hypertensives for CVD end points, but captopril dosing did.
CARVEDILOL PROGRAM	The Effect of Carvedilol on Morbidity and Mortality in Patients with Chronic Heart Failure	Combined analysis of four distinct studies with varied patient enrollment criteria and outcome measures analyzing safety data regarding mortality events (n = 1,094).	Carvedilol reduced mortality from 7.8% to 3.2% (*p* <.001); findings and analysis controversial because this was not a prospective mortality endpoint trial; rather, a pooled analysis.	More data supporting use of beta-blocker (this one with alpha-blocking properties as well) in CHF; there may be important differences between selective and nonselective beta-blockers in CHF.
CASH	Cardiac Arrest Study Hamburg	Prospective, randomized trial of AICD vs. antiarrhythmics (amiodarone, propafenone, metoprolol) in SCD survivors (n = 349, 61 with AICD).	With a mean follow-up of 57 ± 34 mo survival was only slightly higher in the AICD group (*p* = .081; RR = .766; 97.5% CI, 1.112).	This study only suggested AICD therapy slightly better (in nonsignificant sense) in SCD survivals; although not a heart failure trial, the mean EF was approximately 45%.
CASS	Coronary Artery Surgery Study	Survival endpoint randomized study of CABG vs. best medical therapy of ischemic heart disease with 10-yr follow-up (n = 780) performed over a decade ago.	CABG did not prolong life or prevent infarcts compared with medical therapy except when EF <50%.	One of several studies to suggest that coronary revascularization is important in patients with heart failure and ischemia.
CAST	Cardiac Arrhythmia Suppression Trial	Mortality endpoint trial of encainide and flecainide post-MI in patients with premature ventricular contractions and, generally, LV dysfunction.	Potent class I antiarrhythmic agents increase mortality in MI patients with LVD.	Avoid Vaughn Williams class I antiarrhythmics in CHF if possible.
CATS	Captopril and Thrombolysis Study	Double-blind, placebo-controlled clinical trial of captopril in patients receiving streptokinase post-MI with remodeling LV function end points (n = 298).	Occurrence of LV dilation significantly lower (*p* = .018) and development of CHF less (*p* = .04) with captopril.	Early post-MI remodeling study showing ACE inhibitor benefits.
CHARM	Candesartan Cilexetil in Heart Failure Assessment of Reduction in Mortality and Morbidity	Placebo-controlled, blinded, mortality endpoint trial of the angiotensin II receptor blocker candesartan in three types of heart failure patients: those with EF >40%, those with EF <40% and ACE inhibitor intolerance, and those with EF <40% and on ACE inhibitor (add-on therapy).	Trial ongoing.	Will help clarify role of an angiotensin II blocker in a wide spectrum of heart failure patients.
CHF-STAT	Congestive Heart Failure–Survival Trial of Antiarrhythmic Therapy	Survival study of amiodarone vs. placebo in CHF patients with 10 PVCs/h.	Amiodarone overall did not improve survival compared with placebo.	Did not support hypothesis that amiodarone was helpful generally in CHF.
CIBIS	Cardiac Insufficiency Bisoprolol Study	Bisoprolol (a selective beta-blocker) added to diuretics/vasodilator with mortality end point.	Trend toward morbidity reduction without statistically significant reduction in mortality.	Added to portfolio suggesting beta-blockers beneficial in some CHF patients.
CIBIS-II	Cardiac Insufficiency Bisoprolol Study-II	Placebo-controlled mortality endpoint trial of 2,647 patients given bisoprolol for 16 mo.	Significant reduction in mortality.	Longer trial than CIBIS-I with more ill population and higher dose of bisoprolol; 34% reduction in mortality, particularly sudden death.

CIDS	Canadian Implantable Defibrillator Study	Sudden cardiac death survivors randomized to either AICD or amiodarone (n = 659).	There was a nonsignificant 20% relative risk reduction (95% CI, –0.07–0.40; *p* = .142) in total mortality with a stronger trend toward reduction of “arrhythmic death” (relative risk reduction of 33%; 95% CI, –0.07–0.58%; *p* = .094). The study was stratified for EF < or >0.35 with mean EF of 0.33 and 12% with EF <0.20.	Dofetilide appears to be a risky drug to use in CHF patients with a long-term neutral effect on mortality but significant proarrhythmia problem.
COMET	Comparison of Metoprolol/Carvedilol Trial	Active drug control design with metoprolol compared with carvedilol in 4,000 stable CHF patients.	Trial ongoing.	Study will give important insight into possible superiority of nonselective, vasodilating beta-blocker in mild to moderate CHF.
CONSENSUS	Cooperative North Scandinavian Enalapril Survival Study	Enalapril added to digoxin and diuretic in severe heart failure (NYHA IV).	Dramatic reduction in mortality at 6 mo.	ACE inhibitor an important addition in CHF.
COPERNICUS	Carvedilol Prospective Randomized Cumulative Survival Trial	Carvedilol vs. placebo in 1,800 NYHA class IIIB/IV CHF with mortality end point.	Significant reduction in mortality.	Most ill CHF group yet studied with beta-blocker.
DIAMOND-CHF (1999)	Danish Investigations of Arrhythmia on Dofetilide Study (Congestive Heart Failure)	Double-blind, placebo-controlled clinical trial of dofetilide in symptomatic congestive heart failure and severe LV dysfunction with mortality the primary end point (n = 1,518).	During a median follow-up of 18 mo there was no difference in mortality (approximately 41%) with the hazard ratio 0.95; 95% CI, 0.81–1.11; but dofetilide decreased CHF hospitalization and converted atrial fibrillation more but with a 3.3% incidence of torsade in the dofetilide group.	Dofetilide appears to be a risky drug to use in CHF patients with a long-term neutral effect on mortality but significant proarrhythmia problem.
DIAMOND-MI (2000)	Danish Investigations of Arrhythmia on Dofetilide Study (Myocardial Infarction)	Double-blind, placebo-controlled mortality endpoint clinical trial of dofetilide in MI survivors with severe LV dysfunction (n = 1,510).	Morbidity and mortality no different in dofetilide and placebo groups.	No antiarrhythmic agent post-MI reduces mortality unlike ACE inhibitor and beta-blockers.
DIG	Digoxin Investigation Group	Survival evaluation to assess the mortality effect of digoxin vs. placebo in stable CHF when used with ACE inhibitor and diuretics (n = 7,000).	No survival benefit with digoxin but morbidity (CHF hospitalizations) reduced.	Digoxin is an important agent in CHF to reduce morbidity but likely has no mortality effect.
DIMT	Dutch Ibopamine Multicenter Trial	Double-blind digoxin and placebo-controlled trials of ibopamine in mild to moderate CHF with exercise capacity, neurohormonal measurements, and function class end points (n = 161).	Digoxin increased exercise time after 6 mo compared with placebo (*p* = .008), whereas ibopamine effective only in patients with EF >0.30. Plasma norepinephrine and renin decreased by both.	Digoxin likely clinically beneficial, whereas ibopamine results need to be placed into the perspective of the other prematurely stopped trials showing detriment (PRIME-II).
ELITE	Evaluation of Losartan in the Elderly	Tolerability and morbidity and mortality study of 722 patients over age 65 with class II, III, IV CHF assigned to either losartan or captopril.	Losartan better tolerated and had lower mortality than captopril.	The angiotensin II receptor blocker losartan may be a reasonable substitute for ACE inhibitor in CHF.
ELITE-II	Evaluation of Losartan in the Elderly-II	Comparison of losartan with captopril with mortality end point in 3,152 NYHA II/IV CHF with EF <40% and age >60.	No mortality difference between ACE inhibitor and angiotensin II blocker in this trial; however, trial not powered to demonstrate equivalence.	Role of angiotensin II blockers in CHF still not clear. One should not substitute an angiotensin II blocker for an ACE inhibitor routinely.
ELVD	Exercise in Left Ventricular Dysfunction Trial	Patients post non–Q-wave MI with EF <0.40 randomized to 6-mo exercise training or control groups with LV volumes and function end points (n = 77).	Exercise training decreased LV volumes and increased EF.	Long-term exercise in post-MI CHF prevents remodeling.
EMIAT	European Myocardial Infarction Amiodarone Trial	Patients 5–21 d post-MI with EF <40% randomized (n = 1,486) with mortality primary end point.	Primary end point, death, not reduced by amiodarone but combined end point of arrhythmic death/resuscitated cardiac arrest reduced slightly.	No definite benefit with amiodarone in post-MI LVD and toxicity of drug significant in this study.
ENOXIMONE	Oral Enoximone in moderate to moderately severe CHF	Randomized placebo-controlled trial of enoximone in combination with digoxin/diuretics with exercise and symptoms primary end points (n = 102).	Enoximone did not improve exercise tolerance or symptoms during 16 wk of therapy, with significantly more dropouts (46% vs. 25%) and more deaths (10 vs. 3; *p* <.05).	Worse survival and questionable benefits raise serious questions about this PDE inhibitor.
ESCAPE	Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness.	Randomized trial designed to test the long-term safety and efficacy of CHF hospital therapy guided by hemodynamics vs. clinical assessment. Primary end point is number of days patients hospitalized or death during 6-mo follow-up (n = 500).	Trial ongoing.	Study will likely demonstrate utility of “hemodynamically” guided CHF therapy.
FACET	Flosequinan ACE-Inhibition Trial	Exercise and QOL endpoint trial with flosequinan, 100 or 75 mg, added to digoxin, diuretic, and ACE inhibitor.	100-mg dose improved patients clinically.	Subsequent mortality trial demonstrated increase in death rates; drug may make patient feel better but at a cost of higher mortality.
FIRST	Flolan International Randomized Survival Trial	Mortality study of conventional therapy vs. continuous i.v. epoprostenol (prostacyclin) in end-stage CHF.	This study was terminated prematurely due to increased mortality and clinical deterioration in the epoprostenol group.	Prostacyclin not an option for chronic parenteral infusion in heart failure; mortality is increased.
GESICA	Group Study of Heart Failure Argentina	Placebo-controlled study of amiodarone in moderate to severe CHF assessing mortality as a primary end point.	Mortality was significantly reduced with amiodarone (42%), compared with placebo (53%).	Suggested amiodarone can be used in some CHF patients.

GROWTH HORMONE	Preliminary Study of Growth Hormone in the Treatment of Dilated Cardiomyopathy	Open label, case series of growth hormone given to IDCM patients with LV function, QOL, clinical class as end points (n = 7).	All parameters improved during 3-mo treatment period (including the development of hypertrophy).	Small pilot study suggesting growth hormone may be beneficial but hypertrophy concerning.
HOPE	Heart Outcomes Prevention Trial	Randomized 2-by-2 factorial design of ramipril and vitamin E in approximately 9,500 patients at high risk of cardiovascular events, including development of CHF.	Impressive reductions in cardiovascular events, including development of CHF, particularly in diabetics with ACE inhibitor but not vitamin E.	ACE inhibitors (ramipril) are powerful agents when given early to patients at risk of cardiovascular events with benefit not entirely due to blood pressure reduction.
HY-C	Hydralazine versus Captopril: Effect on Mortality in Patients with Advanced Heart Failure	Comparison of captopril or hydralazine tailored to hemodynamic goals with respect to mortality in NYHA III/IV CHF (n = 117).	Captopril survival at 1 yr 81% vs. hydralazine (51%; *p* = .05).	Early study demonstrating ACE inhibitor better than hydralazine/nitrates despite achieving same hemodynamics.
IMAC	Intervention in Myocarditis and Acute Cardiomyopathy with i.v. Immunoglobulin	Randomized, double-blind, multicenter trial in 61 patients with new-onset cardiomyopathy who received i.v. immunoglobulin or placebo.	No differences in outcomes, with LVEF being primary end point.	i.v. immunoglobulin likely plays no role in benefiting patients with new-onset cardiomyopathy presumed to be inflammatory in etiology.
IMPRESS	Comparison of vasopeptidase inhibitor omapatrilat and lisinopril on exercise tolerance and morbidity in patients with CHF	Randomized, double-blind, clinical trial with omapatrilat or lisinopril in NYHA II–IV CHF, with exercise primary end point (n = 573).	Exercise tolerance improved similarly in two groups but few CVD events with omapatrilat (7% vs. 12%; *p* = .04) and trend toward fewer deaths plus CHF admissions (RR = .53; 95% CI, 0.28–0.96; *p* = .035).	Pilot trial suggesting omapatrilat could have some advantages over ACE inhibitor in CHF; angioedema question needs to resolved.
LIDO	Levosimendan Infusion vs. Dobutamine	Randomized, double-blind, multicenter comparison of the efficacy and safety of 24-h levosimendan infusion vs. dobutamine in severely decompensated CHF patients (n = 200).	Both drugs hemodynamically active, with fewer deaths in group exposed to levosimendan at 180-d follow-up (concomitant medications not specified/controlled).	Study raises the important question of long-term effects of short-term vasoactive drug infusion.
MACH-I	Mortality Assessment in Congestive Heart Failure	Mibefradil, a T-type calcium channel blocker compared with placebo in 2,390 patients with NYHA II/III CHF on ACE inhibitor, diuretics, digoxin.	Mibefradil increased mortality compared with placebo by 11%.	Calcium channel blockers remain concerning in CHF, with mibefradil likely adversely interacting with drugs that prolong the QT interval.
MADIT	Multicenter Automatic Defibrillator Implantation Trial	Randomized trial of AICD vs. conventional therapy in post-MI patients with EF <35%, nonsustained ventricular tachycardia, and nonsuppressible ventricular tachycardia on EPS.	AICD leads to better survival in this high-risk arteriosclerotic cardiovascular disease population with heart failure; beta-blockers and amiodarone did not appear to have significant effect on hazard ratio.	Provides an alternative strategy for treatment of select patients with heart failure and life-threatening ventricular arrhythmias.
MDC	Metoprolol in Dilated Cardiomyopathy	Effect of metoprolol vs. placebo on survival in dilated cardiomyopathy.	Compared with placebo, metoprolol patients had improved symptoms and cardiac function; 34% fewer primary end points of death or transplant listing with metoprolol.	Provided some support for beta-blocker use in CHF patients but study design criticized.
MERIT-HF	Metoprolol CR/XL Randomized Intervention Trial in Heart Failure	Tested efficacy of adding beta-blocker metoprolol to standard therapy in NYHA II/IV CHF (n = 3,991), morbidity and mortality end points.	Highly significant (35%) decrease in mortality with metoprolol. Trial stopped early.	Additional evidence supporting beta-blocker use in mild to moderate CHF. Metoprolol properties different from carvedilol and bisoprolol.
MEXIS	Metoprolol and Xamoterol in Ischemic Syndromes	Double-blind, active drug controlled evaluation of beta-blockers (one with significant ISA) in MI patients with heart failure with exercise, QOL, and symptoms primary end points (n = 210).	Generally little difference between drugs, but mortality 4.7% at 1 yr for metoprolol and 5.8% for xamoterol, with more withdrawals from xamoterol (22% vs. 17%).	Findings are concerning when juxtaposed to adverse events noted in the xamoterol heart failure trial.
MICRO-HOPE	Microvascular Outcomes in Heart Outcomes Prevention Trial	Substudy of HOPE trial assessing development of nephropathy in diabetics (n = 3,577).	In diabetics, ramipril lowered cardiovascular events by 25% (95% CI, 0.12–0.36; *p* = .0004) and over nephropathy by 24% (95% CI, 0.03–0.04; *p* = .027).	Ramipril reduces CVD events, nephropathy in high-risk diabetics.
MIRACLE	Multicenter InSync Randomization Clinical Evaluation	Randomized exercise and QOL endpoint clinical trial of atrial biventricular pacing in NYHA III/IV CHF patients with wide QRS but no indications for a pacemaker.	Trial ongoing.	Study may justify mechanical approach to CHF that will improve efficiency of cardiac contraction resynchronization and decrease mitral regurgitation.
MIRACLE-ICD	Multicenter InSync Randomization Clinical Evaluation Implantable Cardioverter Defibrillator	Randomized exercise/QOL endpoint clinical trial of atrial biventricular pacing, with device having ICD capabilities in patients with indication for ICD but not a pacemaker.	Trial ongoing.	Extends concepts being evaluated in MIRACLE, but CHF patient applicability being broadened by coupling ICD capabilities to cardiac resynchronization.
MOXCON	Moxonidine in Congestive Heart Failure	Mortality endpoint trial planned for approximately 4,000 NYHA II/IV CHF patients with EF <40%.	Study terminated early because moxonidine associated with increase in mortality.	Reasons for adverse outcomes not clear. Concept of central alpha-blockade in heart failure deserves more scrutiny.
MUNICH MHFT	Munich Mild Heart Failure Trial	Class II CHF patients randomized to captopril, 25 mg b.i.d. vs. placebo, with progression of heart failure major end point (n = 170).	Fewer patients progressed to class IV in the captopril group (11% vs. 26%; *p* = .01).	Early study suggesting ACE inhibitor benefit even at low dose.
MUSTIC	Multi-site Stimulation Cardiomyopathy Trial	Randomized heart failure patients with no pacer indications to biventricular pacer on or off in crossover single-blind design with 6% walk primary end point (n = 58).	Biventricular pacer “on” group had greater increase in 6% walk, peak VO_2, and QOL.	Small clinical trial suggesting biventricular pacing might be helpful in some CHF patients, but observations limited by design problems (crossover).

MUTTI	Multicenter Unsustained Tachycardia Trial Investigators	Randomized trial of EPS-guided antiarrhythmic therapy or simple heart failure treatment in CAD patients with EF <0.40 and asymptomatic unsustained ventricular tachycardia. Outcomes were SCD or cardiac arrest (n = 2,202 with 1,397 in a registry).	Mortality after 5 yr was 48% with inducible ventricular tachycardia vs. 44% without (p = .005).	Study suggests that EPS testing identifies a high-risk group of CAD heart failure patients.
MYOCARDITIS	A Clinical Trial of Immunosuppressive Therapy for Myocarditis	Patients with biopsy-proven “myocarditis” and EF <0.45 randomly assigned (open label) to “standard” care vs. immunosuppression for 24 wk with EF primary end point (n = 111).	No improvement noted with prednisone plus either cyclosporine or azathioprine therapy.	Results did not support routine treatment of myocarditis with immunosuppressive drugs.
OPTIME	Outcomes of a Prospective Trial of Intravenous Milrinone	Randomized milrinone vs. dobutamine study in which patients (n = 950) admitted for CHF management but not decompensation to the point of requiring inotropes were studied to see if length of stay could be shortened.	No impact on length of stay outcomes; more adverse events with milrinone.	Routinely prescribed inotropes in CHF patients generally likely not beneficial and could be associated with an increase in adverse events (new atrial fibrillation and sustained hypotension, p <.05).
PIAF	Pharmacological Intervention in Atrial Fibrillation	Randomized trial of atrial fibrillation patients to diltiazem vs. amiodarone (rhythm control) with symptomatic improvement the primary end point; 17% had cardiomyopathy with symptoms primarily of palpitations, dyspnea (66%), and dizziness observed (n = 252).	23% of amiodarone group converted with 6% walk better, but hospitalizations more frequent (69% vs. 24%; p = .001) and more adverse drug events (25% vs. 14%; p = .036).	Not many symptomatic differences between rate vs. rhythm control with exercise tolerance better, but more hospitalizations and problems with amiodarone (note few “CHF” patients).
PICO	Pimobendan in Congestive Heart Failure	Randomized, double-blind, placebo-controlled trial of the PDE inhibitor pimobendan in CHF, with exercise as primary end point (n = 317).	Pimobendan added to ACE inhibitor/diuretic improved exercise duration with effect on MVO_2 or QOL with more deaths seen in the pimobendan group (RR = 1.8; 95% CI, 0.9–3.5).	Only slight improvement with this oral PDE inhibitor, and potential for proarrhythmia of concern.
PRAISE	Prospective Randomized Amlodipine Survival Evaluation	Effect of amlodipine, a long-acting calcium antagonist, vs. placebo on survival against background of digoxin, diuretic, ACE inhibitor.	Benefits seemed confined to dilated cardiomyopathy group; overall, drug seemingly well tolerated.	Suggested at least one calcium channel blocker might be safe and possibly advantageous in select nonischemic CHF patients.
PRAISE-II	Prospective Randomized Amlodipine Survival Evaluation-II	Randomized, multicenter, placebo-controlled add-on amlodipine therapy in 1,800 patients with dilated, nonischemic cardiomyopathy, with mortality primary end point.	No harm nor benefit detected with amlodipine therapy.	In a properly powered mortality endpoint clinical trial, the calcium channel blocker amlodipine did not confer benefit and negated suggestion of benefit in PRAISE-I.
PRECISE/MOCHA	Prospective Randomized Evaluation of Carvedilol on Symptoms and Exercise/Multicenter Oral Carvedilol Heart Failure Assessment	Patients randomized to placebo vs. carvedilol in three distinct subgroups to accommodate mild, moderate, or severe CHF. Ascending carvedilol dose as tolerated (PRECISE) vs. fixed dose carvedilol (MOCHA).	Trials combined with two others to suggest mortality reduction; effects on exercise tolerance minimal; clinical CHF improved.	Carvedilol may be first beta-blocker (with alpha-blocking properties) to be given regulatory approbation for heart failure therapeutics.
PRIME-II	Prospective Randomized Studies of Ibopamine on Mortality and Efficacy	Placebo-controlled mortality endpoint trial of a novel dopaminergic-1 active agent in 2,200 advanced CHF patients.	Trial stopped prematurely after 1,906 patients because of excessive treatment group mortality.	Although drug has primary effects of peripheral and renal vasodilation without significant inotropic or proarrhythmia, there was a negative mortality impact; drug will likely not be developed.
PROFILE	Prospective Randomized Flosequinan Longevity Evaluation	Effect of flosequinan vs. placebo on survival, against background of digoxin, diuretic, ACE inhibitor.	A higher mortality rate in the flosequinan group (100 mg/d) was observed compared with placebo.	Forced withdrawal of flosequinan from the market in May 1993.
PROMISE	Prospective Randomized Milrinone Survival Evaluation	Survival evaluation of milrinone vs. placebo against digoxin, diuretic, ACE inhibitor background.	Milrinone produced decreased survival and increased side effects compared with placebo.	PDE inhibitors used chronically in heart failure likely to improve symptoms at the risk of higher mortality.
PROVED	Prospective Randomized Study of Ventricular Failure and the Efficacy of Digoxin	Efficacy evaluation in patients with stable heart failure, on digoxin and diuretics, randomized to continued digoxin or withdrawal onto placebo (same design as RADIANCE).	Digoxin withdrawal group demonstrated significant deterioration of exercise and increased treatment failure.	Small trial support for digoxin use in CHF (and caution against stopping drug).
RADIANCE	Randomized Digoxin and Inhibitor of Angiotensin Converting Enzyme Inhibitor	Patients with moderate to severe heart failure were randomized to remain on digoxin or be withdrawn on placebo (same design as PROVED).	Patients withdrawn to placebo had deterioration of exercise performance and worsening symptoms compared with individuals maintained on digoxin.	Triple therapy with ACE inhibitor, diuretic, digoxin likely is best baseline approach to CHF treatment.
RALES	Randomized Aldactone Evaluation Study	Randomized, multicenter, placebo-controlled mortality endpoint trial in 1,663 NYHA class III/IV CHF patients older than 60 yr.	30% reduction in risk of death (p <.001) with low doses of spironolactone (Aldactone).	Older patients with more advanced CHF may benefit with Aldactone added on to other agents to more completely block the adverse neurohormonal milieu associated with heart failure. Hyperkalemia could be a problem.
REFLECT	Randomized Evaluation of Flosequinan on Exercise Tolerance	Randomized, double-blind, exercise tolerance trial of the vasodilator flosequinan in class II/III patients (EF <0.40) on ACE inhibitor/diuretics (n = 193).	After 12 wk, patients exercised better and symptomatically improved on flosequinan.	Although flosequinan improved CHF symptoms, the excess mortality noted in the PROFILE study killed drug.

RENAISSANCE	Randomized Etanercept North American Strategy to Study Antagonism of Cytokines	Randomized, composite endpoint, placebo-controlled, multicenter trial with 2 times weekly injections of tumor necrosis factor modulator added on to standard therapies in NYHA II/IV CHF patients with EF <30%.	Trial ongoing.	Results will give insight into the role of cytokines in heart failure.
RESOLV	Candesartan Cilexetil in Heart Failure Assessment of Reduction in Mortality and Morbidity	Randomized, placebo-controlled, international, multicenter mortality endpoint trial of candesartan in 6,500 patients with NYHA II/IV CHF. Three groups assessed: ACE inhibitor intolerant, EF >40%, EF <40%, and on ACE inhibitor.	Trial ongoing.	Tests angiotensin II blocker across the broad spectrum of CHF. Only ongoing trial evaluating this strategy in ACE inhibitor–intolerant and “diastolic dysfunction” patients.
RESOLVD	Randomized Evaluation of Strategies for Left Ventricular Dysfunction	Double-blind pilot study in which CHF patients randomized to candesartan (several doses), candesartan plus enalapril, or enalapril for a mean of 43 wk with exercise, remodeling and LV function, neurohormones, and safety/tolerability of drugs end points (n = 768).	No differences noted in exercise, functional class, or QOL with LV volumes better and BNP lower with combination therapy.	Candesartan as effective, safe, and tolerable as enalapril in CHF, with candesartan/enalapril seemingly more beneficial for preventing remodeling than either drug alone.
RESOLVD-Beta-blocker	Randomized Evaluation of Strategies for Left Ventricular Dysfunction-Beta-blocker	During RESOLVD Metoprolol-CR given in double-blind factorial design fashion after initial uptitration of candesartan/enalapril with same RESOLVD end points (n = 426).	No differences in exercise, functional class, or QOL but significant improvement of LV function and attenuation of remodeling with greater decrease of angiotensin II and renin (p = .036 and .032), but increase of BNP (p <.01) with metoprolol-CR.	When added to an ACE, ARB, or ACE/ARB combination, metoprolol-CR improves LV function and renin-angiotensin activation.
SAVE	Survival and Ventricular Enlargement	Effect of placebo vs. captopril on survival and ventricular enlargement in LV dysfunction patients following MI.	Captopril improved survival, functional status, and reduced repeat MI compared with placebo.	Even in asymptomatic ventricular dysfunction, postinfarct ACE inhibitor beneficial.
SCD-HeFT	The Sudden Cardiac Death-Heart Failure Trial	CHF patients without AICD indications randomized to amiodarone, AICD, or routine CHF therapy with total mortality end point (n = 2,500).	Trial ongoing.	Study will likely clarify role of routine AICD or amiodarone therapy in CHF patients.
SHOCK	Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock	Randomized, open study of early revascularization strategies (percutaneous and surgical) in patients with post-MI shock (86% on IABC) (n = 302).	Mortality at 30 d no different between medical and revascularized groups, but 6-mo mortality lower in later (50% vs. 63%, p = .027).	Early revascularization should be considered for MI patients with shock.
SOLVD (Treatment and Prevention Trials)	Studies of Left Ventricular Dysfunction Trial	Patients with symptomatic heart failure and decreased EF (treatment trial) or asymptomatic LV dysfunction (prevention trial) were randomized to placebo vs. enalapril.	Enalapril improved survival and symptoms in the treatment trial and delayed onset or progression of heart failure in the prevention trial.	Taken together, trials established concept that ACE inhibitor is first-line therapy in all heart failure patients (not just CHF).
SPICE	Studies of Patients Intolerant of Converting Enzyme Inhibitors	Registry to determine true incidence of ACE inhibitor intolerance in CHF patients with EF <40% and randomized, double-blind, placebo-controlled pilot study of 75 ACE inhibitor patients.	In registry of approximately 10,000 patients, 80% successfully uptitrated on ACE inhibitor. True intolerance noted in a little over 10%, with cough being greatest problem. Candesartan well tolerated in ACE inhibitor–intolerant patients.	Reasonable to say 80% of CHF patients with low EF can be on ACE inhibitor, and the angiotensin II blocker candesartan was well tolerated when ACE inhibitors were not.
SPICE-Registry	Study of Patients Intolerant to Converting Enzyme Inhibitors (clinical registry)	Multinational registry of patients with CHF to determine medication use patterns and reasons for so-called ACE inhibitor intolerance.	Under optimal situations it seems that approximately 80% of CHF patients with depressed EF tolerate ACE inhibitor. In the 20% who do not, cough is the major reason for intolerance.	Under optimal circumstances, we should anticipate being able to get 80% of CHF patients with LV systolic dysfunction on ACE inhibitor.
SPICE-Trial	Study of Patients Intolerant to Converting Enzyme Inhibitors (clinical trial)	Double-blind, placebo-controlled, randomized clinical trial of candesartan to determine tolerability of an ARB in ACE inhibitor–intolerant patients (n = 270).	Over 12 wk of study, statistically equivalent numbers of candesartan and placebo were continued (83% vs. 87%).	ACE inhibitor–intolerant CHF patients seemingly tolerate the ARB candesartan over 80% of the time, with discontinuations being no more frequent than placebo.
STRETCH	Symptom, Tolerability, Response to Exercise Trial of Candesartan Cilexetil in Heart Failure	Multicenter, double-blind, parallel group study of CHF patients on either candesartan or placebo for 16 wk with exercise, functional class, and dyspnea/fatigue index. ACE inhibitor, Ca^{2+} blockers, beta-blockers, and antiarrhythmics not permitted (n = 844).	In a CHF setting with mostly dig/diuretic/vasodilator background therapy, the ARB candesartan was well tolerated and improved heart failure symptoms.	Candesartan appears effective in heart failure patients off of standard ACE inhibitor/beta-blocker therapies.
SUPPORT	Study to Understand Prognosis and Preferences for Outcomes and Risks of Treatment	Case-matching and propensity score analysis done to evaluate right heart catheterize use in critically ill patients (n = 5,735).	Observational study suggesting right heart catheterization associated with increased mortality in all but CHF patients.	Difficult to extrapolate results to “tailored” hemodynamic management of CHF groups.
SWORD	Effect of D-Sotalol on Mortality in Patients with Left Ventricular Dysfunction after Recent and Remote Myocardial Infarction	Randomized, placebo-controlled, multicenter trial in patients with EF below 40% and recent (6–42 d) or remote (>42 d) infarction (n = 3,121).	Study stopped prematurely because of excess treatment mortality (5% vs. 3% death rate, p <.008) in sotalol group.	Even an antiarrhythmic agent with only pure K^+ channel blocking effects has adverse outcome in heart failure patients.
VAL-HeFT	Valsartan Heart Failure Trial	Double-blind, placebo-controlled, multicenter trial of valsartan added on to ACE inhibitor (92% of patients) with approximately 35% on beta-blocker, with all-cause mortality and combined mortality/morbidity end points (n = 5,010).	Largest ARB trial reported to date with ARB/ACE inhibitor combination tested. No mortality benefit, seeming morbidity benefit, but this mostly limited to 7% net on ACE inhibitor. Possible adverse interaction with patients on beta ACE inhibitor and beta-blockers.	Question of ARB’s role in CHF remains unanswered.

VALIANT	Valsartan Post Myocardial Infarction	Double-blind, placebo-controlled comparison of valsartan, captopril, and their combinations after acute MI.	Trial ongoing.	—
VEST	Vesnarinone Survival Trial	Large-scale mortality endpoint trial of 60- and 30-mg doses in NYHA III/IV patients on digoxin, diuretic, and ACE inhibitor.	Increased mortality noted in contrast to prior study, which suggested dramatic benefit.	Role of vesnarinone in CHF now in question; certain subgroups may benefit, but this is yet to be determined.
V-HeFT-I	Veterans Administration Cooperative Vasodilator Heart Failure Trial I	Parallel study of the effects of placebo, prazosin, and hydralazine on survival.	Hydralazine isosorbide dinitrate improved survival; prazosin was no different than placebo.	First study to confirm that vasodilators could save lives in CHF.
V-HeFT-II	Veterans Administration Cooperative Vasodilator Heart Failure Trial II	Parallel study of enalapril vs. hydralazine/isosorbide dinitrate on survival in moderate heart failure.	Enalapril significantly improved survival; hydralazine/isosorbide dinitrate improved EF and exercise.	First to demonstrate incremental benefit of vasodilators with endocrinologic effects.
V-HeFT-III	Veterans Administration Cooperative Vasodilator Heart Failure Trial III	2-by-2 factorial design study evaluating the efficacy of felodipine, digoxin, and placebo.	No mortality reduction noted; felodipine seemingly well tolerated.	Felodipine possibly another calcium channel blocking drug that can be used safely in CHF, although not beneficial.
VMAC	Vasodilation in the Management of Acute Congestive Heart Failure	Randomized, multicenter, nitroglycerin-controlled, symptom/hemodynamic endpoint, clinical trial (n = 500) of Natrecor (BNP) infusion in severe CHF in patients.	BNP superior to TNG, better tolerated and easier to use.	Vasodilating efficacy of BNP in severe CHF demonstrated; VMAC designed to evaluate safety of different infusion strategies, including those not using ICU/PAP pressure monitoring.
WATCH	Warfarin Anticoagulation Trial in CHF	Multicenter, randomized, placebo-controlled trial of anticoagulation vs. platelet inhibition to reduce CHF morbidity/mortality.	Trial ongoing.	Study will clarify wisdom of routine anticoagulation strategies in CHF patients.
Xamoterol	Xamoterol in Severe Heart Failure	Survival endpoint evaluation in 516 CHF patients; placebo-controlled, multicenter, European.	Xamoterol associated with higher mortality at 90-d point.	Inotropic agents with beta-agonist effects increase mortality in CHF patients.

ACE, angiotensin-converting enzyme; AICD, automatic implantable cardioverter-defibrillator; ARB, angiotensin receptor blocker; BNP, b-natriuretic peptide; CABG, coronary artery bypass grafting; CAD, coronary artery disease; CHF, congestive heart failure; CI, confidence interval; CVD, cardiovascular disease; EF, ejection fraction; EPS, electrophysiologic testing; IABC, intraaortic balloon counterpulsation; ICD, implantable cardioverter-defibrillator; ICU/PAP, intensive care unit/pulmonary artery pressure; IDCM, idiopathic dilated cardiomyopathy; ISA, intrinsic sympathomimetic activity; LV, left ventricular; LVD, left ventricular dysfunction; LVEF, left ventricular ejection fraction; MI, myocardial infarction; MVO_2, peak oxygen consumption; NYHA, New York Heart Association; PDE, paroxysmal dyspnea on exertion; PVC, premature ventricular contraction; QOL, quality of life; RR, relative risk; SAECG, signal-averaged electrocardiogram; SCD, sudden cardiac death; TNG, nitroglycerine; VO_2, oxygen consumption per unit time.

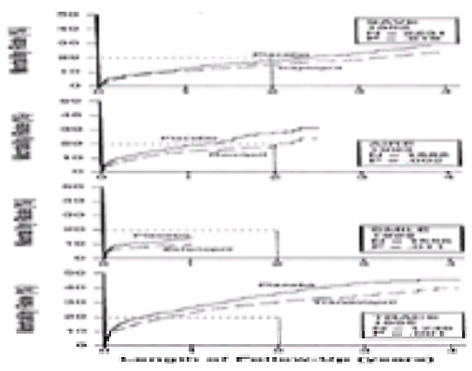
The Cooperative Scandinavian Enalapril Survival Study (CONSENSUS) (83) used an agent that was not only an effective vasodilating antihypertensive drug but one that also blocked certain neurohormonal characteristics of heart failure and demonstrated a profound mortality reduction in severely ill heart failure patients (NYHA class IV). The dramatic CONSENSUS results supported yet a new hypothesis in the treatment of heart failure: the *neurohumoral interdiction hypothesis*. Clinical benefit with respect to mortality reduction could be achieved by blocking certain aspects of neurohormonal compensatory systems characteristic of heart failure, and, specifically, the renin-angiotensin-aldosterone cascade.

Subsequently, V-HeFT-II (84) compared the combination of hydralazine and isosorbide dinitrate to the ACE inhibitor enalapril and demonstrated that enalapril effected greater mortality reduction than did the direct-acting vasodilator combination. This raised the question of whether agents primarily blocking humoral factors were better in heart failure than those with only hemodynamic actions. It is logical that both types of drugs might be important. The syndrome stage in any given patient may have great bearing on outcome with respect to drugs chosen, but this is not entirely clear now. It is interesting to note that the combination of direct-acting vasodilators and ACE inhibitors might be even more effective, but this has not directly been addressed. Some information from the Prospect of Randomized Amlodipine Survival Evaluation (PRAISE) (85) and the V-HeFT-III (86) provide insight into this hypothesis. PRAISE demonstrated mortality reduction, but only in patients with no coronary heart disease. Amlodipine was prescribed as adjunctive therapy to ACE inhibitors and digoxin. V-HeFT-III was a 2-by-2 factorially designed protocol that studied the combination of felodipine, digoxin, and placebo on a background of angiotensin-converting therapy. In this study, felodipine demonstrated no benefit in any group, but harm was not suggested either. PRAISE and V-HeFT-III are also important because they focus on calcium channel blockers in heart failure, which are generally found to be detrimental in this setting. Studies performed with first- and second-generation calcium antagonists usually showed increased morbidity and mortality when prescribed in a heart failure milieu.

The SOLVD program (87,88) evaluated enalapril in asymptomatic or minimally symptomatic patients (the prevention trial) (87) and in patients with mild to moderate congestive heart failure (the treatment trial) (88). Baseline medications generally included diuretics and digoxin. In patients with ejection fraction less than 35% and symptomatic heart failure, enalapril significantly reduced mortality, morbidity, and, importantly, major ischemic events, such as acute myocardial infarction or hospital admission for unstable angina. In fact, the reduction in major ischemic events was more impressive than reduction of any other single morbid event, including hospitalization for heart failure. The SOLVD prevention trial demonstrated significant decrement in the combined end point of congestive heart failure morbidity (hospital admission for heart failure) and mortality. This trial was the first to suggest that a preventive intervention strategy with ACE inhibitors could attenuate progression toward clinically manifest heart failure when used as first-line drug therapy in asymptomatic or minimally symptomatic patients with systolic left ventricular dysfunction. Observations from SOLVD shift the paradigm of therapy from simply a diuretic and digoxin prescription, begun when patients develop congestive heart failure, to instituting ACE inhibitor therapy first even in noncongested, asymptomatic, or minimally symptomatic patients.

In an attempt to finally put to rest the controversy surrounding digoxin use in heart failure, the Digoxin Investigators Group (DIG) Trial (89) followed 7,788 patients with congestive heart failure for 5 years. DIG suggested that digoxin did not significantly affect mortality one way or another but substantially diminished the likelihood that patients would develop worsening heart failure requiring hospitalization. The DIG Trial was performed on a background of diuretic and ACE inhibitor and thus supports the contention that triple therapy is likely the best strategy in congestive heart failure patients. An important result was that a large subset of patients having only diastolic dysfunction with congestive heart failure also saw substantive benefits with digoxin. Some have suggested that a subset analysis in this trial increased risk of “arrhythmic death,” but this conclusion may not be completely justified.

The Survival and Ventricular Enlargement Trial (90) demonstrated that captopril improved survival, functional status, and reduced repeat myocardial infarction rate compared with placebo when this ACE inhibitor was begun the first week after acute myocardial infarction when left ventricular systolic dysfunction in the absence of substantive congestion (ejection fraction less than 40%) was observed. Several other clinical trials after acute myocardial infarction (91,92,93 and 94) (*e*Fig. 92.5.1) have confirmed that ACE inhibitors begun shortly after the event were associated with significant benefit when either asymptomatic systolic left ventricular dysfunction or mild clinical congestive heart failure was present. Captopril, ramipril, zofenopril, and trandolapril, therefore, have been used in this setting, and it is suggested that long-term benefit accrues when a variety of ACE inhibitors are used. Furthermore, several “megatrials” of ACE inhibitors after myocardial infarction conclude that ACE inhibitors given routinely after myocardial infarction (i.e., irrespective of presence or absence of left ventricular systolic dysfunction or congestive heart failure) produce short-term reduction in mortality. The International Study of Infarct Survival IV (95) and Gruppo Italiano Della Infarto Miocardial III trial (96) included patients with a wide spectrum of ejection fractions. Their positive findings suggested that early administration of ACE inhibitors would translate more generally into postinfarct benefit.



***e*FIGURE 92.5.1** Plotted in this figure are the mortality and lengths of follow-up for four trials of angiotensin-converting enzyme inhibitors used in the acute post–myocardial infarction patient with either clinical heart failure (signs and symptoms of congestion) or left ventricular systolic dysfunction that was asymptomatic or mildly symptomatic. The mortality and follow-up periods have been normalized so that the trials can be better compared. Panel I is the Survival and Ventricular Enlargement (SAVE) trial evaluating captopril, panel II the Acute Infarction Ramipril Efficacy (AIRE) study evaluating ramipril, panel III the Survival of Myocardial Infarction: Long-Term Evaluation (SMILE) trial evaluating zofenopril, and panel IV the Trandolapril Cardiac Evaluation (TRACE) trial evaluating trandolapril. The total number of patients included is listed in each box as well as the *p* value for total mortality outcome. Placebo is always the solid line. Marked for convenience of comparison are the 20% mortality and 2-year follow-up points. Mortality reduction was seen with all these angiotensin-converting enzyme inhibitors in a fairly similar population, suggesting that benefits are class related. Still, it is important to note that the patient population did have varying risk profiles: the TRACE placebo group crossed the 20% actuarial mortality between 6 and 12 months, whereas this mark was crossed in AIRE between 12 and 18 months, and in SAVE only after 2 years of follow-up. Use of an angiotensin-converting enzyme inhibitor should be strongly encouraged in patients with heart failure after an acute myocardial infarction and, generally, started within the first week. Obviously, a wide spectrum of post–myocardial infarction patients benefit from this strategy.

Although small clinical trials attempting to evaluate beneficial effects of beta-blockers in heart failure had been published with disparate results, the Metoprolol in Dilated Cardiomyopathy (97) study was the first larger-scale trial to resolve some of the controversy about this strategy. The $beta_1$-selective beta-blocker metoprolol versus placebo was studied in dilated cardiomyopathy patients. Compared with placebo, patients in the active drug limb had improved symptoms with a decrement in the combined end point of survival and need for heart transplant. Many design issues were raised, however, such as the reasonability of including heart transplant as an end point. Although conclusions were tenuous, the observations added some support to the growing portfolio of heart failure therapy benefits with beta-blockers. Subsequently, the Prospective Randomized Evaluation of Carvedilol on Symptoms and Exercise (98) and the Multicenter Oral Carvedilol Heart Failure Assessment (99) trials were completed. These studies demonstrated improvement in patients with mild to moderate heart failure receiving this beta-blocker and vasodilator on top of digoxin, diuretic, and ACE inhibitors. More interesting was the pooled analysis of four large carvedilol treatment protocols, which indicated that mortality was reduced substantially (100). More recently, other studies with different beta-blockers support the contention that these agents should be used, albeit carefully, in patients with heart failure. Cardiac Insufficiency Bisoprolol Studies I and II using bisoprolol (101,102 and 103) and Metoprolol CR/XL Randomized Intervention Trial in Heart Failure (104) using sustained-release metoprolol (104) were also positive beta-blocker studies. The Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD) study has also been completed, and one aspect of this clinical trial evaluated the effects of sustained-release metoprolol in an aggressive heart failure protocol in which an angiotensin II receptor antagonist (candesartan) and the beta-blocker were added to ACE inhibitors and other heart failure medications (generally diuretics and digoxin) (105). Although not a mortality trial by design, when added to ACE inhibitors, angiotensin II receptor antagonists, or both, the use of metoprolol improved ventricular function, reduced activation of the renin-angiotensin system, and resulted in fewer deaths. Perhaps the most ill heart failure patients yet studied with beta-blockers were in the Carvedilol Prospective Randomized Cumulative Survival Trial (COPERNICUS) (106,107 and 108). This mortality endpoint study extended observations of benefit noted in prior trials with carvedilol to more ill NYHA class IV patients. This study did not, however, include patients who could not reach some degree of compensation (euvolemic at trial entry). Nonetheless, COPERNICUS markedly broadened the patient population likely to benefit from these agents, demonstrating that, when carefully titrated, even very ill individuals could tolerate beta-blockers. Interestingly, in the Beta-blocker Evaluation and Survival Trial (BEST), bucindolol, a nonselective beta-adrenergic blocker with mild vasodilating properties, did not show significant overall survival benefit in a demographically diverse group of patients with NYHA class III and IV congestive heart failure (109). Perhaps important was the fact that in BEST the point estimate of mortality reduction favored bucindolol, but the confidence intervals were wide and not statistically significant compared with placebo, yet when white participants only were included in the analysis, benefits were noted (107). In the United States, then, two beta-adrenergic blocking drugs now have approval by the Food and Drug Administration for use in heart failure patients, carvedilol (Coreg) and long-acting metoprolol (Toprol XL).

Antiarrhythmic drugs have not generally fared well in clinical trials evaluating their effects in heart failure patients (27,28,110,111,112,113,114,115,116,117,118,119 and 120). This has been tremendously disappointing. Many patients with substantive ventricular dysfunction have malignant or potentially malignant ventricular arrhythmias. Furthermore, sudden cardiac death (frequently presumed due to ventricular tachycardia and fibrillation) often accounts for this difficulty. It seems logical that efforts to eliminate these arrhythmias should translate into mortality reduction. Many agents studied are potent with respect to elimination of ventricular dysrhythmia. The Cardiac Arrhythmia Suppression Trial (113,114,120) studied encainide, flecainide, and moricizine post–myocardial infarction in patients with multiple premature ventricular contractions and, generally, left ventricular dysfunction. Indeed, in many senses, the patient population resembled the populations of several other trials (90,91,92 and 93). This study was terminated prematurely, however, because of excessive mortality in the treatment groups. All three drugs seemed to exhibit detriment more than benefit when used routinely in post–myocardial infarction patients with ventricular arrhythmias. The Survival with Oral D-Sotalol (115) trial evaluated the effect of D-sotalol on mortality in patients after recent and remote myocardial infarction [again, populations similar to several other trials, including SOLVD (87,88,90,91,92 and 93)] with ejection fraction less than 40%. This trial was stopped prematurely because of excessive treatment group mortality. Even with an antiarrhythmic agent with only pure potassium channel blocking effects, adverse outcome has been demonstrated. Amiodarone may be, arguably, the one exception to this observation. The Group Study of Heart Failure in Argentina (121) was a placebo-controlled (but unblinded) study of amiodarone in moderate to severe congestive heart failure having mortality end points. Mortality was significantly reduced in the amiodarone group compared with placebo (42% vs. 53%), which suggested that amiodarone could be used safely in congestive heart failure patients and might provide benefit. The European Myocardial Infarction Amiodarone Trial (122) randomized patients 5 to 21 days after myocardial infarction who had an ejection fraction less than 40% and evaluated total mortality as a primary end point. Although the primary end point was not affected by amiodarone, the combined end point of presumed arrhythmic death and resuscitated cardiac arrest was reduced slightly. The Canadian Myocardial Infarction Amiodarone Trial (123,124) evaluated patients 6 to 45 days after myocardial infarction and had no ejection fraction entry criteria, but electrocardiographic ventricular arrhythmias, for combined end points of arrhythmic death or resuscitated ventricular fibrillation. All-cause mortality and cardiac mortality were secondary end points. Although this study demonstrated that amiodarone reduces the incidence of ventricular fibrillation or arrhythmic death among survivors of acute myocardial infarction having frequent or repetitive ventricular premature depolarizations, 42% of the treatment group had stopped the drug by year 2 because of toxicity. The Canadian Myocardial Infarction Amiodarone Trial was not a heart failure trial, per se, but many of its subjects had left ventricular dysfunction. Concern has been raised about making strong conclusions from end points such as “presumed” ventricular tachyarrhythmic death and, therefore, use of amiodarone routinely in heart failure patients is still open to question (125). The Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy (126) studied amiodarone versus placebo in congestive heart failure patients generally who had ten premature ventricular contractions per hour on ambulatory monitoring. Amiodarone in this study did not improve survival compared with placebo. Thus, the routine use of amiodarone in patients with heart failure, whether it be manifest as congestive heart failure or left ventricular dysfunction after myocardial infarction, remains highly controversial. Furthermore, it is an expensive therapy in both cost and toxicity. Two large studies of the newest available antiarrhythmic drug, dofetilide, Danish Investigations of Arrhythmia and Mortality on Dofetilide—Congestive Heart Failure (127) and Danish Investigations of Arrhythmia and Mortality on Dofetilide—Myocardial Infarction (128), have now been published. Both trials were primary mortality endpoint studies with the heart failure study assessing mortality in symptomatic congestive heart failure patients with severe left ventricular dysfunction and the myocardial infarction study randomizing patients with severe left ventricular dysfunction after an acute infarct. The heart failure study did show that dofetilide decreased heart failure hospitalizations and converted atrial fibrillation more frequently but with a significant incidence of torsades de pointes in the antiarrhythmic group. In patients with severe left ventricular dysfunction and recent myocardial infarction, treatment with dofetilide did not decrease all-cause mortality, cardiac mortality, or total arrhythmic deaths. However, dofetilide was effective in treating atrial fibrillation and atrial flutter.

Other mortality endpoint heart failure trials have suggested that intervention with certain drugs might actually increase mortality. Studies of flosequinan, milrinone, and prostacyclin (Flolan) are examples. These studies include the Prospective Randomized Flosequinan on Longevity Evaluation (80), the Prospective Randomized Milrinone Survival Evaluation (81), the Xamoterol in Severe Heart Failure (Xamoterol-CHF) (129), and the Flolan International Randomized Survival Trial (78). Milrinone is a potent phosphodiesterase inhibitor demonstrating both inotropic and vasodilating properties. It is an effective drug when used parenterally in acute heart failure patients and may, in fact, be helpful during treatment of chronic and refractory heart failure when given in either chronic or pulsed parenteral infusion fashion (130). However, chronic oral treatment with this drug increased mortality (131). Flosequinan is also likely an “inodilator,” exhibiting inotropic and vasodilating properties, yet it demonstrated increased mortality. Prostacyclin is quite different from phosphodiesterase inhibitors in action and, specifically, does not elicit inotropic effects. Prostacyclin is a potent pulmonary and peripheral arteriolar dilator, yet it was associated with higher mortality than placebo when given chronically to severely ill heart failure patients.

Again, although not a heart failure trial per se, the Multicenter Diltiazem Reinfarction Trial (132) was important because of its demonstration that diltiazem, when routinely administered after myocardial infarction, significantly increased adverse cardiac events in patients with heart failure. Generally, results with calcium channel blocking agents in heart failure have been disappointing, particularly post infarct.

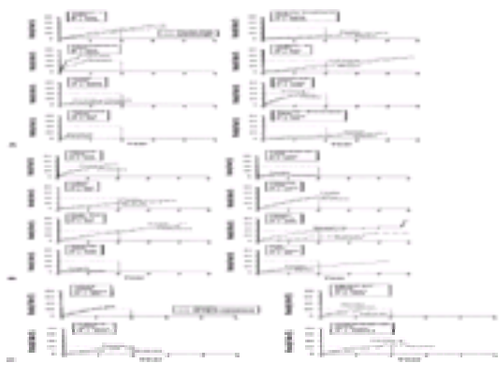
More recently, the Vesnarinone Survival Trial (82) demonstrated a 24% increase in total mortality with the 60-mg dose of vesnarinone ($p < .05$) and a 12% mortality increase with the 30-mg dose (p = not significant). This should be counterposed to a previous vesnarinone study that indicated that this drug reduced mortality substantially at the 60-mg dose, whereas 120 mg increased death rates (133). The lower vesnarinone doses do not, for the most part, produce clinically measurable inotropic or hemodynamic changes in heart failure. Vesnarinone is an interesting proposed heart failure therapy because it may interdict the inflammatory (cytokine or tumor necrosis factor) components of heart failure. Observations are incomplete at this time, but the disparity between outcomes noted in two well-designed, well-controlled, compulsively performed mortality endpoint clinical trials is troubling. One wonders whether vesnarinone may have specific beneficial effects in only a well-defined subset patient population that is yet to be characterized.

Studies with calcium channel blockers generally have demonstrated increased morbidity and mortality in heart failure. PRAISE I and II and V-HeFT-III are the only clinical trials to date that suggest that specific calcium channel blocking agents (amlodipine and felodipine) might not carry such concerns for heart failure patients

(134,135). The calcium channel blocker mibefradil studied in Mortality Assessment in Congestive Heart Failure I actually increased morbidity. This drug is no longer available (136).

Other pharmacologic approaches in heart failure have been studied including the use of human growth hormone, but concern has been raised about the induction of ventricular hypertrophy and diastolic dysfunction with this agent (137). Spironolactone proved quite efficacious in the Randomized Aldactone Evaluation Study trial when added to diuretics, digoxin, and ACE inhibitors in NYHA class II and III patients (138).

*e*Figure 92.5.2 graphically presents selected mortality endpoint clinical trials that have greatly shaped our philosophy regarding best approaches to the patients with heart failure. The figure is arranged so that all of the trials are comparable with respect to total mortality end points and length of patient follow-up. These trials were well performed and therefore provide credible information regarding therapeutic algorithms. Important to note is the fact that a wide spectrum of placebo mortality can be observed, implying that different patient populations have been studied. It is also likely that, over time, patient management strategies have improved more generally.



***e*FIGURE 92.5.2 A–C:** Actuarialized total mortality end points are plotted for select multicenter clinical heart failure trials. The mortality and follow-up periods have been normalized for each study so that placebo mortality can be compared among the different populations. It is important to note that placebo group mortality is quite different from trial to trial, emphasizing that different populations with heart failure were studied. Furthermore, different therapeutic adventures have produced widely disparate results, with some being highly beneficial and others detrimental. Trial results are ordered from top to bottom and right column to left based on their historic sequence of publication. The total number of patients included is listed in each box as well as the *p* value for total mortality outcome. Placebo is always the solid line. Marked for convenience (*dotted line*) of comparison are the 40% mortality and 2-year follow-up points.

SPECIFIC THERAPIES FOR CHRONIC HEART FAILURE

It is important to reemphasize that the principles of chronic heart failure therapeutics are rooted in making the appropriate diagnosis, staging the syndrome (different therapies are warranted for asymptomatic vs. symptomatic patients), addressing diseases causing or precipitating the difficulty, and using strategies that prevent disease progression (e.g., appropriate treatment of hypertension and atherosclerotic cardiovascular risk factors). Patient counseling and general education of family and home care givers is also important but is often ignored.

Suggested Topics for Patient, Family, and Care Giver Education

Table 92.5 presents topics for patient, family, and care giver education and counseling that have been modified from the AHCPR guidelines (72,73). Central to therapy is an explanation to the patient of heart failure and the reason for symptoms, if the patient is symptomatic. Discussion of the cause or probable cause of heart failure is important, as are expected symptoms, symptoms that herald worsening heart failure, and strategies to pursue if symptoms worsen. Instruction with regard to self-monitoring of daily weights, blood pressure, pulse rate, and blood sugar in diabetics is helpful. Explicit explanation of treatment and care plans is important to gain acceptance of therapeutic strategies. One should be specific when discussing patient responsibilities with regard to cessation of tobacco and alcohol use, salt restriction, and fluid intake reduction. The important role of family members or other care givers in the treatment plan should be stressed. Atherosclerotic risk factor intervention is essential, as is the need for obtaining vaccinations at appropriate intervals against influenza and pneumococcal disease. Prognosis should be frankly discussed, and advanced directives elicited when appropriate. This is particularly important for those patients suffering with advanced or end-stage heart failure. Advice should be given to family members with regard to resuscitation efforts should sudden cardiac death syndrome occur. Activity recommendations need to focus on benefits of exercise-based cardiac rehabilitation programs. Recreational, leisure, work, and exercise activities can be frankly addressed, and patients should be encouraged to perform aerobic activities that are symptom limited. Exercise should not necessarily be banned in patients with heart failure. Generally, patients “can do what they can, and can’t do what they can’t.” Dietary recommendations are essential and focus on restriction of salt and excessive fluid intake. Alcohol might be proscribed in certain situations. The effects of medications on quality of life and survival should be frankly addressed, and schemes designed to optimize compliance with treatment and care plans are important. One must emphasize the necessity of taking medications in timely fashion, and it is good practice to provide forms to record medication consumption, pulse rate, blood pressure, and daily weights so that the patient can take an active part in the therapeutic program. One should not ignore the importance of education with regard to atherosclerotic cardiovascular disease risk factor modification. Because ischemic heart disease is the major reason for patients developing heart failure, it makes sense to halt progression of atherosclerosis.

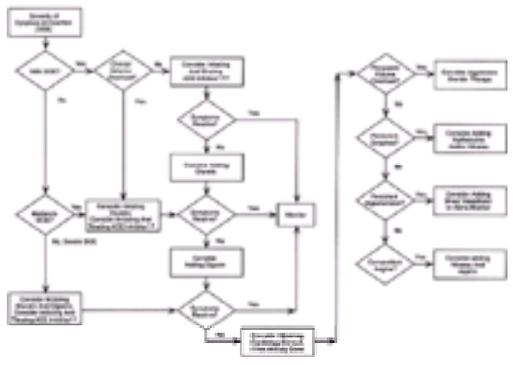
TABLE 92.5 SUGGESTED TOPICS FOR PATIENT, FAMILY, AND CARE GIVER EDUCATION AND COUNSELING

Surgical Therapeutics

When appropriate, surgical therapies can provide dramatic symptomatic relief in patients with congestive heart failure (53,72,74,139). Particularly important is identifying individuals who might benefit from coronary revascularization with percutaneous coronary interventional strategies or coronary artery bypass surgery (74,140,141).

*e*Figure 92.5.3 presents the AHCPR guidelines regarding evaluation and treatment of coronary artery disease in patients with heart failure. This algorithm was included in the AHCPR recommendations because most data support revascularization strategies in coronary disease patients having left ventricular dysfunction. Revascularization is thought to be important in those having significant myocardial ischemia when targeted lesions can be addressed. Although procedure-related morbidity and mortality increase as left ventricular systolic function worsens, substantive benefit can be noted in individuals with profoundly reduced ejection fraction and concomitant ischemia. Provocative tests should be performed to characterize and quantify the relative contribution of nonviable myocardial scar, ischemia, or “hibernation” to the heart failure milieu (139). Atrioventricular valve repair or replacement, even when ejection fraction is significantly reduced, may be an option. Particularly important is the relief of left ventricular outflow tract obstruction. Aortic valve replacement, repair, or valvuloplasty should be seriously considered in all individuals with substantive valve orifice reduction and diminished ejection fraction. It is a challenge to separate patients likely to benefit from aortic valve replacement from those who are not, when ejection fraction is depressed. Factors that may negatively affect outcomes in these patients appear to be substantive myocardial fibrosis and scar, particularly in the setting of ischemic heart disease. Therefore, patients with concomitant coronary artery disease need to be evaluated carefully. Obviously,

repair of congenital defects can be beneficial. Volume and pressure loads created by intracardiac shunts can be quite detrimental in patients with ventricular dysfunction. Assessment of the degree of fixed pulmonary hypertension is essential in separating patients likely to benefit from repair of congenital lesions from those not likely to benefit.



***e*FIGURE 92.5.3** The Agency for Health Care Policy and Research algorithm for evaluation and treatment of coronary artery disease patients with heart failure emphasizes the importance of determining if ischemic myocardium is present so that it can be addressed with revascularization of one sort or another. ACE, angiotensin-converting enzyme.

Relatively recently, an innovative surgical procedure has been proposed as an additional treatment option for select patients with advanced heart failure (142). Partial left ventriculectomy (or volume reduction surgery) in patients with severely dilated hearts due to cardiomyopathy may make some patients better. Ventricular remodeling involves removal of a wedge of cardiac tissue from the enlarged heart to relieve myocardial wall stress and reshape the cardiac chamber. This operation is usually performed concomitantly with attempts to reduce mitral and tricuspid valve leakage. However, outcomes after this procedure were not optimal, with only one-third of patients seeing long-term improvements. The operation has largely been abandoned (143,144). On the other hand, resection of myocardial scar tissue or aneurysm formation after myocardial infarction appears to be a more rational procedure in the sense that patients undergoing this later remodeling operation have myocardial scar tissue removed rather than actual muscle (145). More traditional left ventricular aneurysmectomy is effective in select ischemic heart disease patients with significant focal dyskinesia of the left ventricle (particularly when mitral regurgitation is present and substantive). Cardiac transplantation can play an extraordinarily dramatic role in truly end-stage patients without contraindications to this operation. The problem is that donor organ supply is inadequate, and, at best, only 2,000 to 3,000 of these operations can be performed annually around the world. Dynamic cardiomyoplasty is a procedure that involves mobilization of a latissimus dorsi muscle into the chest, wrapping the heart, and then training the skeletal muscle to become fatigue resistant with an electrical stimulating device that is coupled to a pacemaker (146,147 and 148). Anecdotal experience suggests that this procedure can effect symptomatic improvement in some class II and III patients and has an acceptable mortality risk. Unfortunately, the cardiac myostimulating device is no longer available. Other even more innovative surgeries include the insertion of a variety of endomyocardial splinting devices and epicardial wraps designed to extrinsically reshape the heart into a more normal configuration. Clinical trials are ongoing with the so-called MyoSplint and Acorn devices (145).

Pharmacotherapeutic Approaches

Figure 92.5 presents an overview algorithm for drug management of patients with heart failure. Again, drug therapy needs to be linked to staging the heart failure syndrome severity and determining whether the problem is due to left ventricular systolic dysfunction or so-called diastolic dysfunction (meaning, generally, that the left ventricular systolic ejection fraction is greater than approximately 45%). At the core of therapy for systolic dysfunction are ACE inhibitors, with digoxin and diuretics added when congestive heart failure is present. Beta-blockers are also critical drugs to use, generally added to the triple-therapy core. Long-acting nitrate preparations may be important for dyspnea relief. If an ACE inhibitor cannot be used because of intolerance or undesirable pharmacologic effects, one should consider the combination of hydralazine and isosorbide dinitrate or, alternatively, angiotensin II receptor blocking agents. As has been repeatedly emphasized, if coronary artery disease is present, consideration of revascularization is important. In patients with atherosclerosis generally, use of lipid-lowering drugs should also be considered. For patients with diastolic dysfunction, treatment options are less well defined. In individuals with congestive heart failure but relative preservation of left ventricular systolic function, one should first attempt to make a diagnosis of an infiltrative cardiomyopathy and base treatment on symptoms. Perhaps the most important drugs in diastolic dysfunction are nitrates and vasodilating agents, with diuretics used to control fluid retention states, but this is contentious. *e*Table 92.5.1 lists alternatives to diuretics, beta-blockers, and ACE inhibitors that might be useful in patients with hypertension or high normal blood pressure who have heart failure associated with either systolic or diastolic left ventricular dysfunction.

***e*TABLE 92.5.1** MEDICATIONS OTHER THAN DIURETICS, BETA-BLOCKERS, AND ANGIOTENSIN-CONVERTING ENZYME INHIBITORS TO TREAT HYPERTENSION OR HIGH NORMAL BLOOD PRESSURE IN PATIENTS WITH HEART FAILURE

Drug dose (mg)	Initial dose (mg)	Maximum dose (mg)	Major adverse reactions
Direct vasodilators			
Hydralazine	10 t.i.d.	75 t.i.d.	Headache, nausea, dizziness, tachycardia, lupus-like syndrome
Minoxidil	2.5 q.d.	80 q.d.	Fluid retention, hair growth, thrombocytopenia, leukopenia
Alpha$_1$-adrenergic blockers			
Doxazosin	1 q.d.	16 q.d.	Postural hypotension, dizziness, syncope, headache
Terazosin	1 q.d.	20 q.d.	Similar to doxazosin
Prazosin	1 t.i.d.	10 t.i.d.	Similar to doxazosin
Centrally acting alpha-blockers			
Clonidine tablets	0.1 b.i.d.	0.6 b.i.d.	Sedation, dry mouth, blurry vision, headache, bradycardia
Clonidine patch	0.1 weekly	0.3 weekly	Same as clonidine; contact dermatitis
Guanabenz	4 b.i.d.	64 b.i.d.	Similar to clonidine
Guanfacine	1 q.d.	3 q.d.	Similar to clonidine
Angiotensin II receptor blockers			
Candesartan	16 q.d.	32 q.d.	Hypotension, hyperkalemia, rash, renal insufficiency
Irbesartan	150 q.d.	300 q.d.	Hypotension, hyperkalemia, rash, renal insufficiency
Losartan	25 q.d.	50 b.i.d. or 100 q.d.	Hypotension, hyperkalemia, rash, renal insufficiency
Telmisartan	40 q.d.	80 q.d.	Hypotension, hyperkalemia, rash, renal insufficiency
Valsartan	80 q.d.	320 q.d.	Hypotension, hyperkalemia, rash, renal insufficiency

Specific Strategies

Positive Inotropic Agents

Pharmacologic effects that make digitalis attractive in heart failure include its positive inotropic action and negative chronotropic effects, as well as the agent's ability to modulate neurohormonal factors (by increasing baroreceptor sensitivity), to attenuate sympathetic nervous system tone, to decrease norepinephrine concentration, and to diminish renin-angiotensin levels (30,31,149). Controversy about using digoxin has centered around proper patient selection and drug dosing (29,31). Little debate exists regarding its utility in congestive heart failure patients with atrial fibrillation. In this situation, it is not clear whether digoxin is more helpful by controlling heart rate or by precipitating other beneficial effects, such as positive inotropy or baroreceptor readjustment. In a survey regarding physician practice in the management of congestive heart failure published in 1986, among 2,700 physicians actively treating patients with heart failure, approximately two-thirds of respondents considered digitalis effective in improving exercise tolerance, but fewer than one-third believed this drug could prolong life. Indeed, only approximately 30% reported that they would use digitalis as first-line therapy in patients with congestive heart failure with normal sinus rhythm. In the SOLVD Registry, 65% of patients with an ejection fraction of less than 20% were receiving digoxin compared with only 29% with ejection fractions of 36% to 45% (47).

Two clinical trials have placed the contemporary role of digoxin in patients with heart failure and normal sinus rhythm into better perspective. The Prospective Randomized Study of Ventricular Failure and the Effect of Digoxin (PROVED) (150) and the Randomized Assessment of Digoxin on Inhibitors of the Angiotensin-Converting Enzyme (RADIANCE) (151) were designed to assess the contribution of digoxin therapy to a patient's clinical status when used in a setting of either diuretic (PROVED) or combination diuretic and ACE inhibitor therapy (RADIANCE). These trials are particularly important because they clarify the role of triple heart failure therapy in patients with congestive heart failure. Both trials were simultaneously performed and identical in design, with the exception of baseline drugs permitted. Patients were required to have mild to moderate congestive heart failure with ejection fraction less than 35%. They were treated with digoxin and diuretics in

PROVED and digoxin, diuretics, and ACE inhibitors in RADIANCE. In both studies, a blinded randomization schedule determined which patients were to have digoxin replaced by placebo. Patients were required to be quite stable on their existing therapies. End points of the trials included maximal exercise capacity, incidence and probability of treatment failure with and without digoxin, control of signs and symptoms of congestive heart failure, and changes in certain parameters of ventricular function. Patients were all in sinus rhythm. Both studies demonstrated that withdrawal of digoxin therapy led to significant increase in the probability that heart failure would worsen over time with reduction in exercise tolerance. Digoxin therapy also was related to improved ventricular performance manifest by increasing ejection fraction. Importantly, pooled analysis of outcome in patients from both trials demonstrated that the lowest probability of treatment failure was seen in patients treated with the triple-drug combination (31). Although the combination of digoxin and a diuretic was far better than a diuretic alone, and the combination of diuretic and ACE inhibitor was similar to the digoxin and diuretic combination, triple-drug therapy clearly was best. Furthermore, this trial suggested that withdrawal of digoxin in stable congestive heart failure patients was associated with higher adverse event rates, and that stopping this drug should be avoided.

Gaining insight into the effect of digitalis on survival has been more difficult. In 1981, Moss et al. evaluated the effect of digitalis therapy on 4-month postdischarge cardiac mortality in 812 patients after acute myocardial infarction (152). Overall, there was an insignificant difference in mortality among treatment cohorts, but in the group with combined ventricular dysfunction and arrhythmias, digitalis was associated with increased mortality. In 1983, Ryan et al. evaluated the effects of digitalis on survival in high-risk patients with coronary artery disease using the Coronary Artery Surgery Study data bank (153). This report failed to confirm the observation of Moss et al. A year later, Madsen et al. analyzed 1,599 patients discharged from the hospital after acute myocardial infarction who were also on digitalis therapy (154). This drug was not an independent predictor of late mortality. Bigger et al. (155) evaluated another set of patients after myocardial infarction, but, in contradistinction to Ryan and Madsen, suggested that postinfarction survival was inversely and significantly related to serum digoxin concentration, with higher serum digoxin levels (and, generally, dose) associated with reduced long-term survival. After adjusting for the presence of atrial fibrillation and left ventricular dysfunction, however, serum digoxin concentration was not significantly related to survival. In 1985, Byington et al. (156) evaluated the Beta-Blocker Heart Attack Trial (BHAT) database and found that 250 (13%) of the 1,921 placebo-treated patients were receiving digitalis at the time of randomization. These patients experienced a higher incidence of in-hospital complications, such as pulmonary edema, persistent hypotension, atrial fibrillation, and heart failure, as well as demonstrated a greater frequency of complex ventricular arrhythmias. Multivariable logistic regression analysis adjusting for many independent factors usually predictive of mortality demonstrated that the use of digitalis was no longer independently associated with mortality. It is likely that patients receiving this drug had more extensive cardiovascular disease and greater morbidity than those not receiving digitalis and that their higher mortality was more related to the severity of underlying disease than to digitalis administration. Mueller et al. evaluated the experience in the Multicenter Investigation of the Limitation of Infarct Size (157) and reached the same conclusion as did the inquiry of the BHAT database.

The DIG Trial seemingly has given a definitive answer regarding digoxin's effect on mortality (89). This trial evaluated almost 8,000 patients with digoxin added to a background of ACE inhibitor and diuretics. Approximately 1,000 patients had congestive heart failure but preserved left ventricular systolic function (ejection fraction greater than 45%). The trial was relatively nonselective, with inclusion criteria being a history of clinical heart failure with current or previous evidence of low output (manifest by historic limitation of physical activity), normal sinus rhythm, chest radiograph, and ejection fraction performed within 6 months of trial entry, and evidence at some time of congestion (i.e., peripheral or central edema, jugular venous distention, pulmonary rales, or chest radiographic pulmonary edema). The primary end point was total mortality in patients with left ventricular ejection fraction less than 45%, and secondary end points included reduction in hospitalization for worsening congestive heart failure, cardiovascular mortality, death due to progressive heart failure, all-cause hospitalization, and quality of life. In this trial, 93% of patients were maintained on ACE inhibitors long term, with diuretics being used in 82% and long-acting nitrates in 42%. Outcome of this trial demonstrated that digoxin had a completely neutral effect on mortality. Still, digoxin reduced hospitalization and favorably affected the combined end point of death or hospitalization due to worsening congestive heart failure. There was a trend toward increased death due to arrhythmic events in analysis of certain subgroups, which has led some investigators to urge caution with prescription of this drug (29). However, the most appropriate interpretation of study results may be that digoxin has been shown safe, with substantive reduction in clinically significant morbid events, and that the effects are incremental to ACE inhibitor and diuretic therapy in patients with congestive heart failure. Analysis of the diastolic dysfunction subset demonstrated the same beneficial outcome results noted in the trial more generally. Digoxin appears effective in this group of patients as well. Routine digoxin prescription will, no doubt, become a more contentious issue.

Use of plasma digoxin levels to monitor therapy has been common. The diagnosis of digoxin toxicity seems to be related to elevated plasma levels, but few data are available concerning the relationship of plasma levels to their physiologic effects. In 1972, Redfors first explored the relationship between plasma digoxin concentration and clinical effects using the reduction in heart rate in patients with atrial fibrillation as an end point (158). Some observations on systolic time intervals suggested that higher digoxin doses and levels produced more inotropic effects. Slatton et al. have demonstrated no significant differences between 0.125-mg and 0.25-mg doses of digoxin with respect to echocardiographic ventricular contractility parameters (159). A significant difference was observed between 0.125 mg and placebo. This should be coupled to an analysis of the pooled PROVED and RADIANCE trial database, which split patient cohorts into tertiles of serum digoxin concentration (0.5 to 0.9 ng per mL; greater than 0.9 to 1.2 ng per mL; greater than 1.2 ng per mL) (160). The difference between the median change in exercise time when digoxin and placebo groups were compared was significantly different for each tertile of digoxin level. Patients receiving placebo did worse in every respect. The placebo group with a baseline digoxin level greater than 1.2 ng per mL had the largest decrement in exercise time after placebo was substituted for digoxin, but the fact that a statistically significant difference was noted in all groups suggested that, even at lower serum concentrations, digoxin is effective. A similar observation was made when the percentage of patients was determined in whom clinical congestive heart failure was developing. Low levels of digoxin and low doses were equally beneficial when this end point was considered. Thus, it appears that digoxin was superior to placebo regardless of plasma concentration. It is likely that high doses and levels of digoxin are unnecessary for efficacy in congestive heart failure patients.

Newer Inotropic Agents

As mentioned, few inotropic agents have met the challenge of both morbidity and mortality reduction in patients with heart failure (20,26,130). Although some (e.g., Xamoterol, milrinone, and flosequinan) have seemingly improved patient symptomatology, this has occurred generally in a setting of increased mortality. It is important to distinguish chronic therapy with these oral drugs from the use of inotropic agents, such as dobutamine and milrinone, in the acute heart failure setting or as last ditch attempts to control symptomatology when given parenterally to advanced heart failure patients on a long-term basis.

A great deal of attention has been directed toward vesnarinone (82,133). This drug is an orally active quinolinone preparation that exerts its positive inotropic effect not only by inhibiting phosphodiesterase, but also by decreasing the delayed outward and inward rectifying potassium current, increasing intracellular sodium by prolonging opening of sodium channels, and prolonging the action potential on a rate-dependent basis. Initial studies demonstrated that, in patients with heart failure, vesnarinone improves quality of life and exercise capacity and was well tolerated, without a seeming proarrhythmic effect. One large survival endpoint clinical trial of nearly 500 patients with left ventricular ejection fraction less than 30% who were treated with digoxin and an ACE inhibitor had a remarkable 62% reduction in risk of all-cause mortality and a 50% reduction in combined morbidity and mortality with the 60-mg dose (133). These results were highly significant, but they should be balanced against the dosage of 120 mg per day, which significantly increased mortality in this study. One side effect of vesnarinone is neutropenia, which occurs in 1% to 5% of patients exposed to the compound. The results of this clinical trial were particularly intriguing. Although vesnarinone has some phosphodiesterase activities, the mechanism of action is not entirely clear. Of interest, the drug attenuates certain aspects of cytokine activation in patients with heart failure. Vesnarinone appeared to offer benefits that apparently may have little to do with inotropic properties. Indeed, lower doses of the drug did not demonstrate significant inotropic or hemodynamic effects. All these conclusions, however, have been tempered by the more recently completed Vesnarinone Survival Trial, which was also a large-scale, placebo-controlled, multicenter, mortality endpoint study (82). Vesnarinone Survival Trial demonstrated an excess of mortality in the 60-mg dose group. This dose was associated with an increase in sudden cardiac death without favorable effect on secondary end points of quality of life, hospitalization, or worsening heart failure.

Ibopamine is an inotropic drug once considered for use in heart failure patients because of its dopaminergic activity (20). Ibopamine is the prodrug of epinine and stimulates dopamine-1 and dopamine-2 receptors as well as the $beta_1$-and $beta_2$-adrenergic receptors. There is a dose-related hemodynamic and inotropic response with this drug, and patients with heart failure had beneficial hemodynamic and renal blood flow changes, without inotropic effects, at lower doses. Several trials have suggested that the drug is beneficial when exercise performance end points were used to judge efficacy; however, the multicenter Prospective Randomized Ibopamine Trial of Mortality and Efficacy II trial was prematurely stopped because of increased mortality (79,161). Subgroup analysis of this study has revealed that the increased mortality was associated with concomitant use of the antiarrhythmic amiodarone.

Many explanations have been proposed to explain the rather dismal performance of inotropes in more recent clinical trials, but evidence-based explanations remain elusive. It is interesting to note the contemporary shift toward greater use of beta-blocker therapy in congestive heart failure patients as opposed to drugs affecting beta-receptor augmentation. Still, there remains the belief, fueled by the intuitive logic of positive inotropic agents in this setting, that these drugs will have a role in the management of heart failure. A preferred pharmacologic profile for inotropic drugs likely includes the requirements that neurohormonal activity should be attenuated or at least not exacerbated, heart rate should not be increased, and pharmacologic effects should not promote propagation of ventricular arrhythmias or increase myocardial oxygen consumption. One new drug, levosimendan, may represent an emerging inotropic compound that could prove beneficial in heart failure patients (162). This drug is available for intravenous use in Europe, and the oral formulation is now in clinical trials. In experimental models, levosimendan has demonstrated an antiischemic effect and has an action independent of traditional cyclic adenosine monophosphate pathways. It appears to be a "calcium-sensitizing" drug. It will be interesting to see if this compound is but one more inotropic drug failing to keep its promise.

Diuretics

Long the mainstay of congestive heart failure treatment, diuretics continue to play an important role (136). It is essential, however, that their utility be placed into proper perspective. Diuretics, for example, have never been studied in large-scale mortality trials in patients with heart failure but no overt congestion. There is no question

that they are essential agents to relieve the volume-overload states associated with congestive heart failure, but congestion is not necessarily always present in the majority of patients with heart failure. Furthermore, patients may develop congestive states that resolve with pulsed or intermittent diuretic therapy (163,164). As can be seen in *e*Table 92.5.2, substantive difficulties are possible, including hyponatremia, hypokalemia, metabolic alkalosis, and increased uric acid levels, setting the stage for overt gout or worsening renal function. Carbohydrate metabolism is frequently disturbed, with resultant hyperglycemia, insulin resistance, decreased insulin secretion, and nonketotic hyperosmolar states. Lipid perturbation is also a problem, but its significance is not well understood. Diuretic-specific side effects include the ototoxicity of furosemide, gynecomastia, and galactorrhea with spironolactone, metabolic acidosis caused by carbonic anhydrase inhibitors, and hyperkalemia caused by potassium-sparing diuretics, such as triamterene, spironolactone, and amiloride. When treating congestive heart failure, generally the least toxic drug (thiazides, such as hydrochlorothiazide or chlorthalidone) is prescribed in the lowest dose necessary to induce effective diuresis (*e*Table 92.5.3). As congestion worsens, longer-acting loop diuretics (such as furosemide, bumetanide, or torsemide) are prescribed. Occasionally, for particularly refractory edematous states, combinations of diuretic classes may be necessary. It should be emphasized that failure to mobilize salt and water is often due to inadequate sodium and fluid restriction, particularly in individuals recently diuresed and at risk of rebound sodium retention. Ensuring low sodium consumption is essential to success with these compounds. Acute resistance is generally overcome with an increased single diuretic dose. Chronic resistance can be addressed with the coadministration of thiazide or potassium-sparing diuretics with a loop diuretic. Using combinations of agents active at different points of the nephron is essential. From a pharmacokinetic standpoint, overcoming diuretic resistance by simply increasing diuretic dose is important. Altered bioavailability may account for some aspects of diuretic resistance, and there are different absorption kinetics associated with furosemide, bumetanide, and torsemide. Switching among these oral loop diuretics may be helpful. Alternatively, giving diuretics intravenously may accomplish the same end point.

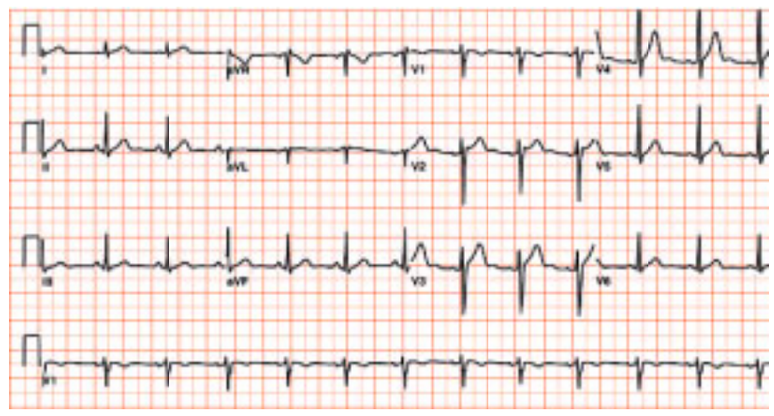
***e*TABLE 92.5.2** COMMON PROBLEMS WITH DIURETICS

Electrolyte disturbances
Hyponatremia
Hypokalemia
Hypomagnesemia
Hypocalciuria
Hyperuricemia
Metabolic alkalosis
Carbohydrate metabolism perturbation
Hyperglycemia
Insulin resistance
Decreased insulin secretion
Nonketotic hyperosmolar state
Lipid abnormalities
Increased low-density lipoprotein
Increased very-low-density lipoprotein
Increased total cholesterol
Increased triglycerides
Diuretic-specific side effects
Furosemide: ototoxicity
Spironolactone: gynecomastia and galactorrhea
Acetazolamide: metabolic acidosis
Potassium-sparing diuretics: hyperkalemia

***e*TABLE 92.5.3** MEDICATIONS COMMONLY USED IN CHRONIC HEART FAILURE TREATMENT PROTOCOLS

Drug	Initial dose (mg)	Target dose (mg)	Recommended maximum dose (mg)	Major adverse reactions
Thiazide diuretics				
Hydrochlorothiazide	25 q.d.	As needed	50 q.d.	Postural hypotension
Chlorthalidone	25 q.d.	As needed	50 q.d.	Hypokalemia, hyperglycemia, rash; rare severe reaction includes pancreatitis, bone marrow suppression, and anaphylaxis
Thiazide-related agents				
Metolazone	2.5 q.d.	As needed	10 b.i.d.	Same as thiazide diuretics
Loop diuretics				
Furosemide	10–40 q.d.	As needed	240 b.i.d.	Same as thiazide diuretics
Torsemide	10 q.d.	As needed	200 q.d.	Same as thiazide diuretics
Bumetanide	0.5–1.0 q.d.	As needed	10 q.d.	Same as thiazide diuretics
Ethacrynic acid	50 q.d.	As needed	200 b.i.d.	Same as thiazide diuretics
Potassium-sparing diuretics				
Spironolactone	25 q.d.	As needed	100 b.i.d.	Hyperkalemia, gynecomastia (spironolactone only)
Triamterene	50 q.d.	As needed	100 b.i.d.	—
Amiloride	5 q.d.	As needed	40 b.i.d.	—
Select angiotensin-converting enzyme inhibitors[a]				
Enalapril	2.5 b.i.d.	10 b.i.d.	20 b.i.d.	Hypotension, hyperkalemia, renal insufficiency, cough, skin rash, angioedema, neutropenia, nausea, dysgeusia
Captopril	6.25–12.50 t.i.d.	50 t.i.d.	100 mg t.i.d.	—
Lisinopril	5 q.d.	20 q.d.	40 q.d.	—
Quinapril	5 q.d.	20 q.d.	40 q.d.	—
Beta-blockers				
Bisoprolol	1.25 b.i.d.	5 q.d. (£85 kg); 10 q.d. (>85 kg)	20 q.d.	Same as carvedilol (plus vivid dreams)
Carvedilol	3.125 b.i.d.	25 b.i.d. (£85 kg); 50 b.i.d. (>85 kg); (minimally effective dose 6.25 b.i.d.)	25 b.i.d. (£85 kg); 50 b.i.d. (>85 kg)	Bradycardia, hypotension, atrioventricular block, worsening congestive heart failure, bronchospasm, fatigue
Metoprolol	12–25 b.i.d.	100 b.i.d.	100 b.i.d.	Same as carvedilol (hypotension may be less)
Metoprolol-CR/XL	12–25 q.d.	200 q.d.	200 q.d.	Same as carvedilol (hypotension may be less)
Angiotensin II receptor blocker				
Losartan	25 q.d.	50 q.d.	100 q.d.	Diarrhea, dyspepsia, orthostatic dizziness
Candesartan	16 q.d.	32 q.d.	32 q.d.	—
Valsartan	80 q.d.	160 q.d.	320 q.d.	—
Digoxin	0.25 q.d.	As needed	As needed	Cardiotoxicity, confusion, nausea, anorexia, visual disturbances
Hydralazine	10–25 t.i.d.	75 t.i.d.	100 t.i.d.	Headache, nausea, dizziness, tachycardia, lupus-like syndrome
Isosorbide dinitrate[b] (Isordil)	10 t.i.d.	40 t.i.d.	80 t.i.d.	Headache, hypotension, flushing
Isosorbide mononitrate				
Imdur	30 q.d.	As needed	240 q.d.	Same as isosorbide dinitrate
ISMO	20 b.i.d.	As needed	40 q.d.	Same as isosorbide dinitrate

[a]Angiotensin-converting enzyme inhibitors available, with dosages known to reduce mortality.
[b]Mortality benefit noted when given in combination with isosorbide dinitrate.
Modified from Konstam M, Dracup K, Baker D, et al. *Heart failure: evaluation and care of patient with left-ventricular systolic dysfunction. Clinical practice guideline.* AHCPR publication no. 94-0612. Rockville, MD: Agency for Health Care Policy and Research, U.S. Department of Health and Human Services, June 1994.



A 30-year-old male patient with U waves secondary to hypokalemia.

An 83-year-old female patient with hyperkalemia.

A 41-year-old with hyperkalemia.

A 9-year-old male patient with hyperkalemia and QRS widening.

It must be remembered that by reducing blood volume, diuretics lower cardiac filling pressures, with subsequent reduction in wall stress, pulmonary edema, and peripheral congestion. All these effects are advantageous, but reduction in plasma volume might adversely activate the renin-angiotensin-aldosterone and sympathetic nervous systems, paradoxically promoting further sodium and water retention while increasing impedance to left ventricular ejection. This effect could eventually contribute to the progression of heart failure remodeling. For this reason, diuretic therapy alone is not justified during heart failure treatment. The one exception might be the use of diuretics for treatment of hypertension (165,166). Long-term studies assessing major disease-specific outcomes in hypertensive patients receiving diuretics have demonstrated reduction in the incidence of stroke, congestive heart failure, coronary disease, and total mortality. This should be contrasted to outcomes noted with calcium channel blockers, which are meager with respect to similar benefits in hypertensives. Beta-blocker therapy in hypertensive patients is also effective in preventing stroke and congestive heart failure. When used primarily as antihypertensive agents or as adjuncts to control blood pressure, diuretics likely provide substantial benefits (166). Still, compulsive attention to the serum electrolyte profile is necessary.

The best method for initiating diuretic prescription is controversial. Some patients may respond to transient pulses of diuretics with resolution of the congestive state; with a low-salt diet, these patients do not require long-term diuretic therapy. This seems a wise tactic to take but is underused. Other patients might need intermittent, but regular, oral pulses of diuretics, whereas some require continuous administration of diuretics in large doses or combinations. Stopping diuretics entirely or creating an interval drug holiday should be considered in patients who have been on diuretics for chronic congestive heart failure but resolved their fluid retention state (164).

Direct-Acting Vasodilators

Elegant studies of pressure volume curves generated from echocardiographic study of normal and failing hearts have given additional insight into how the ventricle might best be manipulated to allow an effective transfer of the mechanical energy of ventricular contraction to cardiac output (37). Reducing the operating end systolic pressure toward a more energetically optimal level without changing contractility might give the energy-starved failing heart a better chance of healing. Care must be taken, however, that this energetically optimal position is not exceeded, because this might reflexively activate the sympathetic nervous system and renin-angiotensin-aldosterone axis. That is why concomitant use of beta-blockers, ACE inhibitors, or specific angiotensin II–receptor blockers might be a wise strategy, although it is not yet well characterized.

It is now well accepted that preload and afterload diminution in patients with heart failure reduces short-term morbidity and, with certain agents, long-term mortality (167). Relaxing venous capacitance vessels diminishes preload, whereas peripheral arteriolar dilation drops afterload and impedance to ventricular emptying. Venous capacitance vessels can be dilated by nitrates, such as nitroglycerin, nitroprusside, isosorbide dinitrate, and mononitrate preparations. Arterial resistance vessels are dilated by hydralazine. *e*Table 92.5.3 summarizes dosages and major adverse reactions for select agents. The combination of arterial and venous dilation occurs with ACE inhibitors and some alpha-adrenergic blockers (e.g., guanabenz and clonidine). Calcium channel blocking drugs are arteriolar dilators as well, but, as mentioned, concern exists about their use in the heart failure setting. Dilation of the arteriolar bed alone, without concomitant venous dilation, may fail to achieve sustained morbidity and mortality benefit. Likewise, although sudden dyspnea can be alleviated with acute administration of short-acting sublingual nitroglycerin, long-term attenuation of neurohormonal or mechanical responses by the failing ventricle may not be observed. Remember, it was the combination of hydralazine and isosorbide dinitrate in doses that provided balanced vasodilatory effects that were suggested as beneficial in the V-HeFT-I trial (77). Although isolated use of long-acting oral nitrates in congestive heart failure patients is thought to be useful at times, there are significant issues surrounding the development of nitrate tolerance, and no current preparation has regulatory labeling indicating this use (168,169 and 170). The nitrovasodilators, as a group, induce nitric oxide within vascular smooth muscle cells. This results in guanylate cyclase activation, which causes increases in cyclic guanosine monophosphate with subsequent vasodilation. Particularly in the setting of

atherosclerosis, endothelial dysfunction is associated with decreased nitric oxide availability, and nitrate supplies exogenous nitric oxide to the vascular wall and improves the vasodilator state. When nitrates are given, endothelium-dependent stimulation causes relaxation rather than constriction, which is characteristic of endothelial dysfunction. Evidence also suggests that nitrites have antiplatelet effects that might be important in patients with ischemic heart disease with respect to platelet aggregation and thrombosis. Nitrate tolerance develops, however, when blood levels are constantly elevated. Hemodynamic effects, as well as antianginal activity, are lost with chronic exposure to these agents. There is some suggestion that enhancement of vascular superoxide production secondary to exposure to nitrates may be an important mechanism in the development of tolerance (169,170). *In vitro* studies suggest that hydralazine, which has an antioxidant effect, prevents the nitrate-mediated formation of vascular superoxide and thus prevents nitrate tolerance. This observation may provide an explanation for benefits seen in V-HeFT-I with the combination of isosorbide dinitrate and hydralazine (77). By virtue of its capability to become a sulfhydryl donor, captopril is another drug that might combat nitrate tolerance. Alternatively, nitrate tolerance can be reversed after a washout period of 10 to 12 hours with thrice-daily administration patterns of isosorbide dinitrate (rather than every 4-, 6-, or 8-hour dosing schedules). Alternatively, isosorbide mononitrate preparations given once daily (Imdur) or in an asymmetric twice-daily fashion (ISMO) can obviate tolerance. If nitroglycerin patches are used, they should be limited to 8- or 12-hour administration periods, either at night to combat nocturnal dyspnea or during the day to treat exercise intolerance and dyspnea (169,170).

Angiotensin-Converting Enzyme Inhibitors

As might be anticipated from reviewing heart failure clinical trials (*e*Table 92.4.1 and Fig. 92.1 and Fig. 92.2), ACE inhibitors have now assumed the role of first-line drug in patients with heart failure. The reason for this is their multifactorial benefits, including interdiction of the renin-angiotensin-aldosterone system and balanced arterial and venous vasodilation. Significantly, a broad spectrum of heart failure patients have been studied with respect to ACE inhibitor use. Clinical trials that included asymptomatic patients with systolic left ventricular dysfunction (e.g., SOLVD prevention trial) (87) as well as extremely ill NYHA class IV congestive heart failure patients (e.g., CONSENSUS) (83) justify their use in such a wide spectrum. Every effort must be made to get patients with heart failure on a drug of this class at a proper dose. *e*Table 92.5.3 lists selective ACE inhibitors that have been evaluated extensively with mortality endpoint clinical trials so that the proper target dosages can be defined. It is important to remember that many smaller double-blind, placebo-controlled clinical trials have demonstrated the ability of ACE inhibitors to relieve dyspnea, improve exercise tolerance, and decrease the incidence of hospitalization for patients with mild to moderate heart failure. Furthermore, these drugs appear to prevent development of symptomatic congestive heart failure in many patients with asymptomatic left ventricular systolic dysfunction. In patients without symptoms, ACE inhibitors should be considered first-line drug therapy (even as monotherapy), with digoxin, diuretics, and possibly beta-blockers becoming important additive components as congestive symptoms develop. Although the beneficial effects of ACE inhibitors are likely related to “class” actions, regulatory labeling has been based on the types of clinical trials performed. For example, some agents have been suggested as useful in the postinfarct setting, and others have been given labeling approbation for mortality as well as morbidity reduction in heart failure patients. *e*Table 92.5.4 describes a reasonable ACE I dose-titration sequence for hospitalized patients. The prescription of these drugs in dosages similar to those used during clinical trial performance and in similar patient populations appears to be important (144). It has been suggested, for example, that underdosing of captopril is common. This may be fueled by fear of causing unacceptable reduction in blood pressure or worsening renal function. As discussed previously, defining optimal blood pressure in patients with ventricular dysfunction and heart failure is a contentious issue, and no precise target pressure can easily be identified. It appears, however, that the lowest blood pressure a patient can tolerate without significant orthostatic symptoms or renal dysfunction is the best in any specific clinical setting. *e*Table 92.5.4 proposes a schema for initiating ACE inhibitor therapy when patients are hospitalized with substantive congestive states. This schema is based on using the shorter-acting agent captopril acutely and avoiding it during aggressive diuretic administration. Although low doses are used initially, higher doses should be mandated (171). After patients have been exposed to the short-acting drug, switching to a longer-acting preparation such as enalapril or lisinopril seems reasonable so that compliance can be increased by decreasing multiple dosing points. Reasonable target dosages are 150 mg daily for captopril, 20 mg daily for enalapril, and 20 mg for lisinopril. Patients who are at risk for developing orthostatic hypotension after ACE inhibitor exposure include those with hyponatremia, azotemia, volume depletion, and orthostatic dizziness or syncope (172,173). Problems can be avoided with simple dosage adjustment techniques or reduction of aggressive diuretic therapies. It is important to remember ACE inhibitors are likely more important than diuretics in the heart failure patient long term, and therefore, when congestive states are relieved, it is more appropriate to sacrifice diuretic administration so that ACE inhibitors can be begun or maintained rather than continuing high diuretic dosages (or continuing diuretics at all). Still, ACE inhibitors can be challenging to administer. In the SOLVD study analysis of adverse effects of enalapril in 6,797 patients (double-blinded and placebo-controlled) followed over a 40-month average period, 28% of participants randomized to drug compared with 16% in the placebo group reported side effects (172). Enalapril use was associated with a higher rate of orthostatic hypotension (15% vs. 7%), azotemia (4% vs. 2%), cough (5% vs. 2%), fatigue (6% vs. 4%), and hyperkalemia (1.2% vs. 0.4%). All these observations were statistically significant. Angioedema occurred in 0.4% of patients exposed to the ACE inhibitor. Side effects resulted in discontinuation of blinded therapy in 15% of the treatment group compared with 9% in the placebo group. One must put the benefits of ACE inhibitors in perspective, however, and stopping the drug for a mild but troublesome cough might not be in the best long-term interests of the heart failure patient.

***e*TABLE 92.5.4** INITIATING ANGIOTENSIN-CONVERTING ENZYME I THERAPY IN HOSPITALIZED PATIENTS: RAPID TITRATION SCHEME

Captopril incremental increase: 6.25 mg → 12.5 mg → 25.0 mg → 50.0 mg t.i.d.
Hold diuretic 1 h before and 1 h after initial dose
Begin 12.5 mg orally (6.25 mg in labile[a] patient)
After 2 h, increase dose (if tolerated) to 25 mg orally
After 6 h, increase dose (if tolerated) to 50 mg t.i.d.
Target dose is 150 mg/d
Enalapril incremental increase: 2.5 mg → 5.0 mg → 10.0 mg b.i.d.
Hold diuretic 1 h before and 1 h after initial dose
Begin 5 mg orally (2.5 mg in labile patient)
After 6 h, increase dose (if tolerated) to 10 mg orally
After 12 h, increase dose (if tolerated) to 10 mg b.i.d.
Target dose is 20 mg/d
Chronic maintenance angiotensin-converting enzyme I targets[b]
Captopril, 50 mg t.i.d.
Enalapril, 10 mg b.i.d.
Lisinopril, 20 mg q.d.
Ramipril, 20 mg q.d.

[a]Labile patients are those with hyponatremia, azotemia, volume depletion, and orthostatic hypotension.
[b]Other angiotensin-converting enzyme I inhibitors have labeling approbation for heart failure therapy, but those selected are representative of short-, medium-, and long-term agents.

More recently, attention has been directed toward the question of differential effects of drugs based on race. Indeed, African-American patients with heart failure seemingly have a worse prognosis than Caucasians. To address this issue with respect to ACE inhibitors, an analysis of the SOLVD database has been published (174). Using a matched cohort design in which up to four white patients were matched with each black patient, a total of 1,196 white patients were compared with 800 black patients. The average duration of follow-up was approximately 34 months. The black and white patients had similar demographic and clinical characteristics, but the black patients had higher rates of death from any cause (12 vs. 10 per 100 person-years of follow-up) and of hospitalization for heart failure (13 vs. 8 per 100 person-years of follow-up). Despite similar doses of drug in the two groups, enalapril therapy, as compared with placebo, was associated with a 44% reduction (95% confidence interval, 27% to 57%) in the risk of hospitalization for heart failure among the white patients (p <.001), but with no significant reduction among black patients (p = .74). At 1 year, enalapril therapy was associated with significant reductions from baseline and systolic blood pressure and diastolic blood pressure among the white but not among the black patients. No significant change in the risk of death was observed in association with enalapril therapy in either group. The conclusion of this study was that enalapril therapy is associated with a significant reduction in the risk of hospitalization for heart failure among white patients with left ventricular dysfunction, but not among similar black patients. It is important, however, to note that this observation simply underscores the need for additional research on the efficacy of therapies for heart failure in black patients. It does not mean that ACE inhibitors should not be prescribed in this cohort. Furthermore, it must be pointed out that this was a retrospective analysis that was not prespecified. Furthermore, this type of observation has not been recapitulated with at least one beta-blocker, carvedilol, in clinical trials (see Beta-Adrenergic Blocking Agents, later in this chapter).

Angiotensin II Receptor Blockers

An alternative to ACE inhibitors might be a specific angiotensin II receptor antagonist (146,147). Such drugs might induce similar benefits to those observed in heart failure patients on ACE inhibitors, without some of the side effects seen with these agents (172,173,176). On the other hand, these compounds do not affect potentially beneficial cyclooxygenase pathways, which are activated by ACE inhibitors (176). Small clinical trials have demonstrated that the first commercially available angiotensin II receptor blocking agent, losartan, when given to patients with symptomatic heart failure, produced beneficial hemodynamic effects in the short term as well as after 12 weeks of therapy (173). There was a dose-related response, with 50 mg daily of losartan effecting the most significant changes, but higher doses likely not helpful. Hemodynamic effects are similar to ACE inhibitors with respect to reducing preload and afterload and increasing cardiac output. Furthermore, these agents are effective in preventing left ventricular hypertrophy in animals.

The first large-scale clinical trial with mortality endpoint data to give some insight into use of specific angiotensin II receptor blockade in patients with heart failure was the Evaluation of Losartan in the Elderly study (177,178). This multicenter, international clinical trial was a prospective, double-blind, randomized, parallel-group, captopril-controlled study performed in 722 ACE I–naïve patients (1:1 group randomization) age 65 years or older (66% older than 70 years) with mild to moderately symptomatic heart failure (primarily NYHA class II and III) and left ventricular ejection fraction of 40% or less. Mean ejection fraction was approximately 30%, and

patients primarily had heart failure due to coronary heart disease (68%). The primary end point was development of renal dysfunction after drug titration, defined as an increase in serum creatinine by 0.3 mg per dL from baseline. Secondary end points were combined mortality from all causes and heart failure hospitalization and mortality and hospitalizations for heart failure individually. Tertiary end points included drug tolerability and focused on symptomatic hypotension, potassium increase (greater than 0.5 mmol per L), cough, or other side effects prompting drug discontinuation. Drug administration protocol gives some insight into losartan dosing. After a 2-week placebo run-in, patients received either captopril (6.25 mg titrated to 12.5 mg, 25 mg, and then 50 mg three times daily) or losartan (12.5 mg titrated to 25 mg and then 50 mg daily). Dose increases generally occurred at 7-day intervals, as tolerated. Patients were followed for 48 weeks. The incidence of persistent renal dysfunction was the same (10.5%) in losartan and captopril cohorts. Losartan did appear to be better tolerated in this trial, with 27 patients stopping captopril because of dysgeusia, rash, or angioneurotic edema compared with none in the losartan group. It is interesting that the secondary mortality end point (composite of death and heart failure hospital admissions) demonstrated less all-cause mortality in the losartan group. This benefit was observed early and persisted throughout the 48-week observation period. This study prompted the Evaluation of Losartan in the Elderly II trial, which was a larger clinical trial having mortality as the primary end point (179,180). In contrast to Evaluation of Losartan in the Elderly trial, the second trial had no beneficial effect on mortality according to initial data analysis.

Still, the hypothesis that angiotensin II receptor antagonists might be beneficial in heart failure is intriguing because ACE activity may not be completely suppressed by traditional ACE I therapy because angiotensin II can also be formed by non-ACE or tissue chymase-dependent pathways (181,182 and 183). The more complete blockade of angiotensin II activity is theoretically more beneficial, but one reason to think these drugs might not be as effective as ACE I in heart failure is their lack of effect on bradykinin. As alluded to previously, bradykinin actions seem related to nitric oxide, and prostacyclin release, which may mediate vasodilation, is thought to be beneficial in these patients. On the other hand, bradykinin might account for some of the ACE I adverse reactions, such as cough, angioneurotic edema, and dysgeusia (173,175). Losartan could therefore provide more complete blockade of the tissue-active ACE systems without increasing bradykinin, which, in addition to being associated with certain mediators of vasodilation, can also precipitate norepinephrine spill.

Other studies addressing angiotensin II receptor blocking drugs in heart failure include the RESOLVD, Valsartan Heart Failure Trial, and Candesartan in Heart Failure—Assessment of Reduction in Mortality and Morbidity projects. RESOLVD focused on candesartan and was a double-blind (pilot) study (with 768 patients) in which congestive heart failure patients were randomized to candesartan in several doses, candesartan plus enalapril, or enalapril, for a mean of 43 weeks with exercise tolerance, ventricular function, quality of life, neurohormone levels, and tolerability of drug treatment protocol as end points (184). No differences were noted in exercise, functional class, or quality of life measurements, but left ventricular volumes decreased with natriuretic peptide and aldosterone levels significantly lower with the combination of an ACE inhibitor and angiotensin II receptor blocking drug. Perhaps more important was the fact that candesartan was as effective, safe, and tolerable as enalapril in congestive heart failure patients, with seemingly more beneficial effects when the drugs were combined than when used alone.

A second RESOLVD report details the addition of long-acting metoprolol to ACE inhibitors and candesartan (105). In this portion of the RESOLVD pilot program, metoprolol-CR was given in double-blind factorial designed fashion after the initial uptitration of candesartan or enalapril or their combination in 426 patients. The primary reason for this trial was to determine tolerability of extensive neurohormonal blockade with the combination of an ACE inhibitor, angiotensin II receptor blocker, and beta-blocker. No differences in exercise, functional class, or quality of life were noted between any of the groups, but significant improvement of left ventricular systolic function and attenuation of detrimental remodeling with a greater decrease of angiotensin II and renin levels was noted when metoprolol was added. Particularly impressive was the reduction in heart size and improvement in left ventricular systolic dysfunction in the group receiving an ACE inhibitor, candesartan, and the beta-blocker metoprolol.

Exploring the potential for added benefit with an angiotensin II receptor blocking drug was the Valsartan Heart Failure Trial (185). This study was a double-blind, placebo-controlled multicenter clinical trial of valsartan generally added onto an ACE inhibitor (92% of patients concomitantly on ACE inhibitors) with approximately 35% of the population on beta-blockers. All-cause mortality and combined mortality and morbidity were end points in this trial of over 5,000 patients. Results were preliminarily reported at the November 2000 American Heart Association meeting. This was the largest angiotensin II receptor blocking drug trial reported to date, and no mortality reduction was noted. Patients were, however, less likely to be hospitalized for worsening congestive heart failure when taking valsartan. Interestingly, perhaps there was an adverse interaction with patients on both ACE inhibitors and beta-blockers when valsartan was added. This is somewhat at odds with the previously summarized RESOLVD beta-blocker observations. We will have to await further clarification of this issue.

Perhaps the Candesartan in Heart Failure—Assessment of Reduction in Mortality and Morbidity program will help resolve some of these issues (186). Candesartan in Heart Failure—Assessment of Reduction in Mortality and Morbidity is actually three independent international parallel placebo-controlled mortality endpoint trials of candesartan in patients with congestive heart failure. The first trial of over 2,300 patients is in patients with left ventricular systolic ejection fraction less than 40% and treated with concomitant ACE inhibitors. The second trial is in patients with a similar degree of left ventricular systolic dysfunction but deemed “ACE intolerant.” Almost 2,000 patients will be entered into this trial. Finally, a third trial of over 2,500 patients will evaluate candesartan in individuals with congestive heart failure and ejection fraction greater than 40%. This program obviously will be testing the angiotensin II receptor blocking agent candesartan across the broad spectrum of chronic congestive heart failure and is the only ongoing trial of these agents evaluating this strategy in ACE-intolerant and “diastolic dysfunction” heart failure patients.

Calcium Channel Antagonists

Calcium channel blockers, as a group, are an example of agents that may create significant problems in patients with heart failure. Although these drugs are very effective in lowering systemic vascular resistance, they generally have negative inotropic effects. Granted, newer drugs in this class seem to have less negative inotropic activity and more potent selective peripheral vasodilatory effects. Still, to date, no sustaining symptomatic or mortality benefit, overall, has been demonstrated for these drugs when used in patients with congestive heart failure. At best, effects seem to be neutral for a few select compounds (amlodipine and felodipine) (85,86). Indeed, in patients who have had acute myocardial infarction complicated by left ventricular systolic dysfunction, calcium channel blockers have proved detrimental more often than not, with a greater chance of adverse effects seen in patients randomized to drugs such as nifedipine and diltiazem. Because patients with heart failure frequently have concomitant ischemic heart disease or hypertension, calcium channel blockers are frequently found as therapies in heart failure patients. Indeed, in the late 1980s, more patients in the SOLVD registry were on calcium channel blockers than on ACE inhibitors (47). Although this has changed somewhat more recently, it has been suggested that significant numbers of patients with heart failure (probably around 20%) are still taking these drugs. This strategy might best be reassessed on an individual patient basis. In the patient with heart failure, for example, control of hypertension with ACE inhibitors, diuretics, beta-blockers, angiotensin II receptor blockers, or other agents summarized in Table 92.6 may be preferred strategies. Treatment of angina pectoris with nitrates can be considered a substitute for treatment with calcium channel blockers. It should also be emphasized that, although ACE inhibitors are not acutely antiischemic in their actions, clinical trials have consistently demonstrated long-term diminution in major atherosclerotic heart disease end points (187,188). Patients with heart failure and angina pectoris should have aggressive attempts at percutaneous or surgical revascularization or medication therapies refocused on long-acting nitrates and beta-blockers.

TABLE 92.6 COMMON PITFALLS IN THE TREATMENT OF HEART FAILURE: FACTORS PREDISPOSING TO HEART FAILURE DECOMPENSATION

To date, amlodipine (85) and felodipine (86) have been the only two agents studied with reasonably designed clinical trials to suggest no detriment with the drugs. Because of the importance of this issue, details of these two studies should be reviewed. The PRAISE (74) trial randomly assigned 1,153 patients with severe chronic congestive heart failure (NYHA class III or IV) and ejection fraction less than 30% to either placebo or amlodipine for 6 to 33 months, while their usual therapy (digoxin, diuretics, and ACE inhibitors) was continued. Prerandomization stratification occurred based on a diagnosis of ischemic versus nonischemic heart disease etiology. Primary end point was all-cause mortality and hospitalization for major cardiovascular events. The primary end point was reached in 42% of placebo and 39% of the amlodipine group, an insignificant 9% reduction in the combined mortality and morbidity events (p = .07). In coronary artery disease patients, there was no difference between the amlodipine and placebo groups in the occurrence of a prior end point. On the other hand, among patients with nonischemic heart failure, amlodipine reduced the combined risk of fatal and nonfatal events by 31% (p = .04) and the risk of death by 46% (p <.001). Amlodipine, therefore, did not increase cardiovascular morbidity or mortality in patients with symptomatic and relatively severe heart failure and may actually decrease mortality in patients with nonischemic dilated cardiomyopathy. PRAISE II is critically evaluating this specific issue. V-HeFT-III (75) studied 451 male patients with NYHA class II or III symptoms, with chest radiographic cardiothoracic ratio greater than 0.66, echocardiographic left ventricular internal diastolic diameter greater than 2.7 cm per m^2, and ejection fraction less

than 45%. Background therapy was enalapril. Patients were randomized in factorial fashion to digoxin or placebo and then to felodipine or placebo. The cohort mean age was 63 years, approximately 53% had coronary heart disease accounting for their heart failure, and the mean ejection fraction was 30%. At the end of the 18-month follow-up period, total mortality was 31 deaths in the felodipine and 29 in the placebo groups (*p* = NS). Cardiovascular mortality also was not significantly different. Subgroup (coronary artery disease vs. nonischemic, NYHA class II or III, ejection fraction greater or less than 30%, norepinephrine levels, exercise time, or digoxin use) mortality risk ratios did not suggest that any particular set was benefited or harmed by felodipine. At the 27-week follow-up point, ejection fraction was significantly increased by felodipine compared with placebo, as was exercise time. The group on felodipine noted a decrease in atrial natriuretic peptide levels compared with placebo. In the early dosing phase, felodipine seemed associated with worsening heart failure. Conclusions from this trial are that felodipine, in ACE inhibitor–treated patients with mild to moderate heart failure, improves left ventricular function and certain humoral factors but does not produce any apparent effect on long-term morbidity or mortality. Although the small number of deaths in V-HeFT-III does not exclude an increase or decrease of mortality from felodipine, the overall experience suggests that this drug may be safe when used for other indications in mild to moderate heart failure. Still, this conclusion has to be balanced by the fact that these other conditions are usually hypertension or angina pectoris. There are many alternative strategies. It is interesting that the observations in V-HeFT-III were somewhat discordant with those of PRAISE in that no mortality benefit was seen in nonischemic veteran patients. Possible explanations for this difference include the fact that PRAISE enrolled NYHA class III and IV patients, whereas V-HeFT-III enrolled class II and III subjects and turned out to be underpowered with respect to mortality end points (too few events occurred). Other explanations might be that the nonischemic stratification scheme was flawed (no stress test was done in PRAISE to exclude ischemia, and neither study required coronary angiography). Alternatively, one could postulate that the PRAISE subgroup finding was a chance occurrence or that amlodipine really is quite different from felodipine.

Beta-Adrenergic Blocking Agents

As suggested earlier, the portfolio supporting beta-blocker use in patients with heart failure is rapidly expanding, with information suggesting that, although these agents may be difficult to use at times, significant benefit can accrue (189,190,191 and 192). The clinical trials Cardiac Insufficiency Bisoprolol Study, BEST, Prospective Randomized Evaluation of Carvedilol on Symptoms and Exercise/Multicenter Oral Carvedilol Heart Failure Assessment, Multicenter Oral Carvedilol Heart Failure Assessment, Metoprolol CR/XL Randomized Intervention Trial in Heart Failure, and COPERNICUS (*e*Table 92.4.1) have evaluated a variety of heart failure subsets. These trials should be compared with older, classic clinical trials evaluating the routine use of beta-blocker therapy after myocardial infarction. The BHAT (192) and Timolol Post-Infarction Trials (193) both demonstrated positive impact with beta-blockers after myocardial infarction with respect to survival and major ischemic events. Indeed, the group seemingly having the greatest beneficial impact with propranolol (Inderal) in BHAT was the one with heart failure during hospitalization. It has been difficult to sort through some of the issues regarding beta-blocker benefits, possibly because of the major differences between these drugs despite their all being classed in the same group. Beta-blockers generally can be categorized with regard to their ability block the different beta- and alpha-adrenergic receptors. Some are relatively $beta_1$ selective, and others are not. Additionally, some agents have intrinsic sympathomimetic activity. Finally, some agents, such as the drug carvedilol, combine $beta_1$- and $beta_2$-adrenergic receptor blocking activity, with alpha-blocking capabilities as well. In trials involving $beta_1$-selective beta-blockers in patients with left ventricular dysfunction, with or without acute myocardial infarction, no effect on sudden cardiac death was generally found. This may be due to interdiction of only one beta-receptor, with the second beta-receptor still permitting active signal transmission to the myocyte, which could perpetuate risk of arrhythmic death. It is interesting that trials using nonselective agents after myocardial infarction (propanolol and timolol) noted diminution in sudden cardiac death rates.

In a series of four randomized, placebo-controlled multicenter trials (100) of the nonselective beta-blocker carvedilol (remembering that alpha-blocking activity is also present with this drug), pooled analysis showed a 33% risk reduction for death. Analysis of each individual carvedilol trial demonstrated an interesting disparity: Although the studies, for the most part, had primary end points of exercise tolerance, they were generally not affected by carvedilol. Other data from these trials indicated that congestive heart failure symptomatology and NYHA functional classification and general patient well-being were significantly improved by carvedilol. These individual trial results, as well as the combined analysis, suggested a significant reduction in mortality.

As alluded to in the discussion of clinical trials, bisoprolol and long-acting metoprolol were demonstrated to be quite effective in patients with mild to moderate congestive heart failure secondary to broad-ranging difficulties and having depressed systolic left ventricular dysfunction (101,102,103 and 104). In contradistinction to the positive mortality trial endpoint results noted in the carvedilol trials, Cardiac Insufficiency Bisoprolol Study II and Metoprolol CR/XL Randomized Intervention Trial in Heart Failure, BEST, studying bucindolol, did not suggest mortality or morbidity benefit. Bucindolol is a nonselective beta-blocker with mild vasodilating properties. BEST focused, perhaps, a bit more on women, African Americans, and advanced heart failure patients. A total of 2,708 patients with NYHA class III (92%) or IV (8%) and left ventricular systolic dysfunction were evaluated. The trial was stopped after the seventh interim analysis because of no significant difference in mortality between the two groups. No harm was noted, and the point estimate for mortality was lower in the bucindolol group, but in a demographically diverse group of patients with NYHA class III or IV heart failure, bucindolol appeared not to be associated with significant survival benefit (109). This observation should not, however, taint the case of beta-blocker therapy for heart failure. As has been pointed out, the confidence intervals for this study overlap those of other trials, and the point estimate for mortality reduction did favor benefit with bucindolol. Furthermore, a significant improvement in survival with bucindolol was actually observed in nonblack patients who made up the majority of individuals enrolled in this and previous beta-blocker trials. Additionally, many of the secondary end points were favorably affected by bucindolol (107).

Nonetheless, this observation of a potential difference between black and nonblack patients in BEST should be counterposed to a report suggesting that benefits of carvedilol prescription in the United States carvedilol heart failure trials program were of similar magnitude in black and nonblack patients (194). As with the question raised previously regarding ACE inhibitor responsiveness based on race in heart failure cohorts, one should temper opinions about this issue until more definitive evidence comes available. These observations in BEST and with carvedilol may simply be the play of chance. Still, there may well be racial differences in the response to drugs that are likely to be characterized (195).

The COPERNICUS trial studied a quite ill population with heart failure (106). Carvedilol was evaluated in a double-blinded mortality endpoint trial of 2,289 patients with, generally, NYHA class IV heart failure manifest by symptoms at rest or on minimal exertion. Importantly, the patients were clinically euvolemic but had an ejection fraction of less than 25%. Patients were observed for almost 1 year during which standard therapies were continued. There was a 35% decrease in the risk of death with carvedilol and a 24% decrease in the combined risk of death or hospitalization. The favorable effects on end points were seen consistently in all subgroups examined and, particularly, in those most ill as reflected by multiple prior congestive heart failure hospitalizations. This study suggests that the previously reported benefits of carvedilol with respect to morbidity and mortality in patients with mild to moderate congestive heart failure were also found in patients with severe heart failure who met trial entry criteria (primarily, euvolemic with severe heart failure). As with other patients started on beta-blockers, cautious and slow uptitration of drug dosage seems the most prudent approach (34).

Perhaps third-generation beta-blocking compounds may be more advantageous in heart failure than selective beta-blocking drugs. It is interesting to note that carvedilol has also been said to have potent antioxidant properties that might provide additional, favorable pharmacologic effects in the heart failure patient. It appears that the ideal beta-blocker for treating heart failure is a compound that is nonselective with regard to beta-receptor blockage, induces vasodilation (generally by alpha-receptor blockade), does not downregulate $beta_1$-receptors, lowers systemic adrenergic activity, decreases cardiac sympathetic tone, causes minimal myocardial depression via negative inotropic effects, and reduces mortality and morbidity associated with the heart failure syndrome.

A few trials comparing metoprolol with carvedilol in heart failure patients are available. Based on these observations, some have suggested that carvedilol with its significant vasodilating and antioxidant properties might be a superior agent (195a). This is, however, a contentious issue, with patients seemingly best served by receiving one of the agents shown undisputedly in clinical trials to have benefited from beta-blocker prescription (196).

Antiarrhythmic Drugs and Implantable Defibrillating Devices

One of the more difficult issues to address in patients with heart failure is how to treat arrhythmia. The incidence of atrial and ventricular dysrhythmia in this patient population is high, and the temptation to use antiarrhythmic drugs is great. As indicated, class I antiarrhythmic agents are problematic in patients exhibiting clinical heart failure, particularly in the setting of an acute myocardial infarction. As reviewed, the Cardiac Arrhythmia Suppression Trial and Survival with Oral D-Sotalol trials (*e*Table 92.4.1) indicated that encainide, flecainide, moricizine, and D-sotalol actually increased mortality. These observations are troublesome because the patient at highest risk of sudden cardiac death seems to be the individual who would benefit most from arrhythmia control. However, this is also the patient likely to have proarrhythmic events associated with antiarrhythmic drug prescription. Indeed, there is a fairly clear-cut relationship between ejection fraction and antiarrhythmic drug efficacy, as well as a direct relationship between heart failure severity and adverse proarrhythmic effects with most compounds. The lower the ejection fraction, the less likely potent antiarrhythmic drugs are to control potentially malignant arrhythmias. Beta-blockers and amiodarone may be possible exceptions to this generalization, but clinical trials have produced disparate results. Amiodarone use is, indeed, more controversial (197,198,199,200 and 201). Amiodarone does seem to be a valuable adjunct during therapy for atrial fibrillation. Unfortunately, amiodarone is expensive and sometimes poorly tolerated, with toxicities that include pulmonary fibrosis, thyroid function disorders, and photosensitization syndromes. It is intriguing, however, to note that low-dose amiodarone may be better tolerated and still have apparently beneficial hemodynamic effects (199). Indeed, any beneficial effects amiodarone may have in the heart failure syndrome might be independent of antiarrhythmic drug action.

Because antiarrhythmic drug therapy has been so problematic in the heart failure patient, use of implantable electronic arrhythmic termination devices may be preferable in patients with potentially malignant ventricular arrhythmias and heart failure. Still, however, it should be realized that many patients who have these devices continue to be on antiarrhythmic therapies. A relatively recently completed clinical trial has given some insight into this issue. The Multicenter Automatic Defibrillator

Implantation Trial (202) was a randomized trial of defibrillating devices versus conventional therapy in post–myocardial infarction patients with ejection fraction less than 35%, nonsustained ventricular tachycardia, and then nonsuppressible ventricular tachycardia at the time of electrophysiologic study. This trial suggested that device implantation led to better survival in this high-risk atherosclerotic cardiovascular disease population with ventricular dysfunction and heart failure. Beta-blockers and amiodarone use did not appear to have a significant effect on the risk reduction ratio in patients assigned to the device group.

Several additional clinical trials have prospectively evaluated the value of antiarrhythmic drugs or defibrillating devices in a setting of ischemic heart failure (coronary heart disease with an ejection fraction of less than 40%) and ventricular tachycardia. Three secondary prevention trials have suggested that an implantable cardioverter defibrillator was superior to antiarrhythmic drugs (generally amiodarone) in reducing mortality. Some have argued that the major benefit of implantable defibrillating devices occurred in those with lower ejection fractions. The Antiarrhythmics vs. Implantable Defibrillators Trial (203), the Canadian Implantable Defibrillator Study (204), and Cardiac Arrest Study—Hamburg trial (205) were secondary prevention trials and should be compared with the Multicenter Automatic Defibrillator Implantation Trial discussed previously and an additional primary prevention trial, Multicenter Unsustained Tachycardia Trial (206).

These observations provide an alternative strategy for treatment of selective patients with heart failure and life-threatening arrhythmias. It must be emphasized that often the best treatment of ventricular arrhythmias in the heart failure milieu is careful attention to relieving the congestive state and optimizing ventricular performance with vasodilators, diuretics, and ACE inhibitors. Correction of fluid balance and electrolyte disorders may be quite helpful. Addressing atrial fibrillation in heart failure is also sometimes critical to improving patients' symptoms. Obviously, care must be taken in these patients to ensure that risk of thromboembolism is as low as possible with anticoagulants. Because of the known adverse outcome of heart failure patients treated with Vaughn Williams class I antiarrhythmic drugs, consideration of the relative risk of using quinidine, procainide, and other similar agents is challenging.

Indeed, it should be emphasized that the American College of Cardiology/American Heart Association guidelines regarding heart failure therapeutics caution against aggressive pharmacologic or mechanical treatment of asymptomatic ventricular arrhythmias (53). To consider either pharmacologic strategies or implantation of arrhythmia-termination devices, patients should have significantly symptomatic ventricular tachycardia (not simply palpitations) or an episode of syncope or sudden cardiac death syndrome.

Ventricular Resynchronization

Because patients with heart failure, systolic left ventricular dysfunction, and wide QRS complexes have dyssynergic contractility, using multisite atrial right and left ventricular pacing strategies has been proposed. So-called biventricular cardiac resynchronization pacing for heart failure is being actively studied, with some trials focusing solely on resynchronization pacing for severe congestive heart failure [Multicenter InSync Randomization Clinical Evaluation (North America); *e*Table 92.4.1], whereas others include defibrillator insertion or antiarrhythmic therapies (Sudden Cardiac Death—Heart Failure Trial, Multicenter InSync Randomization Clinical Evaluation Implantable Cardioverter Defibrillator; *e*Table 92.4.1). Some trials are secondary prevention studies (secondary prevention with heart failure treatment) or primary sudden cardiac death prevention (primary sudden cardiac death prevention with heart failure therapy). Completion of these studies will clarify best strategies regarding defibrillator implantation or coupling defibrillator implantation to resynchronization pacing therapeutics. More recently published data do, however, suggest that patient quality of life and exercise capacity are improved with resynchronization mode pacing. The Multisite Stimulation Cardiomyopathy Trial was the first such study to be reported (207). Particularly interesting is the fact that patients appear to have reduction in mitral regurgitation when undergoing biventricular pacing.

Anticoagulants

Routine anticoagulation in patients with heart failure may not be necessary (75). Patients with substantive congestive heart failure frequently have significant hepatic congestion, and, because of this, anticoagulation can be difficult to achieve safely. Furthermore, with the large number of drugs taken by patients with heart failure (Fig. 92.1 and Fig. 92.2), an important tenet is to continue only those medications with demonstrated effectiveness. This practice helps ensure compliance with drug treatment regimens. Routine anticoagulation in heart failure patients has never been convincingly demonstrated to be beneficial in well-designed clinical trials despite the fact that heart failure patients have relative hypercoagulable states (208). Some studies have suggested a lower incidence of pulmonary and peripheral emboli in patients on warfarin (209), but, on the whole, the data are not overwhelmingly persuasive. It may be prudent to anticoagulate heart failure patients with a history of systemic or pulmonary embolism or when left or right ventricular thrombi are noted on echocardiography. Certainly, atrial fibrillation is a clear-cut indication for careful anticoagulation. Candidates for anticoagulation should be monitored carefully, with a goal of achieving an international normalization ratio for prothrombin times of 2 to 4.

Video 92.6 This 45-degree transesophageal echo view demonstrates the pulmonary artery bifurcation in the center of the screen and the aorta in cross section to the left. This can be useful to see a large saddle pulmonary embolus at the bifurcation. However, smaller, more distal emboli would be missed. *This video must be viewed with QuickTime. PITFALLS IN TREATING HEART FAILURE

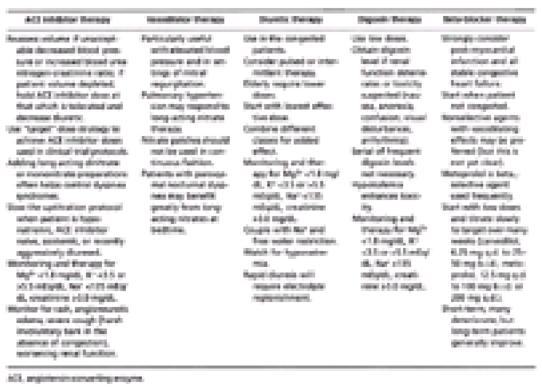
Table 92.6 lists many of the common pitfalls that trap clinicians when evaluating and treating heart failure patients. Inadequate recognition of the syndrome, or symptoms that are related not to cardiac dysfunction but to other conditions, makes any therapeutic adventure a challenge. Starting late in a patient's disease course makes failure to beneficially affect long-term morbidity and mortality more likely. A focus on preventive therapeutics is necessary. Ignoring the patient's underlying disease state and focusing only on symptomatic elements of heart failure sets the stage for recurring difficulties. Granted, some disease processes, such as advanced ischemic heart disease, are difficult to ameliorate. However, it is a mistake to not consider therapies to reverse myocardial ischemia. Obviously, unrecognized hyperthyroidism, hypothyroidism, poorly controlled diabetes mellitus, and inadequate control of hypertension contribute to making the heart failure state worse. Atrial arrhythmias can be quite problematic, and an attempt should be made, if at all possible, to keep patients in normal sinus rhythm. Chronotropic incompetence or certain arrhythmias might respond to pacemaker therapy. Inadequate salt and water restriction sets the stage for hyponatremia, hypokalemia, and dropsical states despite aggressive diuretic use. Excessive alcohol consumption, particularly in patients with dilated cardiomyopathy, is likely harmful and can contribute to worsening heart failure states. Concomitant use of potentially harmful medications (such as Vaughn Williams class I antiarrhythmic drugs and nonsteroidal antiinflammatory agents) might be part of a therapeutic protocol and should be stopped, if possible. Excessive intravascular volume depletion with diuretics can be counterproductive by producing orthostatic symptoms and further activating adverse neurohumoral factors important in the pathophysiology of heart failure. On the opposite side of this spectrum is ineffective diuretic prescription, which does not mobilize fluid adequately: diuretic doses that are too low, combinations that are not rational (e.g., combining two loop diuretics, such as furosemide and torsemide), or failure to switch from oral to parenteral diuretic administration when necessary. Use of inadequate ACE inhibitor doses or failure to start ACE inhibitor therapy is a major difficulty. Every attempt should be made to get patients on target ACE inhibitor doses, and, rather than sacrificing the ACE inhibitor in an aggressively diuresed patient, the diuretic dose should be decreased. Likewise, use of suboptimal doses of vasodilators because of "relative hypotension" can produce a clinical scenario in which high afterload negatively affects cardiac systolic performance. Sometimes we see the reflex prescription of parenteral salt solutions for orthostatic hypotension or hyponatremia. A cycle of aggressive diuretic administration, low blood pressure, parenteral fluid administration, then congestion often develops in hospitalized patients, and this is counterproductive to appropriate long-term therapy. Only patients with shock and clear-cut intravascular volume depletion should have volume-expanding fluids administered. It is best to allow hyponatremia to correct on its own, with salt and water restriction and, possibly, concomitant parenteral loop diuretic administration. Orthostatic hypotension generally responds to bed rest with a reduction in diuretics or, possibly, vasodilators. When the situation becomes confusing and volume status is difficult to clinically assess, failure to use hemodynamic monitoring simply perpetuates the inability to resolve the challenging situation. Ponderosity with cardiovascular deconditioning and poorly compliant patients are difficult situations, but sometimes aggressive counseling and cardiac rehabilitation programs help to ameliorate these challenges. Because of the cytokine liberation that infections produce, not recognizing or treating intercurrent infections in patients with heart failure allows the syndrome to worsen. Furthermore, some difficulties, such as hypoventilation sleep apnea syndromes, when treated with theophylline preparations or nocturnal positive pressure breathing devices, dramatically improve the heart failure syndrome. This is particularly the case in individuals with pulmonary hypertension and right-sided heart failure.

CONSIDERATIONS DURING IMPLEMENTATION OF HEART FAILURE TREATMENT GUIDELINES

Table 92.7 summarizes important issues to consider when initiating heart failure therapy. Assuming that the proper diagnosis has been made, etiology identified, and precipitating causes of clinical decompensation eliminated, clinicians can strive to create effective therapeutic programs. With regard to institution of ACE inhibitor therapy, one must assess and intermittently reassess volume status if unacceptable hypotension or azotemia is present. Decreasing ACE inhibitor dose or adjusting the use of diuretic therapies often allows uptitration of the ACE inhibitor so that optimal doses can be taken. One should use a target dose strategy. These ACE inhibitor doses were chosen for evaluation in the many clinical trials carried out in heart failure populations. When patients are hyponatremic, ACE inhibitor–naïve, azotemic, or have recently been diuresed aggressively, slow upward titration of drug after starting with low doses is reasonable. Serum magnesium levels should be kept above 1.8 mg per dL, potassium levels between 3.5 and 5.5 mEq per dL, sodium greater than 135 mEq per L, and creatinine greater than 3.0 mg per dL if at all possible. Administering magnesium often helps to control hypokalemia. One should monitor patients for development of rash, angioneurotic edema, worsening renal function, and severe cough, which can be blamed on the ACE inhibitor use. This troublesome cough is frequently described as a harsh involuntary bark in the absence of congestion. One must be cautious about the inappropriate discontinuation of the ACE inhibitor, however, because many patients cough due to pulmonary hypertension, pulmonary congestion, or chronic obstructive pulmonary disease that accompanies the heart failure syndrome. It may be inappropriate to discontinue the ACE inhibitor for the latter reasons. Rather, attention to ameliorating these difficulties seems more appropriate. Often, when patients are told of the importance of ACE inhibitor effects, they are willing to continue taking these drugs. Some have proposed substituting angiotensin II receptor blocking drugs, such as losartan, for ACE inhibitor–intolerant patients.



ACE inhibitor therapy	Vasodilator therapy	Diuretic therapy	Digoxin therapy	Beta-blocker therapy

ACE, angiotensin-converting enzyme.

TABLE 92.7 ISSUES TO CONSIDER WHEN INITIATING HEART FAILURE THERAPY

When initiating diuretic therapy as part of the treatment algorithm, make certain that the focus is on either congestion or hypertension. Consider the use of pulsed or intermittent diuretic therapy, use lower doses in elderly patients, and, generally, start with the lowest effective dose of the class chosen. For more intense diuresis, consider combinations of different classes of diuretics. Strive for substantive sodium and free water restriction, and monitor serum solutes to keep the magnesium, potassium, and sodium greater than 135 mEq and creatinine levels reasonable. Remember that thiazide and thiazide-type diuretics and the combination of thiazide diuretics with a loop diuretic can precipitate hyponatremia easily. This is generally the case when free water and sodium consumption is excessive. Again, sodium and water restriction is important to prevent this difficulty. Also important is the fact that a rapid diuresis generally requires electrolyte replenishment.

When digoxin is prescribed for heart failure, it should be used in lower doses than previously suggested. Frequent digoxin levels are not necessary. Serum concentration should be determined if the heart failure syndrome worsens, if absorption problems or patient noncompliance are suspected, if renal function deteriorates, or if toxicity is possible. As with ACE inhibitor and diuretic therapy, it is important to monitor patients intermittently for serum magnesium, potassium, sodium, and creatinine levels.

The use of non–ACE inhibitor vasodilator therapy in heart failure patients can be particularly useful when the systemic blood pressure is elevated (sometimes despite ACE inhibitors) and in the setting of mitral regurgitation. Of course, the combination of hydralazine and isosorbide dinitrate is more frequently used because this combination was the first to suggest that mortality could be attenuated in heart failure populations with vasoactive compounds. When used as mortality-reducing therapies, the drugs should be combined. Pulmonary hypertension often responds nicely to long-acting nitrate therapy. One should be careful to administer these drugs in a fashion that does not produce continuous serum levels of nitrate such that tachyphylaxis might occur. Often, troublesome paroxysmal nocturnal dyspnea or orthopnea improves greatly when chronic long-acting nitrates are administered at bedtime.

Major issues to consider when initiating beta-blocker therapy include considering them in every patient who has had an acute myocardial infarction, particularly in combination with an ACE inhibitor when left ventricular systolic dysfunction is present. Beta-blocker therapy should be begun when patients are stable and not overtly congested. Some suggest that nonselective agents with vasodilating effects (e.g., carvedilol) are preferred. Still, metoprolol is one $beta_1$-selective agent used frequently in heart failure settings, including post–myocardial infarction left ventricular systolic dysfunction. Therapy should be begun with low drug doses and a titration time period of many weeks.

STRATEGIES FOR PERSISTENT CONGESTION

*e*Table 92.7.1 addresses several strategies to consider when there is apparent failure of chronic oral outpatient treatments. One should review the pitfalls listed in Table 92.6 in an attempt to identify ancillary or extraneous issues that might account for this decompensation and then move toward the strategies outlined. Of course, many patients simply have progression of their disease.

***e*TABLE 92.7.1** STRATEGIES TO CONSIDER WHEN CONGESTION PERSISTS DESPITE OPTIMIZED DIGOXIN, DIURETIC, AND ANGIOTENSIN-CONVERTING ENZYME INHIBITOR OR VASODILATOR THERAPY

Placement of pulmonary artery catheter capable of measuring capillary occlusive pressure (cardiac output determination and oximetric mixed venous saturation measurement capabilities also helpful)
Hemodynamically guided
Parenteral vasodilator therapy (nitroglycerine, nitroprusside)
Parenteral inotrope therapy (dobutamine, milrinone)
Continuous parenteral loop diuretic infusion
Infusion of “dopaminergic” or “renal” doses of dopamine (<5 µg/kg/min)
Hemofiltration or ultrafiltration
Peritoneal dialysis

Placing pulmonary artery catheters and objectively measuring hemodynamics is at the root of clarifying confusing or challenging situations. With objective flow and pressure measurements, as well as the frequent determination of mixed venous oxygen saturation, tailoring therapeutics to each patient’s clinical situation becomes possible. Parenteral vasodilator therapy (generally nitroglycerin and nitroprusside) alone or in combination with inotrope infusion (usually dobutamine or milrinone) can be dramatically effective. Continuous diuretic infusions, generally with a loop diuretic, such as furosemide, are an alternative strategy to consider in the patient with refractory edema. Although controversial, infusion of dopaminergic or so-called renal doses of dopamine (less than 5 µg per kg per minute) has been said to be helpful in patients refractory to diuretics and in those with worsening renal function. When substantive dropsy persists despite all of these recommendations, hemofiltration ultrafiltration, or, possibly, peritoneal dialysis frequently removes substantial quantities of volume and improves the patient’s symptoms rather dramatically.

TREATMENT OF ADVANCED OR REFRACTORY HEART FAILURE

*e*Table 92.7.1 lists options to consider for the patient with advanced heart failure. In patients who have progressive and steadily worsening heart failure syndromes, therapeutic tracks become narrowed, but many still exist. When all attempts fail to create an adequate pharmacotherapeutic program that is successful in keeping patients symptom free over the long term, parenteral drug infusion protocols (which generally use dobutamine, dopamine, or milrinone or sometimes combinations of these drugs) can dramatically reduce symptoms. There is a suggestion, however, that these infusion therapies actually increase mortality. One must weigh carefully the risks and benefits of this approach. It may be an entirely acceptable trade-off in the truly end-stage patient suffering greatly from refractory congestive states. Furthermore, the necessity of indwelling central venous catheter line access creates many challenges with respect to provision of skilled care givers and provision of support for administering the drugs. Obviously, infections and catheter malfunction are major difficulties. Whether chronic infusion of these drugs is necessary, or if they can be given in pulsed parenteral fashion once weekly or monthly over shorter periods (6 to 24 hours), is not known. Also unknown is the best strategy to attempt long-term drug weaning. One practice is to infuse these drugs continuously for a 4- to 6-week period and then attempt to wean as an outpatient over several days or weeks.

One should always consider higher-risk standard operative or percutaneous coronary interventional procedures in the patient with advanced heart failure. Although they are not always options, some patients with substantive ischemia or repairable valvular heart lesions have responded rather dramatically. Coronary artery bypass graft surgery, mitral and aortic valve repair or replacement, left ventricular aneurysmectomy, and endoaneurysmorrhaphy can all be effective options. Percutaneous transluminal coronary angioplasty also likely plays a role when objective evidence of ischemic myocardium related to target coronary lesions is apparent. The main challenge is to identify patients with viable and salvageable myocardium, who are likely to benefit from procedures of this sort. Individuals with extensive scarring of their ventricles may not be the best candidates. Several alternative operative approaches are currently being evaluated. These include dynamic cardiomyoplasty, ventricular remodeling surgery, ventricular assist devices, and total artificial heart implantation.

Dynamic cardiomyoplasty involves mobilization of the latissimus dorsi muscle into the chest, encircling the heart, and inserting pacing and myostimulating devices to train the skeletal muscle to become a fatigue-resistant contractile force. Anecdotal experience and some aspects of clinical trial data suggest that patients with moderately severe heart failure may benefit from this procedure. Innovative strategies, which include using the latissimus dorsi to wrap extra cardiac pumps or the aorta to provide counterpulsation, are also intriguing, but not yet well studied. Ventricular reduction or remodeling surgery generally accompanies repair of mitral and tricuspid valve regurgitation and may be an option for certain individuals with ischemic cardiomyopathy. Ventricular assist devices have proved to be lifesaving in acute cardiogenic shock states when they are inserted as an attempted “bridge to recovery” or “bridge to cardiac transplantation.” These devices, as well as cardiac transplantation, are addressed in detail in other chapters.

SUMMARY OF APPROACH TO HEART FAILURE THERAPEUTICS

Table 92.8 summarizes a rational approach to heart failure therapeutics. Tailored therapeutic protocols are based on the progression of patients from insidious to symptomatic to advanced or refractory heart failure settings. It relates the philosophy of prevention to treatment strategies. Also important is the coupling of efforts to address underlying diseases with medication prescription and lifestyle issues, which include increased aerobic activity, optimization of weight, dietary restriction of sodium and fluid, and appropriate vitamin and electrolyte supplementation.

TABLE 92.8 SUMMARY OF APPROACH TO HEART FAILURE THERAPEUTICS

Making an appropriate diagnosis is paramount, as is staging the heart failure syndrome severity. Stopping potentially detrimental drugs, or those of unproved benefit, is as important as beginning appropriate therapeutic regimens designed to prevent functional deterioration, reduce mortality, or control symptoms when symptomatic heart failure (particularly congestive heart failure) is present. Underlying these important principles is the concept that rational polypharmacy is mandatory because these patients are on multiple drugs and combinations of drugs. The fewest drugs possible should be prescribed and dispensed in such a way that the fewest side effects appear and compliance can be high. Finally, the period is over in which chronic bed rest is an important component of heart failure therapy. It is likely that the medications used today achieve the same results of yesteryear’s bed rest prescriptions. We now know it is quite important that patients with all except the severest end stage of heart failure attempt to exercise aerobically. Patients with heart failure should be referred to supervised cardiac rehabilitation programs, if at all possible, to become schooled in aerobic training exercises. This is an adjunctive opportunity for more general patient education as well.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Obviously, individuals frequently managing patients with heart failure have had different experiences and interpret anecdotal or clinical trial data in many ways. Controversy exists. It should be apparent from the foregoing discussion that heart failure treatment protocols are broad and complex. This is because the syndrome is, in fact, a difficult milieu. Much has been learned about designing heart failure treatment protocols, but perhaps most important is the necessity of beginning early in the difficulty to prevent deterioration to advanced stages. Therefore, tailoring therapeutics to each individual’s particular clinical situation seems most important. ACE inhibitors are now first-line treatment for heart failure. Beta-blockers have emerged as rational options, and an argument is even made that they provide greater opportunity for benefits than ACE inhibitors. Still, it is apparent that despite the fact that ACE inhibitors and beta-blockers are now considered first-line therapy, they are frequently not prescribed, are underdosed, or prematurely discontinued. Whether angiotensin II receptor blocking agents are effective substitutes for ACE inhibitors in intolerant patients or, more generally, better than ACE inhibitors is not yet known, although initial data are encouraging. Combining these two drug classes is an intriguing thought. It seems that beta-blocker benefits are most notable over the long term and that, during the short term, patients frequently feel worse. Many argue that digoxin should be prescribed in all congestive heart failure patients for morbidity reduction, and that triple therapy with digoxin, diuretics, and ACE inhibitors is the best basic heart failure treatment protocol in those with congestive states. Antiarrhythmics should be avoided if at all possible, particularly Vaughn Williams class I antiarrhythmic drugs. Alternative strategies might include arrhythmia ablation techniques, implantation of electronic arrhythmia-terminating devices, and, possibly, amiodarone. Amiodarone is one antiarrhythmic agent that may actually be beneficial in some heart failure patients, and it is possible that the toxicity of this drug can be controlled with prescription of much lower doses. Cardiac resynchronization with multisite pacing is emerging as an attractive strategy.

It is not clear if chronic parenteral inotrope infusion reduces end-stage heart failure morbidity and mortality, although most believe that symptoms are substantively reduced at the cost of higher sudden cardiac death rates. Arguably, chronic parenteral inotropic infusion is preferred to intermittent or periodic pulsed infusions. In general, positive inotropic drugs that do not ameliorate adverse neurohormonal profiles seem detrimental to long-term prognosis in heart failure patients, although they may attenuate morbidity. Diuretics should only be used in congestive states or as an antihypertensive agent. It seems that we pay inadequate attention to electrolyte and solute replenishment in many heart failure patients. Furthermore, aerobic exercise is good for heart failure patients, not detrimental, and should be encouraged.

THE FUTURE

Emerging pharmacotherapeutic strategies will likely influence the direction heart failure treatment paradigms take in the future. Preliminary reports using growth hormone in patients with substantive left ventricular dysfunction are intriguing (210). Administration of this humor might beneficially remodel the heart. On the other hand, growth hormone might induce undesired levels of interstitial matrix deposition that results in diastolic dysfunction and unnatural myocyte hypertrophy. Endothelin has been recognized as a paracrine humor important in increasing vascular bed resistance. Endothelin-blocking agents are being studied with respect to their hemodynamic, humoral, and clinical effectiveness (211,212 and 213). A variety of natriuretic peptides have been identified and found useful in characterizing severity of heart failure as well as having some potential therapeutic benefits (214). B-type natriuretic peptide blood concentration measurement now available as a “point of care” test appears to be a sensitive and specific test to diagnose congestive heart failure in the urgent care setting (215). Indeed, this test may become the “CBC” of heart failure as it has been shown to reliably predict the presence or absence of left ventricular dysfunction on echocardiography. This test may be an excellent screening tool for left ventricular dysfunction and may preclude the need for echocardiography in many patients (216). Furthermore, in patients admitted with decompensated congestive heart failure, changes in B-type natriuretic peptide levels during treatment are strong predictors of mortality and morbidity and have been successfully used to guide treatment of patients admitted for decompensated congestive heart failure (217). B-type natriuretic peptide produced by recombinant DNA techniques is now available for parenteral infusion in severe congestive heart failure (218). With the realization that heart failure has inflammatory elements characterizing the milieu, methods to attenuate cytokine trafficking with antibodies or anticytokine agents may prove beneficial. Intriguing studies are ongoing to clarify this issue (19). Simple, durable, and reliable permanent ventricular assist device pumps will become available and will be used as both alternative treatments versus transplantation or bridges to recovery with subsequent pump removal (145). Myoblast implants (219,220) may serve a similar purpose. Even more futuristic is the likelihood that therapies can be designed to interdict the apoptotic signaling loops at a molecular biodynamic level. This would be the ultimate in reversing adverse remodeling (221,222,223,224,225,226,227 and 228).

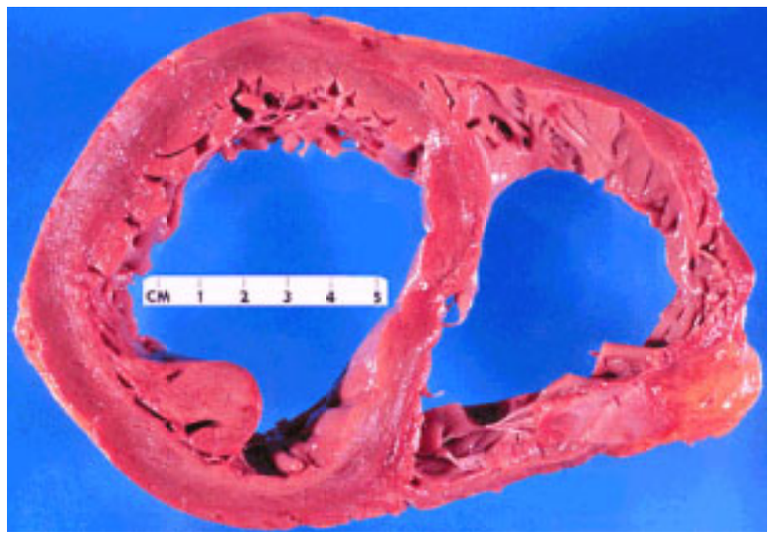
OVERVIEW

Myocardial inflammation underlies cardiac dysfunction in a wide spectrum of disorders, from lymphocytic myocarditis (1,2) to idiopathic dilated cardiomyopathy (IDC) (3). Animal models and clinical studies support viral etiologies in the majority of cases, although specific infectious agents are documented in only a fraction. Therapy remains supportive because, despite this inflammatory pathogenesis and scores of anecdotal series that suggest a therapeutic role for immunosuppression, controlled trials have consistently failed to demonstrate clinical benefit (4,5 and 6). Endomyocardial biopsy, once widely used for diagnosis, is currently not recommended for the majority of cases given the absence of specific biopsy-guided therapies (7). Giant-cell myocarditis remains one exception, as biopsy confirmation of this aggressive disorder may assist in therapeutic decisions, including the consideration of immunosuppressive therapy (8). The potential future role for immune modulatory therapy remains an intense area of investigation.



Dilated congestive cardiomyopathy. Both the left and right ventricles are significantly enlarged. In this example, the left ventricular wall thickness falls within normal limits.

INTRODUCTION

Primary dilated cardiomyopathy or IDC is a leading cause of congestive heart failure in the United States, particularly among young people (9). Although cardiac inflammation is postulated as an important early pathologic event, signs of systemic inflammation are rarely seen at presentation. Myocarditis, an often suspected but infrequently diagnosed disorder of primary cardiac inflammation, is believed to be an early precursor of IDC (10). Whether these two diagnoses are distinct entities or merely separate time points in a pathologic progression remains a matter of significant controversy. Over the last two decades, the search for mechanistic-based therapies for primary dilated cardiomyopathy has focused on the inflammatory pathogenesis. This current intensive period of investigation can be seen as the culmination of nearly two centuries of broad clinical interests in this common and mysterious form of cardiac disease.

HISTORICAL PERSPECTIVE

Clinicians in the early nineteenth century, guided by introduction of the stethoscope by Laënnec, divided cardiac disorders into valvular and nonvalvular (11). “Carditis” was a subset of nonvalvular disease that included vascular and inflammatory forms of cardiac dysfunction and was believed to have a particularly grave prognosis. Although the term *carditis* was gradually replaced by *myocarditis*, this continued for the remainder of the century to be a broad category of nonvalvular forms of myocardial dysfunction.

In the early part of the twentieth century, two important clinical breakthroughs led to an evolution of the concept of “myocarditis” to the modern application. Studies of rheumatic fever by Ashoff demonstrated that cellular inflammatory lesions played an important role in myocardial dysfunction. In addition, coronary artery disease became increasingly recognized as an important etiology for myocardial dysfunction, distinct from primary myocardial inflammation. By the mid-twentieth century, the search for infectious etiologic agents for inflammatory heart disease intensified, with increased recognition of the importance of viral pathogens (12,13 and 14).

The introduction of transvenous endomyocardial biopsy in the latter part of the twentieth century (15) heralded a new age of understanding for primary dilated cardiomyopathy, in which an apparent heterogeneous group of disorders could now be divided into distinct pathologic subsets. With the widespread growth in cardiac transplantation in the 1980s, it was recognized that the common form of cellular inflammation in native hearts, lymphocytic myocarditis, was histologically similar to cardiac allograft rejection. This supported a hypothesized autoimmune pathogenesis and led to a randomized clinical trial of immunosuppression, the Myocarditis Treatment Trial (MTT) (5). The clinical use of endomyocardial biopsy reached its zenith by the early 1990s and has subsequently declined in the absence of biopsy-guided therapeutic interventions. Over the last decade, molecular genetic techniques have been used in an attempt to enhance the diagnostic power of endomyocardial biopsy, in particular, for the detection of viral genomes (16). In addition, an increasing role has been noted for myocardial and systemic inflammatory mediators, including cytokines (1), chemokines (17), and autoantibodies (18) as potential surrogate markers for cardiac inflammation.

INFLAMMATORY CARDIOMYOPATHY: TERMINOLOGY AND CLINICAL SUBSETS

With the increasing use of endomyocardial biopsy for diagnosis, the term *myocarditis* gradually became synonymous with left ventricular (LV) dysfunction with histologic evidence of cellular inflammation. Indeed, as recently as 1995, the World Health Organization task force defined *inflammatory cardiomyopathy* as “myocarditis in association with myocardial dysfunction. Myocarditis is an inflammatory disease of the myocardium and is diagnosed by established histologic, immunologic, and immunohistochemical criteria” (19). In the current age in which biopsy data are infrequently obtained, reliance on histologically defined criteria may be impractical. From the standpoint of clinical practice, myocarditis can be defined more simply and literally as inflammation of the myocardium or heart muscle as assessed by a number of clinical criteria.

The risk of broadened clinical criteria remains that the pathologic and clinical distinction between inflammatory myocarditis and IDC can become somewhat obscured. As stated by eminent cardiac pathologist Michael Davies, “Cardiomyopathy and myocarditis are terms used with an expectation that they are generally understood. In practice, once their definition is attempted, difficulties emerge and their meaning seems less clear” (20). In its broadest definition, *inflammatory cardiomyopathy* includes a heterogeneous set of disorders in which myocardial inflammation plays the primary role in the pathogenesis of cardiac dysfunction. This heterogeneous grouping can be subdivided into more distinct subsets based on the clinical setting of presentation (e.g., pregnancy) or diagnostic histopathology (Table 93.1).

TABLE 93.1 INFLAMMATORY CARDIOMYOPATHY: CLINICAL SUBSETS

For many patients with the clinical syndrome of myocarditis, endomyocardial biopsy is either not obtained or is uninformative. Approximately 30% to 40% (6,21,22) of patients with new-onset, unexplained LV dysfunction have dramatic recovery of systolic function during subsequent follow-up. Myocarditis is the suspected etiology for most cases; however, this conclusion is generally only reached retrospectively. Only a fraction of patients who undergo biopsy have evidence of cellular myocardial inflammation (6).

Among those patients with biopsy evidence of cellular inflammation, most are classified as having “lymphocytic myocarditis” based on lymphocyte predominance in the myocardial cellular infiltrates (23). An eosinophilic predominance can be seen in myocarditis that is associated with an allergic reaction or with peripheral eosinophilia (24,25,26 and 27). Although lymphocytic myocarditis is seen in roughly 10% of biopsied patients (5), only 1% to 2% are diagnosed with giant-cell myocarditis, defined by the presence of multinucleated giant cells in the myocardium (28). The distinction between this disorder and lymphocytic myocarditis is critically important, as

giant-cell myocarditis is a much more aggressive pathologic process with a distinct natural history (8,28).

Myocarditis can also be seen as part of systemic autoimmune disorders such as sarcoidosis (29) or systemic lupus erythematosus (30). These disorders are defined by their respective systemic syndromes in terms of their clinical course and treatment. The histologic appearance of myocarditis as part of a systemic disorder is similar to that seen in isolated myocarditis. The granulomas of cardiac sarcoid in particular can be difficult to distinguish from its histologic mimic, giant-cell myocarditis (31).

IDC may be the most common form of “inflammatory” heart disease despite the fact that IDC endomyocardial biopsy is generally uninformative (3). Peripartum cardiomyopathy, the form of primary dilated cardiomyopathy that is seen as a complication of pregnancy, also likely has an inflammatory pathogenesis, and cellular inflammation is frequently seen on endomyocardial biopsy (32).

PREVALENCE

The prevalence of primary “idiopathic” dilated cardiomyopathy has been estimated at 0.4 per 1,000, with an annual incidence of 0.08 per 1,000 (33). This correlates to approximately 120,000 cases within the United States alone, with 24,000 new cases each year. The prevalence of histologic myocarditis, defined specifically as cellular inflammation on endomyocardial biopsy, varies widely in published series (Table 93.2) but can be best estimated from multicenter studies at approximately 10% to 20% of patients with new-onset IDC (5,6,34). The MTT noted biopsies that were positive for inflammation in only 10% of 2,233 screened patients (5). In a similar fashion, the ongoing European Study of Epidemiology and Treatment of Cardiac Inflammatory Diseases has reported positive biopsies in 17.2% of the first 3,055 patients screened (34). Evidence of myocarditis may be found in 1% to 9% of routine autopsy cases (35,36 and 37) and up to 20% of those that are performed for unexplained sudden cardiac death in young people (38). Although autopsy series and multicenter trials provide estimates for myocarditis with major cardiac consequences (LV dysfunction or sudden death), most cases of myocarditis are likely self-limited and never present to medical attention. The true prevalence of these subacute forms of myocarditis is difficult to determine, as is their role in initiating the pathway that leads to IDC.

TABLE 93.2 PREVALENCE OF MYOCARDITIS IN PUBLISHED SERIES

PATHOGENESIS: LESSONS FROM ANIMAL MODELS

The murine models of myocarditis are the most extensively studied, particularly those initiated with the cardiotropic ribonucleic acid virus Coxsackie virus group B (39,40 and 41) or encephalomyocarditis virus (42). After uptake by receptor-mediated endocytosis, viral proteins are translated, and replication of viral particles is initiated in the cytoplasm of the myocyte (41). Direct virally induced myocyte necrosis can be seen within 3 days, before any inflammatory infiltrates. Viral particles are subsequently released into the interstitium, where they are taken up by phagocytosis by macrophages. Subsequently, macrophage activation leads to cytokine expression, including interleukin-1 (IL-1), interleukin-2 (IL-2), tumor necrosis factor-a (TNF-a), and interferon-g (10).

Cytokine expression, particularly IL-2, results in the activation of natural killer (NK) cells (43). NK cells interact specifically with virally infected myocytes and induce necrosis through the release of perforin and granzymes (44,45). Through this cytotoxic mechanism, NK cells play an important role in viral clearing, as murine models that are deficient in NK cells show a marked increase in viral titers and in the severity of the virally induced myocarditis. Endogenous interferons likely also play a direct role in limiting viral replication. In addition, cytokines induce the expression of inducible nitric oxide synthase in myocytes (46). The subsequent nitric oxide production serves to kill infectious agents directly and to modulate the host immune response.

The activation of cell-mediated immunity initiates the second phase of viral clearing. Within 7 days of viral inoculation, infiltrates of antigen-specific T-lymphocytes are seen throughout the myocardium. These cells can be subclassed based on surface antigens and function into T-helper (CD4+) cells and cytotoxic T-lymphocyte (CD8+) cells (10). Cytotoxic T-lymphocytes, in particular, play an important role in the necrosis of virally infected cells, which results in viral clearing. Viral antigens are reduced to peptides placed in the cell membrane of target cells bound to the major histocompatibility complex (MHC) for presentation to T-cell receptors. The recognition by cytotoxic T-lymphocyte receptors of viral peptide presented by MHC class I antigens initiates myocyte damage of virally infected cells (47). This interaction is dependent on cell contact. The induction of intracellular adhesion molecule-1 as well as MHC class I molecules by interferon-g and TNF-a plays an important facilitatory role (48).

Of the mononuclear cells in the myocardium, 10% to 20% are B-lymphocytes (49). T cell–depleted murine strains inoculated with encephalomyocarditis virus have less myocardial damage and overall less severe myocarditis than do T cell–competent strains (49,50 and 51). In this model, viral titers, the development of neutralizing antibody titers, and viral clearing were similar in T cell–competent and T cell–depleted strains. Although it does not participate directly in cytotoxicity, B cell–mediated humoral mechanisms play an important role in the overall elimination of viral particles.

Although the pathologic processes that are involved in the acute and subacute phases of myocarditis are well defined, there is less certainty regarding the mechanisms of the chronic phase. Approximately 15 days after viral inoculation, culturable virus is no longer detected. By 90 days after inoculation, inflammatory cell infiltrates are no longer seen; however, ventricular enlargement and myocardial fibrosis become prominent (42). This chronic postviral phase closely replicates the clinical presentation of patients with IDC. Viral nucleic acid can be detected by polymerase chain reaction in only a small percentage of mice at 90 days after inoculation (52) and, in a similar fashion, is only seen in a minority of patients with dilated cardiomyopathy (53,54 and 55). The importance of this carrier state for the persistence of myocardial injury and LV dysfunction remains unknown. The absence of detectable virus for the majority of subjects (murine or human) has powered speculation that this phase of chronic insidious myocardial injury is driven by persistent autoimmune pathologic mechanisms.

The potential of cytokine-mediated immune injury to persist long after the resolution of inflammation is supported by findings in transgenic mice. Murine strains that overexpress TNF-a in the myocardium develop lymphocytic myocarditis that is histologically similar to that seen in the virally induced model (56). Although the histologic evidence of myocarditis subsequently resolves, mice go on to develop a dilated cardiomyopathy and die prematurely from heart failure. The ability of TNF-a overexpression to produce progressive LV dysfunction demonstrates that the cytokine response to injury may be as important as the initiating stimulus itself in the subsequent development of dilated cardiomyopathy.

Immunization with cardiac myosin in a murine model elicits a T cell–mediated myocarditis that replicates the histology of the Coxsackie model in a virus-free system (57). In addition, inoculation of susceptible strains with murine cytomegalovirus induces an acute and chronic myocarditis as well as sera that cross-react with murine cytomegalovirus isolates and cardiac myosin (58). These findings support the hypothesis that antigenic similarity between viral and native myocardial peptides (cardiac myosin in particular) perpetuates the chronic inflammatory response.

ETIOLOGY

As in animal models, clinical studies of myocarditis suggest that a viral trigger initiates an immune pathogenesis involving cellular and humoral mechanisms. In serologic studies, enteroviruses, in particular Coxsackie B, are the most common viral agents (59). Adenovirus, influenza A and B, and hepatitis C have also been implicated as important viral pathogens (60,61,62 and 63) (*e*Table 93.2.1). In addition, advanced human immunodeficiency virus (HIV) infection has been associated with myocarditis and dilated cardiomyopathy (64,65 and 66). Whether this reflects a manifestation of HIV infiltration itself or opportunistic systemic infections with myocardial involvement in an immunocompromised host remains uncertain. Additional viral genomes, cytomegalovirus and adenovirus in particular, have also been detected in the myocardium of HIV-positive patients with lymphocytic myocarditis (67).

Nonviral infectious pathogens have also been implicated as the causative agent in myocarditis. Chagas' disease caused by parasitism with the protozoa *Trypanosoma cruzi* is endemic in parts of South America (68). Serologic epidemiology studies indicate that between 15 and 20 million people are infected in Central and South America, with more than 60 million people at risk (69). The infection causes an acute inflammatory cardiomyopathy and in animal models produces elevation in myocardial expression of TNF-a, IL-1b, and IL-6 (70). In its chronic stage, it can develop to progressive dilated cardiomyopathy and is associated with alterations in circulating T-cell subsets (71). This disorder is not seen among U.S. patients in the absence of a significant travel history to endemic areas. Among immunocompromised hosts, myocarditis associated with toxoplasmosis (72,73) or aspergillus (74,75) has been reported, but generally only with signs of other systemic infestation and only rarely as an isolated myocarditis.

Noninfectious triggers can also initiate myocardial inflammation, as demonstrated by peripartum cardiomyopathy, the syndrome of dilated cardiomyopathy that affects women in their last trimester of pregnancy or in the first few months postpartum (76,77 and 78). This disorder follows a similar clinical progression to the virally initiated syndrome, with the exception that the initiating stimulus is likely fetal or placental antigen. Modulation of the maternal immune system is an important aspect of fetal tolerance during routine pregnancy (79,80). Exacerbations of other autoimmune disorders such as multiple sclerosis typically decline during pregnancy because of this modulation, with a subsequent rebound increase generally noted in the postpartum period (81). The period of autoimmune "rebound" phenomenon postpartum is also the most common time for women to present with peripartum cardiomyopathy. Lymphocytic infiltrations of the myocardium can be seen in peripartum cardiomyopathy (82), particularly in patients who are biopsied soon after delivery. Multiparity is a risk factor for the development of peripartum cardiomyopathy (83), suggesting that previous exposure to fetal paternal antigens is important in the development of the pathologic immune response.

Toxins, namely alcohol and chemotherapeutic agents such as doxorubicin (84,85 and 86), can also initiate a progression to dilated cardiomyopathy. In contrast to the virally initiated and peripartum syndrome, these agents appear to act through direct myocardial toxicity. In these syndromes, myocardial inflammation may be more the result rather than the cause of myocardial injury. In addition, up to 25% of primary dilated cardiomyopathies may be familial in etiology (87). Responsible genetic loci have been delineated for several pedigrees and mutations identified in several cytoskeletal proteins, including dystrophin (88), cardiac actin (89), and the myosin heavy chain itself (90). Although inherited abnormalities of the inflammatory response may be important in some pedigrees (91,92,93 and 94), in general, the mechanism of cardiac dysfunction in familial cardiomyopathy appears quite distinct from that evident in the more common sporadic cases.

IMMUNOPATHOLOGY OF PROGRESSION

Whether virally initiated, peripartum, or idiopathic, the most common histologic appearance of myocardial cellular inflammation, lymphocytic myocarditis, is indistinguishable from the appearance of acute allograft rejection in the transplanted heart (95), with a predominance of T-lymphocytes. In murine models, whether the initial immune response is self-limited or results in progressive inflammation and cardiomyopathy is strain dependent (96), supporting a strong role of genetic background in determining outcome. In clinical studies, specific human leukocyte antigen genotypes appear to confer an increased risk of the development of dilated cardiomyopathy (97), suggesting that genetic susceptibility may be equally important in the human perpetuation of immune-mediated injury. Genetic predisposition to autoimmune pathology may be particularly important in giant-cell myocarditis, as a high percentage of patients who present with this disorder also have previously had other autoimmune diseases such as thyroiditis and colitis (8). Perpetuation of myocardial inflammatory disease requires not only antigenic similarity of myocardial and

viral peptides, but also a genetic “background” that facilitates the continuation of the pathologic immune response (98,99).

Increasing evidence over the last decade points toward myocardial expression of cytokines in general and TNF-a in particular as being important driving forces in the development of the end-stage cardiomyopathy phenotype (100,101). Myocardial expression and plasma levels of TNF-a and IL-6 increase as functional status worsens (102,103). The explanted heart from patients who are undergoing transplantation frequently demonstrates inflammatory myocardial infiltrates (104), even in those with coronary artery disease as the primary etiology of their heart failure. This demonstrates that in the end-stage ischemic heart, expression of inflammatory mediators can elicit cellular infiltration of the myocardium and contribute to the decline in cardiac function. The role of myocardial cytokine expression in the progression of heart failure from the compensated to the end-stage phenotype has broadened our appreciation of the inflammatory nature of chronic heart failure and led many investigators to focus efforts at immune modulation on chronic or end-stage disease (105,106).

Circulating cytokines, in particular TNF-a, are markedly elevated in the plasma of patients with acute cardiomyopathy and myocarditis. In contrast to its negative prognostic role in chronic end-stage cardiomyopathy, in acute myocarditis high circulating TNF-a levels may be a marker of a potentially reversible immune injury. In the multicenter Intervention in Myocarditis and Acute Cardiomyopathy (IMAC) study of patients with new-onset cardiomyopathy and myocarditis, higher plasma TNF-a at entry was associated with a higher probability of eventual recovery of LV function (107). The association of high plasma TNF-a at presentation with a higher left ventricular ejection fraction (LVEF) at follow-up closely parallels the earlier findings of the MTT that patients with evidence of active cellular autoimmunity tended to have less severe impairment of LV function (5). Increasingly, investigators are evaluating the role of “surrogate markers” of immune activation as potentially useful diagnostic and prognostic tools (108).

The role of autoantibodies and humoral immunity in clinical disease remains controversial. Antigenic specificity of circulating autoantibodies against myocardial proteins has been demonstrated for the adrenergic beta-receptor (18), myosin (109), and other myocardial peptides (110,111,112 and 113). The presence of autoantibodies in asymptomatic relatives of patients with familial cardiomyopathy supports an autoimmune pathogenesis for these particular pedigrees (92). However, whether autoantibodies are pathogenic or nonspecific epiphenomena associated with myocardial injury remains to be determined.

IMMUNOSUPPRESSIVE AND IMMUNE MODULATORY THERAPIES: LESSONS FROM CLINICAL TRIALS

The immune hypothesis for the progression of myocarditis to dilated cardiomyopathy has led to intense clinical interests over the years in improving ventricular function by blunting or modulating the pathologic aspects of the immune response. The challenge in studying the impact of therapeutic interventions in this disorder has been the clinical heterogeneity and a high spontaneous recovery rate in small subsets of patients. In addition, given the relative infrequency of patients who present with myocarditis and LV dysfunction, single-center anecdotal series are generally quite small, and a multicenter format is required to evaluate therapeutic interventions. Three major prospective randomized trials of immune suppression or modulation have been reported over the last decade, and all three controlled studies failed to confirm the therapeutic benefits that were suggested by anecdotal reports (4,5 and 6) (Table 93.3).

Author (reference)	Agent studied	No. randomized	Primary outcome measure	Result
Parillo et al. (4)	Prednisone	102	Change in EF at 3 mo	Modest benefit (4 EF units vs. 2 EF units in the placebo)
Mason et al. (Myocarditis Treatment Trial) (5)	Prednisone and cyclosporine	111	Change in EF at 6 mo	No significant effect (increase of 10 EF units vs. 7 EF units with placebo)
McNamara et al. (IMAC Trial) (6)	Immune globulin	62	Change in EF at 6 mo	No treatment effect (increase of 14 EF units in both groups)

TABLE 93.3 RANDOMIZED CLINICAL TRIALS OF IMMUNE MODULATION IN MYOCARDITIS AND DILATED CARDIOMYOPATHY

The first major randomized trial of immunosuppressive therapy in inflammatory heart disease was conducted by the National Institutes of Health and enrolled patients from 1982 through 1988 (4). One hundred two patients with an evaluation that was consistent with either IDC or myocarditis were randomized to high-dose prednisone therapy (60 mg per day) or standard therapy. All patients underwent endomyocardial biopsy; however, no strict biopsy inclusion criteria were used. Fifty percent of those enrolled were classified as “reactive” due to either cellular infiltrate in the myocardium, myocardial deposition of immunoglobulins or complement, elevation in the erythrocyte sedimentation rate, or positive myocardial gallium scans.

Overall, a modest increase in ejection fraction (EF) in the treatment group was noted at 3 months (4.3 EF units vs. 2.1 EF units, $p = .054$). Most of the improvement was seen in patients who were classified by these prespecified criteria as being “reactive.” However, despite maintenance therapy for reactive patients with 60 mg prednisone every other day, at subsequent 6-month follow-up, the small therapeutic benefit that was seen at 3 months was no longer evident. The investigators concluded that given the modest, transient nature of the improvement and the significant risk of steroid therapy, prednisone should not be standard therapy for dilated cardiomyopathy.

With the development and wide acceptance of the Dallas criteria, investigators focused therapeutic efforts in this subset of patients when an immune pathogenesis was more clearly evident. The histologic similarity of lymphocytic myocarditis with cardiac allograft rejection led to the belief that a combined immunosuppressive approach, similar to that used to prevent transplant rejection, would be more effective than prednisone alone. This hypothesis was evaluated in the MTT, which randomized 111 patients with a histopathologic diagnosis of myocarditis and an LVEF of less than 0.45 to conventional therapy alone or 24 weeks of prednisone combined with either cyclosporine or azathioprine. The primary outcome that was measured was the change in LVEF at 28 weeks (114).

Recruitment for the MTT was challenging due to the strict biopsy criteria. Local pathologists found evidence of myocarditis on endomyocardial biopsy for only 214 of 2,233 screened patients. Of these individuals, 111 met the other entry criteria and were randomized. Overall, LV function improved significantly over time from a mean of 0.25 at baseline to 0.34 at 28 weeks. No treatment effect was evident with immunosuppressive therapy, as the improvement in LVEF was similar in the two groups (0.10 with immunosuppressive therapy vs. 0.07 in the control group) (Fig. 93.1). No long-term difference in survival was seen ($p = .96$), with an overall mortality of 20% at 1 year and 56% at 4.3 years (Fig. 93.2). In current practice, the absence of therapeutic benefit for immunosuppression in the MTT has all but eliminated its use in adults with suspected myocarditis.

Recent research has focused on the use of intravenous immunoglobulin (IVIG) as an immune modulating agent (115,116 and 117). High-dose IVIG has been used in a number of autoimmune disorders, including idiopathic thrombocytopenic purpura (118), Guillain-Barré syndrome (119), and dermatomyositis (120). Based on effectiveness in Kawasaki's disease (121), a coronary vasculitis in children, pediatricians began investigating its use in myocarditis and reported significant improvement in LV function compared to that of historical controls (122). Subsequently, two small series were reported in adults with new-onset dilated cardiomyopathy and myocarditis (123) and peripartum cardiomyopathy (124) that suggested enhanced improvement in LVEF compared to historical controls.

The therapeutic role of immunoglobulin for adults with recent-onset inflammatory cardiomyopathy was evaluated in the IMAC trial (6). This multicenter study randomized 62 patients to 2 g per kg IVIG or a placebo infusion at the time of initial presentation with new-onset heart failure. All enrolled patients had evaluation that was consistent with a primary dilated cardiomyopathy or myocarditis, had an LVEF of 0.40 or less, and were randomized within 6 months of their onset of cardiac symptoms. All underwent an endomyocardial biopsy; however, patients with and without cellular inflammation on biopsy were included. Overall, the clinical characteristics of the IMAC and MTT study populations were quite similar (*e*Table 93.3.1). The primary end point was the change in LVEF at 6 months after randomization. Overall, LVEF improved significantly from 0.25 at baseline to 0.42 at 12 months. No treatment effect was evident, as the improvement at 6 months was 14 EF units in both groups and at 12 months was 16 EF units with IVIG versus 15 with placebo (Fig. 93.3). Overall event-free survival [events defined as death, transplantation, or need for LV assist device (LVAD)] was 91% at 1 year and 88% at 2 years (Fig. 93.4), and there were no significant differences between treatment groups.

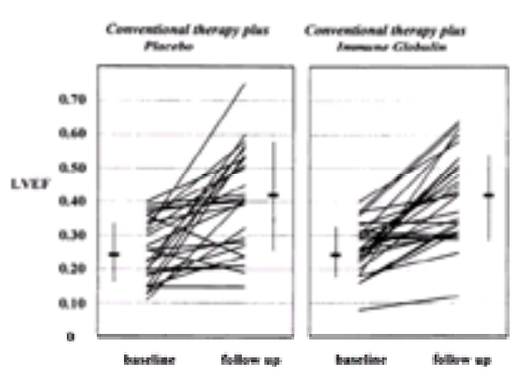

FIGURE 93.3 Left ventricular ejection fraction (LVEF) over time by treatment. LVEF by radionuclide scan at baseline and 12 months postrandomization in patients randomized to placebo and immunoglobulin. Overall, LVEF improved significantly over time (12 months LVEF significantly higher than baseline, p <.001). However, no differences by treatment group were evident (p = not significant for comparisons by treatment). (From McNamara DM, Holubkov R, Starling RC, et al., for the IMAC investigators. A controlled trial of intravenous immune globulin for recent onset dilated cardiomyopathy. *Circulation* 2001;103:2254–2259, with permission.)

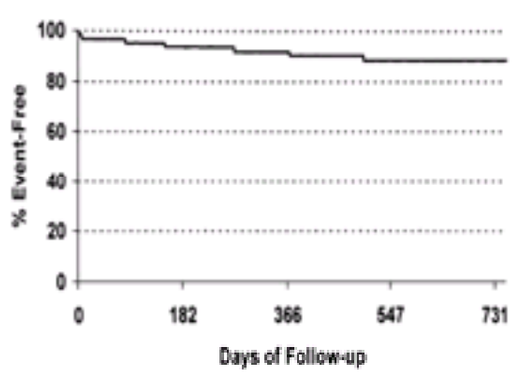

FIGURE 93.4 Event-free survival for patients with new-onset dilated cardiomyopathy and myocarditis enrolled in the IMAC trial (events defined as death, cardiac transplantation, or need for left ventricular assist device). Event-free survival 91% at 1 year and 88% at 2 years.

The IMAC trial provides important insights into the current natural history of new-onset dilated cardiomyopathy and myocarditis. At 1 year follow-up, an improvement in LVEF of at least 10 EF units was noted in more than 50% of patients, including nearly one-third (20 of 62) who normalized their EF (greater than or equal to 0.50). The high rate of spontaneous recovery in the IMAC control group represents a significant challenge for future clinical studies in myocarditis, as the marked heterogeneity of clinical outcomes limits the statistical power to evaluate interventions. Notably, the findings on endomyocardial biopsy (presence or absence of cellular inflammation, fibrosis, or myocyte hypertrophy) were of little prognostic value and did not predict the subsequent LVEF at 1 year (eTable 93.3.2). Higher New York Heart Association functional class at presentation was associated with an increased risk of events during follow-up, but with a trend toward greater LV recovery in survivors (eFig. 93.4.1). The absence of LV enlargement was the best clinical predictor of potential LV recovery. Patients with an LV end diastolic diameter of 6 cm or less at presentation (by transthoracic echo) had an average improvement of nearly 20 EF units during subsequent follow-up.

LVEF at baseline and 12 months by New York Heart Association class at presentation: Patients with baseline and 12-month multiple gated acquisition data only. Higher New York Heart Association functional class at entry was significantly associated with a lower LVEF at baseline (p = .02) but a nonsignificant trend toward a higher LVEF at 12 months. *A fourth class IV patient, excluded from this analysis, had an LVEF of 0.69 at 1 year. (From McNamara DM, Holubkov R, Starling RC, et al. for the IMAC investigators. A controlled trial of intravenous immune globulin for recent onset dilated cardiomyopathy. *Circulation* 2001;103:2254–2259, with permission.)

More recently, investigators of immune modulatory therapies have focused on more chronic populations (i.e., histories of dilated cardiomyopathy greater than 6 months), in which spontaneous recovery is generally rarer. Current therapies under investigation include interferon-g (125,126 and 127), TNF-a soluble receptor (105), and immunoadsorption (128). Immunoglobulin has also been studied in a more chronic population of dilated cardiomyopathy (129) and appears to be more efficacious in this subset than in the acute population of the IMAC study. Although these results in small single-center series suggest benefit, larger multicenter trials are needed to confirm therapeutic efficacy.

A unique approach to the diagnosis and treatment is currently being evaluated by the large multicenter European Study of Epidemiology and Treatment of Cardiac Inflammatory Diseases (130). This study combines conventional histology and molecular genetics in an effort to enhance the ability of myocardial biopsy to delineate distinct patient subsets and guide more individualized treatments, including antiviral therapies. Patients in this trial are randomized to several different treatment arms based not only on the presence or absence of cellular inflammation but also on the basis of myocardial immunoglobulin or complement deposition and the presence of viral genomes. Given the complexity of this randomization design, enrollment is ongoing, with no therapeutic outcomes yet reported.

CLINICAL MANAGEMENT: EVALUATION

Presentation

The classic presentation for a patient with myocarditis is symptoms of chest pain or dyspnea in the setting of an acute febrile illness. However, subacute myocarditis (inflammation with mild or no LV dysfunction) may present without any cardiac symptoms. Occasionally, these cases are surreptitiously diagnosed in the setting of an acute viral syndrome by the incidental finding of electrocardiographic (ECG) abnormalities (131) or elevations of cardiac enzymes (132,133). Just as cardiac symptoms are not necessarily part of the presentation with myocarditis, neither is an acute febrile illness. Fever was present in only a minority of patients in the MTT (5) (eTable 93.3.1).

In patients who present with LV dysfunction, the most common cardiac symptoms are those of congestive heart failure (dyspnea, fatigue, and chest discomfort) (134). In general, heart failure symptoms are more left sided, although signs of right-sided failure, in particular peripheral edema, or symptoms of hepatic congestion (abdominal discomfort or nausea) can be seen. Palpitations are a common presenting complaint and may represent atrial or ventricular arrhythmias (135,136 and 137). Atrial arrhythmias generally reflect left atrial hypertension or irritation from associated pericarditis. Ventricular dysrhythmias, although usually associated with heart failure and significant LV dysfunction, are occasionally seen with relatively preserved LV function and presumably originate from an inflammatory focus within the ventricle (138).

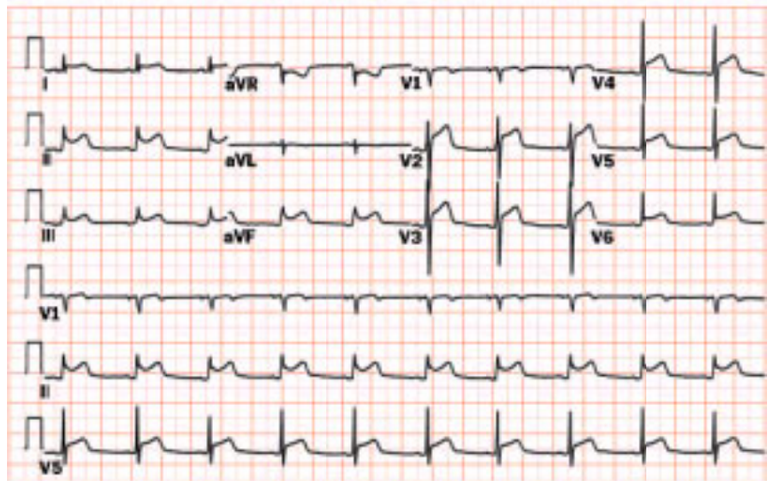
Adult patients who present with symptoms of heart failure due to myocarditis typically do so with no signs of systemic inflammation (5,6) and come to medical attention months after the initial symptom complex began. In this regard, the presentation in young children is distinctly different from that of adults, perhaps reflecting differences in the pediatric viral milieu. Children are more likely to present within days of the onset of symptoms (122) and have more systemic signs of an acute inflammatory state. As patients who present earlier generally have a higher probability of spontaneous recovery once systemic inflammation has resolved, this may lead to a higher probability of significant LV recovery in children.

Diagnostic Evaluation

The clinical examination of patients with suspected myocarditis should focus on signs of ventricular dysfunction. Although tachycardia and borderline hypotension may reflect an acute febrile syndrome, they may also be the first signs of significant hemodynamic compromise. In acute cases, rales on the pulmonary examination provide evidence of left-sided failure; however, in patients with a more insidious presentation a clear lung examination can be heard despite significant dyspnea and marked elevations in left-sided filling pressure. Elevated jugular venous pressure, hepatic tenderness, or peripheral edema is consistent with right-sided failure and suggests right ventricular involvement.

The ECG remains an important clinical tool in evaluating cases of suspected myocarditis (131). Common findings are diffuse and nonspecific ST- and T-wave abnormalities. In cases of fever and acute chest pain, PR depression and diffuse global ST elevation may allow a rapid diagnosis of pericarditis. Low voltage may be evident, particularly in those with an associated pericardial effusion. Occasionally, myocarditis presents with ECG findings suggestive of myocardial infarction in a specific vascular territory. Although this form of myocarditis that mimics the presentation of myocardial infarction has been well described (139,140,141 and 142), it

remains important in such cases to rule out an acute ischemic event and to have a low threshold for proceeding with rapid coronary angiography.



Acute pericarditis. Note diffuse, marked ST-segment elevation with PR-segment elevation in lead aV_R.

Pericardial tamponade. Low QRS voltage and electrical alternans are characteristic findings of tamponade.

Serum analysis for patients with a suspected myocarditis should include creatine phosphokinase (CPK) with appropriate fractionation or, alternatively, cardiac troponin. Elevations of CPK tend to be moderate, in the range of 200 to 1,000, even in cases of fulminant myocarditis. In young men who present with dilated cardiomyopathy with a persistent chronic elevation of CPK, a detailed family history should be obtained, as chronic elevations in CPK may reflect not persistent myocarditis but dystrophinopathy, a familial X-linked disorder (88).

For patients who present with an acute febrile illness, acute and convalescent sera against most common viral pathogens should be performed. Such a panel should include Coxsackie B, influenza A and B, cytomegalovirus, and appropriate adenoviral forms (59). A mild leukocytosis may be seen, particularly with a lymphocyte predominance. Marked leukocytosis should elicit a thorough evaluation for a systemic bacterial infection in which LV dysfunction may be secondary to septicemia. Peripheral eosinophilia should suggest the possibility of eosinophilic myocarditis, a syndrome that is frequently related to drug or other allergies. Serologic testing should include antinuclear antibody and rheumatoid factor, looking for occult connective tissue disease or other systemic autoimmune disease. Testing for other cardiac-specific autoantibodies, for example, those directed against cardiac myosin or the adrenergic beta-receptor, remains investigational and is not part of clinical screening.

In young patients with chronic cough or dyspnea, chest x-ray findings of cardiomegaly or interstitial edema often initiate the cardiac consultation. Usually, marked cardiomegaly is associated with a more insidious progressive course. In these patients, as in chronic dilated cardiomyopathy, findings on chest x-ray of pulmonary edema may be minimal despite markedly elevated left-sided filling pressures. In contrast, acute fulminant myocarditis can present with florid alveolar edema and acute respiratory failure, but, given the short time course of the illness, a relatively normal-sized cardiac silhouette.

In any patient with suspected myocarditis, an echocardiogram should be performed. This one test gives clinicians the maximum information about LV size and function and right ventricular involvement (143,144). The presence of a pericardial effusion, relatively small chamber size with decreased systolic function, and increased LV wall thickness are essentially diagnostic of an active process of myocardial inflammation. In general, decrease in LV systolic function is global, although marked segmental wall motion abnormalities can be seen. However, the echogenicity of the myocardium itself does not change with active inflammation, and therefore the echo images of the myocardium itself do not help in the specific diagnosis of cardiac inflammation. Despite this limitation, echocardiography remains clinically the most useful tool for clinical management and should be a part of any diagnostic evaluation.

In patients with LV systolic dysfunction and significant hemodynamic impairment, consideration should be given to invasive hemodynamic assessment by right heart catheterization. Persistent tachycardia may be compensatory for a decrease in stroke volume and a resultant decrease in cardiac output. As acute myocardial inflammation can affect systolic and diastolic properties, pulmonary capillary wedge and right atrial pressures are frequently elevated out of proportion to the apparent decrease in systolic function. In addition, in any adult patient with cardiac risk factors, coronary artery disease should be ruled out either by angiography or by appropriate noninvasive evaluation given the distinctly different treatment pathway engaged by this diagnosis.

Endomyocardial Biopsy

In the 1960s, the development of techniques for transvenous endomyocardial right ventricular biopsy made possible the antemortem diagnosis of myocardial inflammation (15,145). By the mid-1980s, its critical role in managing patients after cardiac transplant led to increased use in the evaluation of native myocardial disease (146). Infiltrates of inflammatory cells invading the myocardium on biopsy rapidly became the gold standard for the diagnosis of myocarditis, which previously had relied on more indirect clinical assessment. However, the sensitivity of endomyocardial biopsy has historically been limited by sampling error. Biopsy samples are taken from the apical portion of the right ventricular septum, as limiting sampling to this region lessens the risk of complications, namely, acute tricuspid regurgitation or cardiac perforation and tamponade. Autopsy studies of patients who are known to have myocarditis have estimated the sensitivity of endomyocardial biopsy at no better than 60% to 70% because of regional sampling error (147).

In addition, the finding of cellular inflammation as indicative of myocarditis is dependent on interpretation. In an effort to have more consistent pathologic guidelines, a group of leading cardiac pathologists met in Dallas in 1986 to establish a consensus for the definition of myocarditis (148). The Dallas criteria defined “borderline myocarditis” as the presence of mononuclear cell infiltrates without myocyte necrosis (Fig. 93.5A and *e*Fig. 93.5.1) and “myocarditis” as cellular infiltration with myocyte necrosis (Fig. 93.5B and *e*Fig. 93.5.2). Despite this widely accepted consensus, interpretation remains problematic and physician dependent (149). After review by the study pathology panel of the endomyocardial biopsies from patients enrolled in the MTT (all of whom were believed by their local pathologists to have histologic myocarditis), 36% were not thought to have Dallas criteria myocarditis or borderline myocarditis (5). Conversely, a “negative” biopsy does not rule out myocarditis, as patients without cellular inflammation on biopsy may still follow a clinical course that is suggestive of myocarditis. In the IMAC study, 16 of 20 patients who normalized their EF (greater than or equal to 0.50) during follow-up had biopsies that were interpreted as negative for cellular inflammation at entry. Most such cases of reversible LV dysfunction in retrospect had a clinical syndrome that was strongly suggestive of transient myocardial inflammation.

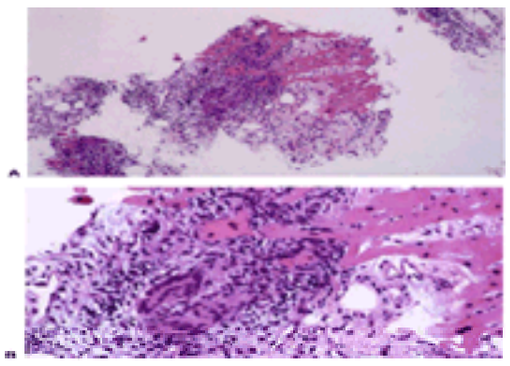
Two additional considerations are important in determining the role of endomyocardial biopsy in the workup of suspected myocarditis. First, for endomyocardial biopsy in native hearts the risk of a major complication, in particular cardiac tamponade, approaches 1% (150,151), significantly higher than in cardiac transplant patients. In addition, currently there are few histologically guided therapies; therefore, biopsy findings of cellular inflammation usually do not change therapeutic plans and are of minimal prognostic value (6,152). This absence of specific biopsy-guided therapy has led the American College of Cardiology to classify endomyocardial biopsy for the evaluation of heart failure due to unexplained myocardial dysfunction as a “class II procedure . . . acceptable but of uncertain efficacy and may be controversial” (7).

In patients with fulminant myocarditis, endomyocardial biopsy may have more clinical utility than in the compensated patient. Patients with fulminant disease and hemodynamic compromise are more likely to have giant-cell myocarditis (*e*Fig. 93.5.3). Although it remains investigational, data from the Giant Cell Registry (8,153) suggest that immunosuppression therapy may be appropriate in patients with giant-cell myocarditis. In addition, biopsy evidence of a dynamic destructive process may help guide the timing of therapeutic interventions such as LVAD placement or cardiac transplantation. Although in this very-high-risk subset biopsy may assist in these therapeutic decisions, it should be performed at a tertiary referral center where such end-stage supportive therapies are readily available.



***e*FIGURE 93.5.3** Histopathologic appearance of giant-cell myocarditis (multinucleated giant cell in the center of the specimen). **A:** ×100 magnification; **B:** ×350 magnification.

MEDICAL MANAGEMENT OF MYOCARDITIS

In the absence of proven benefit in prospective clinical trials, immunosuppressive therapy is not recommended for adult patients with isolated myocarditis. For individuals with myocarditis as part of a systemic autoimmune disorder, such as sarcoid, systemic lupus erythematosus, or polymyositis, immunosuppressive therapy may be beneficial but is generally directed against the systemic disorder (e.g., prednisone for active sarcoid). The need for therapeutic intervention is determined by systemic markers of inflammation (serum CPK from skeletal muscle in polymyositis) and not on measures of myocardial function or findings on biopsy.

The medical therapy of patients with suspected myocarditis is therefore supportive and is dependent on the degree of LV dysfunction. In general, patients with myocarditis can be divided into three broad categories based on the severity of LV compromise: (a) myocarditis and preserved LV function; (b) myocarditis with LV

dysfunction and class I–III heart failure; and (c) myocarditis with LV dysfunction and class IV heart failure, or fulminant myocarditis.

Patients with Myocarditis and Preserved Left Ventricular Function

This group of patients frequently present in a setting of an acute febrile illness with ECG abnormalities or chest pain due to associated pericarditis. Therapy in this case consists of observation and partial restriction of activities. Although chest pain due to isolated pericarditis can be treated with indomethacin or nonsteroidal antiinflammatory agents, these agents should be avoided in cases with myocarditis, as they potentiate myocyte necrosis in murine viral models (154,155 and 156). In the absence of LV dysfunction, there is no indication for beta-adrenergic receptor antagonists or angiotensin-converting enzyme (ACE) inhibitors. In general, it is recommended that aerobic activities or heavy lifting be avoided for at least 6 to 8 weeks (157). Cardiac assessment, generally ECG and echocardiography, should be repeated roughly 6 to 8 weeks after presentation to guard against progressive cardiac involvement. Endomyocardial biopsy is of limited clinical utility and is not recommended. In general, cases of myocarditis with either mild or no LV dysfunction are self-limited and carry an excellent prognosis.

Myocarditis Associated with Left Ventricular Dysfunction and Class I–III Heart Failure

Recommended therapy is similar to that for patients with LV dysfunction in the absence of myocarditis. ACE inhibitors or angiotensin-receptor blockers are recommended for all patients. Pulmonary congestion or symptoms of fluid overload should be treated with a loop diuretic, generally at the lowest effective dose. Digoxin should be added in patients with New York Heart Association class III heart failure; however, given potential proarrhythmic and proinflammatory (158) effects it should be maintained at a low dose and avoided entirely in minimally symptomatic (class I or II) subjects.

Consideration should be given to beta-adrenergic antagonists. Caution should be used, however, in the use of such agents in individuals with relatively small chamber size and tachycardia. In such acute patients with systolic dysfunction without a compensatory increase in LV chamber size, tachycardia is compensatory for low stroke volume, and slowing of the heart rate precipitously can exacerbate a low-output state. Although caution must be exercised, given the potential beneficial effects of blocking adrenergic overstimulation in such patients, low-dose beta-blockade can still be considered.

In the absence of atrial fibrillation or a clinical embolic event, anticoagulation in patients with myocarditis and low EF remains controversial, as in noninflammatory dilated cardiomyopathy. Echocardiography is recommended, and if a mural thrombus (159) is detected, 6 to 12 months of low-dose warfarin with an international normalized ratio of 2 to 3 is recommended. In the absence of a mural thrombus or history of embolic event, warfarin is not universally recommended, and there exists much variation in standard practice.

Video 93.1 Subcostal view of a patient with severe left ventricular dysfunction and multiple mobile thrombi within the left ventricular cavity. (Reproduced with permission from the Adult Clinical Cardiology Self Assessment Program.) *This video must be viewed with QuickTime. If you do not have QuickTime you may download it here.*

In patients with myocarditis and LV dysfunction, ventricular arrhythmias are frequently seen. Although their management is similar to that of other patients with nonischemic cardiomyopathy, it should be noted that the potential stimulus for ventricular arrhythmias, myocardial inflammation, may resolve. In patients who present with cardiac arrest or aborted sudden death, an implantable defibrillator should be considered, given the potential risk of recurrence. However, in patients with symptomatic nonsustained ventricular tachycardia, amiodarone therapy can be considered an alternative. Multicenter studies in congestive heart failure (160,161) have shown that low-dose amiodarone therapy can be used without significant hazard and may actually improve survival in nonischemic cardiomyopathies. Therefore, amiodarone may offer some protection during the acute inflammatory period, with the potential benefit that it can be gradually withdrawn once the inflammatory period has resolved, particularly if systolic function improves. Amiodarone therapy should also be considered for treatment of symptomatic atrial dysrhythmias.

In general, in patients with LV dysfunction, strenuous physical activity is limited for a period of several months. Follow-up evaluation of LV dysfunction in 3 to 6 months and at 12 months after presentation is recommended. In patients with severe LV dysfunction and class II–III heart failure, we generally defer listing for cardiac transplantation for a period of at least 6 to 12 months, as a significant percentage of patients, from 30% to 50%, exhibit substantial improvement in LV dysfunction in the first year after presentation (6,21,22). In patients with persistent severe LV dysfunction at 12-month follow-up and significant functional limitations, metabolic stress testing should be performed to determine if further evaluation for transplant listing is indicated.

Fulminant Myocarditis: Myocarditis Associated with Hemodynamic Compromise and Class IV Heart Failure

Reports from the single-center registry at Johns Hopkins suggest that for patients with acute lymphocytic myocarditis and severe hemodynamic compromise, long-term prognosis (and the probability of LV recovery) may be better than for patients who present with more insidious chronic disease (162). In addition, dramatic recovery of LV function has been reported in patients with fulminant myocarditis that is maintained with LVAD support and has led to renewed interest in the use of assist devices as “bridges to recovery” rather than transplantation (163,164,165,166,167 and 168). Hemodynamic unloading should theoretically rest inflamed myocardium; however, the role of mechanical support in facilitating recovery is difficult to determine, and the use of LVADs is currently reserved for patients who are failing despite maximal inotropic therapy. For patients with cardiogenic shock and aggressive myocarditis, consideration should be given to referral to a tertiary center where both cardiac transplantation and device support are more accessible.

Giant-Cell Myocarditis

In patients with fulminant disease, evaluation for possible giant-cell myocarditis is the primary indication for endomyocardial biopsy. Patients with giant-cell myocarditis were excluded from the Johns Hopkins study, as their prognosis and potential for recovery are significantly worse than for those with lymphocytic myocarditis (8,28). Anecdotal reports (153,169) and the Giant Cell Registry (8) suggest that immunosuppressive therapy, in particular the combination of cyclosporine and the anti–T-lymphocyte antibody muromonab-CD3, may improve transplant-free survival. Given the grim prognosis of giant-cell myocarditis with conventional therapy, immunosuppression should be considered. This remains investigational as the subject of an ongoing multicenter trial.

Postrecovery

For patients whose LV size and systolic function completely normalize, ACE inhibitor therapy and beta-receptor antagonists can gradually be discontinued. In many such patients, subjective limitations in functional capacity and objective limitations in metabolic stress testing may persist, potentially because of a slower recovery of diastolic function (170). Overall prognosis of such patients remains excellent. Although a chance of recurrence of myocarditis exists, most investigators believe that this is seen only in a minority of patients.

Peripartum Cardiomyopathy

For women who are diagnosed with cardiomyopathy during pregnancy, ACE inhibitors and angiotensin-receptor antagonists are contraindicated given potential harmful effects to the developing fetus. Recommendations for management of cardiomyopathy postpartum are similar to those for inflammatory heart disease that is not associated with pregnancy. ACE inhibitors or angiotensin-receptor antagonists are recommended for all postpartum patients. Beta-blockers should be considered but used with caution in patients with small LV chamber size and reflex tachycardia. In general, small LV diameter at presentation predicts a better chance at ventricular recovery, whereas functional class does not. Strenuous exercise should be avoided for 3 to 6 months. Breast-feeding is generally to be avoided given the potential increased metabolic demands on the mother and the potential for certain therapies such as ACE inhibitors to be passed to the child through breast milk. Substantial recovery of LV function is seen in roughly 50% of cases (82,124). In patients with persistent LV dysfunction, subsequent pregnancy should clearly be avoided. In patients with recovered LV function, a risk of LV decompensation with subsequent pregnancy exists, and patients should be monitored carefully.

Pediatric Myocarditis

Children are more likely than their adult counterparts to present with an acute febrile illness and with a positive endomyocardial biopsy (122). As they present more acutely, they appear to have a higher likelihood of ventricular recovery (171,172). ACE inhibitors are recommended for all patients with LV dysfunction (173). Less

experience has been gained with the use of beta-adrenergic receptor antagonists in children, and the use of such agents must be individualized.

A study of pediatric patients with myocarditis suggests that immunoglobulin improves LV function (122). However, this study relied on historical controls, and no randomized trial has evaluated the efficacy of immunoglobulin for this indication in children. Indeed, all previous multicenter trials of immunosuppressive therapy for myocarditis have enrolled only adults, and few controlled data exist to guide therapy for the pediatric patient. In the absence of randomized prospective data, anecdotal reports (169,171) will continue to have a strong influence on practice. Although the benefits of immunoglobulin and steroid therapy remain speculative, they are used more frequently in the management of children with inflammatory heart disease, and randomized trials are clearly needed.

CONTROVERSIES AND PERSONAL PERSPECTIVES

Despite the absence of proven benefit in both the IMAC (6) and MTT trials (5), the search for an immune modulatory therapy which improves patient outcome remains the elusive “Holy Grail” of current myocarditis research. Interestingly, in both trials, patients with more active systemic inflammation actually appeared to have a better prognosis, leading some investigators to question whether suppression of inflammation is the appropriate goal of acute therapy. In the IMAC study, patients with higher initial plasma TNF-a levels tended to have more LV recovery and a higher LVEF at 12-month follow-up (107). In the MTT, patients with an active systemic inflammatory response at presentation (higher white-cell count or autoantibody titer) had less initial impairment of left ventricular function (5). Taken together, these data support the hypothesis that it is not the initial inflammatory event per se, but the myocardial response and subsequent transition to chronic disease that is the true culprit of this pathologic process. For many patients with acute myocarditis, supportive therapy is all that is needed. It is those patients with persistent inflammation who appear to progress toward cardiomyopathy, and identifying and targeting this subset should be the subject of future investigations. Indeed, recent trials in more chronic heart failure suggest a potentially more beneficial therapeutic role for immune modulation than has been seen in previous studies of acute new onset disease (174).

An additional point of controversy remains about whether newer molecular techniques will improve the clinical utility of endomyocardial biopsy and lead to a renaissance of its use in general practice. As important as investigations of gene expression are to the understanding of basic pathogenesis, the same factors which have limited the clinical utility of conventional histology, in particular sampling error, limited tissue availability, and the potential procedural morbidity, will remain significant obstacles despite molecular advances. It is likely that systemic markers of inflammation will be of increasing diagnostic importance, and that future innovations in noninvasive imaging techniques will continue to diminish the current clinical role of endomyocardial biopsy.

THE FUTURE

Primary dilated cardiomyopathy remains an important cause of morbidity. Although myocarditis and cardiac inflammation clearly play a role in its early pathogenesis, the clinical heterogeneity of its natural history remains an enigma. Two similar patients who present with LV dysfunction and myocarditis can embark on distinctly different courses, one to complete recovery and the other to chronic cardiomyopathy, cardiac transplantation, or death. The major challenge in the treatment of inflammatory heart disease is to distinguish at presentation those patients who are destined for recovery from those on the path to end-stage heart failure. In current clinical practice, most tools including endomyocardial biopsy are of limited use in this regard. Future investigations that focus on circulating cytokines or other inflammatory mediators, or on additional molecular techniques to enhance the role of biopsy, are needed to decipher these very distinct subsets.

One added untapped resource for the future will be provided by the ongoing research of the human genome project. Genetic background exerts a powerful influence on outcomes with myocarditis, but the genetic loci that are responsible for modulating recovery remain unknown. The human genome project will provide a wealth of information on human genetic variants for scores of genes of interest over the next decade. Studies of the impact of genetic background on the natural history of the disorder and on the efficacy of therapeutic intervention will be of critical importance. It is extremely likely that the current revolution in human genetics will have a significant impact on how we treat patients with inflammatory heart disease within the next decade.

ACKNOWLEDGMENTS

I am indebted to Dr. Barry London and Dr. Srinivas Murali for their helpful comments, to Dr. Jake Demetris for providing the photomicrographs, and to Mrs. Marge Altvater for assistance in the preparation of the manuscript.
